the protein present is hardened (probably as the result of "tanning" by quinones) to produce a resistant brown or amber coloured material, "sclerotin"; this layer is called the "exocuticle." Outside this there is an extremely thin layer, the "epicuticle," which contains no chitin; this layer is probably complex in structure. but an important constituent of it is a film of waxy material which is responsible for the waterproofing of the cuticle as a whole. Delicate cytoplasmic filaments extend from the epidermal cells, through the substance of the endo- and exocuticle, up to but not penetrating the epicuticle. These are the "pore canals"; they enable the cells to exert their action by the secretion of enzymes, etc., upon the outermost layers of the cuticle. In fact, they ensure that the cuticle remains a living tissue. The entire cuticle is pierced in many places by the ducts of unicellular dermal glands which pour out secretions over the surface. In some insects these glands give rise to a protective cement; in others, to wax or lac. The insect waxes and the shellac of commerce come from this source.

Articulated to the cuticle are hairs of various types, many of which are connected with sensory nerves and constitute sense organs. Or they may be dilated and flattened to form scales, as on the wings of butterflies and moths. Pigmented substances deposited within these scales, or the physical scattering of light caused by the structure of their surface, are responsible for the bright colours of insects. Black or bro n colouring is generally a result of melanin pigments deposited in the substance of the exocuticle.

Growth. — The rigid parts of the cuticle are incapable of stretching or of growth. If the insect is to grow the old cuticle must be shed from time to time, a new and larger cuticle having first been formed beneath. This process is termed moulting or "ecdysis." The epidermis separates from the old skin, the cells divide and arrange themselves in proper form and then lay down the new cuticle. Meanwhile the old endocuticle is digested and the products are absorbed through the new cuticle; the exocuticle is not attacked. In the young stages of insects there are always certain "lines of weakness," usually in the middle of the thorax, where the exocuticle is wanting. When the new cuticle is formed arid digestion of the old is complete, the old skin therefore splits along these lines and the insect can creep out from it. At this stage the new cuticle is still colourless and soft. The insect proceeds to swallow air and distend itself to its full size. It contracts its muscles and so forces the body fluid into the wings causing them to expand. It then sets in motion the oxidative processes within the cuticle which lead to the hardening and darkening of the skin.

The moulting process is initiated by a hormone, which, in some insects at least. is secreted by certain large cells in the brain. In some insects it is the stretching of the body wall which stimulates the secretion of this hormone. In most insects there is a striking change in form, a metamorphosis, at the last moult when the adult stage is reached, and in certain orders (Lepidoptera, Coleoptera, etc.) the final stage is preceded by an inactive pupa. This change in form is likewise controlled by hormones. The *corpus allatum,* a small gland of internal secretion lying close behind the brain, produces a hormone throughout the early stages of growth which prevents the development of adult characters when the insect moults. If this gland is removed from the young caterpillar. for instance, it will turn into a tiny pupa when it moults, and then into a tiny moth.

The phenomenon of diapause or dormancy seen in the egg also appears during the larval or pupal development of insects. All growth may cease and exposure to cold may be necessary before it is resumed. Diapause seems to be caused by an arrest in the secretion of the moulting hormone.

Muscular System and Locomotion. — The movements of insects are brought about by numerous muscles connecting one part of the exoskeleton or cuticle with another. In his classic work Pierre Lyonnet (1762) described **4,061** muscles in the goat moth caterpillar. When the body wall is rigid, as in the grasshopper, the muscles run across the flexible joints from one region of firm cuticle to another. In a soft-bodied insect, such as a caterpillar, the firmness of the body wall is ensured by a general tension or tone in all the muscles which sets up an even pressure upon the body fluids. Many of the movements in such an insect are brought about by the pressure of the blood acting upon points where the muscles have been relaxed.

An insect, such as a beetle or a fly, walking on six legs, supports itself on a tripod, consisting of the anterior and posterior limb on one side and the middle limb on the other, while it carries forward the other three legs. It holds on to rough surfaces by means of claws at the extremity of its tarsi. Many insects are able to hold on to smooth surfaces by means of adhesive organs termed "pulvilli." These bear innumerable hairs with soft flattened extremities. It seems that when these are drawn over a smooth surface they become applied so closely to it that seizure or "adhesion" takes place and the insect is held by surface molecular forces.

When examined physiologically, the muscles of insects do not seem to differ very greatly in their performance from those of vertebrates. Yet it is well known that during flight the wings of insects are vibrated at very high frequencies; the bee will make about 200 wing beats per second, the mosquito nearly 300. It seems likely that these high rates are brought about by the relatively slowly contracting muscles setting up vibrations in the walls of the thorax on to which the wings are articulated.

Nervous System. — The nervous system, like that of vertebrates, consists of elongated cells which convey electrical impulses from one part of the body to another. These cells are termed "neurones"; they consist of a cell body, and an axon filament. The cell bodies of the sensory neurones are located close to the sense organs in the skin, their axon filaments form the sensory nerves which run to the central nervous system. The cell bodies of the motor neurones, the axon filaments of which form the motor nerves running to the muscles, lie within the central nervous system, which likewise contains the cell bodies of the association neurones connecting the various nerve centres together.

The central nervous system consists of a series of ganglia: the supraoesophageal ganglion or brain which receives the nerves from the great sense organs on the head, the eyes and antennae, and is the main centre for the co-ordination of behaviour, the suboesophageal ganglion which innervates the feeding parts, and a series of ganglia supplying nerves to muscles and sense organs of their own segments throughout the thorax and abdomen. To an extent that varies in the different groups of insects, the ganglia become partially fused with one another. None of the ganglia contain centres absolutely vital to the insect: the decapitated insect, deprived of the brain and suboesophageal ganglia can still live and walk; the isolated abdomen can still lay eggs. The individual ganglia can in fact serve as the centres for the simpler reflex actions, such as the withrawal of the leg on pressure. They can even effect the degree of co-ordination necessary for walking. But for the co-ordination of all the complex reactions of the insect to the stimuli it encounters the brain is necessary.

Besides this main nervous system there is also in insects a "peripheral nerve net" containing scattered ganglion cells which net, it has been suggested, is responsible for maintaining the steady contraction or tonus of the muscles. Finally there is a "sympathetic nervous system" which supplies the viscera.

Sense Organs: Vision. — Insects have eyes of two sorts, simple and compound. The simple eyes or ocelli consist of transparent lens-shaped swellings of the cuticle with a retina composed of a few dozen light-sensitive cells immediately below. In many insect larvae the ocelli occur in small groups on either side of the head and they serve for the perception of objects. In adult insects the ocelli occur alongside the compound eyes and are commonly situated in a group of three on the vertex of the head They seem to play no part in vision but possibly serve, like many other sense organs, as "stimulatory organs" which increase the reactivity of the insect to visual stimuli perceived through the compound eyes.

The compound eyes are very elaborate visual organs. They consist of large numbers of facets (some **4,000** in the housefly, 10,000 to 20,000 in the dragonfly) each of which has its own reti-

nal element below. Each facet or "ommatidium" receives a pencil of rays from the object. The whole eye thus projects upon the retina a composite erect image consisting of a mosaic of points of light each contributed by one ommatidium. The fineness of the mosaic and so the acuity of vision, will increase as the number of facets increases. It has been estimated that in the bee, under the best conditions of illumination. the resolving power of the eye is about one-hundredth part as good as that of man.

Insects have a considerable ability to distinguish the forms of objects; bees can be trained to associate black figures of a particular shape on a white ground with the presence of food. But the chief function of the compound eyes is probably to perceive the movement of objects as the stimulating points of light pass from one ommatidium to the next. Insects also perceive colour. The colour sense is particularly well developed in flower-visiting insects like butterflies and bees. Bees can be readily trained to come for food to a particular colour. They also experience the phenomenon of "simultaneous contrast": a gray patch on a blue ground appears yellow to the bee. Many insects can perceive ultra-violet light: moths will fly round a lamp screened by glass transmitting ultra-violet which appears totally black to our eyes.

Sense Organs: Mechanical and Chemical Senses.—At many points on the cuticle of insects there are little hairlike processes connected with a nerve cell beneath. These organs are termed "sensilla." The simplest type is the long hair with an articulated base. These are organs of touch. They occur all over the body but are most evident on the antennae in many insects and on the long tail-like appendages or "cerci" of such insects as the cricket. In the antennae of mosquitoes and on the cerci of crickets these hairs are moved by sound vibrations in the air and thus serve as simple organs of hearing. Other sense organs responding to mechanical stimuli are the "campaniform organs," minute domes set in the cuticle which are stimulated by bending strains in the integument; the "chondotonal sensilla" which have the form of long filaments running from one point to another within the body and which react to changes in mechanical tension; and the peripheral nerve net which probably perceives tension in the joints. Besides the sensory hairs, there are much more highly specialized organs of hearing in certain grasshoppers and crickets, derived from modified chondotonal organs.

The chemical senses of taste and smell are well developed in insects. Organs of taste, which distinguish salt, sweet, sour and bitter qualities, occur chiefly around the mouth parts. But various insects (butterflies and flies) can perceive sweet substances even in very dilute solutions in contact with the tarsi. The organs of smell are usually thin-walled hairs or minute cones situated chiefly on the antennae and palpi, often arising from the floor of a pit. The males of certain moths, which can locate the female by the sense of smell a mile or more away, have bushy antennae covered with these organs. In bees the sense of smell seems curiously like our own; unrelated substances which smell alike to us are also confused by the bee.

Insects can also perceive differences in temperature and humidity. The location of these senses is not always well defined, but in some insects at least they reside in the antennae. Thus the antennae, which assume such diverse forms in different insects, subserve a varied range of senses.

Behaviour.—The physiologist aims at describing behaviour in terms of reflex responses which follow invariably a given stimulus. Many of the reactions of insects to stimuli in the environment can be described in this way, as so-called "forced reactions." But very often these reactions are so much influenced by other stimuli, or by preceding events. that the complex behaviour of insects can not be satisfactorily described in these terms alone; in many descriptions psychological conceptions are made use of, such as conation the innate seeking of some end or goal.

The reactions of an insect are greatly affected by the state of excitation of the nervous system. Any of the sense organs may exert this general stimulatory effect. Insects deprived of the antennae are apt to become very sluggish and difficult to arouse by light or by touching parts of the body If the antenna of one side is removed or the eye on one side covered the insect is liable to circle toward the sound side owing perhaps to the increased muscle tonus in that half of the body. A well-marked response in many insects is "thigmotaxis": if the organs of touch are out of contact with any object the insect becomes active; when contact is regained, as for instance when an earwig or a bedbug crawls into a crevice, it comes to rest and falls into a state of sleep or "akinesis." Separation of the feet from contact with the ground provides an immediate stimulus to flight.

In the orientation of the insect many different physiological mechanisms are utilized. Orientation may.be (1) by "orthokinesis": the insect keeps moving while subjected to unfavourable stimuli, but settles down when it reaches a favourable environment. (2) "Klinokinesis": the insect moves in a straight line in a favourable environment but changes direction frequently in an unfavourable. If the response is violent enough it appears as an immediate "avoiding reaction." (3) "Tropotaxis": the insect compares the intensity of stimulation in two bilaterally symmetrical sense organs, such as eyes or antennae: and inclines toward the favourable side. (4) "Klinotaxis": the insect as it moves about senses first one side and then the other with eyes or antennae and then turns in the direction of the favourable stimulus. Any of the senses that we have discussed, of light, smell, taste, temperature or humidity may be concerned, singly or in combination.

But in addition to these simple reactions the insect sho s a varying capacity for memory, most evident among the ants. bees and wasps, and for the more elementary types of learning; they show complex chains of actions often spoken of as "instinctive behaviour"; and they show, again particularly the bees and wasps, an ability to appreciate time.

Respiration. — The conveyance of oxygen to the tissues and the elimination of the carbon dioxide resulting from oxidation is effected by the respiratory system. As was discovered by Marcello Malpighi (1669) in the silkworm. most insects breathe by means of tracheal tubes, which usually open at the surface of the body through a number of spiracles and conduct air directly to the tissues. The tracheae are invaginations of the cuticle which anastomose and branch among the internal organs. In the larger branches their walls are stiffened and prevented from collapse by a spiral thread. Their finest terminations, which are devoid of this spiral thickening, contain a variable amount of liquid, and are termed "tracheoles." These envelop or even penetrate the tissue cells.

If the spiracles were always open the insect would lose excessive quantities of moisture and would soon die of desiccation. Each is therefore provided with a sphincter and is held closed most of the time, being opened only at intervals as the need for oxygen requires. During activity the spiracles are opened more frequently. In the smaller and less active insects oxygen is conveyed from spiracles to tissues wholly by diffusion. But in larger and more active forms (grasshoppers, bees. flies, etc.) the tracheae are ventilated by alternate contraction and expansion of the body wall. These respiratory movements occur particularly during activity, and in many insects they are made more effective by the expansion of the tracheae at various points to form large thin-walled air sacs. These are ventilated mechanically, but the supply of oxygen through the branches running from them is still dependent on gaseous diffusion. The increased opening of the spiracles and the increased mechanical ventilation during activity are brought about by the accumulating carbon dioxide stimulating respiratory centres in the nervous system.

In aquatic and in parasitic insects there are many remarkable adaptations in the respiratory system. Most of these are concerned with bringing the spiracles, often a single pair of spiracles at one end of the body, into contact with the atmospheric air. But in a few larval insects the tracheal system is closed; it sends a rich meshwork of branches either to the general surface of the body or to special outgrowths ("tracheal gills") on the body surface or, as in dragonfly larvae, within the rectum. These gills enable the insect to obtain its oxygen from that in solution in the water.

The blood of most insects is of little importance in respiration.

In a few larvae (Chironomidae or "blood worms") there is haemoglobin in the blood and under conditions of poor oxygen supply, as when these larvae are living in mud, this pigment acts as a carrier of oxygen.

The Blood and Associated Tissues. — Insects have an open circulation. Throughout most of the body the organs and tissues are bathed directly by the blood or "haemolymph." But this is kept in circulation by a dorsal vessel or heart which pumps it from the hind end of the abdomen and discharges it into the body cavity again in the head. There are also small accessory pumping organs or hearts which ensure the circulation in the wings, legs and antennae.

The blood is a clear colourless or slightly green or yellow fluid which, as we have seen, plays little part in respiration. It contains a few white blood cells or "haemocytes" which act as phagocytes, ingesting microorganisms or debris from disintegrated cells. For the most part these cells do not circulate but adhere to the tissues.

Associated with the circulatory system are other tissues which function in storage of reserves and in intermediary metabolism. The "pericardial cells" occur in little groups along the sides of the heart. Their function seems to be to remove from the blood colloidal material such as unwanted proteins derived from the breakdown of cells. The "fat body" is often the most conspicuous object in the insect abdomen. It serves as a store for fat, glycogen and sometimes for droplets of protein, particularly during hibernation or during the pupal stage, when no food is taken. The "oenocytes" are large clear cells which usually occur in groups below the epidermis. They become active and enlarged during moulting, and probably secrete certain of the constituents that go to form the cuticle.

The light-producing organs of the various beetles (the glow-worm, firefly, etc.) are probably derived from the fat body. They are covered by a layer of translucent cuticle. Within the cells an enzyme "luciferase" causes the oxidation of a substance "luciferin" and almost all the energy liberated appears in the form of light.

Digestion and Nutrition. — Almost every kind of organic material can be used as food by some insect. The feeding mechanisms and the digestive processes of insects are therefore exceedingly diverse. Cockroaches, ants, beetles, caterpillars, chew their food; the blood-sucking bugs and flies pierce the skin and absorb the blood; plant-sucking insects do the same on plants; butterflies can only imbibe nectar. The first and last segments of the gut, the fore-gut and hind-gut, are lined with thin cuticle continuous with that over the body surface. The intervening segment, the mid-gut or stomach has the lining cells freely exposed. Where the insect eats solid food the mid-gut is generally protected by a delicate detached membrane of chitin, the "peritrophic membrane."

The enzymes which digest the food are produced in the salivary glands and in the mid-gut; they vary with the nature of the food, enzymes which digest proteins being most evident when the food contains much protein and so on. The absorption of the products of digestion also takes place in the mid-gut. The hind-gut seems to be chiefly concerned in the absorption of water. At the dilated end of the hind-gut. the rectum. there are groups of enlarged epithelial cells, the so-called "rectal glands." The function of these seems to be to recover as much water as possible from the faeces before they are discharged. They play an important part in the conservation of water.

Insects which feed on substances difficult to digest, such as wood or hair (keratin) commonly have digestive enzymes specially adapted to deal with them. In other insects, such as termites ("white ants"), great quantities of protozoa or other microorganisms are maintained in the gut and serve to digest the food for their hosts.

Besides the energy-providing foods. fats and carbohydrates and the body-building proteins, insects require much the same range of accessory foods or vitamins as do mammals. They find an ample quantity of these when they feed on a mixed diet. But insects which feed solely on blood, or flour, or plant juices, generally harbour symbiotic microorganisms, often within special groups of cells called "mycetomes." These microorganisms provide their hosts with a source of the vitamins that are lacking in their food.

Excretion. — The main excretory organs of insects are the Malpighian tubules. These are blind vessels, varying in number from 2 to 100 or so, lying freely in the body cavity and discharging into the gut at the junction of the mid-gut with the hind-gut. The urine which they produce is mixed with the residue of food from the stomach and the mixture after passing along the hind-gut forms the excreta or faeces. The character of the excreta depends on the type of food eaten. Where this is very watery, as in the plant-sucking insects (plant-lice or aphids and the like), the excreta are wholly fluid; insects such as the mealworm which feed on dry foods discharge a dry powdery excrement from which every trace of water has been removed. In certain insects, notably in caterpillars and in the larvae of such beetles as the mealworm which dry their excrement before discharge, the blind extremities of the Malpighian tubes are closely applied and bound down to the outer wall of the rectum; but the significance of this "cryptonephridial" arrangement is not fully understood.

The chief waste product in the urine is uric acid, which usually appears in solid form as granules or crystalline spheres that become more and more concentrated as the water is reabsorbed. In many insects, besides being discharged in the urine, uric acid accumulates in cells in other parts of the body ("storage excretion"). The stored granules may collect in special "urate cells" scattered through the fat body, in ordinary fat body cells, or in the epidermis, where they account for the chalky colouring of many caterpillars. In other insects, particularly larvae which feed inside the tissues of plants, granules of calcium carbonate may accumulate in quantity in the Malpighian tubules and as "calcospherites" in the cells of the fat body.

The excretions from the Malpighian tubes are sometimes made use of by the insect to strengthen or to colour the silken cocoon spun by the larva before pupation and in a few insects (the ant lion larva and its allies are the best known) a part of the Malpighian tube is actually modified to secrete silk.

Metabolism. — A11 the chemical changes which the constituents of the living body undergo are comprised within the term metabolism. They include the breakdown of the food substances and their building up into all the complex materials needed for growth and reproduction, the breakdown of stored materials to provide energy for movement and the elaboration of all the chemical secretions by the many glands.

From the carbohydrates, the fats and the proteins in the food, insects produce and store the fat and glycogen used for energy production. These are stored mainly in the fat body. During starvation or in hibernation the carbohydrate stores are first consumed, and then the fat. Many insects can subsist for weeks or months upon their stores of fat. Proteins are always necessary for growth and reproduction.

The glands of insects in the skin and elsewhere produce an astonishing range of chemical substances. Some of these such as silk, wax and lac are articles of commerce. Then there are complex venoms, notably in the glands of the stings of bees and wasps; formic acid in certain ant venoms; cantharidin in the beetle called "Spanish fly"; urticating substances in the hairs of caterpillars; stink glands and scent glands and many more. Among the most striking chemical products of insects are their pigments. Some of these such as the yellow carotins, some anthocyanins and flavones, and derivatives of chlorophyll, are derived from their plant food. But many of the most conspicuous, such as the pterine pigments of Pierid butterflies and many other butterfly pigments of an unknown composition seem to be by-products of metabolism which have been utilized in ornament. Production of such pigments may be markedly affected by the surroundings; thus the chrysalides of certain butterflies adapt their coloration to that of the background on which they rest.

The processes of oxidation in the body which accompany the liberation of muscular energy vary enormously in insects with the intensity of their activity. Thus on going from rest to active

flight the oxygen consumption of the bee may increase 48-fold and during flight a bee weighing 100 milligrams may burn sugar at the rate of 3; to 40 milligrams per hour.

Water Metabolism and Temperature. — The most important factors in the environment which influence the physiology of insects are temperature and humidity. The retention of sufficient water in the tissues is a prime necessity of life and we have seen that by having an impermeable cuticle, by keeping the spiracles closed as much as possible and by recovering water from the excreta before they are discharged, insects, in spite of their small size, are able to exist in dry environments.

Insects are greatly affected also by temperature. They are cold blooded or "poikilothermic" animals whose temperature is normally the same as that of their surroundings. But if the surroundings are too cold they are incapable of movement. Certain butterflies at high altitudes can not fly unless the sun is shining and their bodies are warmed by the radiant heat. During flight the contracting muscles produce enough heat to raise the body temperature far above that of the surrounding air. The large hawk moths are unable to take flight until their body temperature has been raised to 32°–36° C. by preliminary fluttering and during flight their temperature may rise above 41° C.

Different insects are able to resist different levels of high temperature; the largest forms can cool themselves to some extent for short periods by the evaporation of water, but few can withstand temperatures much above 50° C. for a period of one hour. There are differences also in their resistance to low temperatures. Insects which pass the winter in the open in cold climates develop in the cold season a condition of "cold hardiness." In this state, in which the total water content of the body is reduced, the insect can be cooled (supercooled) far below the true freezing point of the tissue fluids without the body freezing and without causing any injury. Some insects in this state will resist a temperature of −28° C.

Reproduction. — In most insects reproduction is bisexual, the egg cell produced by the female will develop only after fusion with the spermatozoa1 cell set free by the male. The reproductive system consists of paired sexual glands, the ovaries of the female and testes of the male, paired gonoducts into which the sexual products are discharged and a common duct lined with cuticle, forming the vagina in the female and the ejaculatory duct in the male.

The ovaries consist of chains of developing ova termed "ovarioles." The ripe egg, with a large store of yolk and a fully formed shell, is discharged from the lowest chamber or follicle of the ovariole. But the shell is pierced at one or more points to form a micropyle through which the spermatozoa can enter the egg. The spermatozoa received by the female at copulation pass into a small sac, the spermatheca, connected by a duct to the common oviduct or'vagina. As the egg passes into the vagina several of the filamentous spermatozoa make their way into the micropyle, and one of these fuses with the egg nucleus and initiates its development. The spermatozoa received during a single act of copulation will commonly suffice for fertilizing the eggs throughout the life of the female. In the queen bee the store of sperm received during the nuptial flight lasts for several years.

In both sexes there are accessory glands connected with the reproductive system, some of which may provide nourishment for the spermatozoa, others secrete a protective cement for the egg. In the males of some insects (Lepidoptera, many Orthoptera and Coleoptera) the sperm are not conveyed to the female in a free fluid but enclosed in a membranous sac or "spermatophore" formed by the secretion of the male accessory glands. Likewise in the female, the eggs of cockroaches, locusts and some other insects are not laid singly but are cemented together in an egg capsule or ootheca.

The egg production of insects is influenced by much the same factors as is their growth. It is delayed or prevented at low temperatures; they must have adequate food with sufficient protein in it, or they must carry the requisite stores of protein over from the larval stage; and a hormone secreted by the corpus allatum is necessary. In some insects the presence of spermatozoa in the spermatheca provides a necessary stimulus for egg production; in others a full quota of sterile eggs may be laid by the unimpregnated female. As in growth or egg development, so in reproduction, periods of diapause may supervene, notably during hibernation, when no production of eggs takes place even under favourable conditions of temperature.

There are many special modes of reproduction among insects, some of them very curious. Parthenogenesis occurs sporadically in many insects; in some it is constant, and males are unknown. During their summer generations the aphids (green fly) are both parthenogenetic and viviparous. Viviparity of newly hatched larvae is common in certain flies; the tsetse fly (Glossina) gives birth to a single full-grown larva that has been nourished in the uterine cavity by special "milk glands." Polyembryony occurs in various parasitic Insects: a single egg will split up in the course of development and give rise to some hundreds of larvae. One of the most remarkable phenomena is paedogenesis, which occurs in certain midges, in which the ova in the young ovaries of the larvae or pupae ripen prematurely and develop into larvae which devour and disrupt their parent host.

BIOLOGICAL CONTROL

The control of insect populations by use of parasitic, predatory or pathogenic organisms is termed biological control, as distinguished from other methods of control involving cultural practices or the use of insecticides.

It is generally conceded that under primitive conditions, undisturbed by man, populations of insects, as well as of other organisms, exist in a sort of equilibrium commonly referred to as the balance of nature. Any tendency of a species to increase beyond a certain maximum abundance results in the intensification of the natural forces that work against it and thus reduce its numbers; and, conversely, any tendency to drop below a certain minimum abundance usually results in release from the repressive forces of the environment, so that numbers tend to increase. Experience has shown, however, that the coming of man, with his world commerce, often results in a temporary upsetting of this natural balance. Many of the major agricultural insect pests throughout the world are such because they have been transported from their native habitats, where they are kept under control by enemies or diseases, to new habitats where these restraining forces are absent. The basic idea of biological control of insects, therefore, is that when a species is introduced into a new habitat and becomes seriously abundant because some of the repressive forces are left behind, such as, its insect parasites and predators, it is possible to remedy the condition by seeking out these enemies and introducing them into the new habitat.

The organisms most commonly and most successfully used as agents in biological control have been the insectivorous or entomophagous insects — those having the habit of feeding upon other insects. In biological control the entomophagous species are divided roughly into two categories, parasitic and predaceous. A parasitic insect, according to entomological usage, is one which, through its growing stages, lives and develops either within or upon a single host individual, which usually dies as a result of the parasite attack. A predaceous insect is one that requires several individuals of the prey species to bring it to maturity, this requirement necessitating the capability of moving from host to host during the growing stages. There are, however, many intergradations between the two categories and no definite line of demarcation separates them. Entomophagous insects are found in almost all the principal orders of the class Insecta, but generally speaking, the parasitic species are found mostly in the Hymenoptera and Diptera, while the predaceous species are found mostly in the Coleoptera, Neuroptera, Diptera and Heteroptera.

Each species of insect ordinarily has one or more insect enemies, and some species support a large number of insect parasites and predators. For example, the black scale (Saissetia *oleae*), a pest of oranges and olives in many parts of the world, is attacked by more than 50 species of parasites, as well as by numerous

species of insect predators such as the ladybird beetles (Coccinellidae). The gypsy moth *(Porthetria dispar).* an important pest of forest trees, has perhaps an even greater number of parasitic and predaceous enemies which depend upon it for their subsistence.

Insect parasites, like other parasites, often have very complicated life histories. A knowledge of their biology is an essential part of successful application of the biological control method. Parasitism is usually a highly specialized mode of existence. The parasite must have a means of making contact with its host species. Also, for the greater part of its life, it exists in most intimate relation with its host. This necessitates an extremely delicate adjustment between the two individuals, since the parasite must avoid killing its host until the former has completed its feeding, and still must accomplish the death of the host before the latter fulfils its reproductive functions; else the parasite would be of little or no significance in biological control. Most insect parasites, therefore, must have special biological adaptations enabling them *(1)* to come into contact with their host, (2) to obtain nourishment from the host individual, (3) to secure oxygen from within the host and *(4)* to avoid the discharge of excretory products within the host, possibly injurious to the latter. The many and various ways by which parasitic insects have attained these essential ends form one of the most interesting chapters in the entire field of biology. In fact, the biology of these species takes such a wide variety of forms that it is not possible even to outline them here. Those interested are referred to the book *Entomophagous Insects,* by C. P. Clausen (New York and London, 1940).

History. — The idea of using one species of insect to destroy another long intrigued those biologists who had observed the interrelations of insects in nature. Probably first to suggest that predatory or parasitic insects might be utilized in the destruction of insect pests was Erasmus Darwin *(Phytologia or the Philosophy of Agriculture and Gardening,* London, 1800). Darwin recommended the propagation of the syrphid fly, which he had found feeding on aphids, as a control for the latter. He also suggested that the cabbage caterpillar could be controlled by one of its parasites. presumably *Apanteles glomeratus,* if the parasite could be protected during the time it was in hibernation. Among other early English biologists impressed by the observation that populations of plant-feeding insects were reduced by insects which fed upon them were William F. Kirby and William Spence *(An Introduction to Entomology,* 1815), who suggested that the development of a means of increasing the predaceous ladybird beetles would make it possible to clear the hothouses of aphids and thus render the crops of hops much more certain.

Many other early European scientists appreciated the part played in nature by parasitic and predatory insects, and some actually attempted to utilize this phenomenon in a practical way. M. Boisgiraud, *e.g.,* in *1840,* collected carabid beetles *(Calosoma sychophanta)* and colonized them on poplar trees in France, where they destroyed the gypsy moth caterpillars. In *1843* an organization known as the Society for the Encouragement of Arts and Crafts, in Milan, Italy, offered a gold medal to the person who should succeed in demonstrating how "carnivorous" insects might be used to destroy insects injurious to agriculture. The prize was won by an entomologist by the name of Antonio Villa, who maintained that certain climbing beetles could be used to control tree-inhabiting insects, that other kinds of insects could be used to control insect pests occurring in flowers and still others to control cutworms and certain earth-inhabiting species. However, little in a practical way appears to have come from Villa's suggestions.

These attempts at biological control of insect pests were limited tc the ase of parasitic and predaceous species already inhabiting the particular area where the work was undertaken. The idea of introducing insectivorous species from another country or region seems to have occurred to entomologists somewhat later in the century, after international commerce had resulted in the introduction, into several countries. of insect pests which had not previously occurred within their boundaries. Perhaps the first suggestion of this kind was made by Asa Fitch, of New York, in *1854.* Fitch recognized that the wheat midge, destructive to wheat in the eastern United States, was a native of Europe. His study of the entomological literature indicated that in Europe it was only occasionally injurious, and that there it was attacked by several species of parasites. He maintained that the difference in injuriousness, as between the U.S. and Europe, was a result of the fact that the pest had been brought in without the parasites which kept it in check in its native habitat. Fitch, through correspondence with his entomological colleagues in Europe, actually attempted to introduce these parasites into the U.S., but nothing ever came of it.

The first transfer of an entomophagous species from one country to another, for the purpose of controlling an introduced insect pest, was made in 1873 by J. E. Planchon and Charles V. Riley, of the French and U.S. governments, respectively. Through their efforts, the predatory mite *Tyroglyphus phylloxerae,* which feeds on the grape phylloxera in the U.S., was introduced into France for control of the phylloxera accidentally introduced into that country on grape vines from the U.S. The mite became established but apparently had little effect on the phylloxera probiem, which was solved later by the use of resistant rootstocks.

In *1883* Riley imported the parasite *Apanteles glomeratus* into the U.S. from Europe to control the cabbage butterfly. This parasite became established and of considerable value, although not a complete control for the pest.

The first unqualified success resulting from the transfer of a predatory or parasitic insect from one country or locality to another for suppression of a pest, occurred when the ladybird beetle known as the Vedalia *(Rodolia cardinalis)* was brought from Australia into California, in *1889,* by the U.S. department of agriculture, for control of the cottony-cushion scale *(Icerya purchasi).* This scale was known to have been imported accidentally on nursery stock from Australia in *1869.* By *1883* it had spread to southern California and was doing enormous damage to citrus trees. It became so injurious that banks refused to make loans on infested groves, and the fruit growers finally appealed to the government in Washington for help. The entomologists of the U.S. department of agriculture set to work to develop means of combating the pest. Many recognized types of insecticides were tried and new ones invented, but none gave satisfactory results and the citrus industry appeared to be threatened with disaster. Finally, in *1888,* an entomologist, Albert Koebele, was sent to Australia to search for parasites and predators of the cottony-cushion scale, for shipment to California.

Koebele's search was successful, and two of the species forwarded, the dipterous parasite *Cryptochaetum iceryae* and the Vedalia, became established in California. The Vedalia, particularly, in the presence of so great a food supply, increased with such rapidity that within about *18* months the pest upon which it fed had all but disappeared, and countless numbers of the beetles were starving because they had consumed their own food supply and were unable to subsist upon any food other than the cottony-cushion scale. Thus an introduced pest, which had threatened an important industry providing annually many millions of dollars worth of wealth, was subjugated by the introduction of a predaceous enemy species from its native habitat, at a cost of about $1,500.

The cottony-cushion scale later found its way to other parts of the world, including New Zealand, South Africa, Egypt, Hawaii, Italy, France, Uruguay and Florida. In every case the introduction of the Vedalia was followed by speedy subjugation of the pest. This striking demonstration of the utility of biological control naturally aroused much enthusiasm for the method. Several parasite-hunting expeditions were sent out from California, and valuable insects were introduced as a result of these explorations, including the mealy bug-destroying ladybird beetle (*Cryptolaemus montrouzieri*), about which more will be said later. None, however, proved more outstandingly successful than the Vedalia.

Methods, — Biological control of insect pests may take either of two forms: (1) the importation of one or more species of entomophagous insects or pathogenic organisms, in the expectation that, when established in the new habitat, such a destructive influence will be exerted that the host will subside in numbers to a point where it will do little or no serious damage; (2) the development of means whereby the effect of an introduced or native

entomophagous insect or pathogenic organism, which is unable to subjugate its host unaided, may be increased so as to render its use as a control agency profitable.

Importation of Species.— In work of this kind, one of the most important things to be considered is the native habitat or country of origin of the pest, naturally the most logical place in which to search for effective enemies and diseases, hut not always easily determined. Often the country of origin is unknown, and it is necessary to consider many different factors before setting out on such a quest. Usually, the entomologist attempting to determine the country of origin of an insect species searches the literature for clues, assuming, of course, that the pest has been identified by an expert and that its correct name and systematic relationship are known. A search of the literature will reveal the names of the various countries in which the species has been collected. Such records are usually associated with dates, so that if the species has been dispersed since entomologists began publishing records, the locality where the pest was recorded earliest would most likely indicate the central point of dispersal, or the native habitat of the insect. Sometimes, however, of all the places where the insect is known to occur, obviously no one place is its native home because of its extreme abundance and lack of parasites. Such a situation calls for the exercise of a considerable amount of ingenuity in order to reduce the suspected regions to a small number. The alternative is a random search which might prove almost limitless. Among the factors having a bearing on the origin of an insect species discovered outside its native habitat are the following: *(1)* the natural distribution of its host plants; (2) the distribution of closely related species of insects, on the assumption that related species had a common geographic origin; and *(3)* the lines and means of transport by which the species may have been carried from its native home to the new location. Many sections of the globe can be excluded through a process of elimination, by giving due consideration to these factors, and the search can thus be narrowed appreciably.

Once the native home of the pest has been determined, or the field limited to a few pcssibilities, the actual exploration is undertaken. Trained entomologists familiar with all the biological characteristics of the pest species and experienced in the exploration for, and in the culturing and transportation of, entomophagous insects and pathogenic organisms are assigned to search the selected region. It is their responsibility to forward to the domestic station such promising species as they may discover. Entomologists similarly well qualified are located at the receiving station to care for, propagate and distribute in the infested areas the species sent in by the entomological explorers.

Suitable insectaries and other equipment are essential to proper conduction of this work. It is particularly important that quarantine facilities, in the form of insect-proof rooms, be available, since dangerous material is sometimes unavoidably included in shipments from abroad. This material may consist of host plants bearing insects not known to occur in the area of reception, whose accidental escape might result in the establishment of a new pest. In addition, the parasites and predators themselves are often attacked by other parasites, which, if permitted to escape at destination, might become established in the new habitat and interfere with the efficiency of the desired species. It is therefore necessary to exercise extreme care in the handling of foreign material, so that it may be kept under rigid control at all times.

The development of air transportation has greatly simplified the work of explcration for and transportation of beneficial insects, and the modern tendency is to transport, by air, only the adult parasites themselves, and thus avoid danger of bringing in unwanted species. Regardless of this development, special facilities providing various kinds of physical environments are necessary at the receiving end. This is particularly true when the imported species come from the southern hemisphere to the northern, or vice versa, since their development is then out of synchronization with the seasons in the area of destination, and the rhythm of their development must he upset before they can be established in the new habitat.

When sufficient material of the introduced species is available, colonies are taken to the field and liberated in areas where the host insect is abundant. If possible, especially when the host inhabits regions of varying environmental conditions, colonies are established in several types of ecological habitats, since the new species may thrive in some and not in others. Later, it is necessary to make field collections of the h'ost insect in the regions where the liberations have been made, in order to determine whether the parasite has successfully established itself in the new habitat, and to what extent it may be influencing the populations of its host.

Mass Propagation and Colonization of Species.— To increase the efficiency of entomophagous or pathogenic species introduced or already present in an area, it has been necessary to devise methods of mass propagation or culture. Many species of entomophagous insects fail to exert against the populations of their host insects sufficient pressure to control them, because certain conditions of the environment, such as extreme winter temperatures, reduce them annually to very low numbers They are thus handicapped as the season develops, since they must start with too few, individuals. From such an unfavourable beginning, they are unable to build up to controlling numbers during the season. This has led to a search for inexpensive means of propagating such species for release in the field at proper intervals, to counteract the seasonal reduction in numbers and to assist the species in becoming dcminant over the host insects.

A major problem in the production of entomophagous insects for periodic field colonization is the selection and handling of the plant material upon which the host insect may be cultured in the insectary. It has been found that mealy bugs can be grown satisfactorily on potato sprouts; the moth *Sitotroga,* however, which is used as a host in the propagation of the egg-parasite *Trichogramma,* is best grown on maize or wheat. The plant material should be of such a nature that simple equipment and methods will suffice to produce the host insects in large numbers cheaply.

For further information on this subject, the reader is referred to *Culture Methods for Invertebrate Animals* (1937), by J. G. Needham *et al.,* and *L'Infection Chez Les Insectes* (1933), by A. Paillot.

Biological Control Projects.— In addition to the Vedalia success already recounted, many other examples of profitable use of biological control may be cited, some involving the establishment of nonnative species, and others the mass production and colonization of species, both of entomophagous insects and of pathogenic organisms.

Use of Entomophagous Insects.— The Mediterranean fruit fly (*Ceratitis capitata*) was discovered in the Hawaiian Islands in *1910,* and within a few years became very destructive to several fruit crops. A search for parasites in Africa and Australia resulted in the establishment of several important species in Hawaii in 1913–14. It was found that the parasites were rather ineffective on fruits such as the orange or peach, in which the fly larva develops out of reach of the parasite. On small fruits, however, such as the coffee berry, the parasites proved very effective, particularly the parasite *Diachasma tryoni,* from Australia.

The larch sawfly (*Lygaeonematus erichsonii*), accidentally introduced into Canada from Europe, became so abundant that the larch forests of eastern Canada were largely destroyed, and the pest spread to the western provinces. The intrcduction of the parasite *Mesoleius tenthredinis,* from England, 1910–13, by the imperial parasite service, resulted in a very satisfactory control of the pest after some years.

A related species, the spruce sawfly *(Neodiprion abietis),* was first found in Canada in 1930. There it rapidly assumed epidemic proportions and defoliated thcusands of square miles of forest. The Canadian government, through the imperial parasite service, made large-scale importations of spruce-sawfly parasites from Europe during the period 1933–39. Many species were introduced, and methods for the annual production and colonization of one, *Microplectron fuscipenne,* were worked out. Hundreds of millions of individuals of this parasite were liberated in the infested forests in eastern Canada, and a high percentage of parasitization was secured.

The Japanese beetle (*Popillia japonica*) was first discovered in the eastern U.S. in *1916,* where it did serious damage to lawns, turf and many fruits and ornamental plants. In 1920 the U.S. department of agriculture began a search for the insect enemies of this beetle in the orient, a search which continued for several years. Five species of parasites were established as a result of this search, but on the whole the introductions have not been so successful as it was hoped they might be, owing largely to asynchronization of the life cycles of parasites and host in the new environment.

The alfalfa weevil *(Hypera postica)* was brought to the U.S. accidentally from Europe and by *1911* had become very destructive. Search for parasites in Europe resulted in the discovery of the parasite *Bathyplectes curculionis* in Italy, and its successful introduction into Utah in 1911–12. This parasite often destroys more than 90% of the first brood of weevil larvae and is a valuable repressive iactor in most of the areas inhabited. After its introduction, the weevil population gradually fell until now other control practices are rarely necessary.

One of the largest biological control projects carried out any place in the world has been on the gypsy moth *(Porthetria dispar)* in the U.S. This forest-tree pest originated in Europe and was brought to the U.S. in *1869.* In the *40* years following 1905, when the first importation of parasites began, the U.S. government colonized more than 50 species of foreign parasites and predators, of which *13* species became established, attacking all stages irom egg to pupa. The results are difficult to appraise, since even in its native habitat the gypsy moth is subject to severe fluctuation in numbers, but the general belief is that the introduced enemies have greatly reduced the frequency and severity of the outbreaks. By 1945 the status of the gypsy moth in the U.S. was very similar to that existing in its native home, central Europe.

The history of the brown-tail moth *(Nygmia phaeorrhoea),* another European species occupying much the same region in the eastern U.S. and Canada, is similar to that of the gypsy moth. Many parasites have been successfully introduced from Europe, and the pest seems to have subsided materially.

The satin moth (*Stilpnotia salicis*) has been very successfully controlled in the U.S. and Canada by several European parasites introduced during the pericd 1927–32, particularly by *Apanteles solitarius, Meteorus versicolor* and *Compsilura concinnata.*

One of the most successful instances of biological control is that of the so-called Levuana or coconut moth of Fiji *(Levuana iridescens).* This pest threatened to destroy the principal agricultural industry of

Fiji, *i.e.*, the production of coconuts. The Levuana moth was not known to occur outside the Fiji islands, but the entomologists sought parasites of related species and finally discovered the parasitic fly *Ptychomyia remota* attacking the related *Artona catozantka*, which feeds on coconuts in Malaya and Java. *P. remota* was successfully established in Fiji in 1925, and within a very few months had the Levuana moth under almcst perfect control, so that it was no longer a pest of any economic importance.

A very striking success in the application of the biological control method occurred in connection mith the citrus black fly (*Aleurocanthus woglumi*), a pest introduced accidentally from Asia and of great importance to citrus in the West Indies. In 1930 the U.S. department of agriculture co-operated with the government of Cuba in a search for parasites in Malaya and elsewhere. Of several species discovered, one, *Eretmocerus serius*, mas established in Cuba and within a very short time demonstrated its ability to bring the pest under control. Successful subjugation of the black fly quickly followed the introduction of the parasite into Jamaica, Panamá and Haiti.

An early and outstandingly successful example of biological control of a pest is that of the sugar-cane leafhopper (*Perkinsiella saccharicida*), in Hawaii. The insect was apparently introduced accidentally from Queensland, Australia, in the early part of the 20th century and soon became a major problem for the sugar planters, causing losses estimated at $3,000,000 annually. An extended search for parasites to control this pest was undertaken by the Hawaiian sugar planters' experiment station in 1903 and continued for many years, throughout a large part of the tropical Pacific region. Many species of parasites mere introduced, some of rvhich became established and served to reduce the injury caused by the pest. But it was not until Frederick Muir discovered the predatory bug *Cyrtorhinus mundulus*, in Australia and Fiji, and introduced it into Hawaii, in 1920, that the subjugation of the leafhopper mas complete.

One of the most interesting cases of the utilization of the biological control method, from the international viewpoint, has to do mith the woolly apple aphid (*Eriosoma lanigera*), a native of the eastern U.S., where it is attacked by the parasite *Aphelinus mali*. This parasite has been colonized in ali parts of the globe where the woolly apple aphid has preceded it, something like 50 different countries having undertaken to establish it in their infested apple orchards. The outcome of these numerous attempts has ranged all the way from complete success to complete failure, but in general this world-wide dissemination of the parasite has been a profitable activity.

Two remarkably successful instances of biological ccntrol of mealy bugs have taken place. The avocado mealy bug (*Pseudococcus nipae*) in Hawaii is under perfect control as the result of the introduction from Mexico, in 1922, of the parasite *Pseudaphycus utilis*. The citrophilus mealy bug (*Pseudococcus galzani*) was accidentally introduced into the U.S. before 1914. By 1926 it was causing an estimated damage of more than $1,000,000 per year to the California citrus industry, in spite of extensive production and colcnization of the predaceous coccinellid *Cryptolaemus montrouzieri*. In 1929 the parasites *Coccophagus gurneyi* and *Tetracnemus pretiosus* were introduced from Australia. Within two years it became evident that these introductions would prove effective, and the ultimate outcome was one of the most perfect examples of biological control of an intrcduced pest.

One of the most extensive attempts ever undertaken to bring about biological control of a pest was that in connection with the black scale (*Saissetia oleae*) in California. Koebele, during the 1890s, shipped several species of coccinellids, including *Rhizobius ventralis*, from Australia to California. In 1902 the hymenopterous egg-predator *Scutellista cyanea* was introduced from South Africa, followed by the African parasite *Metaphycus lounsburyi* and several others. Then in 1937 the parasite *Metaphycus helvolus* was introduced from South Africa. This parasite socn proved itself to be one of the most important enemies of the black scale. While the control is not perfect, heavily infested orchards have been the exception rather than the rule since the introduction of this parasite.

The cabbage worm (*Pieris rapae*) was brought under control in New Zeaiand by the introduction, through the imperial parasite service, of the parasite *Pteromalus puparum*, from Europe, during the period 1931–33.

In British Columbia a pest of various fruit and ornamental plants, the scale *Lecanium coryli*, a native of Europe, was controlled by the introducticn of the parasite *Blastothrix sericea* from England in 1928.

The first extensive use of mass propagation in biological control occurred in California, where the common mealy bug (*Pseudococcus citri*) had become an important pest of oranges and lemons. The predatory species *Cryptolaemus montrouzieri*, a ladybird beetle, was used for this purpose, methods for its mass production being developed in 1916, with culture of the host insect on ordinary potato sprouts. By 1930, when *Cryptolaemus* was being used for control of both *P. citri* and *P. galzani* 40,000,000 of the ladybird beetles mere produced and colonized annually, at a cost of about $2.50 per 1,000. In 1931 the introduced parasites *Coccophagus gurneyi* and *Tetracnemus pretiosus* had brought *P. gahani* under control, but the method continued to be used for control of *P. citri*. It is also used extensively in Spain, France and other countries where mealy bugs are pests of economic importance.

Another interesting example of the control of a pest by means of the mass production and colonization of one of its insect enemies is that of the greenhouse white fly (*Trialeurodes vaporariorum*) in England and Canada. This pest attacks a wide variety of vegetables, such as tomatoes and cucumbers, which are grown in greenhouses at certain seasons. The parasite *Encarsia formosa* is cultivated on the white fly grown on tomato and tobacco. In 1930 about 1,500,000 individuals of this parasite were utilized in the British Isles. Later the method was introduced into Canada, where up to 1938 about 1,000,000 parasites were distributed annually. In the producticn of this parasite, advantage is taken of the fact that when the white fly is being grown on tobacco, the parasite attacks it only lightly. If the tobacco plants are grown in the greenhouse along with tomatoes, the tobacco serves as a continual nursery for the production of *Encarsia*, since the parasite does not completely destroy the host on this plant, and the parasites so produced go over to the white fly on tomato plants, upon which they control the hcst.

The parasite most extensively used in mass propagation has been the little egg-parasite *Trichogramma evanescens*. This parasite attacks the eggs of a large number of species of insects, preferring, however, those of moths and butterflies. The parasite is easily produced in insectaries in enormous numbers on the eggs of the Angoumois grain moth (*Sitotroga cerealella*), and it has been utilized almost throughout the world on various pests including the codling moth, the oriental fruit moth, the sugar-cane moth borer, the cotton worm, the European corn borer and others. The results, however, have been very inconsistent. In Russia it is maintained that codling-moth infestations have been reduced as much as 75% as a result of liberations of *Trichogramma*. In the U.S. and Canada, the results have been either negative or inconclusive. In Barbados and Peru, the parasite has been reported used successfully as a control for the sugar-cane moth borer.

The development, in California, in 1943, of the potato tuber-worm method for mass propagation of *Macrocentrus ancylivorus*, an important parasite of the oriental fruit moth (*Grapholitha molesta*), marked a distinct advance in methods of mass production. The oriental fruit moth, a major pest of peach and other fruits in many parts of the world, but particularly in the U.S., is supposed to have originated in Japan or China. The U.S. department of agriculture conducted a very extensive search for the parasites of this pest from 1929 to 1936. During this period 23 or more species of parasites were colonized, but only one, *Inareolata molestae*, became established, and that only in a very limited way. Nothing of practical value came out of these introductions. Unexpectedly, *M. ancylivorus*, which is apparently a native of the U.S., with the strawberry leaf roller (*Ancylis comptana fragariae*) as its favoured host, developed a taste for the fruit moth and destroyed a high percentage of the twig-infesting larvae. It has been common practice to grow this parasite on the strawberry leaf roller for liberaticn in infested peach orchards in the eastern part of the U.S. and Canada. Discovery of the fruit moth in California, in 1942, however, was followed by the development of a new procedure for production of the parasite, it being cultured in insectaries, with the larvae of *Gnorimoschema operculella*, grown on potato tubers in trays, as host insects. During the year 1944, more than 20,000,000 individuals of *M. ancylivorus* were produced and colonized in California, at a cost about one-tenth that of culturing the parasite on the strawberry leaf roller.

It seems probable that the future will witness a considerable extension of the mass-colonization method, not only as an independent control measure, but as an auxiliary to insecticidal treatment. In some instances commercial organizaticns have undertaken the production of parasites or predators for sale to growers.

Use of Pathogenic Organisms.— Diseases caused by bacteria and fungi are often extremely destructive to insects, particularly to those existing under conditions of abnormal crowding. Entomologists attempting to culture insects in confinement often find their efforts nullified by the outbreak of a destructive bacterial or fungous disease. It seems to be the general opinicn that such organisms are so closely dependent upon conditions of the physical environment that attempts to use them in a practical way are likely to prove disappointing, with unpredictable results. Such a conclusion, however, seems too sweeping until a great deal more is known about the subject.

One of the most comprehensive tests made with bacterial diseases was that of F. d'Herelle, who in 1915 reported good results against the locust *Schistocerca peregrina* in North Africa, when cultures of *Coccobacillus acridiorum* were sprayed over the infested area. In other parts of the world and against other locusts, unsatisfactory results mere reported, and the use of this organism for locust control has not been adopted generally. Many other attempts have been made to use bacterial diseases for control of insect pests, usually with inconclusive results.

In one case, namely, that of the Japanese beetle (*Popillia japonica*) in the U.S., the use of bacterial diseases seems to have been strikingly successful. The causative organisms (*Bacillus popilliae* and *B. lentimorbus*) are cultured by inoculating the grubs of the host with spores. From the dried bodies of the diseased grubs, a standardized spore suspension is made, which is then added to precipitated calcium carbonate in such quantity that the mixture contains roughly 1,000,000,000 spores per gram. This material is then incorporated in a carrier such as talcum or marble flour, and is dusted over the infested areas.

The "milky disease," as it is called, is used extensively for Japanese-beetle control in several of the eastern states of the U.S. Experiments have resulted in 90% mortality of grubs in soil inoculated with the spores.

Many species of parasitic fungi are known to attack insects. These fungi often appear in epidemic form and almost exterminate the host species. Grasshoppers, for example, are commonly attacked by the parasitic fungus *Empusa grylli;* the chinch bug (*Blissus leucopterus*), by *Beauveria globulifera;* the apple sucker (*Psylla mali*), by *Entomophthora sphaerosperma,* etc. When conditions are right, these parasitic fungi can be very destructive to their host insects, but controlled experiments have generally cast doubt on the possibility of increasing their effectiveness by artificial means. However, a great deal of research remains to be done before the question of the practical use of fungous and bacterial diseases in the biological control of insect pests can be answered. This is a field in which relatively little fundamental work has been done.

There are many other types of fatal diseases among insects, some caused by Protozoa, others by viruses. Here, too, attempts to make practical use of such diseases have had inconclusive results, but research has been insufficient to justify abandonment of such attempts.

INSECT BITES AND STINGS. Fortunately, few of the billions of insect bites and stings that the population of the world suffers each year result in serious disease. Malaria, yellow fever, typhus, encephalitis, tularaemia, bubonic plague, typhoid fever, anthrax and many other diseases are carried and transmitted by insects. This article concerns itself primarily with host reactions resulting from toxins peculiar to the insect itself and with measures for repelling these insects and treating the disease which their bites provoke.

Most insect bites, such as those of the fly, mosquito and flea, cause an almost immediate reaction in humans consisting of itching, redness and local swelling of the skin. This usually subsides within 2 to 24 hours without leaving any permanent mark. It is believed that this result is an allergic reaction dependent upon salivary components to which the host has developed a sensitivity via previous exposure. Infants receiving their first mosquito bite show no reaction (sensitivity) to the bite, and individuals who receive constant bites over long periods of time may develop an immunity (desensitization) and consequently develop no reaction to the insect bite. Thus. natives frequently hold the erroneous belief that parasites indigenous to the region do not bite them.

Stinging insects such as the bee, hornet or wasp give rise to intensely painful, elevated skin lesions which are transitory and believed to be due to the irritant action of formic acid and an alkaline neurotoxic substance present in the venom. Multiple stings may give rise to alarming systemic illness with fainting, collapse of the circulatory system, difficult breathing and, in rare instances, death. The honeybee leaves its stinger in the skin whereas the wasp does not. Beekeepers eventually develop an immunity to the sting of the bee and they may receive many stings without experiencing any subjective or objective response. Such an immunity can be developed experimentally by repeated injections of bee venom.

Bloodsucking lice (Anoplura) live on or close to the skin and occur in three varieties: the head louse. body louse and pubic louse. They fix their eggs to hair or clothing and periodically feed on their host. Their bites result in severely itchy skin lesions, which when scratched frequently become infected and may thus result in widespread complications.

Bedbugs which live in mattresses, walls and furniture attack their host only in the dark. Though they are usually thought of as denizens of poverty and filth, they not infrequently find their way into the environs of affluence.

Treatment. — Local applications for any bite or sting are of little value other than the removal of insect parts left in the wound or local applications of antiseptic agents to prevent infection. Anti-itch medicines such as menthol or phenol compounds may be applied. For those insects such as lice which reside on the skin, local applications of cuprex, DDT powder or lindane will destroy the insects. However, some insecticides such as DDT are not lethal for the eggs of these insects so that repeated applications over two weeks are necessary to eradicate the colony. Spraying the environs with DDT, chlordan or lindane is usually effective in destroying resident bedbugs, fleas and most other insects.

Repellents.—Much more fiction than fact clouds the question of effective insect repellents. So called oral repellents (compounds believed to repel insects after they are swallowed by the individual) have not been proved of value for the human. However local applications to the skin of such compounds as dimethyl phthalate, dimethyl carbate, Indalone and Rutgers 612 (2-ethyl-1,3-hexanediol) either alone or in combination have been shown to be very effective for general use. A good, all purpose, clothing repellent for mosquitoes, ticks, fleas and chiggers is the mixture: *n*-butyl acetanilide, 30%; benzyl benzoate, 30%; 2-butyl-2-ethyl-1,3-propanediol, 30%; and Tween 80, 10%. This mixture is diluted in one to two parts of water. (RD. B. S.)

INSECTICIDES, chemicals used for destroying insect pests. When employed to protect plants they may be applied in the form of wet sprays, aerosols or as dusts; those most commonly used for this purpose include various arsenicals, nicotine, rotenone, pyrethrum, paradichlorobenzene, DDT, petroleum oil emulsions, soaps, etc.

When it is desired to kill insects that may be present in a room, fumigation (*q.v.*) or the filling of the room with poisonous gases or vapours is resorted to. This method may also be used for plants by enclosing them in tents. Hydrogen cyanide, carbon disulphide and carbon tetrachloride are some examples of the chemicals employed in fumigation. *See* ENTOMOLOGY: *Principles of Insect Control.*

INSECTIVORA, an order of placental mammals of small size, with a dentition adapted to an insect diet. Nearly all members of this order are nocturnal and terrestrial; many, however; are fossorial or arboreal, and a few are aquatic. There are generally five toes, each terminating in a claw; the first toe is never opposable to the others in either the fore- or hind-limb. A full series of teeth, including deciduous or milk molars, is developed, and the cheek teeth as a rule are crowned with sharp cusps. The typical number of teeth is 44, arranged as shown in the formula $i.\frac{3}{3}, c.\frac{1}{1}, p.\frac{4}{4}, m.\frac{3}{3}$; occasionally there is a fourth pair of molars, while the incisors may be reduced to two pairs above and one pair below. The skull is of a primitive type, with a small brain case, the tympanic bone generally ringlike instead of forming a bulla, or bony bulb in the ear region, and vacuities are frequently present in the palate. With the exception of the Potamogalidae, collarbones are always present, and a central bone is usually present in the carpus. The uterus is two-horned; the placenta, so far as is known, is deciduate so that the uterine lining is cast out at birth, and discoidal, or disc-shaped, as in the primates and rodents; the testes are abdominal or in the inguinal canal connecting the abdominal and scrotal cavities; and the teats are numerous.

The stomach is a simple, thin-walled sac; sometimes, as in *Tenrec,* the pyloric and oesophageal openings are close together. In the arboreal forms, which probably feed on plants as well as insects, most of the species possess a caecum.

All the members of the order appear to be highly prolific, the number of young varying from 2 to 8 in the hedgehog, and from 12 to 21 in the tenrec. Scent-glands exist in many species. In most shrews they occur on the sides of the body at a short distance behind the axilla, and their exudation is probably protective, as very few carnivorous animals will touch them. In *Echinosorex* and in *Potamogale* large pouches are situated on each side of the rectum, and discharge their secretions by ducts, opening in the first named genus in front of and in the latter within the margin of the vent. In the tenrec similarly situated glands discharge by pores, opening at the bottom of deep pits.

Representatives of this order are found throughout the temperate and tropical parts of both hemispheres, with the exception of South America (where only a few shrews have penetrated), New

Guinea, Australia and the oceanic islands. *Cynocephalus,* the so-called flying lemur, was formerly placed in the Insectivora; it is now generally regarded as forming a distinct order, the Dermoptera. (*See* CYNOCEPHALUS.)

The Insectivora may be divided into nine superfamilies, three of which are extinct.

Deltatheridioidea.—An entirely extinct superfamily established for Cretaceous and early Eocene forms; it takes its name from *Deltatheridium,* of the Mongolian Cretaceous. The several skulls discovered in Mongolia were not far from the more famous but far less important dinosaur eggs. *Deltatheridium* is known from a fairly complete skull, with a braincase smaller than that of modern insectivores, and with teeth intermediate in form between those of the earliest creodonts and those of carnivorous marsupials.

Tenrecoidea.—This group and the following are sometimes considered to form a suborder of Insectivora. the Zalambdodontia, named from the peculiar cusp-pattern of the molar teeth, the main cusps of which form a triangular pattern. Three families are included here.

Family Potamogalidae is represented by the otter shrew, Potamogale *velox,* an aquatic species with otterlike fur and vertically flattened tail, found in the rivers of tropical Africa from Nigeria to Uganda and Angola. In the skull the zygomatic arch or cheekbone, is absent. The dentition: i.$\frac{3}{3}$, c.$\frac{1}{1}$, p.$\frac{3}{3}$, m.$\frac{3}{3}$=40. This insectivore is about two feet in total length, the tail being about half.

Family Tenrecidae, agrees with the Potamogalidae in the absence of zygomatic arch, but the upper molars have narrower crowns. Teats are present on both the breast and abdomen, and some forms are as spiny as hedgehogs; the group is confined to Madagascar. The incisors vary from $\frac{3}{3}$ to $\frac{2}{2}$; the canine is always present and the cheek teeth are p.$\frac{4}{3}$, m.$\frac{3}{3}$. Subfamily Tenrecinae includes the following genera: the tenrec (Tenrec ecaudatus), is a large, tailless animal, with harsh spiny hair, the incisors are $\frac{2}{3}$ and the young teeth are striped; Hemicentetes, the striped tenrec, is smaller than the tenrec, more spiny and has incisors $\frac{4}{4}$; the hedgehog tenrec (*Setifer setosus*) is hedgehoglike, having the whole dorsal surface covered with spines; the incisors are $\frac{2}{2}$. Subfamily Oryzorictinae includes four genera. Microgale is small and shrewlike, often with a long tail (*M.* longicaudata has head and body 60 mm.; tail 140 mm.) and $\frac{3}{3}$ incisors. Oryzorictes is distinguished by its shorter tail and fossorial habits. *Limnogale mergulus* is a large aquatic form with webbed toes and a long, laterally compressed tail (head and body 150 mm.). Geogale aurita has only 34 teeth; it is also aquatic.

A Palaeocene form from North America, Peroryctes, is referred to the Tenrecoidea. This helps explain the distribution of the tenrecoids. The living West Indian solenodons, the west African Potamogale and the Madagascar tenrecs are all relics of an ancient world-wide stock.

Family Solenodontidae is represented by two species, *Solenodon paradoxus* and S. *cubanus,* the former from Haiti and the latter from Cuba. The family is distinguished by the skull being constricted behind the orbits, the descent of the testes into the perineum, and in having the teats postinguinal. Solenodons, which look like huge rats, have the dentition, i.$\frac{3}{3}$, c.$\frac{1}{1}$, p.$\frac{3}{3}$, m.$\frac{3}{3}$; they have long snouts and tails and their bodies are clothed with long coarse hair. The tail is naked, the whiskers very long and the ears large.

Chrysochloroidea.—Family Chrysochloridae contains the golden moles, confined to Africa. The skull is conical and is not constricted between the orbits; the zygomatic arch and auditory bullae are well developed, the postorbital process absent. The high-crowned cheek teeth are narrowly V-shaped, with three main cusps; a talonid or fourth cusp is present in the uppers and may also be present in the lower teeth. The ears are hidden in the fur and the eyes concealed beneath the skin. The forefeet are specialized for burrowing; the third claw is enormous and scooplike, the second is also large. The hind feet are webbed, with subequal toes. The species are rich brown or gray with a metallic lustre, varying from violet and peacock green to golden bronze. *Chrysochloris,* the typical genus, has 40 (rarely 38) teeth, the lower cheek teeth without talonid. It is a little smaller than a common mole, with short tail, and ranges from the Cape to the Cameroons in Africa. *Chlorotalpa* is found from Cape Province to the Ruwenzori region; the lower molars have a talonid (also in the following genera) and the hind molar is wedge-shaped. *Chrysospalax* of Natal and the Transvaal includes several large species with coarse hair; the root of the cheek arch is greatly expanded, partly roofing the temporal fossa. *Amblysomus,* confined to South Africa, contains several species with 36 teeth.

Erinaceoidea.—The hedgehogs and the gymnuras, or rat-shrews, forming the family Erinaceidae, differ from the shrews in having a broader tympanic ring, a complete zygomatic arch, and the presence of a short pubic symphysis; the family is exclusively confined to the old world. The typical subfamily, the Erinaceinae, or hedgehogs, is easily recognized by the spiny nature of the coat, the rudimentary tail, broad pelvis, and the presence of palatal vacuities; the members of this group are distributed over Europe, Africa and a large part of Asia. Dentition i.$\frac{3}{2}$, c.$\frac{1}{1}$, p.$\frac{3}{2}$, m.$\frac{3}{3}$. The hedgehogs are divided into five genera: (1) Erinaceus, containing the common European species and about 12 other forms from Europe, Asia and the Canary Islands, ranging from Spain to China. In this genus the pterygoids and bullae are normal, the spines on the crown divided into two groups by a median parting which is narrow and inconspicuous, a hallux is present, and the third incisor normally one-rooted. (2) *Aethechinus,* found in Africa and southern Europe, has the coronal parting broad and the third incisor two-rooted. Some of the forms (four or five in number) are smaller and darker than in *Erinaceus,* Aetheclzinus *frontalis,* from South Africa, being dark blackish-brown above, and usually black below. (3) Atelerix, from northern and east Africa, differs from the above mentioned genera in the hallux 'being absent; these hedgehogs are small in size and light buff or brownish in colour. A. *albiventris,* from the Sudan, is a very pale coloured species, while *A.* spinifex, from Nigeria, is a brown form. (4) *Hemiechinus,* a genus containing a number of forms from the southern and eastern Palaearctic region; some species occur in Egypt and northern India. In these hedgehogs there is a median parting on the crown. H. *collaris* is a black form from India; another Indian species is the long-eared hedgehog, H. *megalotis.* Lastly, in (5) Paraechinus, the pterygoids are inflated, and a coronal parting is present; found in southeastern Europe, and from Egypt to India. P. *amir* is a large black-coloured species (head and body 240 mm.), and P. *dorsalis* from Arabia has the prickles on the back bright buff coloured with a dark brown dorsal marking.

The second subfamily, Echinosoricinae, is distinguished by the absence of spines and palatal cavities, the long tail and narrow pelvis. The typical genus, Echinosorex, is represented by a single species (E. *gymnurus*) in Burma, the Malay peninsula, Sumatra and Borneo. Usually the hinder parts of the body and the limbs are blackish, while the head, shoulders and medial part of the anterior back are white, but individuals may be entirely white or pale buff. These rat-shrews are of considerable size (head and body about 420 mm.). Dentition i.$\frac{3}{3}$, c.$\frac{1}{1}$, p.$\frac{4}{4}$, m.$\frac{3}{3}$. The lesser rat-shrews, of the genus Hylomys, are easily distinguished by their much smaller size, very short tail (head and body 140 mm.; tail 23 mm.), and dark volelike coloration. Four races have been described from Borneo, Annam, Siam, Sumatra and Tongking. A closely allied genus is the Szechuan and Yunnan *Neotetracus* in which the tail is of considerable length and the feet large (head and body 120 mm.; tail 63 mm.; hindfoot 26.5 mm). In the Philippines the group is represented by *Podogymnura truei,* in which the hindfoot is greatly elongated.

This group, in many ways the least specialized of the living insectivores, is represented in the Tertiary of Europe and North America. being known since the Eocene.

Soricoidea.—This group includes the moles and shrews, belonging to the families Talpidae and Soricidae. The molar teeth exhibit a W-pattern of cusps, like those of the insectivorous bats. The pubic symphysis is lacking and the orbital and temporal regions of the skull are confluent, there being no post-

orbital processes.

Talpidae, the mole family, is adapted for a subterranean life; the lower ends of the tibia and fibula are united, there is a descent of the testes, the tympanum forms a bladderlike bulla, the zygomatic or cheek-arch, although slender, is complete, there is no pelvic symphysis, the upper molars are five, and the first upper incisor is simple and the lower vertical. Most of the species are burrowing, but a few are aquatic; they have a predominantly animal diet. They are confined to temperate Europe, Asia and North America. Throughout the family the eyes are very small, and in some of the forms are covered with skin; the ears are short, and the forelimbs are generally more or less modified for digging. The true moles of the genus *Talpa* are the typical members of the first subfamily, the Talpinae, in which the clavicle and humerus are very short gnd broad, while there is an additional sicklelike bone on the inner side of the forefoot which is very broad. The dental formula of the genus *Talpa* is i.$\frac{3}{3}$, c.$\frac{1}{1}$, p.$\frac{4}{4}$, m.$\frac{3}{3}$. *T. europea,* the common European mole, is widely distributed over Europe and western and central Asia; the eastern limits of its range are not known. *Parascaptor* is a closely related genus containing one species, P. *leucurus,* from Assam and the adjacent country; it is a small mole with a very short tail and long snout. The genus *Scaptochirus* is considered to contain three species from China; these moles possess very large forefeet and short tails. Another closely allied genus is *Mogera,* which includes a few species of short-haired moles with short tails; dental formula i.$\frac{3}{3}$, c.$\frac{1}{0}$, p.$\frac{4}{4}$, m.$\frac{3}{3}$. These moles come from the far east; M. *wogera,* from Japan, is a large, pale vandyke-brown coloured species.

There remain four North American genera of Talpinae: (1) *Scalops,* a genus with very large forefeet and webbed toes; tail very short, slender and nearly naked, and ears and eyes quite small. *S. aquaticus,* the common mole of the eastern United States and of considerable importance as a fur-bearing animal, is found from Massachusetts to Minnesota and Colorado and southward to Florida and Texas. It is a pale sepia-coloured or slate-coloured mole, often tinged with brown, varying in length in the different subspecies, of which about ten are recognized, from barely 140 mm. to 203 mm. and in colour from light drab to dark sepia and brown. (2) *Scapanus,* a genus with very broad hands, but with toes lacking webs; the tail is rather longer, thick and scantily haired, and the general colour of the body is darker, varying in winter in some forms to black. There are several species, all natives of the Pacific slope where they take the place of the common mole *(Scalops)* of the eastern United States, which they strongly resemble in their habits. *S. townseizdi,* the best known of the group, comes from northern California, Oregon and Washington, where it is common between the Cascades and the coast ranges. It is a large mole, 229 mm. long and blackish in colour, with a plump body and a tail 38 mm. long; *S. orarius,* about 178 mm. long, with the body blackish or grayish in colour, occurs from northern California through Oregon and Washington to British Columbia. S. *latimanus,* similar or slightly larger in size but varying in colour from gray or drab to brown and black, is found from southern California to central Oregon; a larger gray form, var. *alpinus,* 190 mm. long, occurs at Crater lake. (3) *Parascalops,* is a smaller genus, with one species, P. *breweri,* the hairy-tailed mole, found in dry sandy soil from New Brunswick to Georgia and westward to Ohio; the body is blackish, often with brownish gloss; the tail is short, thick, compressed at the base, and very hairy; the toes are not webbed. (4) *Condylura,* the star-nosed mole, which is distinguished by the possession of a fringe of fleshy appendages around the extremity of the snout, 11 appendages on each side. Its general bodily size is about that of the common European mole, but the tail is much longer. The star-nosed mole is blackish in colour and about 190 mm. long; the tail, which is about 64 mm. long, is covered with coarse hair; and the toes are not webbed. One species only is recognized, C. *cristata,* the type locality of which is Pennsylvania; it occurs, but rather infrequently, in wet meadows and marshes from southern Labrador to southeastern Manitoba southward to Georgia and Indiana, often leaving its burrows and running about on the surface.

The second subfamily of the Talpidae is the Desmaninae including a series of animals rather intermediate between moles and shrews, known as the mole shrews. A number of genera have been described, the most important of which are the following: (1) *Urotrichus,* small shrewlike animals with long snouts, and hairy, almost bushy tails; forefeet not markedly enlarged, but more so than in the shrews. *U. talpoides* comes from Japan, from where a number of races have been described (head and body 90 mm., tail 2j mm.). (2) *Neurotriclcus* contains a small shrewlike species, N. *gibbsi,* with large hands and a short hairy tail (head and body 110 mm., tail 36 mm.). (3) *Scaptonyx,* allied to *Neurotrichus,* with a more hairy tail and smaller forefeet; the genus is restricted to China. (4) *Dymecodon,* contains but *a* single species, D. *pilirostris* from Japan; it is smaller than *Urotrichus* and has a proportionally longer, but less hairy tail (head and body 78 mm.; tail 40 mm.). (j) *Uropsilus* a long-nosed, long-tailed genus, with small hands and feet; the tail is short-haired; *U. soricipes* hails from China. (6) *Rhynchonax,* contains a single species from Szechuan, China, smaller than *Uropsilus* and darker in colour. (7) *Galemys* contains the water mole or western desman, from southwestern France and the Italian peninsula. This and the following species show marked adaptation to an aquatic life the toes being webbed and the tail long and flattened laterally. The snout is of considerable length, as also is the soft body fur which is otter-brown above, and yellowish-gray below. Dimensions of the species *(G. pyrenaicus)*: head and body 131 mm., tail 145 mm., hindfoot 38 mm. The last genus (8) *Desmana,* the Russian Desman *(D. moschata)* is very similar in form to *Galemys,* but much larger and more massive (total length 16 in.); it inhabits the streams and lakes of southeast Russia.

Soricidae.—The members of the next family, the Soricidae, are known as shrews. The majority are terrestrial but a few are aquatic. The family is closely related to the moles, with which it is connected by some of the subfamily Desmaninae. The species are, however, distinguished by the ringlike tympanic, incompleteness of the zygomatic arch, and the forward direction of the large lower incisor. The first upper incisor is large and hooklike, with a basal cusp. Following the front tooth above are four to six peglike teeth, known as unicuspids, and two to four below. There are differences of opinion as to the identification of these unicuspids, due to their similarities with each other, the resorption of deciduous teeth before or shortly after birth and the complete fusion of the bones of the skull at an early age. *Sorex,* the typical genus, was considered by E. Brandt to have a dental formula of i.$\frac{4}{2}$, c.$\frac{1}{0}$, p.$\frac{2}{1}$, m.$\frac{3}{3}$, and this is followed in many books; embryological studies by A. Ärnbäch-Christie-Linde suggest that the formula may be i.$\frac{3}{1}$, c.$\frac{0}{0}$, p.$\frac{4}{2}$, m.$\frac{3}{3}$; while most authors use a more conservative formula: i.$\frac{3}{1}$, c.$\frac{1}{1}$, p.$\frac{3}{1}$, m$\frac{3}{3}$. In *Sorex* and its allies the teeth are tipped with brownish-red, in the Crocidurine section the teeth are wholly white. The members of the genus *Sorex* are widely spread over Europe, Asia (north of the Himalayas) and North America. The ears are well developed, the tail long and evenly haired, without the long hairs so characteristic of *Crocidura.* The typical species *S. araneus* is the common shrew-mouse of Europe; it is distributed over the northern portions of Europe and Asia from England and Scotland eastward; southward it reaches central Spain and Italy. As with so many British mammals, it is absent from Ireland. (Head and body 65 to 80 mm.; tail 20–35 mm.; hind-foot 11–14.5 mm.) *S. minutus,* the pygmy shrew-mouse, is considerably smaller, measuring only about 52 mm. in length (head and body); found over the northern part of Eurasia from Ireland eastward, and south as far as the Pyrenees and southern Italy. In North America *Sorex* is represented by 30 or more species, including *S. cinereus,* the common American long-tailed shrew, about 100 mm. long. found from New England and Tennessee to Alaska; S. *fumeus,* the smoky shrew of the northeastern states and *S. vagrans,* the western shrew, abundant in the Rocky mountains and the Sierra Nevada. The American water shrews, formerly considered to form a separate genus, *Neosorex,* are much larger and include three aquatic species, of which the best known is *S. palustris,* characteristic of northern and mountain parts. The feet are large,

with fringes of hair on the toes. In the Asiatic Soriculus one upper unicuspid is lost (dentition: $i.\frac{3}{1}$, c.), $p.\frac{2}{1}, m.\frac{3}{3}$), the tail is relatively longer than in Sorex, equalling or exceeding head and body length. Closely allied to Soriculus is the Chinese *Chodsigoa*, which has lost the minute unicuspid premolar of the former. The single species is confined to highlands in Szechuan, Kansu and Hopei. *Blarinella* quadraticauda from western China is related to Sorex, but differs in its short tail, reduced external ears and well-developed claws. In these characters it resembles the American Blarina, but cranially it shows no approach. The tips of the teeth are lightly pigmented; dental formula: $i.\frac{3}{1}$, $c.\frac{1}{1}$, $p.\frac{3}{1}$, $m.\frac{3}{3}$. Microsorex *hoyi*, one of the smallest of mammals (76 mm. in total length), occurs in northeastern U.S. and Canada; the dental formula is the same as that of Sorex, but the third and fifth upper unicuspids are minute, hidden on the inner side of the tooth row. Notiosorex *crawfordi*, the gray shrew of southwestern U.S., has only three upper unicuspids. It is 82 mm. in total length, with the tail 26 mm. A larger species (N. *gigas*) occurs in the mountains of central Mexico. Blarina brevicaztda, the large short-tailed shrew of the eastern U.S., kills many mice as well as insects; it is dark gray in colour and molelike in appearance, with dentition $i.\frac{3}{1}$, $c.\frac{1}{1}$, $p.\frac{3}{1}$, $m.\frac{3}{3}$. Related species occur in Central America. Cryptotis, a southern genus ranging from Connecticut to South America, is also short-tailed, but is only a little larger in body than the common shrew. It lacks one upper unicuspid but is otherwise much like Blarina. *Neomys*, the Eurasian water shrew, agrees with Cryptotis in having only 30 teeth (four unicuspids), but it is aquatic. The tail is fringed with long hairs on the underside and so are the feet. The fur is very soft, dark slate-gray in colour. *Neomys* ranges from Spain and England to Lake Baikal in central Asia, northward as far as Scandinavia.

The shrews with white teeth are found in Europe, Asia and Africa. The short-haired, long-tailed shrews of Africa with four upper unicuspids are grouped together in the genus *Sylvisorex*, in some the tail is much longer than the body (head and body 60 mm.; tail 85 mm.); in others, as *S. lunaris* from Ruwenzori, the tail is about equal in length to the head and body. In the allied genus *Myosorex*, also from Africa (dentition: $i.\frac{3}{1}$, $c.\frac{1}{1}$, $p.\frac{2}{2}$, $m.\frac{3}{3}$), the tail is long and the fur soft and thick; the openings of the generative organs and vent, although close together, are distinct. Surdisorex is another white-toothed genus containing one or two species; *S.* norae is distinguished by its very short tail (head and body 92 mm.; tail 20 mm.; hindfoot 15 mm.), very soft, deep chocolate-coloured coat and large forefeet. It inhabits Kenya colony. The typical genus of this group, Crocidura, or musk shrew (dentition: $i.\frac{3}{1}$, $c.\frac{1}{1}$, $p.\frac{1}{1}$, $m.\frac{3}{3}$), is found over nearly the whole of Africa and the warmer parts of Europe and Asia; a species has recently been described from the Scilly Isles. The generative openings form a short cloaca with the anal orifice. Tail long, with a number of long, rather bristly hairs in addition to the shorter normal hairs. Some of the largest and smallest members of this genus are found in Africa; the smallest musk shrew, probably the smallest mammal, is C. pasha, from the Sudan. The Suncus shrews with an extra premolar (dentition. $i.\frac{3}{1}$, $c.\frac{1}{1}$, $p.\frac{2}{1}$, $m.\frac{3}{3}$) are considered to represent a distinct genus, Pachyura, which is found over Africa, the warmer parts of Asia, and Mediterranean region. The members of this group all have the typical crocidurine tails, with the long bristlelike hairs. *Praesorex* goliath is a giant shrew from the Cameroons (head and body 170 mm.; tail 102 mm.; hindfoot 25 mm.) related to the *Crocidura* but distinguished by its longer and harsher coat. In Solisorex *pearsoni*, another large form, the tail is shorter (66 mm.) and the fur softer and grayer. *Scutisorex* includes the "tinhatted shrews" from Uganda and the eastern Congo. The skull of this species has enormously developed lambdoid crests which extend backward and are continuous with a posterior extension of the lateral temporal crests (head and body 143 mm.; tail 77 mm.; hindfoot 20 mm.); and the backbone is extraordinarily strengthened.

Anourosorex is an allied genus containing but a single species, **A.** *squamipes*, a small mole-coloured shrew with *a* very short tail (head and body 83 mm.; tail 16 mm.; hindfoot 15 mm.). This genus, which inhabits Szechuan and Tibet, is distinguished from the closely related genus *Diplomesodon*, from the Kirghiz steppes, by the soles of the hindfeet being scaly, not hairy. The latter genus, which also contains only one species, *D.* pulchellus, is further distinguished by its longer tail. Lastly there are two Asiatic water shrews: (1) Chimarrogale, from India to Japan and Borneo, blackish gray above, white below, is distinguished by its long tail with an inferior fringe of elongated hairs; the generative organs open into the same integumentary ring as the anal orifice; the dental formula is $i.\frac{2}{1}$, c.), $p.\frac{1}{1}$, $m.\frac{3}{3}$. (2) Nectogale is similar in appearance to the foregoing genus, the "feathering" of the feet and tail being more developed; in colour it is about like a mole, whitish below.

Moles and shrews are well known from the Oligocene on, with *Nyctitherium* of the Palaeocene and Eocene of North America and Europe, forming a separate, though related family, the Kyctotheriidae. The caves of Puerto Rico have yielded a remarkable addition to the West Indian insectivores in *Nesophontes*, which became extinct in very late Pleistocene times.

Macrosceloidea.—The Macroscelidae contains the jumping or elephant shrews. These have molars the cusps of which are arranged in a W-pattern, which may resemble the crescentlike ridges characteristic of some hoofed mammals. The skull has well-marked postorbital processes. The tarsus is markedly elongated and the lower ends of tibia and fibula are joined. Dental formula, $i.\frac{3}{3}$, $c.\frac{1}{1}$, $p.\frac{4}{4}$, $m.\frac{2}{2 \text{ or } 3}$. The members of this family leap like gerbils or jerboas. The Macroscelididae may be considered to contain seven genera: (1) Macroscelides, or jumping shrews, containing two South African species M. proboscideus from Cape colony and the Orange Free State, and M. *melanotis* from Namaqualand; in this genus the lower molars are two in number and the auditory bullae much enlarged. (2) *Elephantulus* containing the jumping shrews of North, East and South Africa in which the lower molars are two in number, but the auditory bullae are normal, not enlarged. In size about equal to the foregoing genus. The various species extend from Morocco and Algeria (E. *rozeti*) southward to Somaliland, East and South Africa. (3) Nasilio, or the short-nosed jumping shrews, with three lower molars and normal auditory bullae. Like the two allied genera, Macroscelides and Elephantulus, these jumping shrews are diurnal. The genus extends as far north as Angola in the west and Kenya colony in the east. (4) Petrodromus, the four-toed jumping shrews, are distinguished from the foregoing genera in having only four instead of five toes to each front foot; the dimensions are considerably larger and the coat quite different in colour, being pale olive-green on the flanks and rufous on the back (P. tetradactylus, South Africa). The tail is long and clothed in short normal hairs. (5) Mesoctenus, closely allied to Petrodromus, but distinguished by the hairs on the underside of the tail being slightly bulbous at their ends; this genus includes two species M. *rovumae* and *M. nigriseta* from East Africa. (6) Cercoctenus, in which the bulbous, or club-shaped hairs on the underside of the tail are still more developed, two species are recognized: C. sultan from Zanzibar, Tanganyika territory and Kenya colony, and C. schwanni from Portuguese East Africa. (7) *Rhynchocyon*, the long nosed elephant shrews, in which the reduction in the number of toes is carried still further. there being only four toes to each foot. In this genus the snout is much longer, the size of the body considerably greater, and the tarsus still more elongated. The dental formula is $i.\frac{1 \text{ or } 0}{3}$, $c.\frac{1}{1}$, $p.\frac{4}{4}$, $m.\frac{2}{2}$. It has been proposed to divide the genus into two subgenera, the typical one containing the chessboard patterned species (R. cirnei, reichardi, claudi and *stulhmanni*) and *Rhinonax* including R. chrysopygus and R. petersi and its allies. Some of these elephant shrews are very handsomely coloured, R. cirnei from Nyasaland has the posterior part of its back marked with rows of alternate dark and light blotches, giving a chessboard effect. The apical portion of the tail is always white. In the subgenus Rlzinonax equally bright colouring occurs; R. (R.) petersi comes from East Africa and Zanzibar. R. (R.) *chrysopygus* (East Africa) has the body, flanks and limbs deep maroon, and the rump bright orange-yellow coloured.

Tupaioidea.—The tree shrews, family Tupaiidae, have the orbit separated from the temporal fossa by a bar of bone. Like the Macroscelidae they have a pubic symphysis, or union of the two halves of the hip bone below or in front of the pelvis, and they have been grouped with that family as a suborder of Insectivora, the Menotyphla. It is probable that the resemblances between the two groups are not indicative of close relationship but are primitive characters retained by each independently.

Many authors regard the Tupaiidae as lowly organized members of the order Primates, but others are quite unable to consider the genus *Tupaia* and its near relations, *Dendrogale, Urogale* and *Ptilocercus,* as representing anything more than a group of insectivores. Tupaiidae, the tree shrews, confined to the oriental region. in addition to the bony ring surrounding the orbit, are distinguished by the large size of the brain. The dental formula is $i.\frac{2}{3}$, $c.\frac{1}{1}$, $p.\frac{3}{3}$, $m.\frac{3}{3}$. The tupaias or tree shrews are in many ways like squirrels; they are. however, distinguished by their pointed, insectivore-like faces and light-coloured shoulder stripes. The typical genus contains a great number of species and subspecies. *T. ferruginea,* from the Malay peninsula and islands, is bright chestnut-brown in colour with an olive-brown face and tail; the majority of the members of this genus do not exceed 350 mm. (1 mm. = .03937 in.) in total length. *T. pictus,* of Borneo, is a very handsomely coloured tree shrew. chestnut and olive above, with buff shoulder stripes and a black dorsal stripe. From the Rhio archipelago comes a deep chestnut-coloured form known as *T. castanea. T. minor* is a very small species from Borneo, with a hind-foot of only 28 mm., and a total length of about 280 mm.

Tree shrews of the subgenus *Anathana* are distinguished by the inner sides of the ears being more hairy, the larger size of the lower lobe of the ear, and the coarser nasal reticulations. The species come from India and Borneo. A number of handsomely coloured tree shrews have been placed in the subgenus *Tam.* Included in this is a very brightly coloured species from Borneo and Sumatra, *T. tana. T. dorsalis,* from Borneo, is a smaller species, with a well-marked black dorsal stripe extending from the crown of the head to the base of the tail. The genus *Urogale,* allied to *Tupaia,* contains but a single species, *U. cylindura* from Mindanao, in general dimensions and appearance about as in the smaller *Tupaias,* the total length being 250 mm. The smallest members of this family are included in the genus *Dendrogale,* the total length not exceeding 23j mm. These pygmy tree shrews come from Annam, French Indo-China, Siam and Borneo.

The Asiatic pentailed tree shrew (*Ptilocercus lowi*) is also included in this family, although it differs very markedly from all the other genera. The tail is very long, with the proximal two-thirds naked, and the remaining third furnished with a feather-like fringe. This species, the only representative of the genus, is found in Borneo, Sumatra and parts of the Malay peninsula.

The tree shrews are represented by a distinct family in the Eocene of Asia (Anagalidae, for the genus *Anagale*). The relations of the tree shrews with the earliest primates, mentioned above, become the more evident through the Palaeocene and Eocene Plesiadapidae, which are referred to the lemurs.

INSECTIVOROUS PLANTS: *see* CARNIVOROUS PLANTS.

INSEIN, a town and district of lower Burma in the Pegu division, lying immediately to the north of Rangoon. District area 1,914 sq.mi.; pop. (1941) 387,345. The district includes a large tract of the Irrawaddy delta on either side of the Hlaing or Rangoon river and on the east of the Irramaddy itself. In the west the district includes a portion of the southern end of the Pegu Yomas clothed with dense evergreen forest which, in spite of its nearness to Rangoon, was still the haunt of wild elephants in modern times. The Rangoon-Prome line of the Burma railways runs through the district.

INSEIN, the chief town (pop. [1953] 27,030), lies 10 mi. N.W. of Rangoon, of which it became almost a suburb. It has railway workshops, a government engineering school and veterinary college.

INSELBERG. An isolated hill standing above well-developed plains. in appearance not unlike an island above the sea (hence the name). Although the term is sometimes applied generally, most geologists restrict its use to such hills formed under tropical and subtropical conditions, as in Nigeria (*q.v.*), usually formed of plutonic rocks such as granite and gneiss, and characterized by steep curved sides of smooth bare rock. These bare rock domes, which may stand 1,500 ft. above the plains, are more specifically called bornhardts and display an onionlike "peeling" (exfoliation) of concentric rock shells, in thickness from a few inches to 20 ft., from the surface. A pediment, or low-angle slope slightly concave upward, is usually present at the base of the inselberg. In its later stages an inselberg may develop into a *kopje; i.e*, a residual hill composed of a pile of large boulders, in form similar to the granite tors of Devon and Cornwall. Isolated hills similar to inselbergs but formed under nontropical conditions are known as monadnocks. (J. C. PH.)

INSHTATHEAMBA or BRIGHT EYES (1854–1903), American Indian writer and lecturer who promoted public interest in reform of the U.S. government's Indian policies, was born in Nebraska on the Omaha reservation. She was the daughter of a former Omaha chief, Inshtamaza or Iron Eye. His father. Joseph La Flesche. who married an Omaha woman, was a French trader. and Iron Eye also bore his father's name. Bright Eyes was originally named Susette La Flesche but later adopted her Indian name.

She studied at a mission school on the reservation and later was educated at a private school in Elizabeth, N.J. She thereafter was a teacher in a government school on the reservation.

Bright Eyes won wide public interest in 1879 as an outspoken advocate of Indian rights. In that year she toured the eastern states to call attention to the government's arbitrary action against the Ponca tribe. In 1877 the Poncas, related to the Omahas, had been forced to leave their reservation on the Niobrara river in South Dakota and to emigrate to the southern Indian territory. The tribe found living conditions there intolerable, however, and led by chief Standing Bear traveled north on foot for about 600 mi., arriving at the Omaha reservation in March 1879. The Indians were arrested and ordered to be returned to their new home. On April 30, 1879, the federal district court held, however, that they should be freed under a writ of habeas corpus.

Bright Eyes, noted for her eloquence as a speaker, edited *Ploughed Under, the Story of an Indian Chief* (1881). She died on the Omaha reservation, near Bancroft, May 26, 1903.

INSIDE PASSAGE or INLAND PASSAGE is a sheltered sea route extending from Seattle, Wash., approximately 1,000 mi. to Skagway, Alaska. Protection from winds and storms is provided by Vancouver Island, by a series of islands lying eastward of Hecate strait and, in Alaska, by the Alexander archipelago (*q.v.*). Vacationers have favoured this waterway, both for its great natural beauty and its customary smoothness.

The greatest width of the chain of islands is about 80 mi. Their rugged topography is concealed beneath heavy forests and dense undergrowth. Several small glaciers may be seen from the channel. Rainfall is heavy, and may be expected at any season.

Navigation. — The shores of the channel drop off sharply, and in most places there is ample depth for all vessels. Anchorages are numerous. Tidal currents attain considerable velocity in places. Extensive surveys have practically eliminated unmarked pinnacle rocks which have caused several notable marine disasters. Pilotage is not required, but is desirable.

Principal towns along the passage include Victoria, Vancouver and Prince Rupert in British Columbia and Ketchikan, Wrangell, Petersburg, Juneau and Skagway in Alaska. (J. E. CL.)

INSIGNIA, MILITARY. Ever since men first organized themselves into large groups for fighting they have employed cer-

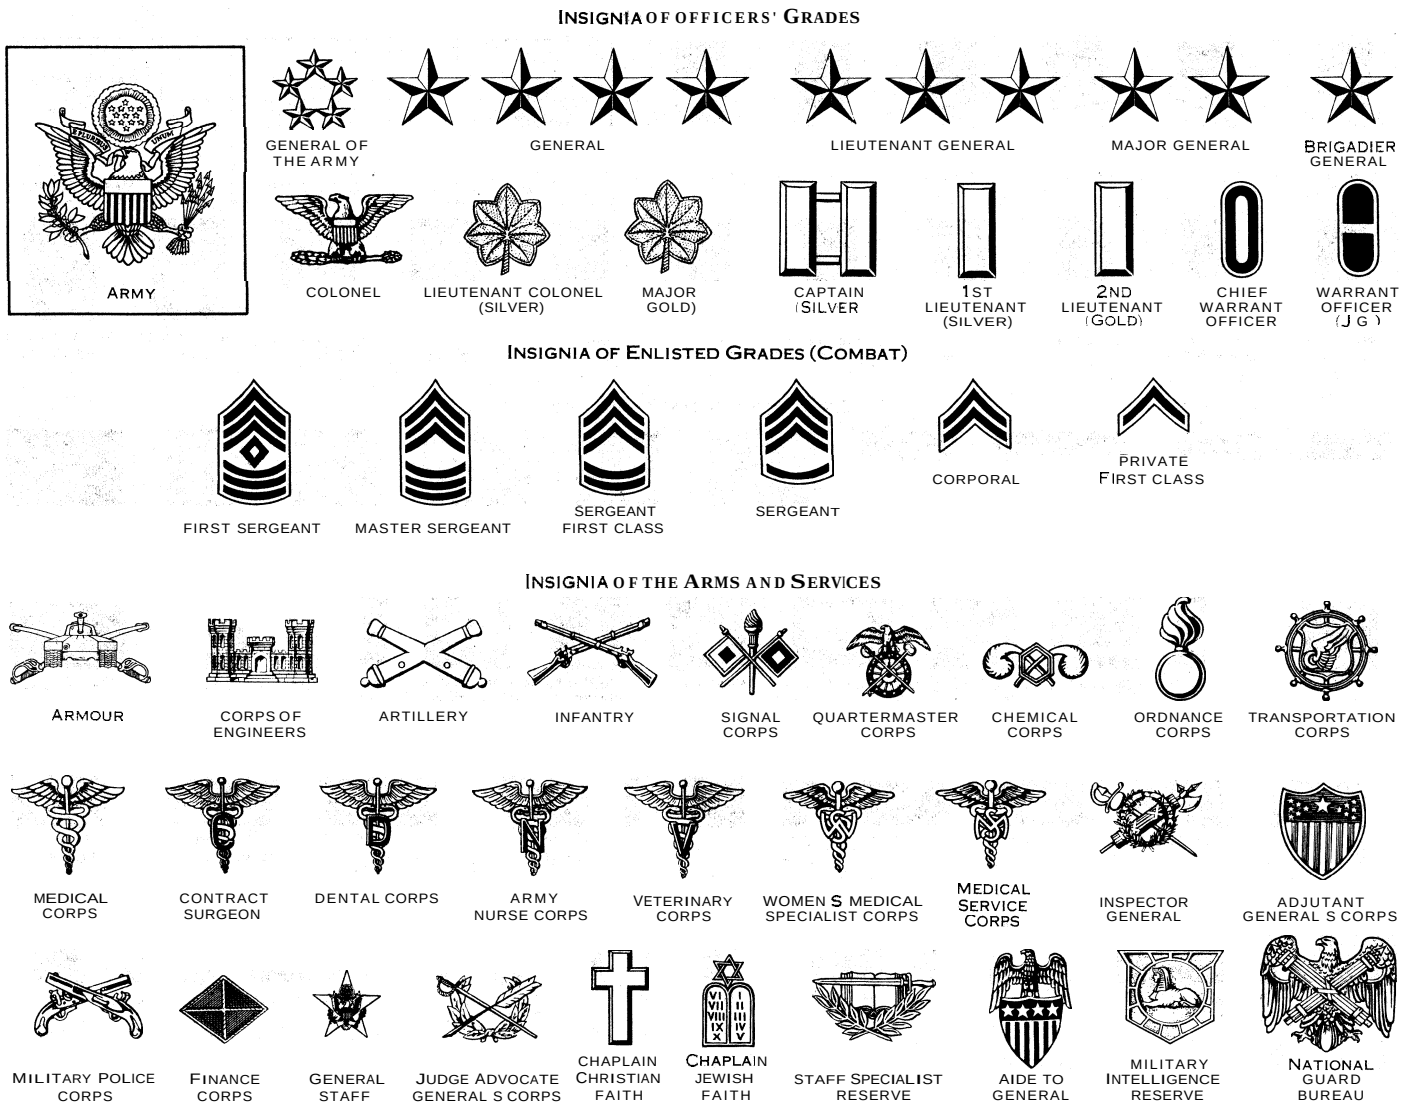

FIG. 1.— INSIGNIA OF RANK AND BRANCHES IN THE U.S. ARMY

tain signs or insignia to indicate their rank, branch of service and special duties or qualifications. Except for commanders of high rank, insignia were usually rather simple in ancient and medieval forces, but since the 18th century insignia for all ranks have developed along rather complicated and rigid lines. Many different devices have been used, including cockades, epaulets, hat cords, ribbons, buttons, badges, ornaments, bars, clasps, chevrons, stripes, braids and shoulder patches. The uniform itself may indicate a man's rank, in a general way; it may also show his branch of service. (See UNIFORMS.) Insignia of organizations are discussed in COLOURS, MILITARY.

UNITED STATES

In spite of many interesting stories about origins, the early development of rank insignia in the United States was a haphazard affair. At the start of the American Revolution it was difficult to distinguish between officers and enlisted men of the Continental army. Some "badges of distinction" were deemed necessary. Gen. George Washington wore "a light blue ribband across his breast between his coat and waistcoat." A brigadier general was assigned a pink ribbon; a major general a purple ribbon; and aides, green. Field officers were distinguished by hat cockades, red or pink. Captains wore yellow or buff cockades while lieutenants wore green. An epaulet on the shoulder with a silver star to denote the rank of general came into use near the end of the war. The colonel's eagle did not appear until about 50 years later.

Army.— The insignia of the arms and services of the U.S. army

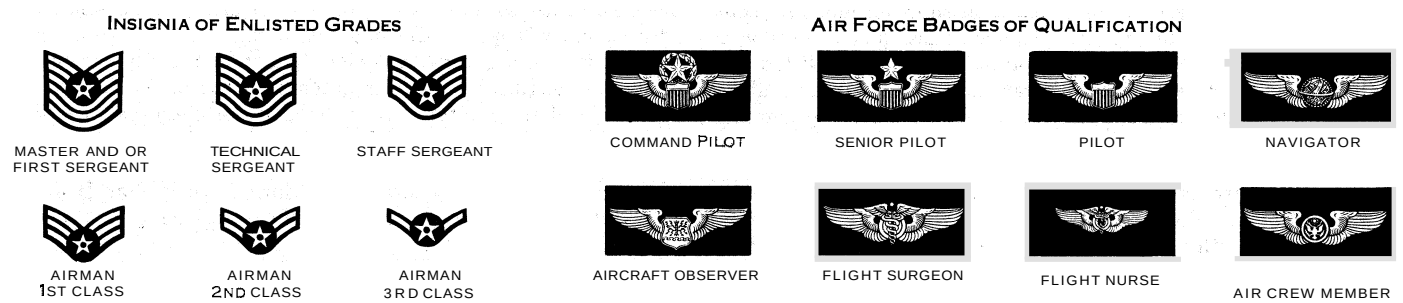

FIG. 2.— INSIGNIAOF RANK AND BADGES OF QUALIFICATION IN THE U.S. AIR FORCE. THOSE FOR OFFICERS' GRADES ARE THE SAME AS THOSE FOR THE ARMY (FIG. 1)

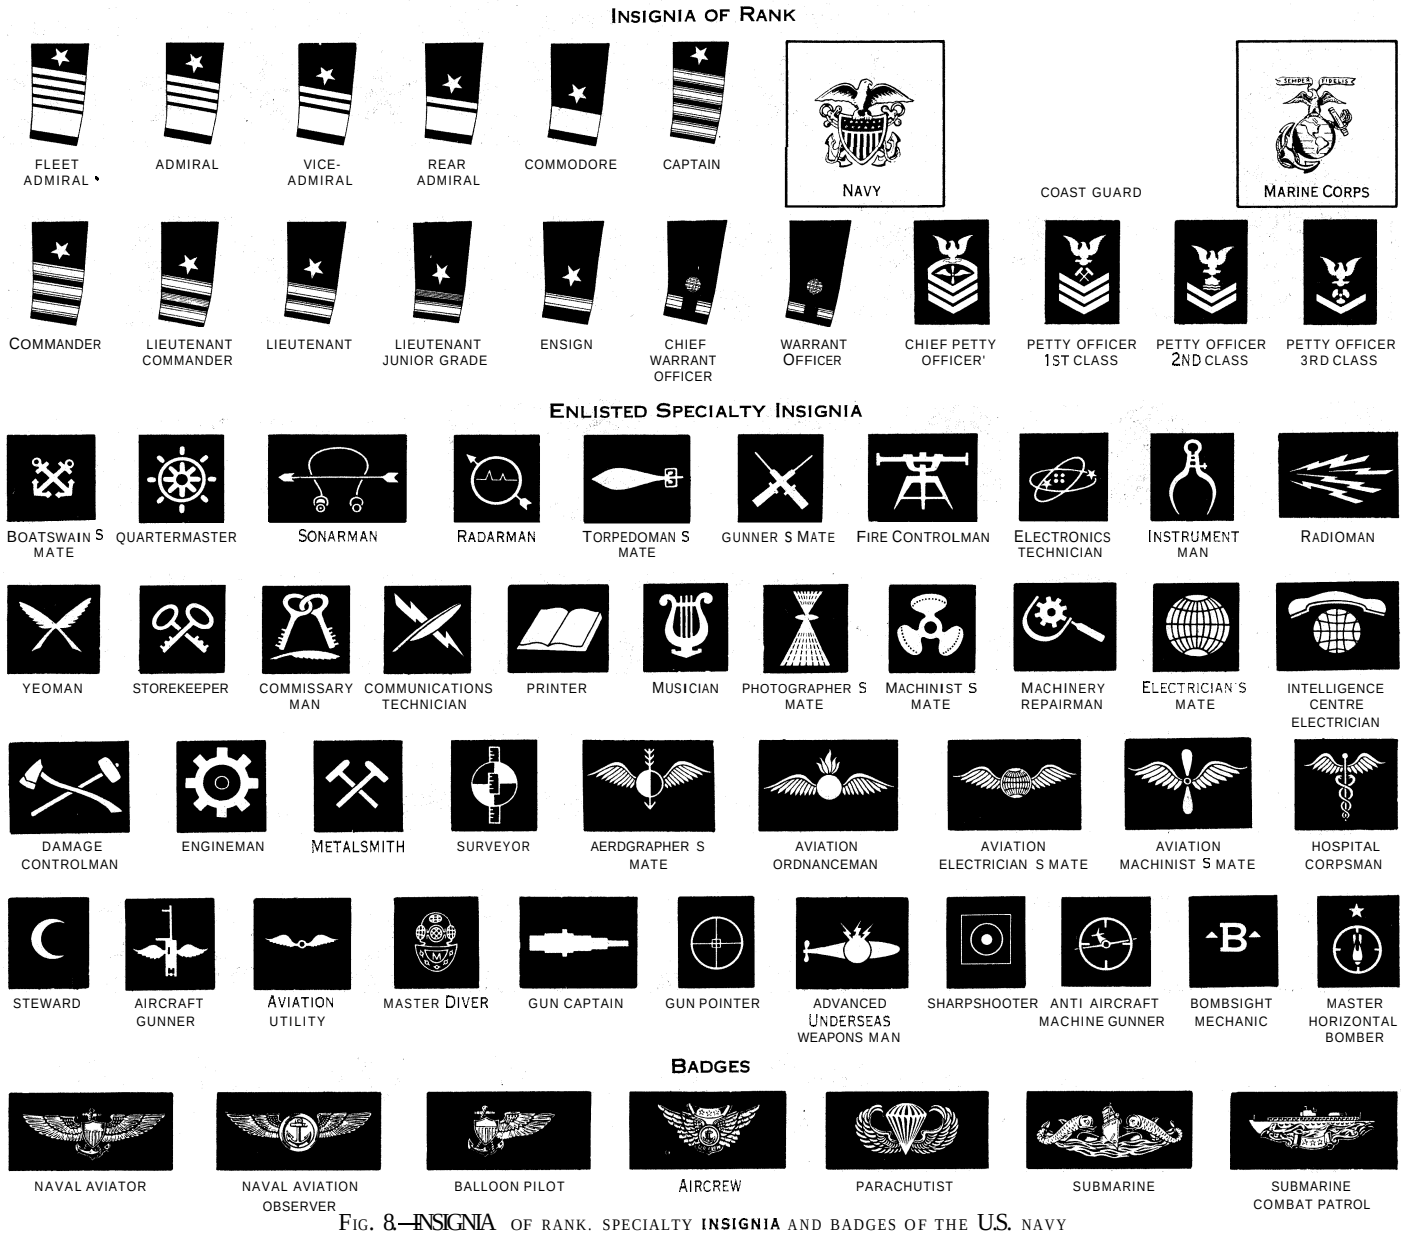

FIG. 8.—INSIGNIA OF RANK, SPECIALTY INSIGNIA AND BADGES OF THE U.S. NAVY

in the 20th century have followed a fairly consistent pattern and have borne an understandable relationship to the functions of the arm or service to which they apply. The crossed flags and torch of the signal corps and the flaming bomb of the ordnance corps are examples. (See fig. 1.) The latter is said to be the oldest of U.S. insignia, having been adopted in **1832.** Originally the flaming bomb represented both artillery and ordnance and was embroidered in gold on officers' long-skirted coats. In addition to such devices, each branch of the army has a distinctive colour — infantry, light blue; armour, yellow; artillery, scarlet; and so on

Insignia of grade are normally worn on shoulder loops by commissioned and warrant officers. Noncommissioned officers wear gold-coloured chevrons (point up) on both sleeves. Enlisted specialists wear an eagle device with varying numbers of arcs above and chevrons below on both sleeves. On some uniforms, commissioned officers wear rank insignia on their right shirt collar and on their garrison caps; enlisted men wear unit insignia or regimental crest on the garrison cap. All personnel wear grade insignia on combat helmets. Combat leaders wear a green cloth loop around the middle of both shoulder loops of the outer garment. Branch insignia are worn on the left collar or, by officers, on both coat lapels.

In 1959 the U.S. army made minor changes in the titles and insignia of enlisted grades. The two lowest grades remained unchanged but the insignia of sergeant became three chevrons without an arc or "rocker." Others were as follows: staff sergeant — three chevrons above one arc; platoon sergeant or sergeant first class — three chevrons above two arcs; master sergeant — three chevrons above three arcs; first sergeant — three chevrons above three arcs with a lozenge between the chevron and arcs; sergeant major — three chevrons above three arcs with a five-pointed star between chevron and arcs.

Members of colour-bearing units such as regiments, separate battalions and service schools wear small enameled shields bearing the regimental, unit or school coat of arms in the middle of both shoulder loops on the outer garment. Members of major commands, armies, corps, divisions and independent commands often wear distinctive shoulder patches on the upper part of the left sleeve of their outer uniform. Many of these patches were designed for units serving in World Wars I and II and the Korean war. Both officers and enlisted men may wear the shoulder patch of the overseas unit they served with during World War II or the Korean war. This is worn at the top of the right sleeve of the uniform.

Officers on duty with the general staff of the department of the army in Washington, D.C., wear a green, black and gold medallion (general staff identification badge) on the right breast pocket.

FIG. 4.—BADGES OF RANK IN THE BRITISH ARMY AND NAVY. BRANCHES OF THE NAVY AND FLYING BADGES

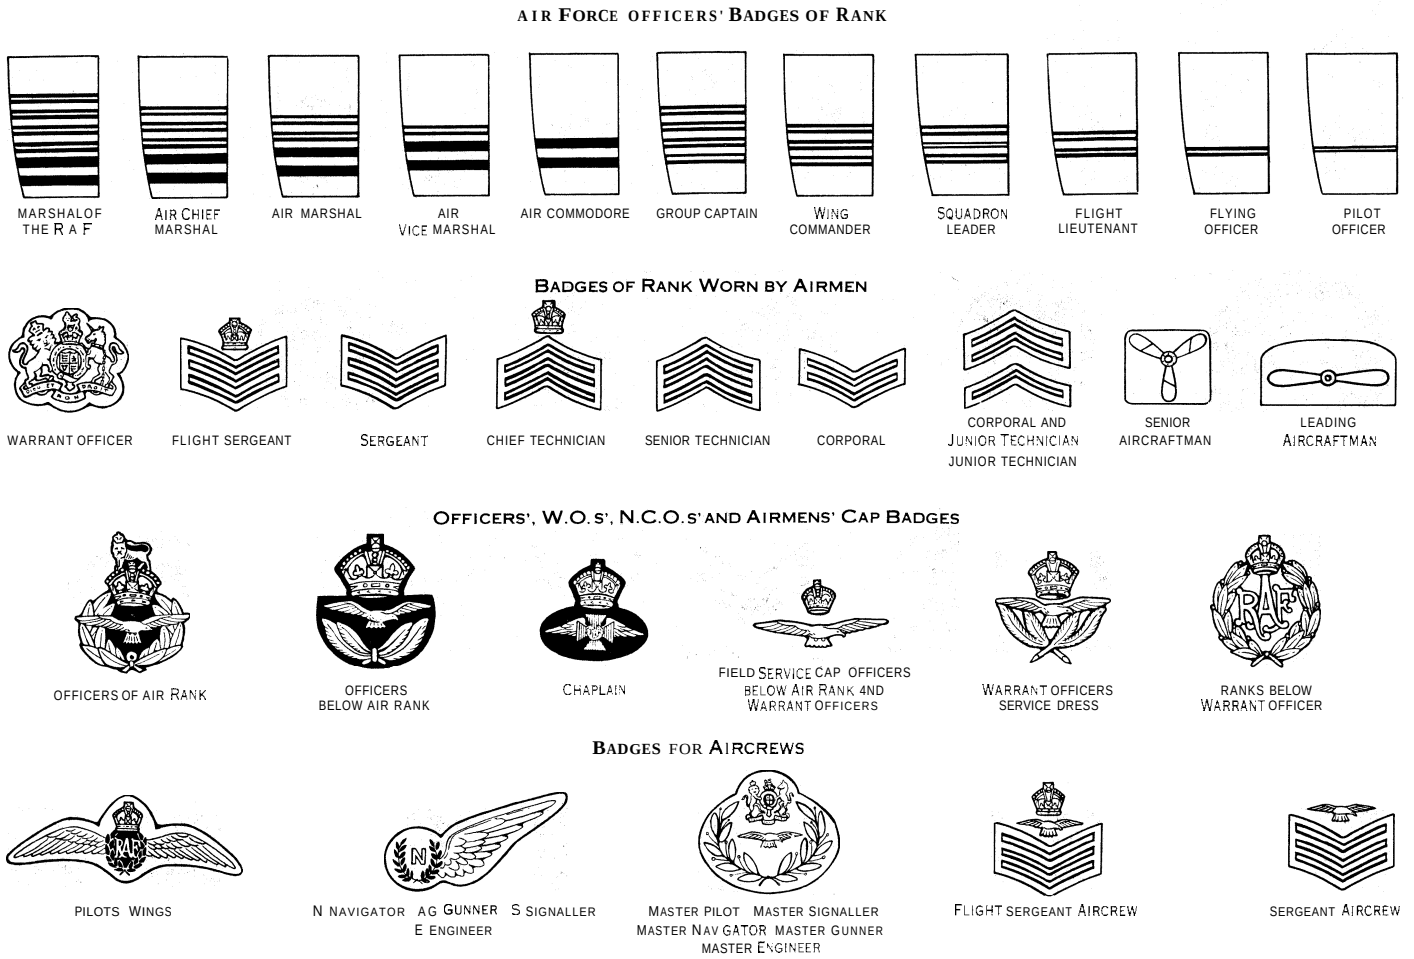

FIG. 5.— BADGESOF RANK AND CAP BADGES OF THE BRITISH AIR FORCE FOR OFFICERS. AIRMEN AND AIRCREWS

After one year's service on the army general staff, the officer is permitted to wear this insignia permanently. A similar device, the department of defense identification badge, is awarded to U.S. armed forces personnel who serve on the staff of the department of defense and is worn on the left breast pocket.

The letters "U.S." in a circle are worn by all army and air force enlisted personnel on the right coat collar and on both collars by basic trainees. Officers wear the "U.S.," without background, on both coat collars when branch insignia are worn on the lapels. On certain working uniforms the words "U.S. Army" in gold on a black background are worn on the upper left breast.

Navy.—Commissioned and warrant officers of the navy wear stripes indicating rank on coat sleeves or shoulder boards, the colour of the stripes depending on the colour of the uniform. Devices above the stripes distinguish between line and staff corps officers. Rank may also be designated by metal insignia of the army type except that warrant officers wear single bars broken by blue instead of brown. Such insignia are worn on both shoulder loops of the raincoat and on both shirt collars by line officers. Staff corps officers and warrant officers wear the rank device on the right shirt collar and the staff corps or specialty insignia on the left. As in the other services, the higher ranks (commander and above) are distinguished by braid ornamentation on visors.

Navy enlisted personnel of the three lowest pay grades are designated by diagonal stripes worn on the left sleeve. Petty officers wear chevrons (point down) surmounted by an eagle and, in the case of the top two pay grades, by one or two stars. Between the chevrons and the eagle is a device indicating the petty officer's specialty. The device, as a whole, is known as a rating badge. Until after World War II seven specialty ratings (signalman, boatswain's mate–coxswain, fire controlman, gunner's mate, torpedoman, quartermaster and turret captain) were worn on the right sleeve, all others on the left. Thereafter, all rating badges were worn on the left sleeve. Depending on the uniform, enlisted rank insignia are of silver, blue, white, khaki, silver-khaki or green. Petty officers with 12 years' good conduct wear gold rating badges.

Naval aviation badges for navy, marine corps and coast guard personnel are spread wings of gold colour worn above the left breast pocket. Submarine, parachutist and aircrew badges are worn in the same manner. The name of his ship, aircraft squadron or other special unit may be worn by an enlisted man below the rank of chief petty officer. Before World War II these unit identifying marks were worn on the hatband of the winter "flat" hat. During the war they were ordered removed and the words "U.S. Navy" substituted. In the mid-1950s identifying marks were again authorized, but were to be worn on the right sleeve just below the shoulder seam.

Marine Corps.—Marine officer insignia are the same as those for the army except that warrant officers' bars are broken by scarlet stripes rather than brown. Officers wear their rank on both shirt collars and shoulder loops. Marine gunners wear the warrant officer's rank insignia on the right collar and a bursting bomb device on the left. Naval medical officers, chaplains and others serving with fleet marine forces and wearing marine uniforms wear their rank device on the right collar and their staff corps device on the left.

Enlisted men wear chevrons of rank on both sleeves and metal chevrons on the collars of certain working uniforms. All officers and all enlisted men of lance corporal rank or above wear a scarlet stripe along the outer seam of each trouser leg with the blue uniform. The marine corps emblem is worn on all headgear, coats and jackets, and by enlisted men on both shirt collars. Rank insignia is also worn on combat helmets, utility caps and garrison caps. Shoulder patches, worn by marines during World War II, are no longer authorized. There are no branch insignia.

Coast Guard.—Coast guard officers and enlisted men wear insignia identical to those of the navy except for the officers' and chief petty officers' cap devices and the shield worn by officers in place of the navy's line or staff corps devices. Enlisted men wear the shield on the right sleeve, just above the cuff.

Air Force.—Insignia of rank for officers of the air force are the same as the army's except for warrant officers whose bars have medium blue rather than brown stripes.

Enlisted ranks are designated by silver-coloured chevrons on a dark blue background, rounded point downward, and a silver-coloured star with a centre of dark blue.

As in the other services, air force aides and attachés are distinguished by aiguillettes. These are worn on the left shoulder except for presidential aides who wear them on the right. Aides are further identified by collar insignia designating the office or commander to whom they are assigned. Air force aviation badges are spread wings of silver colour bearing identifying centre designs and worn above the left breast pocket.

Service Stripes.—Enlisted men of all services wear diagonal service stripes denoting length of active service on the lower part of the left sleeve. The World War I overseas and wound chevrons and the World War II and Korean war overseas bars may be worn on the left sleeve by personnel of the army and air force.

GREAT BRITAIN

Officers wear insignia of rank on shoulder straps; warrant officers and noncommissioned officers wear insignia on their sleeves. Cap badges and buttons indicate branch of service. (See fig. 4.)

Army.—The lower officer grades (lieutenants and captains) are indicated by one, two or three diamond-shaped stars or "pips" on the shoulder straps. The higher grades are indicated by a crown or combination of a crown and stars. Officers of general rank wear on the shoulder straps a baton and sword crossed, with either a star or crown or both. A field marshal wears crossed batons in a wreath. Warrant officers (referred to as sergeant majors) wear the following insignia on lower sleeves: warrant officer, class I, royal coat of arms; warrant officer, class II, crown. Enlisted men (referred to as "other ranks") wear chevrons, point downward, on both upper sleeves as follows: staff sergeant, three chevrons surmounted by a crown; sergeant. three chevrons; corporal, two chevrons; lance corporal, one chevron. Good conduct is indicated by chevrons, point upward, on lower sleeves.

Royal Air Force.—Insignia are worn on shoulder straps and sleeves; shoulder insignia are the same as those of the navy. Sleeve stripes range from one narrow stripe for a pilot officer to one broad and four narrow stripes for marshal of the Royal Air Force.

If service dress uniform is worn, stripes are not gold but white on dark blue trimmings. A pilot is further distinguished by a pair of wings worn on the left breast; an observer or navigator wears one wing. Noncommissioned rank marking is gray on dark blue background and follows that of the army.

Royal Navy.—Officers' ranks are indicated, generally, as in the U.S. navy. However, the rank of sublieutenant is equivalent to the U.S. rank of lieutenant (j.g.), and the sleeve insignia is a single stripe; sleeve markings of one and one-half stripes are not used. There is no rank equivalent to the rank of ensign. The British employ a "curl" above the braid ( ), where the U.S. navy uses a star, and they use various colours of "distinction cloth" between the gold braid stripes on the cuff to signify specialist branches. Executive officers wear no coloured cloth between the stripes. Noncommissioned rank indicates in each case, as in the United States, the man's specialty. (See fig. 4.)

OTHER COUNTRIES

Canada.—Insignia of the Canadian forces follow the British pattern. but the word "Canada" appears on shoulder straps or just below the shoulder seam. The wings worn by flying personnel bear the initials RCAF for Royal Canadian air force.

German Federal Republic (West Germany).—*Army (Heer).*—General officers of the army wear gray shoulder loops edged in gold except at the outer end. Gold diamond-shaped "stars" indicate rank; a gold wreath encircles the star at the outer end of the shoulder loop for all general officers. A general wears four stars; lieutenant general, three stars; major general, two stars; and brigadier general, one star. Field grade officers have gray, silver-edged shoulder loops ornamented with silver stars and a silver wreath at the outer end of the shoulder loop: colonel, three stars; lieutenant colonel, two stars; major, one star. The silver wreath is omitted for company grades: captain, three stars; first lieutenant, two stars; lieutenant, one star.

Warrant officers, master sergeant, and sergeant first class wear gold chevron type insignia on gray shoulder loops. Warrant officer I, one gold chevron with diamond; warrant officer II, two chevrons with diamond; chief warrant officer III, three chevrons with diamond. Master sergeant, two gold chevrons; sergeant first class, one gold chevron. The following enlisted men wear their gold rank insignia on the upper sleeves: sergeant senior grade, two chevrons; sergeant, one chevron; corporal technicians, three oblique stripes; corporal, two oblique stripes; private first class, one oblique stripe; recruit, no rank insignia.

All commissioned and noncommissioned ranks wear coloured collar tabs to designate branch of service. General officers wear red collar tabs and general staff officers wear reddish-purple tabs.

Navy (Marine).—Commissioned rank is shown by gold stripes on sleeve cuffs and on shoulder boards, a star being above the cuff stripes. An admiral wears one broad and two medium stripes; a vice-admiral, one broad and one medium-width stripe; rear admiral, one broad and one narrow stripe; captain, four medium stripes; commander, three medium stripes; lieutenant commander, two medium stripes and one narrow stripe in the centre; lieutenant, two medium stripes; junior lieutenant, one medium and one narrow stripe; ensign, one medium stripe.

The following ranks wear gold chevrons on both sleeve cuffs: chief warrant officer III, three chevrons with diamond at their peak; chief warrant officer II, two chevrons and diamond; warrant officer I, one diamond and chevron; chief petty officer senior, two chevrons; petty officer junior, one chevron. The next lower ranks wear their gold insignia on both sleeves between the elbow and shoulder: petty officer, 1st class, two chevrons; petty officer, 2d class, one chevron; petty officer, 3d class, three oblique marks; seaman, two oblique marks; seaman apprentice, one oblique mark; seaman recruit is without insignia or rank.

Air Force (*Luftwaffe*).—Insignia are identical with those of the army except that the collar tabs are yellow for ranks other than general officer.

German Democratic Republic (East Germany).—In uniforms and insignia the armed forces retain most of the characteristics common to the German military forces of World War II.

Army.—Officers' rank is shown on the shoulder loops. An army general wears a plaited knot made up of five loops of sets of three cords, outer cords gold, central one silver, with four five-sided silver ornaments, arbitrarily called stars. A colonel general wears the same knot as an army general, with three stars; lieutenant general wears the same knot with two stars; and major general wears the same knot with one star. Shoulder loops for all general officers are superimposed on a red background while those of field grade officers are superimposed on a solid background coloured to indicate the branch of service. A colonel wears a knot made of four silver cords and designed in six loops, with three square-shaped pips of gilt; lieutenant colonel wears the same knot with tno pips; major wears the same knot with one pip. A captain wears a shoulder loop covered with eight parallel rows of silver cord, the colour of the outside piping indicating arm or service; superimposed on the cord are four pips. A first lieutenant wears the same shoulder loop with three pips; lieutenant wears the same shoulder loop with two pips; and second lieutenant wears the same shoulder loop with one pip.

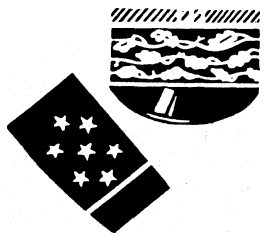
Noncommissioned officers of the first three grades wear plain shoulder loops with two parallel rows of piping, the outer row coloured to indicate branch of arm or service. A master sergeant wears two silver pips and a sergeant, first class, one silver pip; staff

corporal (*Unteroffizier*) wears the same shoulder loop with no pips. Other enlisted ranks have shoulder loops ornamented with a single strip of piping coloured to show branch or service. A staff private, first class (Stabsgefreiter) wears two white cross stripes at the end of the shoulder loop; a private, first class, wears one white stripe; and a private wears a plain shoulder loop.

Navy.—Commissioned rank is designated by sleeve braid and, for lieutenant commander and above, by gold shoulder boards similar to those of the army, but mounted on turquoise-blue background. An admiral wears three silver stars on gold shoulder board cord; on his sleeve, one broad stripe and three medium gold stripes. A vice-admiral wears two stars on his shoulder board and one broad and two medium gold stripes on his sleeve. 4 rear admiral wears one star on the shoulder board and one broad and one medium gold sleeve stripes. A captain wears a silver cord shoulder board with three gold stars and one broad gold sleeve stripe. A commander wears two stars and four medium stripes on sleeve. A lieutenant commander wears one star and three medium stripes. A senior lieutenant wears two medium stripes and one narrow stripe; his shoulder loop is the same as an army captain's, but with blue piping. A lieutenant wears two medium stripes and the same type of shoulder loop with three pips. A junior lieutenant wears one medium and one narrow stripe and two pips. An ensign wears one medium stripe on his sleeve and one pip on his shoulder loop. The lower ranks wear shoulder loops only.

Air Force.—Insignia in the main follow the army but commissioned rank is on both the shoulder loop and collar patch. General officers' shoulder loops are of gold cord mounted on a light blue background; the stars are silver; the collar patch is blue with gold ornamentation. Field grade shoulder loops are of silver cord on light-blue background; the stars are gold; the collar patch is light-blue ornamented by silver wing and wreath. Enlisted men wear plain, light-blue collar patches with white wing centred, and shoulder loops similar to those of the army but of blue piping.

France.—Army.—Commissioned insignia are worn on the kepi, the beret and shoulder loops; marshals and generals may also wear stars indicating grade on sleeve cuffs. General officers wear a khaki field kepi bearing stars; dress kepi is ornamented with gold oak leaves. Silver stars indicating ranks of combatant arms and gold stars denoting ranks in the services are superimposed on black shoulder loops: marshal of France, on shoulder loop and sleeve cuff, seven stars and on kepi three rows of gold oak leaves (see Fig. 6); general of the army, shoulder loop, cap and cuff, five stars; lieutenant general, four stars; major general. three stars; brigadier general, two stars. Officers of the rank of colonel and below wear a kepi with gold, silver or gold and silver stripes around the top to indicate rank; the cap is coloured to indicate branch of service; shoulder loops have similar stripes superimposed on them, the stripes coloured according to arm or service: colonel, shoulder loop and kepi, five gold stripes; lieutenant colonel, three gold and two silver stripes; major, four gold stripes; captain, three gold stripes; lieutenant, two gold stripes, second lieutenant, one gold stripe. Chief warrant officer, a gold stripe with a red thread. Warrant officer, one silver stripe with a red thread. Warrant officer kepis have a single gold or silver band around which a narrow red stripe is twisted.



COURTESY OF D VAN NOSTRAND COMPANY, INC.

FIG. 6.—INSIGNIA OF A MARSHAL OF FRANCE, ON KEPI AND CUFFS

Noncommissioned officers wear chevrons (point up) on both sleeves; the kepi is plain. Master sergeant, four gold chevrons; sergeant, first class, three gold chevrons; sergeant, one gold chevron; corporal. first class, two chevrons in colour of arm or service on bottom, topped by one gold chevron; corporal, two chevrons in colour of arm or service; private, first class, one chevron in colour of arm or service. Noncommissioned officers wear a similar number of bars on their garrison caps. Officer candidates wear a broken gold stripe on their shoulder loops.

Navy.—No shoulder boards are worn, but an officer's badge (small gold tab) is worn on the tip of each shoulder. Flag officer cap bands are ornamented with gold braid; caps of captains and below bear gold stripes corresponding to rank. Sleeve insignia for commissioned officers are: admiral, five silver stars; vice-admiral of the fleet, four silver stars; vice-admiral, three silver stars; rear admiral, two silver stars; captain, five gold stripes; commander, three gold and two silver stripes; lieutenant commander, four gold stripes; lieutenant, three gold stripes; junior lieutenant, two gold stripes; ensign, one gold stripe; warrant officer. first class, two narrow and one wide gold stripe; warrant officer, second class, one narrow and one wide gold stripe; chief petty officer, three diagonal gold stripes; petty officer, first class, two diagonal gold stripes; petty officer, second class, one diagonal gold stripe. Leading seaman, first class, three diagonal red stripes; leading seaman, second class, two diagonal red stripes; able seaman, one diagonal red stripe.

Air Force.—Commissioned rank is designated by gold stars or gold and silver stripes on the sleeve cuffs; no shoulder loops are worn, but an officer's badge, a small gold tab, is worn on the tip of each shoulder. General officer cap bands are ornamented with gold braid; caps of colonel and below bear gold stripes corresponding to rank: general, five stars; lieutenant general, four stars; major general, three stars; brigadier general, two stars; colonel, five gold stripes with a separation between the third and fourth; lieutenant colonel, same as colonel but the second and fourth stripes are silver; major, four gold stripes, the fourth one separated; captain, three gold stripes; lieutenant, two gold stripes; second lieutenant, one gold stripe. Warrant officer ranks are the same as in the army.

Noncommissioned officers wear shoulder loops with chevrons thereon as follows: master sergeant, one gold cross stripe, plus three gold chevrons; sergeant, first class, three gold chevrons; sergeant (professional), two gold chevrons; sergeant, one gold chevron; corporal, first class, two orange and one gold chevron; corporal, two orange chevrons; private, first class, one orange chevron.

U.S.S.R.—*Army.*—Following the Russian Revolution the Red army attempted to abolish distinctions of rank in both uniforms and insignia. However, by World War II, this policy had given way to one of specific styles for various grades, with insignia worn on collar patches and on sleeves. In 1943 new uniform regulations were promulgated by which the Red army restored the once hated shoulder-board type epaulets (pogoni) of the Imperial Russian army and reintroduced the tsarist-type standing collar and related insignia, modified in details, but generally conforming to that of the Imperial Russian army. In 1956 the Soviet ministry of defense published new uniform and insignia regulations modifying slightly and refining the general system of insignia established in 1943.

Soviet army personnel wear a variety of insignia to indicate rank or grade, arm or service, and in some cases employment. Rank or grade is shown by the ornamentation on the coat collar, sleeve cuffs and service cap; by the width and number of stripes on outer trouser seams; and by the arrangement of braid. Rank and grade are also indicated by the number, size and arrangement of stars (for officers) or stripes (for enlisted men) on the shoulder boards. Arm or service is shown by the coloured piping on uniform components, colour of service cap band, stripes and piping on shoulder boards, colour of collar tabs and by emblems on the shoulder boards, collar lapels and collar tabs. Variations in the width of shoulder boards, colour of braid, stars and rank stripes distinguish between the combatant and noncombatant officers. In addition, some emblems indicate the employment of the wearer within his arm or service.

Dress shoulder boards for all officers except those belonging to the services have silver stars on a gold background. Service branch officers wear dress shoulder boards with gold stars on a silver background. Dress shoulder boards for all army marshals and line generals have a crisscross, gold pattern and red piping; generals of technical troops wear crimson piping. Generals of the

medical, veterinary, legal and administrative services wear shoulder boards slightly narrower in width than those of other branches. Shoulder-board insignia denoting rank consist of the following: marshal of the Soviet Union, one large silver star plus national emblem; chief marshal of the arm, one large silver star surrounded by a silver wreath; marshal of the arm, one large silver star; general (general *armii*), four stars; lieutenant general (general *polkovnik*), three stars; major general (general *leitenant*), two stars; brigadier general (general maior), one star. Field grade officers are distinguished by two stripes (coloured according to arm or service) down their shoulder boards with medium-size stars on them as follows: colonel, three stars; lieutenant colonel, two stars; major, one star. Company grade officers have one stripe down the centre of their shoulder boards and their ranks are distinguished by small-size stars as follows: captain, four stars; senior first lieutenant, three stars; first lieutenant, two stars; second lieutenant; one star.

Enlisted ranks wear both dress and field shoulder boards. On the latter, the branch colour is designated by the piping, the background colour of the shoulder board being olive drab. Some field shoulder boards have claret-coloured rank stripes; others have gold or silver stripes. Emblems denoting branch of service are not worn by enlisted men on field shoulder boards. The branch colour covers the surface of the dress shoulder board and a gold metallic device (except veterinary soldiers who wear silver) denotes the branch. Black piping is worn on the dress shoulder board with the exception of artillery, armour, motor transport, medical and veterinary personnel, who display crimson piping. The number and position of the stripes used to indicate enlisted rank are: master sergeant (*starshina*), a broad transverse stripe placed on the portion of the shoulder board nearest the neck, with a medium stripe running lengthwise down the centre of the shoulder board; senior sergeant (starshi serzhant), one broad cross stripe placed nearest the neck; sergeant (serzhant), three narrow cross stripes; junior sergeant (mladshi serzhant), two narrow cross stripes; private, first class (yefreitor), one narrow cross stripe; private (*ryadovoi*), no stripes.

The colour of the arm or service is displayed on the collar tabs, on the upper edges of collars, on sleeve cuffs, on headdress and on trouser seams. In addition, the colour is also used to form the stripes and piping on dress shoulder boards.

Soviet army paratroopers and antitank personnel are regarded as specialists. **A** paratrooper wears an outline of a white parachute with a red star above the canopy on a blue diamond-shaped field; the antitank soldier wears crossed cannons on the left arm. Other specialist insignia are worn on the right breast of the uniform.

Air Force.—Soviet air force insignia follow the army pattern, with sky-blue as the branch colour.

Navy.—Insignia of commissioned officers generally follow those of the United States. For example, a star is above the top stripe for all commissioned ranks. Sleeve insignia of line officers and those of the naval engineer service are: admiral of the fleet, one broad and four medium-width gold stripes on the sleeve; admiral, vice-admiral and rear admiral each has one less medium stripe: captain, one broad stripe; commander, four medium stripes only; subcommander, three medium stripes; lieutenant commander, two medium stripes and one narrow stripe; senior lieutenant, two medium stripes; lieutenant, one medium and one narrow stripe; junior lieutenant, one medium stripe. Commissioned naval officers also wear shoulder boards patterned after those of the army.

Japan.—Army.— General officers of the ground self-defense force are identified by polished silver stars (with rounded points) worn on the collar of shirt or blouse. All other officer grades wear metallic insignia with a dull silver finish. A lieutenant general wears three large stars, a major general, two. Field and company grade officers wear their rank insignia on the uniform collars; the stars are of medium size and are mounted on a metal plate. **A** colonel wears three stars; a lieutenant colonel, two; a major, one. Company officers have small silver stars on one end of the metal plate and embossed gold bands on the other end. A captain wears one star and three gold bands; first lieutenant wears one star and two gold bands; second lieutenant, one star and one gold band. Noncommissioned officers' insignia are on the same type of silver metal plate with black stripes grooved in it as follows. master sergeant, three stripes; sergeant, first class, two stripes; sergeant, one stripe. Privates wear gold chevrons (on green background) on both sleeves between the elbow and shoulder as follows: leading private, three chevrons; private, first class, two chevrons; private, one chevron; recruit, one gold bar.

Navy.—Rank and insignia of the Japanese maritime self-defense force follow the U.S. navy pattern. Commissioned officers wear gold stripes on sleeve cuffs or shoulder boards; the device above the stripes is a gold-lace cherry blossom. The chief of the maritime staff wears a special, more ornately designed blossom. **A** vice-admiral wears one broad and two medium stripes; rear admiral, one broad and one medium stripe; captain, four medium stripes; commander, three medium stripes; lieutenant commander, two broad stripes with one narrow stripe centred; lieutenant, two medium stripes; junior lieutenant, one medium and one narrow stripe; ensign, one medium stripe. Chief petty officer wears three gold chevrons with cherry blossom above rounded top of insignia; petty officer, first class, blossom, with two chevrons; petty officer, second class, blossom, one chevron; petty officer, third class, three red chevrons topped by pink cherry blossom; seaman, three red chevrons without blossom; seaman apprentice, two red chevrons; seaman recruit, one red chevron.

On less formal uniforms, silver metallic rank insignia are worn on both shirt collars by all ranks down to and including petty officer, second class: vice-admiral, three large blossoms; rear admiral, two large blossoms; captain, three small blossoms on an oblong plate; commander, two small blossoms on an oblong plate; lieutenant commander, one small blossom on an oblong plate; lieutenant, one blossom and three pink stripes on metal plate; junior lieutenant, one blossom, two pink stripes; ensign, one blossom, one stripe. Chief petty officer wears silver plate with three black stripes; petty officer, first class, silver plate, two stripes; petty officer, second class, one stripe. All other ranks wear red chevrons on sleeves, the cherry blossoms being blue for petty officer, third class.

Air Force.—Insignia of the air self-defense force are the same as those of the army except that privates wear silver-thread chevrons instead of gold.

Italy.—Army.—Commissioned rank is shown on shoulder loops which are of silver braid for general officers. A lieutenant general wears three gold stars on silver braid; a major general, two gold stars; a brigadier general, one gold star. For prestige purposes, generals holding certain key assignments are permitted to wear four stars set on red underlining. Shoulder loops of other grades are of the same material and colour as the uniform, field grades having gold piping: a colonel wears three gold stars; lieutenant colonel, two gold stars; major, one gold star. Shoulder loops of company grade officers are plain khaki: captain, three gold stars; first lieutenant, two gold stars; second lieutenant, one gold star. Warrant officer rank is designated by longitudinal stripes displayed on the shoulder loop; the highest grade is Aiutante di Battaglia, three gold stripes on red background; warrant officer, grade I, three gold stripes; warrant officer, grade II, two gold stripes; warrant officer grade III, one gold stripe.

Enlisted ranks wear sleeve chevrons, point downward, as follows: first sergeant, one wide gold chevron above two narrow gold chevrons; sergeant, one wide gold chevron above one narrow gold chevron; first corporal, one wide black chevron above two narrow black chevrons; corporal, one wide black chevron above narrow black chevron; private, first class, one wide black chevron. Specialist (armourer, parachutist, tank driver, etc.) insignia are worn just above the chevron. Lapel patches are worn by all ranks. The colour of three-pointed lapel insignia indicates the regiment or other assignment in cavalry; the colour and combination of colours of two-pointed insignia shows the regiment or other assignment in infantry or tank corps; the colour or combination of colours of one-pointed lapel insignia indicates arm, service or regiment of any other branch.

All ranks wear metal cap insignia designating arm or service and general officers wear the same distinctive cap insignia: lieu-

tenant general, gold; other general officers, silver.

Navy.—Commissioned rank is indicated by gold braid, on cuffs and by gold stars on shoulder boards. A vice-admiral wears five gold stripes, the upper one with curl, the lower one waved; a rear admiral wears the same with one less stripe; commodore, same as rear admiral with one less stripe; captain, one broad stripe surmounted by three narrow, the upper one with curl; commander, same as captain, with one less narrow stripe; lieutenant commander, same as for commander, with one less narrow stripe; lieutenant, three narrow stripes, upper one with curl; lieutenant, junior grade, same as for lieutenant, with one less stripe; ensign, one narrow stripe with curl. Chief petty officers wear the following on their shoulder straps: class I, three gold stripes; class II, two gold stripes; class III, one gold stripe. Seamen are identified by chevrons, point downward, on their sleeves: sergeant, one broad on top and two narrow chevrons below; petty officer, one broad and one narrow gold chevron; first corporal, one broad red and two narrow stripes; seaman, first class, one narrow red stripe.

Air Force.—Commissioned rank is shown by gold patches on the cuffs; the patches are similar in design to those of the navy except that the curl is diamond-shaped. Lieutenant general, five gold stripes of medium width, upper one curled in a diamond shape, lower one waved; major general, same with one less stripe; brigadier general, same as major general with one less stripe. Commissioned officers wear a shoulder strap with gold spread wings inside gold piping. Enlisted men wear rank insignia on shoulder loops. Warrant officers are distinguished by stripes; other ranks by chevrons. Aiutante *di* Battaglia, three gold stripes with gold star superimposed; warrant officer, class I, three gold stripes; class II, two gold stripes; class III, one gold stripe. First sergeant, one broad and two narrow gold chevrons; sergeant, one broad and one narrow gold chevron; first corporal, two broad and one narrow red chevron; corporal, one broad and one narrow chevron.

Republic of China.—Army.—General officer grades are indicated by five-pointed, gold stars worn on both the right and left collar of the shirt or on both shoulder loops of the coat. Stars for generalissimo and general, first grade, are linked in a circle; the three stars of general, second grade, in a triangle—for the collar insignia. However, when worn on shoulder loops the stars are in line: generalissimo, five stars; general, first grade, four stars; general, second grade, three stars; lieutenant general, two stars; major general, one star.

Field grade officers' rank insignia consist of various sizes and numbers of gold plum blossoms worn on the right collar of the shirt or on both shoulder loops of the coat. A colonel wears three plum blossoms; they are linked in triangular fashion if on the collar, in line if on the shoulder loop. A lieutenant colonel wears two plum blossoms, a major, one. Company grade officers wear a varying number of parallel gold bars in the same fashion as field grade insignia; captain, three bars; first lieutenant, two bars; second lieutenant, one bar. There is no rank identification for junior lieutenants and warrant officers. When rank insignia are worn on the shirt, field and company grade officers wear branch of service insignia on the left collar.

Noncommissioned officers wear metal chevron plate badges on the left sleeve just below the uniform shoulder seam. No rank identification is worn by enlisted men below corporal. A master sergeant wears a red metal badge edged in gold, with three gold chevrons above a gold plum blossom, below which are from two to four gold horizontal bars, depending on the pay grade; sergeant, first class, two green metal badges edged in gold, with three gold chevrons and three gold horizontal bars below the plum blossom; sergeant, green badge with three chevrons and two bars; corporal, same as sergeant but with only one gold bar.

Metallic branch of service insignia is generally patterned after that of the U.S. army. General officers wear plum blossom insignia in lieu of specific branch insignia.

Navy.—The system of rank identification generally adheres to that of the U.S. navy. For line officers a small circular wreath of rice stalks is worn above the sleeve cuff stripes in lieu of the star of the U.S. navy. On the shoulder boards the Chinese National sun insigne is worn between the button and the rank insignia for all line officers. Flag officer shoulder boards are gold with silver stars and insignia, and black piping on sides.

Air Force.—Rank insignia worn on the shoulder loop of the blouse consist of a varying number of wide and narrow gold bars, a spread-winged eagle being near the button end of the epaulet: general, two wide and three narrow bars; lieutenant general, two wide and two narrow bars; major general, one narrow and two wide bars; colonel, one wide and three narrow bars; lieutenant colonel, one wide and two narrow bars; major, one narrow and one wide bar; captain, three narrow bars; first lieutenant, two narrow bars; second lieutenant, one narrow bar; warrant officer, no rank insignia.

In lieu of shoulder loops the same rank insignia is worn on the right collar of summer uniform shirt with specialist identification on the left collar; warrant officer wears specialist identification on both collars. Specialist insignia: for general officer, a five-pointed gold star with plum blossom, centred; pilots, spread wings with a three-bladed propeller, centred; mechanic, aircraft engine and two-bladed propeller; other specialist insignia follow U.S. army patterns.

While insignia is prescribed for enlisted airmen it is seldom worn. Instead airmen wear their name and rank written in Chinese characters on a cloth tab worn on top of the left breast pocket.

Communist China.—Up to and after its conquest of the China mainland in 1949 the Communist or People's Liberation army used no metallic badges or other insignia indicating military rank or branch of service. Commissioned officers could be recognized at times by the type of weapons carried, by coloured arm bands either worn on the right arm or wrapped around the butt of their pistols. The higher ranking officers could often be recognized by the presence of armed guards accompanying them. This largest Asiatic army at the turn of the mid-20th century exerted great efforts to conceal the identity of its commissioned and noncommissioned leaders. However, in 1956 the armed forces of Communist China adopted a new uniform system incorporating shoulder boards and insignia designating ranks and branches of service. This system was generally patterned after that of the Soviet armed forces.

Army.—All commissioned officers of the army wear shoulder boards of Soviet style except that branches of service are not indicated by coloured piping; both the stripes and piping are red. Shoulder boards have solid interwoven gold surfaces with rank insignia superimposed. For general officers, combat arms and political officers the shoulder boards are gold with silver stars superimposed; for administrative and technical staff officers they consist of a gold background with gold stars. The designs are as follows: supreme marshal, one large star wreathed by silver pine sprays, and the national seal; marshal, same as supreme marshal less the wreath around the star; senior general, four small stars aligned down the centre of the shoulder board; colonel general, three medium stars; lieutenant general, two medium stars; major general, one medium star.

All field grade ranks have shoulder boards bearing two centre red stripes between which stars are placed as follows: senior colonel, four small stars; colonel, three stars; lieutenant colonel, two stars; major, one star.

Company grade shoulder boards have one centre stripe of red. Rank is distinguished as follows: senior captain, four small stars; captain, three stars; first lieutenant, two stars; second lieutenant, one star; warrant officer, plain shoulder board. Enlisted men wear their rank insignia on red collar tabs in the shape of parallelograms. A single, gold horizontal centre stripe on the tab identifies the three top grades: senior sergeant, three stars; sergeant, two stars; corporal, one star; private, first class, two stars; private, second class, one star.

Metallic devices denoting branch of service are worn by officers and enlisted men on the red collar tabs. General officers wear red tabs with gold piping in lieu of branch insignia. There is no insignia for infantry; plain red tabs identify members of this arm.

Navy.—Shoulder boards and rank insignia are the same as army except that the stripes and piping are black. The collar tabs are

black with white or silver piping; and anchor is in the centre.

Air Force. — Insignia are the same as army insignia except that collar tabs and shoulder-board stripes and piping are sky-blue. The collar tabs bear a set of wings in the centre.

INSKIP, JOHN SWANEL (1816–1884), U.S. evangelist and editor, was born in Huntingdon, Eng., on Aug. 10, 1816. His family emigrated to the United States and settled in Pennsylvania, where Inskip entered the ministry of the Methodist Episcopal church at an early age.

Noted for his eloquence in the pulpit, he served in various church posts in Pennsylvania and Ohio and elsewhere, and for a number of years was pastor of churches in New York city. He also edited the Christian Standard (Philadelphia). Early in the Civil War he served as a chaplain with a New York regiment.

Inskip, who became the first president of the National Camp Meeting Association for the Promotion of Holiness in 1867, won a wide reputation as an evangelist and led revival campaigns in the United States and other countries, including England, India and Australia.

In *Methodism* Explained and Defended (1851), Inskip argued against segregated seating of men and women at church services, a controversial contemporary issue in churches in western states, He died at Ocean Grove. N.J., on March 7, 1884.

INSOLATION, the amount of solar radiant energy received in a given time on a unit horizontal area at any specified place on the surface of the earth or in the atmosphere. It is usually expressed in totals for periods of a day, a week, a month or a year.

Insolation generally denotes the actual amount of energy received after depletion by the atmospheric gases, dust and clouds, although it can express a hypothetical condition, such as the energy received through a perfectly transparent atmosphere.

(H. R. B.)

INSOMNIA, or the inability to sleep adequately, is a common enough symptom in modern life and varies greatly in degree.

Three varieties of insomnia may be roughly distinguished: the inability to fall asleep at the onset for a variable period; the frequent awakening with incapacity to resume sleep for some time; the waking up at an unduly early hour with no subsequent sleep.

Every individual case must be investigated carefully on its own merits, and the physician is frequently taxed to the utmost to combat the symptom on rational and not empirical lines.

The responsible causes may have a bodily basis or must be sought in the mind. Among the former must be enumerated the evident factors of pain or discomfort from any cause: shortness of breath, cough, frequency' of urination, itching, palpitation. Febrile conditions, high blood pressure and other circulatory disturbances, toxic states and organic disease of the brain are also responsible.

In many forms of mental derangement insomnia is a frequent symptom and often heralds its inception. This is specially so in anxiety conditions, where unpleasant dreams may exaggerate the sleeplessness, and here the sufferer may fear to lose consciousness because of these experiences which he cannot control. In neurasthenia and many hysterical states insomnia is likely to be prominent.

In such psychoses as manic-depressive insanity, dementia praecox, confusional insanity and general paresis, such a symptom is generally part of the clinical picture. (C. S. R.; X.)

INSPIRATION is strictly the act of drawing physical breath into the lungs as opposed to "expiration." Metaphorically the term is used generally of analogous mental phenomena; thus we speak of a sudden spontaneous idea as an "inspiration." The term is specially used in theology for the condition of being directly under the divine influence, as the equivalent of the Greek θεοπνευστία (2 Timothy iii, 16).

Similar in meaning is ἐνθουσιασμός, enthusiasm (from ἐνθουσιάζω from ἔνθεος). Possession by the divine spirit (πνεῦμα) was regarded as necessarily accompanied by intense stimulation of the emotions.

The Doctrine of Communion.—The possibility of a human being becoming the habitation and organ of a divinity is generally assumed in the lower religions. In the popular religion of China some of the priests, known as the Wu, claim to be able to take up into their body a god or a spirit, and thereby to give oracles. The Maoris at the initiation of the young men into the tribal mysteries sing a song, called "breath," to the mystic wind by which they believe their god makes his presence known. An Australian woman claimed to have heard the descent of the god as a rushing wind.

In some savage tribes blood is drunk to induce the frenzy of inspiration; music and dancing are widely employed for the same purpose. Dionysus, the god of wine in Greece, was also the god of inspiration; and in their orgies the worshippers believed themselves to enter into real union with the deity. In Delphi the Pythia, the priestess who delivered the oracles, was intoxicated by the vapour which rose from a well through a small hole in the ground.

As the oracles were often enigmatic, they were interpreted by a prophet. In Rome the inspiration of Numa was derived from the nymph Egeria; and great value was attached to the books of the Cumaean Sibyl. In Arabia the *kahin* (priest) was recognized as the channel of divine communication. Inspiration may mean only possession by the deity, or it may mean further that the person so possessed becomes the channel through which the deity reveals his word and will. (See J. A. Macculloch's *Comparative Theology,* ch. xv, 1902.)

Prophecy in the Old Testament in its beginnings is similar to the phenomenon in other religions (1 Sam. ix, 8, x, 10–11). The prophesying in which Saul took part probably included violent movements of the body, inarticulate cries, a state of ecstasy or even frenzy. The phrase "holy spirit" in Acts, as applied to the Apostolic Church. probably indicates a similar state of religious exaltation; it was accompanied by speaking with tongues, inarticulate utterances which needed interpretation (1 Cor. xiv. 27). In every religious revival, when the emotions are deeply stirred, similar phenomena are met with. Such a movement was Montanism in the 3rd century. At the Reformation, while Luther was at the Wartburg, fanaticism broke out, and spread from Wittenberg; prophets went about declaring the revelations which they had received. The Evangelical revival in the 18th century also had its abnormal religious features. The Revival in Scotland in 1860 was marked by one curious feature — the Gospel dance — when in their excitement men and women got up and spun round and round till they were exhausted. Spontaneous praise and prayer marked the revival in Wales in 1905–06.

Prophecy, as represented by the writings of the prophets, arose out of this state of religious exaltation, but left behind many of its features. The function of the prophets was to interpret the course of history as the divine providence for the chosen people Israel, so as to communicate God's Word and Will in judgment or in mercy. They were divinely endowed for this function by their inspiration. While these prophets seem to have continued in the exercise of all their normal faculties, which were stimulated and not suppressed, yet they do claim a distinctive divine activity in their consciousness, and distinguish with confidence their own thoughts from the revealed word. That abnormal psychic states, such as visions and voices, were sometimes experienced is not improbable (see 'Theodore H. Robinson, *Prophecy and the Prophets*), but the usual prophetic state seems to have been one of withdrawal of attention irom the outer world, absorption of

interest in the inner life, devout communion and intercession with God, and the divine response in a moral or a spiritual intuition rather than an intellectual ratiocination. Possession by the Spirit in its external manifestations is ascribed to Gideon, Jephthah, Samson, Saul, Elijah; but even when the same language is used of the later prophets, it is probably such an inward state as has just been described which is to be assumed.

A feature inseparable from this later phase of prophecy is *prediction.* For the warning or the encouragement of the people the prophet as Jehovah's messenger declares what He is about to do. Thus the fall of Samaria in 722 B.C., the deliverance of Jerusalem in 701, the overthrow of the kingdom of Judah in 586, the return from exile in 537 were all heralded by prophecy. This prediction was no shrewd political conjecture, but an application to existing conditions of the permanent laws of God's government. The abnormal phenomena of inspiration, the presence and operation of the Holy Spirit, in the Apostolic Church, have already been noticed.

The New Testament.—While Paul does not deny nor depreciate these charisms, as tongues, miracles, etc., he commends as the more excellent way the Christian life in faith, hope and love (1 Cor. xii. 31). The New Testament represents the Christian life as an inspired life. It is living communion with Christ, and therefore constant possession of the Holy Spirit. Every Christian, in the measure in which he has become a new creature in Christ, is a prophet, because he knows by the enlightening of God's Spirit "what is the good and acceptable and perfect will of God" (Romans xii. 2). An occasional state of divine possession in the other religions becomes in the prophets of Israel a permanent endowment for a few select agents of God's revelation; but when that revelation is consummated in Christ, inspiration becomes the universal privilege of all believers.

Apologetics.—While there is much superstition in the view of inspiration found in many religions, and much imposture in the claims to the possession of it, yet it would be illogical to conclude that this feature of religion is altogether human error and not at all divine truth. Man's knowledge of God is conditional, and therefore limited by his knowledge of the world and himself, and has accordingly the same imperfection. The reality of a divine communion and communication with man is not to be denied because its nature has been imperfectly apprehended. We must estimate the worth of inspiration by the higher and not the lower stages, by the vision of an Isaiah or the consecration of a Paul; but at the same time we must be prepared to recognise its lowly beginnings,

In dealing with the inspiration of the Bible, to which the use of the term has in the Christian Church been largely restricted, it is important to remember that inspiration is primarily personal; and that it assumes varied forms and allows varying degrees.

Other religions besides Christianity possess their sacred scriptures and the claim of inspiration is advanced for some of them, as by Hinduism for the *S'ruti* (hearing) writings as distinguished from the *Smriti* (recollection), Zoroastrianism for the Zend-Avesta, Islam for the Koran. But Buddhism advances no such claim for its *Tripitaka* (three baskets), nor Confucianism for its classics.

Exegesis.—The Pentateuch was accepted as authoritative law by the Jewish Church in 444 B.C. About two centuries later the Prophets (including the histories as well as the prophetic writings proper) were also acknowledged as sacred scriptures, although of inferior authority to the Law. In the century before the Christian era the Writings, including Psalms and Proverbs, were included in the Canon. Palestinian and Hellenistic Judaism disagreed about the recognition of the books now known as the Apocrypha. The writers of the New Testament use the Old Testament as holy scriptures, as an authoritative declaration of the mind and will of God; but the inaccuracy of many of the quotations, together with the use of the Greek translation as well as the original Hebrew, forbid our ascribing to them any theory of verbal inspiration. By the middle of the 2nd century the four Gospels were probably accepted as trustworthy records of the life of Jesus. The Epistles were accepted as authoritative in virtue of apostolic authorship. By the end of the 3rd century the use and approval of the churches had established the present canon.

The doctrine of the inspiration of these writings in the Jewish and Christian Church now claims attention. Inspiration is first of all ascribed to persons to account for abnormal states, or exceptional powers and gifts; in this doctrine it is transferred to writings, and its effects in securing for these inerrancy, authority, etc., are discussed with little regard for the psychic state of the writers.

The New Testament affirms the inspirations of the Old Testament (Matt. i. 22, xv. 4, Mark xii 36, Acts i. 16, Romans iii. 2, ix. 25, Heb. i. 1, 1 Peter iv. 11). The term is used in regard to the Scriptures in 2 Timothy iii. 16. The Spirit of Christ is said to have been in the prophets (1 Peter i. 11); and it is affirmed that "no prophecy ever came by the will of man; but men spake from God, being moved by the Holy Spirit" (2 Peter i. 21). The constant use of the Old Testament in the New confirms this doctrine of inspiration.

Contemporary Jewish thought, as expressed by Philo, Josephus, and the Talmud according to Weber, was in agreement with this view of the Old Testament. But the nature of this inspiration must be more closely defined, and hence have arisen a number of theories of inspiration which can be only briefly mentioned. The theory of *verbal inspiration,* which was held by Plato, Philo, the Apologists, the Fathers, and the Protestant Scholastics, ignores the data which the Bible itself offers. The theory of *dynamic influence or degrees of inspiration* recognises that the human personality is not entirely suppressed by the direction and control of the Spirit; but it does not offer us any sure guidance in discriminating the human and the divine factor, and in estimating the value of the contents of the Bible. The theory of *essential inspiration* in claiming inspiration only in matters of doctrine and conduct (anticipated in Aquinas' distinction of *direct* and *indirect* inspiration, and favoured by Erasmus, Hugo Grotius, Baxter, Paley, etc.) betrays a too intellectualist standpoint in the emphasis it lays on correctness in theology and ethics, and ignores the progressive character of revelation.

Protestantism.—The theory of the Reformers (though not of their successors, the Protestant scholastics)—might be called that of *vital inspiration,* as its emphasis is on religious and moral life rather than on knowledge. While giving to the Scriptures supreme authority in all matters of faith and doctrine, the Reformers laid stress on the use of the Bible for edification; it was for them primarily a means of grace for awakening and nourishing the new life in the hearts of God's people. By the enlightening work of the Spirit of God the Word of God is discovered in the Scriptures: it is the *testimonium Spiritus Sancti* in the soul of the Christian that makes the Bible the power and wisdom of God unto salvation. By thus laying stress on this redemptive purpose of the divine revelation, the Reformers were delivered from the bondage of the letter of Scripture, and could face questions of date and authorship of the writings frankly and boldly. Hence a pioneer of the higher criticism in Great Britain, W. Robertson Smith, was able to appeal to this Reformation doctrine (quoted in Denney's *Studies in Theology,* p. 205). The Reformers' application of this theory to the Bible was necessarily conditioned by the knowledge of their age; but it is a theory wide enough to leave room for our growing modern knowledge of the Bible.

Résumé.—Briefly stated, these are the conclusions which our modern knowledge allows. (1) Inspiration, or the presence and influence of the Divine Spirit in the soul of man, cannot be limited to the writers of the Scriptures; but, comparing the Bible with the other sacred literature of the world, its religious and moral superiority cannot be denied, and we may, therefore, claim for it as a whole a fuller inspiration. (2) As different writings in the Bible have more or less important functions in the progressive divine revelation, we may distinguish degrees of inspiration. (3) This inspiration is primarily personal, an inward enlightening and quickening, both religious and moral, of the writer, finding an expression conditioned by his individual characteristics in his writing. (4) The purpose of inspiration is practical; the inspired men are used of God to give guidance in belief and duty by declaring the word and will of God as bearing on human life. (5)

As revelation is progressive, inspiration does not exclude defects in doctrine and practice in the earlier stages and their correction in the later stages of development. (6) As the progressive revelation culminates in Christ, so He possesses fullest inspiration; and it varies in others according to the closeness of their contact, and intimacy of their communion with Him. (7) As the primary function of Christ is redemptive, so the inspiration of the Bible is directed to make men "wise unto salvation." (8) It is the presence and influence in the souls of men of the same Spirit of God as inspired the Scriptures which makes the Bible effective as a means of grace; and only those who yield themselves to the Spirit of God have the witness in themselves that the Bible conveys to them the truth and the grace of God.

INSTALLATION, the action of installing or formally placing some one in occupation of an office or place. The word is used of the ceremonial induction of an ecclesiastic, such as a canon or prebendary, to his stall in his cathedral choir. Similarly knights of an order of chivalry are ceremonially led to their stalls in the chapel of their order.

INSTALLMENT CREDIT. Installment credit, or hire purchase, as it is known in Great Britain, is the means by which most durable consumer goods of the industrial nations are paid for. Wherever automobiles, refrigerators, laundry equipment and other such products play an important role in the lives of the people, installment credit is a large item in the financial structure of the country. In all the wealthy countries of the world, the greatest single use of installment credit is for the purchase of passenger automobiles. In the United States, for example, beginning in the 1920s, and with the exception of the period immediately after World War II, from 60% to 70% of automobiles have been bought on the installment plan.

Installment credit commonly refers to credit extended to families, individuals or households, as contrasted with businesses or governments. It is repayable in installments at regular intervals. In the extension of sales credit, the contract sometimes provides that the goods purchased will not become the legal property of the purchaser until every installment has been paid. As a rule, in case of default, all previous payments are forfeited to the lender and he may also take possession of the goods. The British Hire Purchase act of 1938 provided that the seller could not take back the goods without a court order if the purchaser had paid one-third or more of the hire-purchase price. Credit extended to business firms or governments is frequently repayable in installments, but such credit is not included in the concept of consumer installment credit.

Installment credit constitutes the great bulk of all short and intermediate household credit in most countries, but households also have other debts that do not provide for regular periodic payments. The total of household debts (exclusive of house mortgages) is commonly referred to as consumer credit. Installment credit may be best understood as a major part of all consumer credit.

A large volume of installment credit depends on the employment and income conditions of the public and on the types of goods which are produced and sold. A population which makes great use of installment credit is one which receives its income in regular periodic amounts, generally in the form of wages and salaries. At the same time, these incomes must be large enough for the population to be able to afford rather expensive durable consumer goods.

Accordingly, installment credit has grown in importance as larger portions of the public became periodic wage and salary earners; as these incomes'became large enough to provide for luxury durable goods; as technology provided durable consumer goods; and as the public developed a taste for these goods.

History.—Household or consumer debt is a very old human institution. So long as consumer goods have been articles of commerce, whenever they have been produced by someone other than the consumer and then bought by the consumer, there has probably been consumer credit. But in most cases and throughout most of the world's history, the extension of credit was a personal matter between the seller and the buyer; the debt was not highly institutionalized; and provision for regular periodic repayment was not set forth in a written contract.

Installment loans for the purchase of durable consumer goods, such as furniture, appeared in the 19th century, but it first received serious public attention and became of great economic importance shortly after the end of World War I. The burgeoning sales of passenger automobiles during the 1920s were made possible in large measure by installment credit. Some retailers were able to supply the money necessary to finance credit extensions. In the 1920s, however, there was a rapid growth of a new type of institution known as the finance company.

This type of firm bought instruments of indebtedness from the retailers and collected from the debtors the sums due periodically. Some of these finance companies were from their very inception owned by or closely associated with manufacturers. The most notable example was the General Motors Acceptance corporation (G.M.A.C.), which was organized in 1918. Devoted to financing the sale of General Motors products, it became the world's largest consumer finance organization. Most finance companies, such as the Commercial Credit company of Baltimore, Md.. have been independent of both manufacturers and retailers. Some operate on a large scale over an entire country, or even in several countries, while others limit their operations to small areas. In Britain and Australia during the late 1950s many finance companies came to be closely affiliated with commercial banks, but such connections did not develop in the United States.

Even before the dramatic increase in installment financing of durable goods in the 1920s another aspect of consumer financing had become a matter of social concern, particularly in the United States. In the 19th century, as an increasing proportion of the population moved into the urban centres and became employed on a wage or salary basis, cash borrowing for consumer purposes grew rapidly in importance. It came to be widely believed that social evils were related to this borrowing and that it should be publicly controlled. Such borrowing by individuals and households was not new, of course, but it was of increasing magnitude and social concern.

The commonest historical form of consumer lending has been pawnbroking; *i.e.,* the lending of money upon the security of household goods or personal effects. As pawnbroking developed in the late middle ages, it soon was subjected to legal controls. Special charters regulated the lenders' responsibility for the safety of the pledged property, the conditions of its forfeiture, the ratio of loans to value of the property, maximum loans to certain classes of people, and maximum interest rates. The most frequent maximum interest rate permitted in the late middle ages was $43\frac{1}{3}\%$, or two pence on the pound per week. Higher rates, however, were not uncommon. (See PAWNBROKIKG.)

Alongside the pawnshops, moneylenders or "loan sharks" operated during the 19th century, advancing funds in violation of the usury laws to wage and salary workers. The facts about this business are not well known, but it was believed to involve social abuses. As a result, in the United States beginning about the second decade of the 20th century, various states undertook to provide for supervised businesses to make small loans. (See MOKEY-LENDING.)

These supervised lenders, known as small loan companies or consumer finance companies, were authorized to make loans in limited amounts, charging rates in excess of those permitted under the usury laws. For example, charges might be at a rate of $3\frac{1}{2}$ cents per dollar per month on amounts up to $300. This charge was supposed to be all-inclusive, providing for investigation, collection, bookkeeping and losses as well as full interest. Such credit has sometimes been criticized on the grounds that borrowers

tend to keep themselves perpetually in debt or that lenders encourage them to borrow continuously and unnecessarily. Total loans of the licensed lenders increased from about $20.000.000 in 1917 to about $400,000,000 in 1937. Control of the operations of moneylenders in Britain was provided by acts of parliament in 1900 and 1927. These acts did not provide a legal escape from the usury laws, as was the case in the United States, but provided for controls and limitations in a field that was otherwise not subject to legal limitation.

In the United States, at the same time that escape from the usury laws governing cash loans was being provided by the small loan laws, escape was also provided in the form of durable goods sale credit by the legal doctrine of the time sales contract. Under this doctrine, if a price were placed upon a product to be sold on a credit basis, the difference between this price and the price prevailing if the commodity were sold for cash was judged not to constitute interest and not to be subject to the usury laws. The great expansion of sales of automobiles and other consumer durable goods in the 1920s in the United States was financed in large measure by installment credit without reference to the usury laws of the states.

The rapid growth of consumer credit in the 1920s aroused great public interest and discussion. The development was widely regarded by publicists as unsound from the standpoint of the general economy, somewhat immoral, and unwise from the standpoint of the financial advancement of the borrowers. Despite these widespread attitudes, the desires of the consumer and the salesmanship of retailers and manufacturers resulted in an extremely rapid growth of installment debt. It is estimated that installment debt in the United States rose from $1,000,000,000 in 1920 to $3,000,000,000 in 1929. In response to the widely expressed disapprobation of consumer credit and fears of adverse economic reaction to its growth, some economists and many representatives of finance companies developed theories that consumer credit was necessary for prosperity. They maintained that installment sales credit was necessary for the distribution of the new durable goods among broad groups of the population, and thereby to permit the development of industry on an efficient and highly productive basis.

When the 1929 depression overtook the world, consumer credit proved on the whole a very sound asset. Finance companies survived better than commercial banks, and their assets proved better than the commercial bank assets. Accordingly, the consumer credit business in the 1930s was not the subject of reform legislation. such as that enacted to deal with farm finance, home finance, corporate securities and the stock exchanges. Indeed, the record of consumer credit appeared relatively so good that the commercial banks of the United States, as they rose from the depression, rapidly entered the consumer credit business themselves. By the beginning of World War II they held $1,500,000,000 of installment paper, compared with $1,600,000,000 held by the sales finance companies and $700,000,000 held by other lenders, chiefly the personal finance companies.

But while the depression brought relatively few losses to the holders of consumer credit, it did lead to some critical examination of the subject. Some observers continued to feel that installment credit would contribute substantially to economic instability. Some thought that the collection of funds from the income stream by holders of installment paper during economic depression contributed substantially to a decline in consumer expenditures and to the furtherance of economic collapse. They thought that this might have been a factor in the 1929–33 depression and again in the 1937–38 recession. The completion of some major studies of consumer credit about the end of the 1930s in the United States helped to form a basis for adoption of special government wartime controls of consumer credit. The lack of confidence in general monetary controls *(see* CENTRAL BANK) that developed during the 1930s created a favourable climate for the consideration of special credit controls when excessive credit expansion threatened upon the outbreak of war.

In the United States special regulation of consumer installment credit was adopted by the federal government for the first time in Aug. 1941. These controls were premised on the lack of effective general credit controls, the desire to channel materials into avenues most necessary for the prosecution of the war and possibly a widespread feeling that consumer credit is unwise from either a personal or social standpoint. Consumer credit controls generally took the form of a down payment requirement or limits on the amount that could be borrowed in relation to the value of the object to be purchased. and limits on the period over which repayment could be extended. In Great Britain the wartime control of consumer credit was a part of price control. It was primarily a control of the rate of finance charge and mas chiefly a means of preventing the use of finance charges to circumvent the control of other prices. From 1943 to 1947 an outright prohibition of installment buying or hire purchase trading of most commodities was enforced.

Control After World War II.—The significance of consumer credit controi was small during the war because the production of most goods customarily financed with installment credit was brought to a halt. At the end of the war, consumer credit controls took on a new role. As production of consumer goods was resumed. the supply was far less than the demand. Continuation of consumer credit controls helped to limit demand, and this in turn contributed to solution of the problem of allocating the limited supply among consumers.

The British government after the war placed restrictions from time to time on capital issues of hire purchase companies. Such limitations were in operation from 1945 to mid-1954 and again from Feb. 1955 to Feb. 1959. In the United States, the government had difficulty deciding when to relinquish control over consumer credit terms. Restrictions were first dropped on Nov. 1, 1947, but in the face of continued inflation, excessive demand for consumer durable goods, and limited general monetary controls, special consumer credit limitations were again put into effect from Aug. 16, 1948, to June 30, 1949.

With the outbreak of hostilities in Korea, regulation of consumer credit was reinstituted in the United States in Sept. 1950 and continued until May 1952. The lack of such controls after that date may be explained in part by the availability of general credit controls, such as the purchase and sale of securities by the central bank, the adequate supply of consumer goods, the difficulties of enforcing such controls and the lack of public agreement that the special control of consumer credit is socially desirable. During the three periods when consumer credit has been under control by the federal government in the United States, administration of the control has been in the hands of the federal reserve system (*q.v.*), implemented by its regulation W.

Just as the United States was abandoning consumer credit controls in 1952, Great Britain was adopting such controls. From 1952 to 1960 the United States made no use of such regulations, but they played an important role among the economic stabilization instruments exercised by the British government. Credit limitations related to British price control disappeared with the abolition of price control on April 30, 1953. In the meantime, on Feb. 1, 1952, England had entered upon a full-scale control of hire purchase as a means of general economic policy implementation. This type of control was in use the greater part of the time during the following decade, Feb. 1952–July 1954, Feb. 1955–Oct. 1958, and again beginning in April 1960. During the periods when controls were in effect the prescribed time for repayment was usually 24 months, while the initial deposit requirement for automobiles, as an example, varied from time to time from 15% to 50%.

Adoption of consumer credit control in Great Britain after it was abandoned in the United States may have been due to several factors. Other means of general credit control may have been more effective in the United States, where the cash reserve requirements on the commercial banks are very effective. Central bank influence on bank cash reserves in the United States exercises a greater influence on total demand than do the general controls of the Bank of England. Furthermore, the balance-of-trade problem of Great Britain, the extent of economic planning, and controls in other fields have created a greater predilection for specific

controls of consumer credit.

The nature and timing of consumer credit controls in Canada for purposes of economy stabilization have been similar to developments in the United States. Indeed, it may be said that the 1950s saw the United States and Canada move away from consumer credit controls as an instrument for procuring economic stability, while many other countries were making substantial use of the device.

Consumer Spending Decisions.—Installment credit is used for two chief purposes: the purchase of durable goods that are acquired only occasionally, and other large expenditures that cannot readily be paid out of current income. Installment credit enables consumers to spend within a limited time period more than their current income. Purchases made in one month can be paid for out of the income of several months. Tax and insurance payments. annual vacation costs and school tuition payments may be expenditures of such a character.

Consumers may obtain the use of durable goods by a variety of methods: (1) Other assets may be liquidated. (2) Previously accumulated savings may be used, or funds may be saved out of current income until enough is saved to buy the commodity or service. (3) Monthly payments may be made over a period of time. (4) Goods may be obtained by lease or rental. (5) Relatively cheap goods may be bought at the outset and later he discarded or exchanged and better goods acquired as current income permits, the process being repeated indefinitely. If, for example, the $300 that might be required as down payment on a $3,000 car is devoted to purchase of a used car and the amount that mould be required to make the monthly payments on the new car are accumulated, a better used car costing $1.500 can be bought after about a year, or a new $3,000 car can be bought after something over two years.

These methods are obviously not altogether distinct or mutually exclusive. but their enumeration is of some value in thinking about the subject of consumer credit. It is scarcely possible to demonstrate that one method of acquiring consumer goods is better than another. Each of them is used, and each best meets the needs of some consumers. It may be argued that the saving up and working up methods are best or cheapest, but this suggestion is rather pointless for people who cannot bring themselves to follow the necessary procedures. It may he that for the great bulk of the population it is psychologically impossible either to save up money for major expenditures or to improve methodically the quality or quantity of its durable goods. Yet the consumer may genuinely desire, in spite of costly finance charges, to use installment credit for the high quality durable goods and major expenses, such as vacations. in preference to goods and services which may be simultaneously financed out of current income.

The quantity of consumer credit has depended and will depend on the pattern of goods and services bought by consumers. On the other hand, the availability of consumer credit has determined, to some extent, the pattern of goods and services bought. To the extent that increased levels of consumption take the form of using durable goods, such as automobiles, or engaging in concentrated expenditures, such as vacations or Christmas gifts, consumer credit increases in volume. When expenditures of these types are increasing relative to others, consumer credit will tend to grow more rapidly than income. Consumer tastes, however, may turn toward the leasing of durable goods, the utilization of services, such as commercial laundries, recreation or the purchase of expendable goods. Such expenditures, which do not involve long-term installment credit, can drop the growth rate of installment credit until it is even with or lower than the growth rate of income.

Borrowing to buy goods such as automobiles bears some relation to the probable length of efficient life of the purchase. A periodic reduction of the debt by a certain amount may correspond roughly to the rate of depreciation. A very common period for paying for a new automobile in the United States in the late 1950s was three years. The longer the average useful life of a product, the greater may soundly be the maturity of the indebtedness.

Many consumers see fit to borrow at interest rates ranging from 8% to possibly 20% while holding liquid assets nhich yield from 2% to 4%. While such a practice may seem irrational and undesirable, this may not be the practical fact. The consumer may feel that if he borrons, he will be under the discipline of repaying, while if he uses his liquid assets, he will not replace them, and later he will be in a worse financial position than if he had borrowed.

Accumulation of savings and simultaneous borrowing at much higher rates of interest. even from the same institution, may be in a sense costly or wasteful, but this may be the only way in which many households can regulate their spending and contribute to personal peace of mind and maximum satisfaction. The millions of consumers who borrow year after year, even though they have liquid assets, belie the belief that consumer installment credit is a great swindle. In the main, the users like such credit because it enables them to make the best adjustment to the need for financial planning.

Installment credit has sometimes been thought of as a means whereby the individual or family can early enjoy a level of living which is justified only by the anticipation that income will be higher at a later stage of life However, the major consumer uses of installment credit do not offer much to this end of evening out consumption over an individual's or family's life span An automobile buyer, 22 years of age, may reasonably expect a higher income at age 35. but the payments on the car must be made nithin the next tno or three years.

Consumer credit does not on the whole provide a means for maintaining a family's level of living in the case of temporary decline of income. Debt is incurred primarily at times of increased employment, increased overtime and rising nage rates. It may be argued that since the monthly payments must on the whole continue to be paid at a time of declining income, spendable funds are made more uneven by installment credit. Some consumer installment debt is incurred at times of reduced income, but such credit plays a small role compared with credit associated with prior or simultaneous increases of incomes. Automobile loans and other types of consumer credit rise in times of increased employment and income; the cash loans of the consumer finance companies, the credit unions and the commercial banks also increase most in time of prosperity.

Cost of Consumer Credit.—Installment credit outstanding in the United States by 1960 amounted to over S40.000.000.000, and total finance charges each year were from 15% to 18%. It thus appears that consumers paid more than $6,000,000 000 per year for the use of the installment credit method of acquiring their purchases.

The reason for this high cost is that the extension of credit to consumers generally involves cost to the seller or lender. In a few instances. such as the sale of electricity and gas to consumers, either prepayment or credit is technically necessary. In this and some other cases the extension of credit may be less costly to the seller than would collection of cash simultaneously with supplying the goods or service. But, generally speaking, the seller incurs extra costs by virtue of not collecting cash at the time of the sale. In the case of the simple charge account, which is technically payable soon after the receipt of a monthly bill. the costs are generally borne by the seller or, in a sense, by the customers (both those paying cash and those buying on credit). A specific charge is almost always made for all types of installment credit. Compared with other types of credit, the charges for this kind are quite high. While governments and businesses with good credit standing have commonly been able to borrow for 4, 5, or 6 cents per dollar per year, consumers borrowing relatively small amounts, and having a less reliable or undetermined credit status, have commonly paid from 8 to 42 and more cents per dollar per year.

Provision of consumer credit requires a large and complicated organization for investigation of the borrower, keeping records and collecting delinquent accounts. Provision must also be made for losses. Costs vary greatly, depending upon the size of the credit and the character of the borrower. The cost of investigating borrowers and making collections is much less per dollar in

the case of large loans than in the case of small loans. Accordingly, the rate of interest charged must be higher on small borrowings than on large. Lenders who confine their business to persons of a relatively high degree of financial responsibility can lend at lower rates than can those who lend to the financially less reliable. This may be one reason why rates charged by the commercial banks are generally less than the rates charged by some other classes of lenders. Credit unions are also able to make small charges on loans because they have lower costs for investigation, collection and loss. Needless to say, it behooves the wise borrower to patronize the lowest-priced lender who will recognize his eligibility for credit. The level of rates paid by consumers for loans has sometimes reflected their unwillingness or inability to bargain or shop around, and some lenders have made very high and, in a sense, unjustified profits. But. in the main, the level of charges has been necessitated by the costs involved.

Consumer Protection.— Historically. consumer credit in the United States has had either to operate illegally or to find some way to avoid the usury laws of most states. Many states have prohibited lending at a charge of more than about S cents per dollar per year. Many states have also provided that under government supervision loans can be made by special institutions up to limited amounts at rates above the usury rate. They have generally provided these limits by h \ rather than by making provision for their determination by administrative action as is generally the case with public utility and other governmental price control. The other chief way in which consumer credit charges higher than those permitted by the usury laws have been practical has been for the price of goods sold on installments to be higher than the cash price.

After World War II, this means of circumventing the usury laws was questioned. Some influential observers came to regard the charges as extortionate; some court decisions indicated that the sales price doctrine should not be regarded as a legitimate means of circumventing the usury laws, but as a violation of them. As a result, many states provided by law for interest on sales credit beyond the basic usury limit.

The cost of consumer credit has long been a matter of public and social concern. By way of reform it has been suggested that lenders be required to give better information to borrowers (buyers) regarding credit costs. Information requirements may be of several kinds. The law might require, for example, the quotation of both the credit sales price and the cash sales price. Such is the basic nature of the British acts of 1938 and 1954 and of laws enacted in about half the states of the United States after World War II. An alternative information requirement may be for the credit cost to be stated in the form of a rate per annum on the unpaid balance. This was the nature of proposed legislation introduced into the U.S. senate in 1960 (S. 2755–86th congress, 2nd session). *See* also CREDIT UNION; DEBTOR AND CREDITOR LAW; MONEY-LENDING; PAWNBROKING; USURY.

INSTERBURG (CHERNYAKHOVSK), a city at the point where the Angerapp and Inster rivers join to form the Pregel river, about 50 mi. E. of Königsberg (Kaliningrad), after 1945 in east central Kaliningrad *oblast,* Russian S.F.S.R.; it was formerly in the province of East Prussia. Pop. (1959 est.) 30,000.

The junction of railways to Memel and Allenstein, Insterburg became known for its considerable trade in cereals and wood and for the horse breeding carried on extensively in the neighbourhood. In addition to flax spinning and iron founding. industries such as the manufacture of machinery, cement, leather and beer were developed there. The town church has been celebrated for its fine mood carvings.

Insterburg, the "burg" on the Inster, was founded in the 14th century by the knights of the Teutonic order. Having passed to the margraves of Brandenburg, the village which had sprung up round the castle received civic privileges in 1583. During the next century it prospered greatly, partly a result of the settlement in it of several Scottish trading families. In 1679 it was besieged by the Swedes; in 1690 it suffered severely from a fire; and in 1710–11 from pestilence. It was occupied by the Russians in 1914 and again in Jan. 1945.

At the Potsdam conference it was awarded to the Russians, who renamed it after the Soviet general who led the forces that captured it during World War II.

INSTINCT (Latin *instinctus,* "impulse," "instigation"). Popular and literary use of this word is loose: it has been applied to behaviour driven from within ("the mating instinct asserts itself in spring"), to nonlearned behaviour ("the kitten knows instinctively where t~ find the mother's nipple") and to unconscious or unpremeditated behaviour ("I put my foot on the brake instinctively"). In studies of animal behaviour it has often been applied to relatively complex behaviour which serves a vital end, is at least partly caused by an internal urge and need not be learned. However, it is being realized that the dichotomy instinctive—noninstinctive based on this complex of criteria, or even on any one of them, is not helpful, and modern students of animal behaviour prefer to classify behaviour in a very different way. Yet the aspects mentioned—of adaptedness, of causal organization and of development of behaviour in the individual—remain central themes of investigation.

Adaptedness.—A great many aspects of animal behaviour contribute to survival, and the functional significance of even the most trivial details is the object of research. Most behaviour involves processes in the sense organs, in the nervous system, in the muscles and in hormone-secreting glands, and each of these processes is adapted to contributing toward survival. This is demonstrated in such diverse phenomena as the simple prey-catching movement of the praying mantis, the more complicated action chains such as the "dance" of the honeybee scouts; such complexly adjusted movements as bird flight; the sensory refinements employed in species and individual recognition; symbiotic relationships such as those between flowers and their pollinators; the employment of learning when the situation demands it; the cooperation between individuals in social behaviour; and many other phenomena. In short, the correct functioning of behaviour is recognized as being subject to ruthless pressure of natural selection just as any other life process.

Yet it is obvious from the many things an animal does not do that animal behaviour is remarkably restricted in many respects. Many ground-breeding birds can roll an egg back into the nest, but they invariably use the clumsy method of balancing it against the bill, although a foot or a wing would be better tools and possess the required muscular equipment; gulls, although capable of learning, rarely learn to select a hard substrate when smashing shells by dropping them from the air. Further, unusual circumstances often lead to miscarriage of behaviour and so reveal the limitations of adaptedness.

Thus, animal behaviour, while highly complex, variable and adapted, is yet restricted in scope and seems on the whole to be limited by the machinery evolved in adaptation to the demands of survival under natural conditions.

Even the criterion of learned or nonlearned does not allow a simply dichotomous distinction between two types of behaviour. Learning probably applies to more than one type of adaptive change in behaviour machinery during the life of the individual. Learning by imitation is extremely rare in animals; examples from apes have been reported, as they have from some birds which learn their full song by hearing fellow members of their own species, but most animals develop the behaviour typical of their species even when reared in isolation. Isolated canaries, for instance, build typical canary's nests when mature. However, many animals learn by practice. While birds develop the basic pattern of flight without practice, subsequent perfection of skill does depend on it; this may happen extremely rapidly as in cormorants, where one abortive landing attempt may suffice to cause striking improve-

ment with the second attempt. Yet many skills develop without practice; thrushes smash snails expertly when encountering them for the first time.

Even behaviour which is neither imitated nor learned by practice may be subject to learning in another way: it can be conditioned; *i.e.*, change its responsiveness to outside stimuli. Thus pigeons learn to respond to water by drinking, and many songbirds learn to avoid obnoxious insects after one or a few penalized responses. Yet many animals react selectively to appropriate situations the first time they meet them: gull chicks hatched in an incubator respond by crouching to the alarm call of their own species and peck selectively at the parent's bill tip when soliciting food; some butterflies respond selectively to blue and yellow flowers or paper substitutes the first time they feed. In other instances such changes in responsiveness are independent of experience; *e.g.*, the appearance of reproductive responses of many animals upon reaching maturity. Even animals which learn a great deal may fail to apply their ability to learn as widely as human beings would do, and this would seem to indicate in the latter a nonlearned "predisposition to learn"; gulls which learn very readily where their nest is located have no predisposition to learn where to smash their shells.

Thus many behaviour patterns are at the same time learned and nonlearned, the growth of their machinery being the result of complicated interactions between internal and environmental ngents. To make a sharp distinction between learned and nonlearned leads to a false dichotomy when applied to behaviour; rather it should be applied to influences governing the development of behaviour machinery, and modem studies try to unravel the interaction of a great variety of inherent and external growth-controlling factors.

Complexity. — Instinctive behaviour has often been considered to be more complicated than simple motor patterns such as reflexes, which have been said to involve "the whole animal." However, this difference is no longer regarded as important, for there seem to be all gradations from simple to complex movements; a frog wipes its side or back with a hind leg when the skin is irritated, and this, although a very simple movement, shows relatively good orientation and is thus more complex than the simplest possible reflex. On the other hand the newly born chicks of many birds crouch at the parents' alarm, and although this is usually called instinctive it is simpler than a frog's wiping reflex.

While it is useful to analyze behaviour into its components, it is not useful to prejudice such analysis by the application of a dichotomy between complex and simple movements and to draw an arbitrary line between instinctive and noninstinctive movements on this criterion.

Causal Organization. — The distinction between behaviour caused by an internal urge and purely reactive behaviour is also considered false, partly because most behaviour is neither purely reactive nor purely spontaneous. Modern research tends to avoid the catchword "instinct" as applied to behaviour patterns, and instead tries to unravel the causal organization of behaviour without prejudice.

Although there is only fragmentary knowledge on the subject, it is already clear that behaviour is organized in hierarchical systems with excitatory and inhibitory relationships of many kinds, and with complex interrelationships between causal chains. These systems are never completely at rest and their excitatory state is subject to continuous change.

The initiation of movements (*i.e.*, the change from one type of activity to another) can be caused by external stimuli or by internal changes or by both combined. Thus many animals of the temperate zones respond to increasing day length (received by light-sensitive organs) by changes in the activity of hormone-secreting glands, which make the animals migrate, select a suitable habitat and proceed with nest building, courting a mate, etc. In all these activities an animal responds in a variety of ways to sensory stimulation, yet a reduction of the sex hormone level (for instance, by castration) abolishes the readiness to respond to many of these very stimuli.

There are many indications that the central nervous system in the intact animal is continually stimulated both by internal agents (humoral, sensory, nervous) and by the "rest output" of peripheral sense organs, and that the machinery of each major behaviour system is never completely at rest. Apart from this, there seem to be humoral and nervous agents which control the general excitatory state. Which behaviour pattern is performed at any one moment seems to depend on the particular unbalance of the conditions facilitating or inhibiting the various systems. On the other hand the external stimuli which, given a certain state, initiate a response are specific. Their effectiveness depends first of all on the sensory equipment of the animal, which is often very different from human equipment and from that of other species.

Thus bats are sensitive to ultrasonic vibrations; many insects can see ultraviolet radiation; on the other hand, the majority of animals cannot hear properly. Second, the stimulus situation eliciting or inhibiting a particular response is often very restricted: the males of some butterflies, for instance, pursue any moving object when they are in sexual condition, irrespective of its shape and colour.

Which of the available sensory information is responded to is often controlled by the internal condition or "mood," and it is known that this condition can centrifugally affect the responsiveness of sensory systems.

Most behaviour patterns are sequences or chains of simpler movements. Such action chains often begin with searching behaviour which may be spontaneous, and this is continued until the next link in the chain appears. The switch from one link to the next is sometimes caused by internal changes, as has been demonstrated for the mating chain of the male fruit fly, but in other instances it is mainly caused by external stimuli, as for instance in the hunting behaviour of the digger wasp *Philanthus triangulum*. Probably both internal and external control of switching are involved in most instances. Each link itself is a complex movement of variously integrated muscle movements.

Many behaviour chains terminate in an end act such as swallowing food, or in the perception of an end situation such as a shelter out of reach of a predator; the end of a chain is usually marked by an internal change indicated by a reduced readiness to perform the same chain again. This "drive reduction" is often caused by "negative feedback," *i.e.*, information reaching the system as a consequence of the activities performed or of the situation reached, which counteracts the stimuli evoking these activities. Thus reduction of the feeding drive in rats partly results from food stimulating the stomach after ingestion; the readiness to fly in the saturnid moth *Automeris* is reduced by the activity of the central nervous flight mechanism itself.

The part played by feedback systems in behaviour is certainly highly varied and complex, but whether central nervous fatigue or other depletion phenomena can contribute to drive reduction is uncertain.

There is interaction between the major behaviour systems as well as between the various parts of each system, but on the whole major systems inhibit each other mutually, so that at any particular moment the movements of the most strongly aroused system appear to the exclusion of all others. When two systems are simultaneously aroused, various "conflict movements" may occur. These may consist of components of the two patterns combined in a "mosaic"; they may be intermediate or "compromise" movements; the full movement of one pattern may appear with a different orientation; components of both patterns may appear in quick alternation; or a completely irrelevant movement may be performed ("displacement activity"). Interaction on lower levels is responsible for the co-ordination of limbs in locomotion, or even of parts of limbs such as fin rays. Such interaction is partly controlled by the central nervous system, partly by reflex loops, and it may affect both the temporal order and the amplitude of contractions.

Instincts. — Neither innateness, nor spontaneity, nor complexity, therefore, is useful as a criterion for the separation of instinct from other behaviour categories. The term "an instinct," however, has been used as a name for the machinery responsible for the organization of major, functionally unitary behaviour systems,

such as feeding, mating, antipredator behaviour, etc., and when used in this way, it is a term comparable to digestive system and merely indicates a phenomenon to be studied. However, in view of the conceptual confusion which the use of such different criteria has created even this usage of the word is increasingly avoided.

Evolutionary Aspects.—Since the growth of the machinery underlying many elements of behaviour, whether affected by the environment or not, is often very stable in successive generations, many motor patterns are relatively constant during evolution, and this is why closely related species are usually similar in their behaviour. Yet evolutionary change does occur and as a consequence no two species behave exactly alike.

Simple mutations have been shown to effect behaviour changes. Much indirect evidence has been collected showing that natural selection can account for adaptive evolutionary change. Conversely, behaviour also affects evolution; such activities as habitat selection, food selection and mate selection seem to have been instrumental in the splitting-up of species.

Animals and **Man.**—It is too early for an assessment of the ways in which human behaviour has evolved from the ancestral animals' roots. There is, on the one hand, no doubt about the large differences between man and all animals, exemplified by such capacities as foreseeing the future outcome of a planned course of behaviour; man's extremely complicated learning abilities which in turn allow him to pass on acquired knowledge from generation to generation; his tendency to use moral criteria; the retardation of certain aspects of ontogeny which, for instance, prolongs the infantile curiosity or tendency to explore; his ability to utilize specific experience for general purposes; etc.

On the other hand it is becoming increasingly clear that these could well be differences of degree. Man's freedom of action is undoubtedly limited by his evolutionary past. The best way to gain insight in this problem is through comparative studies, particularly of those species most closely allied to man. A major obstacle hampering such work is the fact that man has two sources of knowledge about his own behaviour of which only one can be used for the purpose of comparison. Every human being can observe his own behaviour as if he were an outsider, and record his observations in the same way as behaviour of animals.

Subjective experiences however are not directly observable in animals and cannot therefore be used for comparison. Because our everyday language deals with both types of observables it is not suited as a tool of behaviour research. This is perhaps the main reason why a strictly scientific comparison of the behaviour of animals and man has not yet proceeded very far,

(N. TN.)

INSTRUMENT, that which can be used as a means to an end, hence a mechanical contrivance, implement or tool; the word is more particularly applied to the implements of applied science, in mathematics, surgery, surveying, etc., while those of the handicrafts are generally known as "tools." A specific use of the term is for the various contrivances used to produce musical sounds, "musical instruments."

In law an "instrument" is any formal or written document by which expression is given to a legal act or agreement. This is a classical use of the Lat. *instrumentum*, a document, record. The term may be used in a wide sense, as a mere writing, meant only to form a record, or in a particular sense with reference to certain statutes.

For example, the Stamp act of 1891 defines an instrument as an expression including every written document; for the purposes of the Forgery act of 1861 a post-office telegram accepting a wager has been defined as an instrument.

INSTRUMENTATION is the aspect of music which deals with timbre and with the technical possibilities and characters of instruments and voices. The treatment of the orchestra has for the last hundred years been the most popular branch of the art. Hence the vogue of the narrow term "orchestration." The colloquial word "scoring" is the only adequate name for an art that ought to include all other aspects of timbre and performance, such as chamber music (*q.v.*), pianoforte writing and organ registration.

Method of Study.—The first requisite for good scoring is an imagination exercised by training. Rules are not enough; and neither is mere practical experience. Schumann's scoring grew worse as experience discouraged him; and a student who masters good rules without training his imagination merely protects himself from learning by experience. Many musicians who ought to know better are doing serious mischief by denying the possibility of arm-chair score-reading. Exaggerated claims are harmless for they are nearer to the truth of what an accumulation of study can achieve. The common-sense of the matter is obviously this: the arm-chair reader can vividly imagine effects that he has heard; he can recognise similar effects when he sees them in a score that is new to him; and so with effort and practice he can realise the effect of known sounds in new combinations. The complexity of the combinations has, in reason, little to do with the difficulties of imagination; and familiarity with the type of music is always a paramount factor.

William Wallace, in *The Threshold of Music*, seems to believe that modern progress in orchestration has produced new cerebral powers. This is a fallacy: listeners or conductors who have become familiar with Richard Strauss's orchestration will vividly imagine the sounds of a page of the master's latest and fullest scoring long before scrutiny has shown more than the main entries and the general type of colouring. But such readers may get nothing but abstract grammatical propositions from a page of Palestrina if they have never heard pure polyphony sung without accompaniment in a vaulted building. The music of each great period has its own proper scoring which sounds well under its proper conditions. The student should take opportunities of hearing each kind of music well produced; and he should multiply his experience by reading the scores of all periods, besides those of his own day. An imagination thus trained is obviously useful to conductors. It is not less useful to composers, for it is no mere antiquarian lore but a widely generalised capacity to imagine correctly all kinds of significant musical sounds. Its possessor will never produce the woolly scoring of the unimaginative composer who goes by rule; and if he makes errors of calculation these will be remediable as errors of imagination are not.

Rules are useful in preventing errors of calculation. The only extant treatise on instrumentation that gives correct rules is the posthumous work of Rimsky-Korsakov. Starting with the proposition that good scoring is good part-writing. this brilliant and fantastic Russian composer lays down surprisingly severe rules for combining good part-writing with well-balanced orchestral values. At first it seems incredible that any free art could live on such terms; yet the marvellous purity of Mozart's orchestration supports Rimsky-Korsakov's system in an art a century earlier and far more complex. For there is less wonder that Rimsky-Korsakov's colouring should be pure since his ideas never overlap, and his hundreds of illustrations from his own works consist (except for a few scraps of recitative) exclusively of a-bar or 4-bar phrases that repeat themselves. We shall not learn Mozart's art from this, and rules will not endow us with Rimsky-Korsakov's imagination. Nor was that imagination equal to distinguishing blunders from subtleties in the score of his friend Moussorgsky's *Boris Godounov*. Much less, then, is it to be trusted when he dismisses Beethoven's orchestration with the remark that the execution of Beethoven's ideas is far inferior to their conception. This really means that the narrow cross-section of Beethoven's ideas that comes within the aesthetic range of Russian ballet-music could have been scored more easily and brilliantly by a Russian composer in 1890. Apart from this, Beethoven is doubtless not infallible. But perkiness starves the imagination.

Pure 16th Century Polyphony.—In the article HARMONY (*q.v.*) the grammar of pure polyphony is shown to be equivalent

to the art of vocal scoring. A modem choir soon learns the truth of the 16th century rules when it faces the task of unaccompanied rehearsal. The old rules secure singability as well as euphony. But they also leave the composer's imagination free for many subtleties. Our stereotyped full chorus of soprano, alto, tenor and bass is roughly that of the 16th century, though we have forgotten the ways of the genuine boy-alto who delights in manly growls down to D and becomes shy above A in the next octave. The 16th century knew no other alto, and Palestrina has 17 ways of grouping 4 parts and 12 different ways for 3 parts, besides equally various 5-part and 6-part grouping. In 8-part works for double choir the two choirs are often contrasted, as in Palestrina's motet and mass *Hodie Christus natus est,* where the second choir, led by the altos, makes a terrestrial antiphony to a choir of angels.

The infinite subtleties of 16th century part-writing are beyond the scope of this article and very remote from the experiences of any instrumental music. But every conductor and every composer may learn much from Palestrina's and Lasso's devices of producing by part-crossing beautiful progressions that would be crude if the planes of tone were not kept distinct. In all later periods the distinction of planes of tone is a fundamental principle. In the 16th century it enters into these delicate intricacies, and appears more obviously in the rule formulated by the first composers for double and triple choirs, viz., that the harmony of each choir must be complete even when all are singing together. Lasso disregards this rule, but its common-sense becomes evident when the choirs are on opposite sides of the building.

Archaic Instrumentation. — At the end of the 16th century monody arose. It was the art of non-polyphonic vocal declamation with an instrumental accompaniment. With characteristic acumen the Italian monodists promptly recognised that voices and instruments will not meet on the same plane of tone. Not all composers understood the new problems. The habit, in private performance, of using viols to replace missing voices in madrigals had gone far to make composers incautious in dealing with more penetrating instruments. The flat-backed viols with their husky and reedy tone (nowadays still noticeable in the double-bass) were already giving place to the royal family of the violin in all its sizes; this family was no longer on singing terms with voices; yet many composers at first saw no difficulty in using any instrument as equivalent to any other instrument or voice at the same pitch. Schütz (1585–1672) writes for triple and quadruple choirs of voices mixed with instruments. He writes the words under the instruments as well as under the voices; he often merely designates a part *Vox instrumentalis;* but he also takes the trouble to suggest *Tromba o flauto,* as if these instruments, in low register, had the same weight! Beauty often emerges from the chaos— associated with some practical suggestion that leaves us in doubt whether the composer knew what he achieved; as when Schütz proposes that his wonderful *Lamentatio Davidi,* a perfectly scored masterpiece for bass voice, 4 trombones and organ, should be played with two violins an 8vo higher as a substitute for the first two trombones!

Continuo Instrumentation. — By the time of Bach and Handel instrumentation had become a mature art; but an art depending on conditions no longer familiar to us. When these conditions are restored the resulting aesthetic system completely justifies itself. It recognises that no group of instruments can make homogeneous harmony like a vocal chorus, but that all instrumental scoring consists normally of a top, a bottom, and a *tertium quid* that completes the harmony but remains in the background. Bass instruments support the bass; all other instruments, whatever their pitch, are aesthetically top parts, and their most elaborate counterpoint does not profess to make their tones blend. They are woven into patterns of coloured threads, not blended like the colours of a landscape. The *tertium quid* is provided by an organ or a harpsichord; and it obeys the normal grammar of choral harmony. Only a keyboard instrument can provide such harmony ready-made on one plane of tone. At the present day one of the commonest faults of unimaginative scoring is the habit of treating the orchestra like a 4-part chorus. Continuo orchestration shows the true principle with drastic clearness, but it shelves the problem of how to keep subordinate parts in their places. The continuo player represents an army of slaves upholding an aristocratic civilisation.

Besides gaining a capacity to attack discords boldly, the vocal chorus has undergone a radical change in the treatment of the bass voice when supported by instruments. When the tenor is low but still interior to the harmony, the bass is no longer obliged to go lower, but is free to sing in its upper register, crossing freely above the tenor but relying on instruments which double it an 8ve lower as the true bass. Bach and Handel never once cross the bass over the tenor in any other way; the tenor in such places never gives the true bass. And Bach's so-called unaccompanied motets thus show in every line that they were conceived as supported by at least an instrumental bass. In fact. unaccompanied choral writing practically disappears from classical music between Palestrina and Schubert. It appears modestly in part-songs, and is first taken fully seriously by Brahms; though some older conductors of choral societies honourably kept up its tradition.

The basis of the continuo orchestra was, as now, the string band, an instrumental chorus of first and second violins, violas and violoncellos, supported an 8ve lower by double-basses which are never independent. Wind instruments did not form a complete mass of harmony but stood out against the strings in double or triple threads of each timbre, except when (as often in Handel) they doubled the strings. Flutes were used much more in their lower registers than we think fit in modern orchestration. In the organ-loft of a vaulted building low flutes are more effective than in ordinary concert-rooms. The ordinary flute is called traverso. The term flauto, with the use of the treble clef on the bottom line, indicates the flute-à-bec, a kind of flageolet, with rather a higher range. Bach uses pairs of each kind in the *Matthew Passion* but not in the same movements.

Oboes are also used in threes or pairs, and the ordinary oboe alternates with a variety a 3rd lower, the oboe d'amore, with the bell (and therefore the tone) of a cor anglais. Strauss has revived it. The real cor anglais figures in Bach's orchestra as the oboe da caccia or the taille. Some authorities tell us that one or other of these was not an alto oboe but a tenor bassoon. It is easier to relabel a museum specimen than to rewrite the whole of Bach's oboe da caccia music.

Bassoons hardly ever emerge from doubling the bass. The *Quoniam* of Bach's *B* minor Mass is a bass solo accompanied by a horn, two bassoons and continuo. It would be delicious if we could find proper acoustic conditions for it and could handle the continuo discreetly enough. A great moment is the rising of the spirit of Samuel in Handel's *Saul,* where the bassoons are as ghostly and awesome as the prophet's message. In large enough numbers they would also astonish us in Handel's scoring of the "thick darkness" in *Israel in Egypt.* Handel, whose oratorio performances were on a large scale, must have had more reed-tone than string-tone in his orchestra; for he often had 20 oboes and 20 bassoons. Multiplication greatly mellows the tone of an instrument; and we, who seldom hear more than 4 oboes in unison, even in Mahler's 8th symphony, must not hastily judge our ancestors on this point.

Trumpets and horns, not being provided with modern valves, could produce only the natural harmonic series of the key to which their length of tube was set. That series does not close up into anything like a scale until the 8th harmonic. Accordingly trumpeters devoted themselves to acquiring extraordinary command of the delicate distinctions of high lip-pressures *(enzbouchures)* between the 8th and 20th harmonics. A long mouthpiece, with a little play in its adjustment, enabled the trumpeter to correct the out-of-tune 11th, 13th and 14th harmonics. (This secret was already forgotten by 1785, so that Burney, describing the Handel Centenary Festival, tells us that whenever the G and G♯, alternately represented by the 11th harmonic, were heard in "The trumpet shall sound" displeasure was seen on every countenance.) Humbler players called themselves *Principal-blaser* and produced the lower notes to which the tight-tipped clarino-player could not descend. Horn-players developed a similar hazardous technique of high notes. In modern performances special training and special instruments are required for early 18th century trumpet and horn

music. A modern tendency to strain all instruments up to high notes has facilitated this revival. Trombones, when they occasionally appear in continuo orchestration, are treated exactly like choral voices, and are, indeed, mainly used in unison with the chorus. A soprano trombone at first completed the group but Bach already had to replace it by some kind of slide-trumpet (corno da tirarsi).

Bach's full orchestra consists, then, of the string band (preferably larger than he ever had) oboes (ordinary or d'amore) in pairs or threes, flutes or flutes-à-bec in pairs or threes, bassoons (taken for granted) in unison with the basses, three trumpets (two clarini and one principal) three horns (not often used together with the trumpets) and a pair of kettle-drums. If the string band is large the wind parts, other than the trumpets, should be doubled, trebled, or (in festival performances) multiplied. The organ supplies the continuo in choruses, and the harpsichord supplies it in solo movements The pianoforte is really (as Philipp Emanuel Bach already urged) better than the harpsichord, if only the player will avoid a self-assertive touch.

The orchestral combinations of solo movements range from Handel's perfunctory *tutti unisoni* to Bach's and Handel's richest schemes. Instruments obsolescent from incompatibility or feebleness live awhile in the arias and recitatives, protected from competition with the orchestra; and so we learn from Bach's *Passions* and *Trauer Ode* the use of the lute and viola da gamba, and from Handel's *Alexander Balus* the use of the theorbo, a large double-necked lute. Each movement has its own scheme of instrumentation as a set pattern which cannot change while the movement lasts.

The scheme of a chorus with independent full orchestra is in three planes of tone. These planes do not interfere with each other, and each plane has variants of the same harmonic scheme which would produce appalling collisions if all were projected on to a single plane (say, in an arrangement for two pianofortes). The principal plane is that of the voices. Above it, mostly higher in pitch, all the instruments that are not doubling the bass flourish with more rapid detail than the voices. Behind, and supporting the whole, is the continuo which moves more slowly than the chorus. The bass is common to all the planes, though it is enlivened by instrumental details. The results of this scheme, realised by competent execution under scholarly guidance, are as true in our age as they were when Bach and Handel wrote. Scholarship must show us the right conditions for performance, but it need not recover too precisely the actual original conditions. An old man who had been a chorister under Bach at Leipzig once told Wagner's teacher, Weinlig, how Bach's cantatas were performed. His account was, "It went atrociously and we always got a flogging afterwards."

Symphonic **Orchestration.**—Gluck (*q.v.*) laid down one of the cardinal principles of symphonic as well as dramatic orchestration when he said that instruments ought to be used according to dramatic vicissitudes. This means that for Gluck it is neither sufficient nor often possible to use them according to a set pattern. Another cardinal principle results from the disappearance of the continuo. This first happened merely by neglect, as the severe training needed for it repelled a generation of musicians excited by non-polyphonic styles. But mere neglect soon passed into a disposition to make the orchestra provide its own continuo. If old music sounded hollow without a continuo, why should not new music contrive better? This at once put many instruments into categories unrealized by Bach and only sporadically realized by the eclectic Handel. An instrument could now have two values: one, the old cantabile function; the other a capacity to provide unobtrusive notes for the background. Holding-notes for the horns revealed a wonderful beauty and usefulness in this way, with all a singer's power to s ell and diminish the sound.

The bassoons became the hardest worked wind instruments in the early symphonic orchestra, for they could do everything required of continuo-work, from doubling the bass to supplying the many notes the natural horns could not reach. Their tone, so beautifully if unwittingly described in *The Hunting* of *the Snark* as "meagre and hollow but crisp, like a coat that is rather too tight in the waist, with a flavour of will-o'-the-wisp" had a most useful capacity for vanishing; and "too tight in the waist" is a very apt description of instruments which, like the bassoon and the viola, show in their half-veiled tones the results of a compromise between the dimensions proper to their pitch and the practicable stretch of human hands.

The viola had at first a curious position in the early symphonic style. That style was so unpolyphonic that the viola could for a long time find nothing to do but to double the violoncello in the upper octaves as the basses double them in the lower. The result is so good that in early symphonies it is carried out mechanically even where it takes the violas above the second violins. But Mozart uses this primitive device with full imaginative insight in mature works where he hardly less often divides the violas into two independent parts.

The trumpets of the symphonic orchestra have become degraded to the fanfares and signallings of the Principal-blaser. The clarino player was finally ousted by players of a cheap substitute called the clarinet, which could play high trumpet parts with ease, if with rather a vinegar tone. But the clarinet had a wide compass; these trumpet-sounds are its worst. Below them it had a rich cantabile octave, and below that a few rather dull notes; and below these a coldly mysterious and reedy lowest octave, the chalumeau register. The dull middle notes proved astonishingly useful for continuo purposes; they are higher than the bassoon can attain without self-assertion, and they are not limited like the horn notes. Gluck uses the clarinet only in this neutral region; and even Mozart gives the instrument nothing better when the orchestra is in the key of D. This primitive treatment survives as late as Beethoven's and Symphony, and revived by him in quite a late work, the fugal overture, *Zur Weihe des Hauses* (op. 124).

But when Mozart uses clarinets in the keys of A major, E major, E flat and B flat he reveals the clarinet as richer and more resourceful than any other wind instrument. The chalumeau octave is deliciously nutty in arpeggios, and dramatically hollow in sustained notes. The cantabile octave is magnificent (see the trio of the minuet of the great E flat symphony, for its contrast with echoes on the flute and with low arpeggios on the second clarinet). The military high notes (or "fife sounds") Mozart does not care for. Beethoven's view of the clarinet is less sympathetic than Mozart's, his idea of its cantabile register being just a tone too high. Schubert understands it perfectly.

The oboe can never efface itself. Run through the individual wind-parts of some such encyclopaedic score as Wagner's *Meistersinger* and you will be astonished at the unfailing beauty of the oboe parts and at the large tracts of drudgery in the excellent, uncomplaining clarinets.

The flute has no power in its lower octave and blends with other instruments in none, except, paradoxically, with extremely high Bach-like trumpet notes (if the experiment were ever tried). But in its top octave (from A to A) it is a very adequate and euphonious treble to the wind-band, and gains greatly by doubling. Haydn hardly ever writes his orchestral flutes high enough and often seems to expect low notes to be heard under conditions that would not have satisfied Bach. It is possible that his long period of experiment at Esterhazy did him less good than he or historians have thought. His Esterhazy symphonies show that he had a primitive orchestra diversified by astonishing solo players. He was able at Esterhazy to produce horn-passages that would astonish Bach. But in the world outside he found that orchestras, though better in the rank and file, were seldom troubled by virtuoso members. In his Iast symphony the theme of the finale is a typical and easy horn tune, but he dare not give it to the first horn of Salomon's London orchestra except under cover of a tutti! All his mature scoring is full of strokes of genius but deeply marked with signs of disillusion.

Beethoven's Instrumentation.— Beethoven enlarged the range of orchestral thought more than any composer between Gluck and Wagner. The circumstance of his deafness made him the victim of some miscalculations; and pedantic views of orchestration lead many critics to exaggerate these into grounds for a worse perkiness than Rimsky-Korsakov's damaging patronage of

Beethoven's scoring. Two things must be learnt by everybody who wishes to understand Beethoven; first, that errors of calculation are not the same thing as errors of imagination; secondly, that a symphony is not an opera. Beethoven's errors of calculation are no greater than those of any composer who has not been able to hear a rehearsal of his own orchestral work. Their correction, as shown by Weingartner *(Ratschlage),* is rquivalent to any pianoforte player's control of his own touch, and would amount to little more than a conductor's ordinary exercise of his skill were they twice as extensive.

Errors of imagination do not exist in Beethoven's art; and only a school of criticism by rule of thumb would suppose that they did. Compared with Mozart's, Beethoven's scoring is rough, redundant and capricious. But Beethoven's ideas are not Mozart's and can be expressed neither in Mozart's nor in Wagner's scoring. When critics tell us that bars 5–8 of the first movement of Beethoven's 8th Symphony are badly scored, all they mean is that to let two oboes and a flute crowd in upon a quiet phrase in the clarinet is not a proper way to score the first fateful appearance of a Wagnerian *leit-motif,* which may not be heard again for an hour. But it is an admirably dramatic and symphonic way to score a formal phrase which is going to be shouted at the top of the full orchestra immediately afterwards. The conductor need only say four words to the oboes, "Let the clarinet through," and the passage becomes perfectly clear. But it is already intelligible without any such precaution, and only bad playing can spoil it.

The symphonic orchestra which suffices for Beethoven, and for Brahms two generations later, consists of strings, pairs of flutes, oboes, clarinets, and bassoons, one or two pairs of horns, a pair of trumpets and kettledrums. Trombones, reserved for climaxes, are used in spacious 3-part harmony, and Beethoven requires them in three sizes, alto, tenor and bass. For lack of the alto trombone many of Beethoven's top notes must nowadays be lowered; and then our smart young orchestrators blame Beethoven for his ill-balanced chords. The full wind tone is extended upwards by the dangerously shrill piccolo, and downwards by the contrafagotto which gives the bass a richness without asserting itself. The big drum, cymbals and triangle are called "Turkish music" and, when used at all by Beethoven, are used according to Viennese ideas of Turkishness. Beethoven's intentions, whatever we may think of their execution, cover the whole field of symphonic art; and it is to dramatic orchestration that we must look for any addition to his range of thought.

Dramatic Orchestration. — The change from continuo-orchestration to the symphonic style was, as we have seen, essentially a change towards drama. Hence the dramatic and symphonic styles do not become separated at once; and with Mozart, who was equally happy in both, they are not easy to distinguish. The distinction is. even in Mozart, a paradox to people who think that opera is the most dramatic form of music. Sonatas and symphonies, even by Mozart, turn out to be far too dramatic for the stage. The fight at the beginning of *Don Giovanni* is perfectly adequately represented in musical sequences which would be too cold for any but his earliest symphonies. Theatre music will no more stand a symphonic environment than stage scenery will stand daylight.

And yet there is no limit to the refinement of dramatic orchestration whether in Mozart or Wagner. The gradations that a symphonic composer uses in 20 bars must be spread over a hundred in any continuous part of an opera, even on Mozart's scale. Here we already have a reason why opera should encourage very delicate gradations. Wagner's scale is given by the three minutes of the chord of E flat at the beginning of *Das Rheingold;* but still more significant is his management of a tensely emotional quarter of an hour with no more orchestra than strings and two horns, without double-basses, in the first act of *Die Walküre.* His enlargements of the orchestra all have an ultimate effect of purifying the timbre and so removing complications from the method of scoring. There was nothing new in large orchestras: both Mozart and Beethoven had rejoiced in performances with double wind; and in Wagner's early Dresden days Spontini requisitioned "douze belles contrebasses" for the performance of his operas. The experienced Wagner of Bayreuth is contented with eight.

A great stimulus was given to all orchestration by the invention of ventil trumpets and ventil horns. When these instruments thereby acquired a complete scale the aesthetics of all brass instruments needed reconsideration. Unimaginative composers of course saw no difficulty. A trumpet penetrates everything else like a red-hot poker, so why not give it the melody in every tutti? Wagner thought otherwise; he felt that brass tone was coarse unless it was used in large harmonic masses, and he accordingly invented new brass instruments to make the masses complete and coherent. Meanwhile he took his wind instruments in threes instead of twos. Already in the comparatively simple scores of *Der Fliegende Hollander* and *Lohengrin* this greatly clarified the colour-scheme. Half the art of scoring for wind instruments in the classical symphonies consists in making the best of the fact that instruments of contrasted tones will not make homogeneous triads when taken in couples. In *Tristan und Isolde* the threefold arrangement (two oboes and cor anglais; two clarinets and bass clarinet) adds its advantages to the maturest Wagnerian harmony, with a polyphony as profound as that of Beethoven's last quartets. In the tetralogy of *Der Ring des Nibelungen* Wagner takes his wind groups in fours, and introduces his new brass instruments. They originated in the bass-tuba which had come to replace the grotesque ophicleide and the still more primitive serpent as a bass to the trombones. These makeshifts had served Mendelssohn's purpose and failed to serve Berlioz's. The tuba could put an imposing bass below the trombones. Its tone is fat and puffy whereas that of the trombone is red-hot. A sensitive ear may notice, and a wise ear may refuse to notice, that the tuba is putting a black line below the red. But Wagner saw the possibility of a new aesthetic value here; and so in his tetralogy five tubas ranging from contrabass to high tenor show as clear a contrast from trombones as oboes from clarinets (Rimsky-Korsakov utterly fails to grasp this point).

The composers, having learnt new powers from such enlargements, can henceforth use these powers without extra apparatus. The orchestration of *Die Meistersinger* is the most complex in all Wagner, just because it is written for Beethoven's orchestra plus one tuba and a harp, and, of course, the now ubiquitous ventil horns, the most perfect of all continuo-players. In *Parsifal* the extra tubas are abandoned but the remaining contrabass-tuba has permanently won its independence of the trombones.

It seems paradoxical to leave Berlioz out of account in a history of instrumentation. Yet, short of a detailed appreciation of his individual strokes of genius, all that can be said of him is that he drew attention to the subject in an epoch-making but capricious treatise, and that he achieved all that was possible to a highly imaginative musician who happened to hate polyphony. And that is more than some critics might expect. But it cannot have much direct influence on more ordinary musicians.

Post-Wagnerian Instrumentation. — A great many loudly proclaimed "new" tendencies in orchestration are nothing but the discovery of some single elementary principle. It would be quite easy to write a history of post-Wagnerian scoring in which single characteristics from each of the historic schools here described were assigned haphazard, one to each living composer; and quite impossible to argue against its results. The silliest a *priori* theories seem incontrovertible if we forget how music is actually made. If, for example, we believe that music is made for instruments instead of instruments being built to make the best music they can, we may come to believe in the theory ascribed to Stravinsky, that each instrument should produce no passages that are not peculiar to its own timbre and inappropriate to any other. This is as if no gentleman should ever say anything that could be said by a lady; and vice versa.

When we have dismissed all such precious nonsense, several real phenomena remain. New harmonic ideas, such as multiplanar harmony, depend inextricably on instrumentation as surely as did the classical grammar of counterpoint. Less important is what Richard Strauss has called *al fresco* orchestration. This means a perception that there is not only safety in numbers, but a high aesthetic value in the average result of sixteen wild-cat attacks at

a passage that no individual can play properly. It is doubtful whether that is the real reason of the spiendour of such passages. For one thing, the splendour is enhanced by rehearsal, and in the best orchestras the players eventually learn such passages fairly accurately.

Mahler made a systematic study of the possibilities of very large orchestras; almost a quarter of the size of that of our Crystal Palace Handel festivals, but with music specially written for them. His 8th Symphony is a choral symphony requiring at least 750 performers, and going much more satisfactorily with 1,000. Berlioz never really contemplated anything larger. Such propositions are not decadent; they are severely disciplinary and require an imagination of the highest efficiency. On a large scale most orchestral colours fade; especially horns, which must be greatly multiplied if they are to tell.

More fascinating to most artists, and more practical in the present lean years, are the aesthetics of small groups and chamber-orchestras. But this is a subject which cannot be pursued here. It is as much as a young composer's prospects are worth to come before modern critics without a new aesthetic system of his own invention. But a general article cannot deal with such private affairs. (D. F. T.)

INSTRUMENT OF GOVERNMENT, the name given to the decree, or written constitution, under which Oliver Cromwell as "lord protector of the commonwealth" governed England, Scotland, and Ireland from Dec. 1653 to May 1657.

The Long Parliament was expelled in April 1653 and the council of state dissolved; the Little, or Nominated, parliament which followed ended its existence by abdication; and Cromwell, officially lord general of the army, with a new council of state, remained the only recognized authority in the country. It was in these circumstances that the Instrument of Government, drawn up by some officers in the army, prominent among whom was John Lambert, was brought forward, and after certain emendations accepted by Cromwell on Dec. 16. Consisting of 42 articles, the Instrument placed the legislative power in the hands of "one person, and the people assembled in parliament"; the executive power was left to the lord protector, whose office was to be elective and not hereditary, and a council of state numbering from 13 to 21 members. The councillors were appointed for life; 15 were named in the Instrument itself, and Cromwell and the council were empowered to add six. To fill vacancies parliament must name six persons, of whom the council would select two, the choice between these two being left to the protector. A parliament was to meet on Sept. 3, 1654, and until that date the protector with the consent of the council could make ordinances which would have the force of laws. After the meeting of parliament, however, he had no power of legislation, nor had he any veto upon its acts, the utmost he could do being to delay new legislation for 20 days. A new parliament must be called "once in every third year," elaborate arrangements being made to prevent any failure in this respect, and for five months it could not be dissolved save with its own consent. The parliament, composed of a single chamber, was to consist of 460 members—400 for England and Wales, and 30 each for Scotland and Ireland—and the representative system was entirely remodelled, growing towns sending members for the first time, and many small boroughs being disfranchised. A large majority of the English members, 26j out of 400, were to be elected by the counties, where voters must possess land or personal property of the value of £200, while in the boroughs the franchise remained unaltered. In Scotland and Ireland the arrangement of the representation was left to the protector and the council. Roman Catholics and all concerned in the Irish rebellion were permanently disfranchised and declared incapable of sitting in parliament, and those who had taken part in the war against the parliament were condemned to a similar disability during the first four parliaments. The protector was empowered to raise a revenue of £200,000 in addition to a sum sufficient to maintain the navy and an army of 30,000 men, and religious liberty was granted "provided this liberty be not extended to Popery or Prelacy." The chief officers of state were to be chosen with the consent of parliament, and a parliament must be summoned at once in case of war. The practical effect of the Instrument was to entrust the government of the three countries to the parliament for five months out of every three years, and to the protector and the council for the remainder of the time. Although the Instrument bristled with possibilities of difference between parliament and protector, "it is impossible," as Gardiner says, "not to be struck with the ability of its framers."

Cromwell governed according to the Instrument until the meeting of parliament on Sept. 3, when he endeavoured to obtain parliamentary sanction for the Instrument. Prolonged disputes followed and he dissolved the parliament on Jan. 22, 1655, without obtaining his object. Regarding the Instrument as still in force, the protector sought for a time to rule in accordance with its provisions; but new difficulties and growing discontent forced him to govern in a more arbitrary fashion. A second parliament met in Sept. 16 j6, and in the following May Cromwell assented to the Humble Petition and Advice, which supplanted the Instrument of Government.

The text of the Instrument is printed in S. R. Gardiner's *Constitutional Documents of the Puritan Revolution. See* also *S. R.* Gardiner, *History of the Commonwealth and Protectorate,* vols. ii. and iii. (1897–1901); and T. Carlyle. *Cromwell's Letters and Speeches,* ed. S. C. Lomas (1904)

INSTRUMENTS, ELECTRICAL MEASURING. Although the electrical power and communication industries are the largest users of electrical measuring instruments, most branches of science and technology depend on electrical measurements for information and for the control of processes and machines. Indeed. it would be difficult to find a research laboratory or a modern factory in which electrical measuring instruments do not, in one way or another, play a vital role.

The varied uses of electrical instruments make it desirable first to consider broadly the principles on which they operate, before undertaking a detailed examination of representative types. This article, therefore, is divided into the following sections:

I. Electrical Units
II. Absolute Measurements
  1. Lorenz Apparatus
  2. Current Balance
III. Primary Electrical Standards
  1. Standard Ohm
  2. Standard Cell
IV. Indicating Instruments
  A. Current and Voltage Measurements
    1. Potentiometer
    2. Galvanometer
    3. Permanent Magnet Moving-Coil Instruments
      (a) Rectifier Instruments
      (b) Thermocouple Instruments
      (c) Electronic Voltmeters
    4. Iron-Vane Instruments
    5. Electrodynamic Instruments
    6. Electrostatic Voltmeters
    7. Instrument Transformers
  B. Power Measurements
    1. Electrodynamic Wattmeter
    2. Electrostatic Wattmeter
    3. Bolometer
  C. Energy Measurements
    1. Commutator Watt-Hour Meter
    2. Induction Watt-Hour Meter
  D. Resistance Measurements
    1. Ohmmeter
    2. Wheatstone Bridge
  E. Capacitance and Inductance Measurements
V. Recording Instruments
VI. Bibliography

In most instruments with which electrical current, voltage or power are measured some property of the electrical quantity to be measured is used to evoke a mechanical force: and it is this mechanical force which gives a measure of the electrical quantity. The reaction between a magnetic field and a current-carrying conductor, the attraction or repulsion of electrically charged bodies, are effects that are commonly used to produce such a force. More elaborate means are frequently employed—the heating effect of electrical current in a conductor may be used to raise the

temperature of a thermocouple junction, generating an electromagnetic force (e.m.f.) and producing a current in an auxiliary measuring circuit.

Photoelectric and photovoltaic cells are also employed as the sensing elements of -electrical measuring instruments. In the measurement of such electrical quantities as resistance, inductance and capacitance, an instrument which utilizes a mechanical force is commonly employed to detect or measure the current or voltage produced in some element of a bridge, potentiometer or other network in which the unknown quantity is being measured by comparison with other similar quantities of known magnitudes. Thus at the heart of most electrical measuring instruments is an element which converts an electrical into a mechanical effect for detection or measurement.

I. ELECTRICAL UNITS

In any measurement, the value describing the quantity must necessarily be assigned in terms of some unit. The units in which electrical quantities are measured have been defined in such a way that they are simply related to the internationally accepted units of length, mass and time (metre, kilogram and second) which form the basis of mechanical measurements. Karl Friedrich Gauss showed in 1833 that magnetic quantities could be measured in terms of mechanical units, and he proposed units (which he called absolute, abbr. abs.) that were based on mechanical units of length, mass and time.

This concept was amplified by Wilhelm Weber, who showed in 1851 that a complete system of electrical units could be defined in terms of mechanical units. The work of Gauss and Weber formed the basis of a decision by the British Association for the Advancement of Science to define and establish a system of electrical units based on the metric system of mechanical units. Experimental determinations, sponsored by the association, led to the issuance in 1864 of the British association ohm, which was intended to embody the unit of resistance so defined. This unit was found later (1878) to differ by more than 1% from its intended absolute value, but the principles on which the British association units were based gained international acceptance at the Paris Electrical congress of 1881. This congress also described "reproducible" standards which should embody as closely as possible, the "absolute units of resistance and of current. The ohm was to be represented by the resistance at 0° C. of a column of mercury 106.3 cm. in length, having a uniform cross section (very nearly 1 sq.mm.) and a total mass of 14.4521 g. The ampere was to be represented by the unvarying current that would deposit 0.001118 g. of silver per second from a silver nitrate solution. Public bill 105, passed by the United States congress on July 12. 1894, made these units, embodied in the reproducible standards and defined in terms of the metric units, the legal units of electrical measure in the United States.

It was recognized that the units embodied in the reproducible standards did not correspond exactly to the absolute units defined in terms of the mechanical units and, to avoid confusion. the former were designated as "international" units. In 1910 representatives of the national laboratories of France, Germany, Great Britain and the United States carried out measurements at the national bureau of standards in Washington, D.C., and assigned values to standard resistors and standard cells from each of the collaborating countries, in terms of international units. From that time until 1948, the 1910 determinations and the international units served throughout the world as the basis for electrical measurements.

A series of determinations of the units of resistance and of current directly in terms of mechanical units, performed in the national laboratories of several countries, culminated in 1948 in the adoption of a new set of absolute units which differed by a few hundredths of a per cent from the previously accepted international units. At the same time the International Committee on Weights and Measures recommended that the metre be used as the unit of length and the kilogram as the unit of mass in defining the electrical units. Thus all electrical measurements derive ultimately from the prototype metre and kilogram preserved at the International Bureau of Weights and Measures in Sevres, Fr., and from the second defined in terms of the motion of the earth.

While the differences are small between the international units used in measurements before Jan. 1, 1948, and the absolute units employed since that date, these differences are by no means negligible in accurate measurements. The differences in these units are given in the accompanying table.

Conversion Table for Electrical Quantities
International Units to Absolute Units

Resistance	1 int. ohm	= 1.000495 abs. ohms
Electromotive force	1 int. volt	= 1.000330 abs. volts
Current	1 int. ampere	= 0.999835 abs. ampere
Charge	1 int. coulomb	= 0.999835 abs. coulomb
Inductance	1 int. henry	= 1.000495 abs. henrys
Capacitance	1 int. farad	= 0.999505 abs. farad
Power	1 int. watt	= 1.000165 abs. watts
Energy	1 int. joule	= 1.000165 abs. joules.

II. ABSOLUTE MEASUREMENTS

The basic measurements which must be performed to establish the electrical units in terms of mechanical units require the utmost care in the design and construction of the required instruments and a very high degree of skill in their operation in order to assign sufficiently accurate values to the primary electrical standards. These considerations have effectively limited absolute electrical measurements to the national laboratories which, in the various countries, are legally charged with the duty of establishing and maintaining standards.

The national bureau of standards (Washington, D.C.), the National Physical laboratory (Teddington, Eng.), the Physikalisch-Technische Reichsanstalt (Berlin) and more recently the P-T Bundesanstalt (Braunschweig), have all carried out such determinations, as have the national laboratories of Japan, the U.S.S.R., Canada and Australia. Their results have been intercompared by means of the standards maintained at the international bureau in Sevres; and there is no doubt that the electrical units are closely the same throughout the world.

The absolute determination of two of the electrical units permits the assignment of values to all the others through simple relations, such as Ohm's law. Hence, all of the important absolute measurements have been either ohm or ampere determinations. There are various ways in which the ohm and ampere can be determined in terms of length, mass and time; a single example of each will serve to illustrate the principles involved.

1. Lorenz Apparatus. — This device, sometimes used in the ohm determination, is one of the simplest to describe. It consists of a metal disk which rotates in the magnetic field of a coaxial cylindrical coil that carries a current **I.** If M is the mutual inductance between the coil and disk (the magnetic flux through the disk for unit current in the coil) and n is the number of revolutions per second of the disk, any radius of the disk cuts across the whole flux MI each revolution or MnI lines of force per second. This, by definition, is the e.m.f. $E = MnI$ developed between the centre and edge of the disk. If the current in the coil also passes through a resistance R it develops a potential difference $V = RI$ between the terminals of the resistor. The e.m.f. E is compared to the potential difference V by opposing them to each other with a galvanometer as the detector of their difference. When the speed of the disk is varied, a speed can be found at which $E = V$ or $MnI = RI$, so that $R = Mn$. The mutual inductance M is a constant of the apparatus and can be computed from the dimensions and number of turns in the coil and the diameter of the disk. It will be observed that resistance has been determined as the product of a calculable mutual inductance and a frequency (revolutions per second).

Other ohm determinations have employed different forms of calculable mutual inductors or calculable self inductors, but in each instance resistance is determined as the product of an inductance that can be calculated from measured coil dimensions (length) and a frequency (time). It should be noted that the combination of a calculable capacitance and a frequency may equally serve to determine resistance as a function of length and

time.

2. Current Balance.—The current balance. used in absolute ampere determinations, is an instrument in which the force between current-carrying conductors is measured. In one form the balance has a coil of wire suspended from one arm of an accurate equal-arm beam balance. This coil carries the current **I** to be measured. It is free to move in the field of a coaxial fixed coil which carries the same current.

The force between the fixed and movable coils is $F = I^2 \partial M/\partial X$, where $\partial M/\partial X$ is the rate of change of their mutual inductance with displacement along the line of motion. The weight of the movable coil (in the absence of current) is counterweighted at the opposite end of the balance beam, and the force. upward or downward between the coils when carrying current. is balanced by an added mass m on the appropriate balance arm. This force is mg, where g is the acceleration of gravity at the place where the experiment is performed. The two forces being equal, we may write

$$I\partial M/\partial X = mg \text{ or } I^2 = \frac{mg}{\partial M/\partial X}.$$

The coils are so constructed that the value of $\partial M/\partial X$ can be computed from measurements on the coils. It should be noted that the current is measured in terms of mass, length and time.

Because the measured current exists only at the time of measurement, the experiment is used in practice to assign a value of e.m.f. to a standard cell by opposing this e.m.f. by an equal potential difference IR, developed by passing the measured current **I** through a resistance R of known value.

Thus, both an absolute ohm and an absolute ampere determination are required to assign an e.m.f. value to the cell; but the combined determinations yield two physical standards (a standard resistor and a standard cell) in terms of which the electrical units are always available in the intervals between absolute determinations.

III. PRIMARY ELECTRICAL STANDARDS

Although the values of the electrical units are initially assigned through absolute ohm and ampere determinations, they are preserved and made continuously available in the various national laboratories in terms of groups of 1-ohm resistance standards and of standard cells of known e.m.f. These groups of resistors and cells are designed to be as stable as possible and are compared at intervals with each other and with similar standards from other national laboratories to insure that their values remain constant.

1. Standard **Ohm.**—Manganin is the resistance alloy used in all standard resistors and in most precision resistors of high quality. It consists of about 84% copper, 12% manganese and 4% nickel; it is characterized by its low temperature coefficient of resistance and its low thermal e.m.f. against copper. Its resistivity is about 25 times that of copper.

The Thomas standard, designed by James Thomas in 1930, has become generally recognized as the most stable of 1-ohm standards. In its construction, bare manganin wire is wound on a mandrel and annealed at 550° C. in an inert atmosphere. It is then slipped on a silk-insulated metal coil form, fixed in place without introducing mechanical strains, and hermetically sealed in a dry double-walled container. After the wire has attained equilibrium with the small amount of air sealed in with it between the double walls of the container, no further change of resistance occurs. A group of 1-ohm Thomas-type standards is used to maintain the value of the ohm at the U.S. national bureau of standards. No member of this group has changed by as much as 1 part in 1,000,000 over a 10-year interval.

2. Standard Cell.—Early attempts to establish a stable reference standard of voltage were not entirely successful. The Daniel1 cell (1836) had electrodes of copper and zinc with zinc sulfate as electrolyte, and produced an e.m.f. of 1.08 v. However, such cells lasted only a few weeks and were reproducible only to about 1% accuracy.

The Clark cell (1872) used electrodes of mercury and zinc amalgam in a saturated solution of zinc sulfate to produce an e.m.f. of about 1.43 v. These cells were also rather short lived and had a relatively large temperature coefficient of e.m.f. The Weston cell (1892), with electrodes of mercury and cadmium amalgam in a saturated solution of cadmium sulfate, has an e.m.f. of about 1.0186 v. at 20° C. and represents a great improvement over the earlier standards. When properly made from suitably purified materials, Weston cells can be constructed to have the same e.m.f. within a few microvolts, and may be expected to maintain a constant value over many years.

Some of the cells which were constructed in 1906 as part of the primary standard of e.m.f. for the United States are still in use at the national bureau of standards after more than half a century. The e.m.f. of the cadmium normal cell at any temperature t° C. is given by the formula

$$E_t = E_{20} - 0.0000406(t - 20) - 0.00000095(t - 20)^2 + 0.00000001(t - 20)^3.$$

When kept in a controlled temperature environment and properly used, the cadmium normal cell is the most accurate standard of voltage known. The average e.m.f. of a group of such cells in a constant-temperature bath is used at each of the national laboratories as the standard of e.m.f.

A second form of cadmium cell having the same electrodes but with an unsaturated solution of cadmium sulfate as electrolyte (becoming saturated at 4° C.) is much used as a standard of e.m.f. for general laboratory and measurement work. It has a useful life of only about ten years, but its temperature coefficient of e.m.f. is much smaller than that of the saturated cell (about $\frac{1}{8}$ as large) and it will tolerate much rougher usage.

IV. INDICATING INSTRUMENTS

In a quite general way, instruments which indicate the value of current or voltage in an electrical circuit have certain features in common. The quantity to be measured is caused to produce a mechanical force on a pivoted or suspended member: tending to rotate it. The rotation is opposed by a mechanical spring, and the equilibrium position of the movable element, where the torque resulting from the action of the electrical quantity is just balanced by the counter torque of the displaced spring, depends on the magnitude of the electrical quantity. This equilibrium position is indicated by a pointer attached to the moving element, and its reading on an appropriate fixed scale is a measure of the electrical quantity.

Such a mechanical system, rotating about a fixed axis under the action of opposing forces, will tend to oscillate about its equilibrium position unless damping means are provided to absorb the energy of motion and bring the system to rest. Two types of damping are regularly used. Magnetic damping utilizes conductors which form a closed electrical circuit and move in the field of a permanent magnet. The motion of the conductor in the field induces an e.m.f., and the resulting current dissipates energy as heat in the resistance of the circuit. The circuit may be the local eddy-current circuit of a metal vane or sheet attached to the moving element, or it may include the coil which forms the moving element (as in a galvanometer) together with the external circuit to which it is connected. Fluid damping makes use of the viscous flow of air (sometimes oil or another liquid) across a moving element to absorb the energy of motion. In practice a vane, attached to the rotating element of the instrument, moves with small clearance in a closed chamber. The air which it compresses ahead of it as it moves flows back over its edge and provides the desired energy absorption. In either fluid or magnetic damping, energy of motion is absorbed by the damping mechanism and dissipated as heat in bringing the moving system to rest. In the design of an instrument, damping is usually adjusted to he somewhat less than critical, *i.e.*, the moving system overshoots its equilibrium position slightly and quickly settles back to its proper indication.

Instruments whose indicating element turns in bearings have additional frictional forces which oppose motion. Because the deflecting torque is always small, it is essential that bearing friction also be minimized. and such bearings usually consist of hardened steel pivots turning in sapphire cup jewels with the bearing contact area held to the smallest value which will support the weight of the moving system. Where friction must be further reduced,

diamond pivots in sapphire bearings have been used to advantage. Bearing friction can be avoided altogether by suspending the indicating system from thin metal ribbons or "torsion bands" which also act as the instrument springs. This is done where the deflecting torque is extremely small (in galvanometers) or where the instrument has to endure heavy shock or vibration in use.

A. Current and Voltage Measurements

Instruments used to measure current or voltage have many features in common. In fact. any instrument whose basic response is to current can be adapted to the measurement of voltage and an instrument which responds to potential differences can be adapted to the measurement of current. This follows from Ohm's law. that the voltage E appearing across a resistance *R* which carries a current *I* is the product of the current by the resistance $E = IR$. Thus, if a known resistance be connected in series with a current-sensitive device, the response of the instrument is a measure of

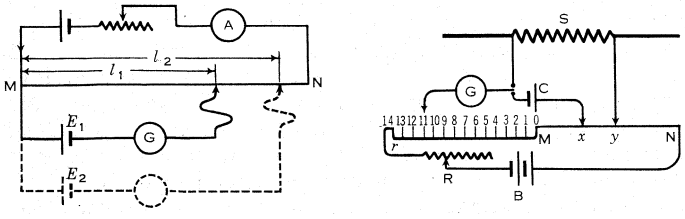

FIG. 1.— POTENTIOMETER
(A) Slide-wire type: (B) Compton type

the voltage across the combination.

Similarly, if a voltage-sensitive device be placed across a known resistance carrying a current. the instrument response is a measure of the current in the resistor.

1. Potentiometer. — The potentiometer is the most precise instrument available for measuring direct current or voltage. It consists of a circuit in which voltages are compared with the known e.m.f. of a standard cell. An elementary potentiometer could be a long uniform slide-wire *MN* (see fig. 1 A), which carries a fixed current **I.** If R is the resistance of the wire per unit length, the voltage difference between two points on the wire separated by a distance *l* is $E = RIl$. Then if a cell of known e.m.f. E_1 in a series with a galvanometer G to detect the presence of any potential difference, is connected to two contacts on the slide-wire and one of them is moved until the galvanometer indicates that the voltages are equal, $E_1 = RIl_1$, where l_1 is the distance between the contacts at balance.

On substituting another cell of e.m.f. E_2 and moving the contact until a voltage balance is again obtained at a separation l_2, then $E_2 = RIl_2$. If the wire is uniform and the current, measured at the ammeter A, remains constant between the two balances,

$$\frac{E_2}{E_1} = \frac{l_2}{l_1} \text{ or } E_2 = E_1 \frac{l_2}{l_1}.$$

The unknown e.m.f. E_2 is thus determined from the known e.m.f. E_1 and the ratio of slide-wire lengths required to balance E_1 and E_2 against the potential drop along the wire.

The potentiometer can be made direct reading and at the same time more convenient to operate by the following modification, known as the Compton potentiometer (see fig. 1 B). Suppose the slide-wire is 1 m. long, its resistance 10 ohms and it carries a current of 0.01 amp. The total voltage drop along it will be 0.1 v. or 0.0001 v. per millimeter. Then any number of fixed resistors of 10 ohms each can be connected in series to one end of the slide-wire and, for the same current, will each have a voltage drop of 0.1 v.

The diagram of fig. 1 B shows a potentiometer with such a slide-wire MN, a standard resistance S and a dial of 14 fixed coils, whose current is supplied from a battery B and adjusted to proper value with rheostat R by using a reference cell C. If C were a cadmium cell having an e.m.f. of 1.0187 v., the left-hand contact (on the dial) could be set on the eleventh contact of the dial (1.0 v.) and the right-hand contact at 187 mm. from the left-hand end of the slide-wire (0.0187 v.). The total voltage drop will exactly balance the e.m.f. of the reference cell (1.0187 v.) when the current is brought to its proper value by adjusting the rheostat R, and the potentiometer is ready for use. Any other source of voltage up to 1.5000 v. can now be substituted for C and balanced by varying the positions of the dial and slide-wire contacts. At balance the voltage may be read directly from the dial and slide-wire contact positions.

Higher voltages, up to 1,000 v. or more, can be measured by using a volt box, which consists of a group of series resistors of known ratio such that, when the high voltage is placed across the group, a low voltage (within the range of the potentiometer) appears across a section and is measured. The total voltage is then the potentiometer reading multiplied by the volt-box ratio. For example, a volt box could be made up with 10,000 ohms resistance and tapped at a point 100 ohms from one end. This voltage divider would have a ratio of 100:1 and could be used to measure voltages up to 150 v. on the potentiometer described above. If a current is to be measured. it is passed through a resistance (1 ohm, 0.1 ohm, 0.01 ohm, etc., depending on the magnitude of the current) and the voltage drop across the resistor is measured with the potentiometer. For example, a current of 100 amp. through a 0.01 ohm shunt would develop a voltage drop of 1 v., and this could be measured on the potentiometer.

The potentiometer is not only the most precise of all D.C. instruments, but is also the basic tool in a measurement program. It measures voltage and current in terms of standard cells and standard resistors that need not be more than a single step removed from the primary electrical standards. Simultaneous measurements of current and voltage can be used to measure power, since power is the product of current and voltage in a circuit. Thus, the potentiometer is the instrument with which D.C. ammeters, voltmeters and wattmeters are calibrated.

2. Galvanometer. — The galvanometer, for indicating extremely small currents. is usually a suspension instrument. In its common form, the d'Arsonval galvanometer, the deflecting system consists of a light coil of wire suspended between the pole pieces of a permanent magnet by means of a copper or gold ribbon a few thousandths of an inch wide and less than a thousandth thick. A small mirror, mounted on the coil, serves as an optical pointer and indicates the coil position by reflecting a light beam onto a fixed scale.

Current is conducted to and from the coil by the suspension ribbons, and the reaction of the current in the coil with the radial magnetic field in which it is suspended produces a torque that tends to rotate the system. The action can be likened to that of a tiny motor winding up a spring.

Modem galvanometers may have a sensitivity of as much as 1 mm. of deflection (on a scale 1 m. distant from the mirror) for a current of 0.00001 μamp. (10^{-11} amp.), with a coil resistance of 800 ohms. Current sensitivity is increased by using more turns of finer wire in the moving coil and by reducing the cross section and stiffness of the suspension ribbon.

Galvanometers may also be used for the detection or measurement of very small voltages in closed electrical circuits. In this instance it is advantageous to use a few turns of relatively coarse wire in the moving coil. A galvanometer having a resistance of 12 ohms and a response of 1 mm. for 0.1 μv. (10^{-7} v.) in a 2;-ohm circuit is an example of a modern voltage-sensitive instrument. In general, current-sensitive instruments are characterized by relatively high resistance, while voltage-sensitive instruments have low resistance.

In addition to appropriate current or voltage sensitivity, it is important in selecting and using a galvanometer that consideration be given to the resistance of the circuit in which it is to be used. This should be equal to or slightly greater than the critical damping resistance of the instrument in order that the moving system slightly overshoot its equilibrium position and come to rest in the minimum possible time. If the circuit resistance is too low. the galvanometer will be overdamped and its motion will be sluggish; if too high, the galvanometer will be underdamped and the moving system will oscillate about its equilibrium position with gradually decreasing amplitude.

In addition to its use for the detection and measurement of minute currents or voltages of constant value, the galvanometer may be used ballistically to integrate a transient current or voltage pulse of short duration. The electric charge in a capacitor can be measured by allowing it to discharge through a galvanometer and observing the magnitude of the moving system's first excursion from its rest position. The response of the instrument to a current of short duration defines the coulomb sensitivity. The deflection is proportional to the time integral of current, or to electric charge.

Similarly, a voltage pulse arising from changes in a magnetic field linking a coil of wire is a measure of the total change in coupling between the field and coil, the time integral of voltage during the change. This type of response is defined by the e.m.f.-time (or flux-linkage) sensitivity of the galvanometer.

Thus. a galvanometer has four different sensitivities which describe its performance in various applications. It is of interest to note that only one of them, current sensitivity, is completely defined solely by the galvanometer design constants — the strength of the magnetic field in which the coil moves, the area turns of the coil and the stiffness of its suspension. Voltage, coulomb and e.m.f.-time sensitivities are all functions of resistance of the circuit to which the galvanometer is connected. Both steady-state and transient voltage response increase with decreasing circuit resistance, while response to a transient current increases with increasing circuit resistance.

As stated above, the galvanometer and numerous other types of indicating instruments make use of the reaction between a magnetic field and a current-carrying conductor to achieve a measure of the current in the conductor, or of some related quantity. However, it is not essential that the current be carried by an indicating element suspended in the field of a fixed magnet system as is done in the d'Arsonval galvanometer.

Similar response can be accomplished, and with equal sensitivity, by making a magnet the moving element, and conducting the current through fixed coils. In galvanometer applications the chief advantage of this alternative construction is that the suspensions of the moving system, which do not now have to carry current, can be made of extremely fine quartz fibres, with much reduced stiffness. As the response of the indicating system depends on balance between the driving torque (resulting from the interaction of the magnetic fields of magnet and current) and restoring torque (resulting from suspension stiffness), the lower driving torque available in this arrangement is compensated by reduced suspension stiffness.

The principal disadvantage of the moving magnet, fixed-coil galvanometer is that its response is affected by the ambient magnetic field to a much greater extent than is the fixed magnet, moving-coil arrangement. For reasonable performance a moving magnet galvanometer must be elaborately shielded from external magnetic fields by a series of nested enclosures of high-permeability material, and for best results the construction must also be astatic, *i.e.,* the moving magnet and coil system must be arranged in matched pairs in such a manner that the torques resulting from a uniform external field will be in opposite directions and neutralize one another, while the torques are additive that result from the reaction between the suspended magnets and the current in the coil pairs. Despite the high sensitivity that can be achieved with this arrangement, it is little used in modern practice because of the difficulty of achieving adequate shielding from external magnetic fields.

3. Permanent Magnet Moving-Coil Instruments. — This basic class of instruments is used for indicating direct currents and voltages. The indicating system is similar to that of the d'Arsonval galvanometer. A coil with an attached pointer rotates in the field of a permanent magnet. In order that the angular response of the moving system be uniform, the magnet structure is designed so that its field is radial throughout the length of the air gap in which the coil turns.

Another design requirement is that the magnet maintain an unchanging field in the air gap, so that the calibration of the instrument shall not change in time. This requirement leads to the use of the characteristic horseshoe shape for instrument magnets of tungsten or chromium steel, whose length must be very great compared to their cross section for optimum energy storage, and to short thick magnets when dispersion-hardening steels such as alnico are used.

The moving-coil system usually turns on pivots in jewel bearings, and the attached pointer moves over a graduated scale from which the value of current or voltage is read. In this construction spiral springs are used to conduct current to the coil and to supply the required counter torque. In some instances the moving system is suspended between taut metal bands which act both as springs and as current leads. This construction avoids the friction of mechanical bearings, and is used in some types of precision instruments.

For low current values (microammeters and milliammeters with ranges up to perhaps 20 milliammeters [ma.]) the current to be measured is carried by the springs and coil of the instrument. Larger currents would produce a significant temperature rise in the springs and alter their stiffness. Consequently, currents larger than 20 ma. are passed through a resistor (or shunt) across which a millivoltmeter is connected in parallel. Thus a voltage-sensitive element, responding to the voltage drop (up to 50–100 mv full scale) across the current-carrying shunt, is used to measure larger currents. Its scale is marked. of course, in terms of current in the shunt. All permanent magnet moving-coil ammeters use such a parallel circuit arrangement. For small currents the shunt may be within the instrument case. For large currents, where a substantial amount of heat must be dissipated by the shunt, it must be external to the instrument.

In measuring voltages it is always desirable that the current drawn by the instrument be small in order to minimize both the power consumed by the instrument and the load it imposes on the voltage source. Hence, for the measurement of direct voltages, a permanent magnet moving-coil system which will attain full-scale deflection with a current in the range from 0.1 to 10 ma. is used together with a series resistor (or multiplier) of such resistance that the rated voltage of the instrument produces full-scale current. The instrument scale is marked to read the voltage impressed on the combination of moving element and multiplier. Here also, for low and moderate ranges where the power dissipation is small. the multiplier is incorporated into the instrument case; for high ranges the multiplier is frequently external and must be connected in series with the instrument.

Permanent magnet moving-coil instruments respond to the average value of their operating current and so, while they are ideally suited to the measurement of undirectional currents and voltages, they cannot be directly used for the measurement of alternating currents, which vary rapidly and continuously between equal values in opposite directions, so that the average value is zero. The torque produced on the moving system of such an instrument would reverse in direction with each reversal of current, with the result that the coil could never move from its zero position, or at most would vibrate about it with small amplitude. However, such indicating systems can be adapted to the measurement of alternating currents by one of several devices.

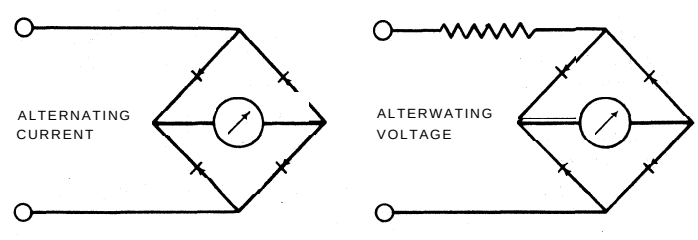

FIG. 2.—RECTIFIER INSTRUMENT CONNECTIONS
(A) Milliammeter; (B) voltmeter

(a) Rectifier Instruments. — Copper oxide and other types of dry rectifiers can be used in combination with permanent magnet moving-coil indicating systems in the construction of voltmeters and low-range milliammeters for measuring alternating voltages

and currents in the power and audio-frequency regions.

A full-wave four-element bridge-type rectifier, connected as shown in fig, 2, is used with the A.C. input impressed across one bridge diagonal and the D.C. milliammeter connected across the other. For voltmeters a resistance of appropriate value is connected in series with the input terminals. The rectifier assembly consists of copper disks, $\frac{3}{16}$ in. or less in diameter, with a surface layer of cuprous oxide, assembled into a stack with appropriate electrodes and sealed in a housing. Small disks are used to keep the current density high in the rectifying surfaces (with low consequent forward resistance). and to keep the capacitance of the bridge low in order to reduce the errors of the instrument at the higher audio frequencies. The milliammeter responds, as mould any D.C. instrument, to the average value of the current in its moving coil.

For engineering applications the root-mean-square (r.m.s.) value of current or voltage is generally desired, and consequently the scales of most rectifier instruments are marked in terms of r.m.s. values for an assumed sine-wave input. This scale convention coupled with the actual response to average rather than r.m.s. vaiues results in errors of indication on nonsinusoidal inputs. Also both the forward and reverse resistances of the rectifier elements have large but different temperature coefficients of resistance, resulting in a substantial temperature coefficient of indication. Because of their frequency, wave form and temperature errors, rectifier instruments must be considered as devices of low or moderate accuracy. However, they are very rugged, have high sensitivity and are quite suitable for audio-frequency applications in which accuracy requirements are moderate. Also. the D.C. mechanism is directly available when the rectifier is disconnected. Consequently, this type of instrument is widely used in compact test sets with which, by suitable switching, both A.C. and D.C. currents and voltages can be measured.

Such instruments, with a large number of A.C. and D.C. current and voltage ranges, are very convenient for use on the test bench, in electronics laboratories and in servicing electronic and electrical equipment.

(b) *Thermocouple* Instruments. — The permanent magnet moving-coil systems for alternating current and voltage measurements are also employed in thermocouple instruments. The current is passed through a heater element (usually a fine wire) in thermal contact with one junction of a thermocouple. The thermocouple, consisting of wires of two different metals or alloys joined together in series, has the property of generating a small e.m.f. where the junction points between the dissimilar metals are at different temperatures. Thus, at the thermocouple junction in contact with the hot wire, an e.m.f. is generated which is proportional to its temperature rise and hence to the square of the current to be measured. The thermocouple circuit is completed by a low range D.C. millivoltmeter and its scale is marked in terms of the r.m.s. value of heater current.

A thermocouple voltmeter uses the same arrangement but with the addition of a resistance in series with the heater element. In this instance the millivoltmeter scale is marked in terms of the r.m.s. input voltage across the resistor-heater combination. Since the instrument responds to the square of the heater current, no wave form error results on nonsinusoidal inputs.

Depending on the size and resistance of the heater element, current indicating instruments are made with full-scale ranges from 1 ma, to 100 amp. At higher current ratings a thin-walled tube rather than a wire is used as the heater element. With proper heater construction and thermocouple arrangement, such instruments can be used to indicate current with negligible error from D.C. to 1 mc. in frequency, and with small errors up to 100 mc. They are much used for radio-frequency current measurements and, with suitable precautions, can also be used as transfer instruments. In this latter application, mhere their response is identical for equal values of direct or alternating current, they can be used to calibrate instruments that respond correctly only to alternating currents, *i.e.*, to transfer an A.C. calibration back to the basic D.C. standards by means of the potentiometer, standard cell and standard resistors.

Thermocouple voltmeters make use of heater elements of low current rating (a few milliamperes) and are useful from D.C. up through the audio-frequency range without serious error. With properly constructed resistance multipliers, having negligible inductive or capacitive residuals, the frequency range can be extended upward to 1 mc. or more. These instruments can also be used for transfer measurements from direct to alternating voltages if proper precautions are observed.

(c) *Electronic* Voltmeters. — Vacuum-tube voltmeters also make use of D.C. indicating elements. In one of its simpler forms, such a voltmeter has an input circuit in which a miniature diode is arranged to charge a capacitor. A low-range D.C. milliammeter or a microammeter is connected with a high series resistance across the capacitor, and the current is a measure of the input voltage. If the discharge time of the resistor-capacitor combination is long compared with the period of the input voltage, the current in the D.C. meter is practically constant, and the response depends on the peak value of the input voltage.

Thus the lower frequency limit of the arrangement is determined by the time constant of the discharge circuit; the upper frequency limit for operation without substantial error is fixed by the distributed parameters of the input circuit and may be 100 mc. or more. It is fairly general practice to mark the scale in terms of r.m.s. values for an assumed sine-wave input and, as the response is to peak values, wave-form errors will appear on a nonsinusoidal input.

It should be noted that in the above arrangement, as is usual for indicating instruments, the power required to accomplish and maintain a deflection is supplied by the source on which a measurement is being made. This is not true of all electronic voltmeters. Starting with the same input circuit, a diode and capacitor, the voltage of the charged capacitor may be impressed on the grid of a triode or a more elaborate vacuum tube which acts as the initial element of a D.C. amplifier.

In such an arrangement the auxiliary power source which is an integral part of the amplifier supplies the power to operate the indicating instrument, and the drain on the measured source is extremely low. This is of great importance if the voltage from a high-impedance source is being measured.

There are many types of electronic voltmeters that use elaborations of the basic circuits above. The performance of the amplifier may be stabilized by a feedback loop of appropriate design. Also, such a circuit may be preceded by an attenuator for multirange operation, or by a preamplifier to extend the range of measurements to lower voltages. A typical commercial electronic voltmeter has an input impedance of 8 megohms at low frequencies, an input capacitance of 10 micromicrofarads, ranges from 0.1 to 150 v. and a frequency influence of no more than 3% up to 50 mc. and 12% at 100 mc.

4. Iron-Vane Instruments. — These are the commonest type of ammeters and voltmeters for laboratory and switchboard use at commercial-power frequencies. Such instruments can be built to measure current or voltage to all the accuracy needed for most engineering work, and still be produced more cheaply than any other type of A.C. instrument of equal accuracy and ruggedness. A vane or plate of high-permeability steel, together with spring, pointer and damping structure, forms the moving element of the instrument. This vane is situated in the field of a stationary electromagnet consisting of a coil of wire and, usually, a second iron vane which is fixed in position. The excitation of the electromagnet derives from the current or voltage to be measured, and the motion of the vane. when the electromagnet is excited, is always such as to increase the flux through it. Thus the torque produced by the reaction between the magnetic fields of the stationary and moving elements is in such a direction as to increase the inductance of the combination.

The energy stored in the magnetic field of a current-carrying inductor is proportional to the second power of the current, and it follows that the torque in the moving element increases with the square of the current in the fixed coil. Hence the response of the instrument is to r.m.s. current or voltage.

It should be noted that in this construction the measured cur-

rent does not go through the moving element, and the sole function of the instrument spring is to provide the required counter torque. Approximately 200 amp.-turns are required to produce a deflection of 90° in the actuating coil of a portable instrument with a 5-in. scale. The coil, about 1 in. high, may be mound with the needed turns of appropriate size wire for any desired range; *i.e.*, 40 turns for a 5-amp. instrument or 200 turns for a full-scale current of 1 amp. For the highest range that is possible in a 200 amp.-turn instrument—200 amp.—a single turn casting is used. For a milliammeter, a coil of 4,000 turns will give a full-scale sensitivity of 50 ma.; such a coil, connected in series with an appropriate resistance, is used in a voltmeter. Throughout the entire group of instruments the iron structure and moving system are identical.

The operating magnetic field of an iron-vane instrument is relatively small, at most 60–75 gausses at full-scale deflection. As a consequence, moderate external fields will have a significant effect on the deflection unless the entire operating system, coil and vanes, is enclosed within a magnetic shield. For example, an error of as much as 10% may result frdm operating an unshielded instrument in a 5-gauss field; but the corresponding error in a properly shielded instrument may be no more than a few tenths of 1%.

While the most common use of iron-vane instruments is at commercial-power frequencies, they are by no means limited to these applications. They can be used effectively at frequencies well above 1 kc. However, the frequency range over which an individual iron-vane instrument may be employed without significant errors of indication is quite limited; both ammeters and voltmeters should be calibrated at a frequency that does not differ by more than 10% from that at which they are to be used.

The change of response of an ammeter with frequency results principally from eddy currents in the iron vanes and other metal parts of the structure within and around the coil. These eddy currents, whose magnitudes are proportional to the square of the frequency, give rise to local magnetic fields that modify the reaction between the iron vane and the field of the coil carrying the measured current. Thus, the torque of the moving system and the indication of the instrument for a given current is a function of frequency. This eddy-current effect is also present in voltmeters, but here there is another important source of frequency error. The inductance of the instrument's current coil, proportional to the square of the number of turns, becomes quite large in a voltmeter, whose coil may have several thousand turns. Consequently the combined impedance of the coil and series resistance increases substantially with increasing frequency, while the voltage at the instrument terminals, required to provide operating current in the coil, increases at a corresponding rate.

As the voltmeter scale is marked in terms of the voltage needed at the instrument terminals to produce the operating current, the frequency range of the instrument is limited by the impedance change. The operating range can be substantially increased by shunting a portion of the voltmeter multiplier by a capacitor to compensate for the coil inductance but, since capacitive reactance decreases, there will be an upper frequency limit at which compensation is no longer adequate.

5. Electrodynamic Instruments. — Electrodynamic ammeters and voltmeters are usually made only in the best accuracy classes (laboratory standard and portable standard instruments) and are little used outside the calibration laboratory, although instruments of a similar construction are used almost universally to measure electric power. This is because they are much better adapted to make precise measurements of po er than is any other type of instrument, whereas, for current and voltage measurements, the less expensive and more rugged iron-vane instruments are adequate in most engineering work.

Electrodynamic instruments are, however, used in the laboratory to check the calibration of other less precise A.C. ammeters and voltmeters, and to transfer calibrations from D.C. standards to instruments that respond correctly only to alternating currents and voltages.

Electrodynamic instruments make use of the magnetic fields of two sets of coils, one fixed and the other movable. Each coil carries a current which is a function of the current or voltage to be measured. and the reaction between the fields of the fixed and movable coils supplies the torque for the moving system. Here also, as in the iron-vane instruments, the energy storage in the magnetic fields of the coils is proportional to the square of the coil current, and electrodynamic instruments respond to r.m.s. current or voltage.

In the usual construction a moving coil is pivoted or suspended in the field of a pair of fixed coils, and has attached to it springs, pointer and damping vane. The moving-coil current is carried by the instrument springs and is limited to a fraction of an ampere. As the available torque is small, the weight of the moving system must be kept low. The result is a structure that is considerably less rugged than is the moving system of an iron-vane instrument.

The operating field is usually less than 60 gausses for full-scale deflection, and either the entire operating mechanism must be protected by a magnetic shield against external fields or the coil system must be astatic so that the presence of external fields will not result in any net deflecting torque.

In an electrodynamic voltmeter the fixed and moving coils are connected in series to carry the entire current, and a suitable multiplier fixes the voltage range. A low-range electrodynamic milliammeter would also have its coil system connected in series to carry the entire current. However, as the current capacity of the instrument springs limits the moving-coil current, higher current ranges make use of a parallel-coil arrangement. The fixed coils, which can have whatever current capacity is required, carry all but a small fraction of the measured current and have in series with them a resistor of appropriate size and current capacity. The moving coil, also with a resistor in series, is connected in parallel with the fixed-coil-resistor combination. The time constant of each branch of the circuit, *i.e.*, the ratio of inductance to resistance, must be the same in order that the division of current shall not change with frequency. Modem electrodynamic ammeters are seldom built in ranges above 10 amp. A current transformer together with a 5-amp. instrument is generally used for precise measurement of higher currents.

Frequency errors in electrodynamic ammeters arise from two causes. Metal present in coil supports and other parts, and in the instrument shield, will have eddy currents induced in it and will cause a change in deflection with changing frequency, in the same manner as for an iron-vane instrument. However, by proper construction eddy-current errors can be kept to a considerably lower level than is possible in the iron-vane ammeter. In addition to eddy-current errors, another must be expected. Because of the parallel branches, the ammeter coils operate in a closed loop of comparatively low impedance, and the coupling between fixed and moving coils will produce a circulating current in this closed loop, resulting in a torque which is a function of frequency. Frequency errors in electrodynamic voltmeters arise from eddy currents and from the self-inductance of the coil system. These also are similar in kind but smaller in amount than are to be expected in iron-vane voltmeters.

Before using an electrodynamic instrument in transfer measurements, the difference in its performance on D.C. and at the desired frequency should be checked.

6. Electrostatic Voltmeters. — In this type of instrument the deflecting torque results from the action of an electric field on charged conductors (electrodes). Such instruments are useful at low voltages when no appreciable current can be drawn from the circuit. They can also be designed for use at extremely high voltages. In fact the total range of voltage covered, with small errors in measurement, is greater than for any other class of deflecting instrument. They are built regularly in ranges from 50 to 100,000 v. Any good electrostatic voltmeter can be considered as a low-loss capacitor, so that on D.C. voltage, the operating current (after the initial charging current) is merely the very small leakage current required by the insulation resistance of the instrument (which may be as much as 10^{14} ohms).

On A.C. voltages the current is determined by the capacitance of the instrument and the frequency, the operating current in-

creasing with increasing frequency as the reactance decreases. A 15,000-v. instrument, having a capacitance of 20 micromicrofarads, would require 120 μamp. for full-scale deflection at a frequency of 60 c.p.s.

In low-voltage electrostatic voltmeters the fixed and moving systems consist of groups of flat interleaved sector plates. As fixed and movable plate systems are insulated from each other, a voltage impressed between them results in the appearance of charges of opposite sign on the two sets of plates. The force of attraction between these charges produces a torque which is opposed by a spring or, in the case of a suspended system, by stiffness of the suspension bands.

In higher-voltage instruments, where large clearances must be maintained between the electrodes to prevent electrical breakdown of the surrounding air, fixed and moving elements may be sectors of coaxial cylinders, or the combination of a fixed flat disk and a moving cylindrical sector. Damping may be either by means of a vane attached to the moving element, moving with small clearance in a closed sector box, or by means of a disk which moves in the field of a permanent magnet.

Energy storage in the electric field of the voltmeter is proportional to the square of the voltage between its electrodes, and the response of the voltmeter is to the r.m.s. value of the impressed voltage. Operating torque is always small in electrostatic instruments, and may be increased only within rather narrow limits by increasing the capacitance between the fixed and moving electrodes. If either the number of plates or their area is increased, the weight of the moving system will be greater, with a consequent increase in bearing friction. If capacitance is increased by decreasing electrode separation, a limit is reached in low-voltage instruments at the mechanical clearance required for reliable operation, and at high voltages by the clearance needed to avoid corona or electrical breakdown.

Electrostatic voltmeters have a response that is independent of frequency and indeed, if they are suitably constructed and operated, they have no differences in indication on direct or alternating voltage. Thus, they can serve as transfer instruments to determine the difference between A.C. and D.C. response of other types of instruments. In fact, the National Physical laboratory of Great Britain employs electrostatic instruments as their basic transfer standards in the same way that the national bureau of standards of the United States uses electrodynamic instruments.

7. Instrument Transformers. — Ratio devices in the form of transformers are needed to extend the range of alternating current instruments. so that current, voltage, power and energy can be measured with instruments of moderate size and capacity. This is important in the laboratory, and of even greater importance in commercial metering. Here power is frequently handled in large blocks at high currents and voltages, and it is necessary that the devices used to measure large currents or high voltages be both accurate and of low power consumption. The requirement of low power consumption precludes the use of shunts for current measurements beyond a few amperes and of series resistors in voltage circuits beyond a few hundred volts.

A transformer consists of two coils of wire, closely coupled by means of a magnetic circuit of high permeability which threads through both coils. It is the property of such an arrangement that when one coil (the primary) is excited by an alternating current, an alternating voltage of the same frequency is induced in the other coil (the secondary). If the secondary circuit is completed by an external impedance that is very large compared with the impedance of the transformer winding, the ratio of the voltages at the primary and secondary terminals of the transformer is very nearly the same as the ratio of turns in the primary and secondary windings. This is an elementary picture of a voltage transformer. On the other hand, if the secondary circuit of the transformer is completed by an impedance that is very small, the ratio of currents in the primary and secondary circuits is very nearly equal to the reciprocal of the primary-secondary turn ratio, and one has a current transformer.

Thus, the two basic types of instrument transformers (for voltage or current transformation) are similar in that each consists of a primary and secondary coil closely linked by a high-permeability magnetic core. They differ in details of construction and in the conditions under which they operate. A voltage transformer, used to step voltages down from high to low values, may have many times as many turns in its primary as in its secondary winding. It supplies a very small operating current to the high-impedance voltage circuits of the instruments connected across its secondary winding, at a voltage which is a known fraction of the voltage across its primary winding. A current transformer, used to step currents down from high to low values, may have many times as many turns in its secondary as in its primary winding; in fact, the primary winding is often either a single turn or even the high-current conductor passed through the central window of the magnetic core. It supplies the low-impedance current elements of instruments or meters connected across its secondary winding with a current which is a known fraction of the current in its primary winding.

Voltage transformers are usually designed with a 120-v. secondary, and current transformers with a 5-amp. secondary. Primary voltages may be 200,000 v. or more in some instances, and the rated primary current of current transformers sometimes ranges as high as 12,000 amp. Both by refinement of design and by the use of high-quality magnetic core materials, the modern instrument transformer produces a current or voltage for the instruments connected across its secondary terminals that is within a few hundredths of 1% of the intended value, and consumes very little power in its operation. Good instrument transformers reflect accurately, on a known reduced scale, the current or voltage of their primary circuits, and thus serve to broaden enormously the range of A.C. values that can be measured with relatively simple instruments.

B. Power Measurements

The power at any instant in an electric circuit is the product of that current in the circuit and the voltage across its terminals at that instant, and is a measure of the rate at which energy is being transformed or made available. For direct current under steady-state conditions, power can be calculated from a measurement of any two of three quantities — current **I**, voltage E, resistance R— by using the appropriate one of the following relations

$$\text{Power} = EI = I^2R = E^2/R.$$

In the case of an alternating current the instantaneous power varies continuously as the current and voltage go through a cycle of values.

If the current and voltage are both sinusoidal, the time average of power, which is usually the quantity of interest, is given by the expression

$$\text{Power} = EI \cos \phi$$

where E and **I** are the r.m.s. or effective values of voltage and current respectively, and ϕ is the electrical angle between them. Cos ϕ is the power factor and may assume any value between unity and zero as the phase angle between voltage and current varies from 0° to 90°.

1. Electrodynamic Wattmeter. — This instrument, of similar mechanical construction to the electrodynamic instruments already described, is well suited to the measurement of A.C. power at low frequencies. The field coils of the instrurnent are connected in series in the circuit so that their current is that of the load being measured, and the moving coil (with appropriate resistance) is connected across the load so that its current is proportional to the load voltage. Then the instantaneous torque from the reaction of the field-coil current with the moving-coil current is proportional to the product of the current and voltage in the circuit, and hence to the instantaneous power. As the variations of instantaneous pomer are too rapid for the moving system to follow, the equilibrium position it takes up will correspond to the average torque and therefore to average pomer. The instrument scale is marked in watts. The voltage and current elements are brought out to separate terminals so that they may be connected properly to the load circuit.

For small or moderate currents (up to 5 or 10 amp.) the load current is sent directly through the field coils of the wattmeter.

For voltages up to perhaps 300 v., the moving-coil circuit, including a series resistor to limit its current to 25 ma. or less, is connected directly across the load. When power measurements involve larger values of current or voltage, instrument transformers of appropriate ratios are used to step down at the instrument to values that can be applied to a wattmeter having a 5-amp. current range and 150-v. voltage range.

The use of electrodynamic wattmeters for power measurements is restricted to low frequencies, a few hundred cycles per second at most, because of eddy currents and self-inductance of the moving-coil circuit, both of which tend to alter the phase relation between the magnetic fields of the current and voltage elements of the wattmeter, and give rise to errors of indication that increase with increasing frequency. These frequency errors can be made negligibly small at commercial-power frequencies by suitable design and construction, and the electrodynamic wattmeter is much used as a transfer instrument for the calibration of other A.C. instruments in terms of D.C. measurements of current and voltage. Such D.C. measurements can be referred readily to the basic electrical standards of resistance and e.m.f. by means of a laboratory potentiometer.

2. Electrostatic Wattmeter. — The electrostatic wattmeter is substantially free from eddy-current and inductance effects, and can be constructed to be independent of frequency over a much broader range than can the electrodynamic instrument. Hence, it also is used as a basic transfer instrument by several of the national standards laboratories. However the available torque is quite small, as with all other electrostatic instruments. Because its construction is inherently delicate and the techniques of operation require great care and skill, the electrostatic wattmeter is almost never used in routine power measurements. The instrument torque results from the electric field between fixed and moving electrodes, but the electrode arrangement is more elaborate than in the electrostatic voltmeter.

There are two sets of stationary electrodes maintained at a potential difference proportional to the load current. This potential difference is provided by the voltage drop across a resistor that carries the load current. The voltage drop across the load is impressed between the moving element and the midpoint of this shunt (*i.e.*, at the mean potential of the two stationary electrodes). The instantaneous torque is proportional to the product of load voltage and load current at any instant, and the deflection of the moving element is proportional to the average power into the load.

3. Bolometer. — The wattmeters described above are designed to measure power into a load, and are applicable only at low frequencies. The accurate measurement of power into a load becomes more difficult with increasing frequency, and no simple or even adequate techniques are available for such measurements at radio or microwave frequencies. However, the power output of a generating circuit can be accurately measured at any frequency by absorbing the output and converting the electrical energy to heat. This can be done in the laboratory with a calorimeter in which the rate of heat production, measured by differential temperature rise, is a measure of the power output of the generator.

A more convenient means of measuring power output is with a bolometer bridge. A thermistor element, having a very large temperature coefficient of resistance, forms one arm of a Wheatstone bridge and is arranged to absorb energy from the generator. Its resistance change, as its temperature rises with the absorption of energy, becomes a measure of the power output of the generator. Such a device can be calibrated in terms of the product of the measured direct current and voltage required to produce the same resistance change in the thermistor.

C. Energy Measurements

The measurement of electrical energy is, from the viewpoint of economics, one of the most important of electrical measurements. Where electric power is generated or consumed, the commodity that is sold is energy, the time integral of power. The basic unit of power is the watt, and the corresponding unit of energy is the watt-second or joule.

More familiar units are the watt-hour (3,600 watt-seconds) and the kilowatt-hour (36×10^5 watt-seconds or 1,000 watt-hours). This latter unit, the kilowatt-hour, is the energy unit commonly used in billings for electrical service.

1. Commutator Watt-Hour Meter. — Developed by Elihu Thomson in 1889, this device is commonly used for metering D.C. energy. It is essentially a small motor provided with a magnetic brake and geared to a register or set of dials, whose count is proportional to the total number of revolutions. The gear train between the rotor shaft and the register dials is of such a ratio that the dials read directly in kilowatt-hours. The motor field consists of a few turns of heavy copper wire carrying the current of the load being metered.

The armature (or rotor) current is proportional to the line voltage. In this respect the instrument resembles the electrodynamic wattmeter, and its driving torque is proportional to the product of load current and line voltage. The armature has a silver commutator and silver- or gold-tipped brushes; it is carried on jewel bearings to minimize friction. For proper operation it is essential that the rotor speed be proportional to driving torque (and to the power being metered), and this is assured by providing a retarding or braking torque of sufficient magnitude to keep the speed of rotation rather low.

An aluminum disk is attached to the motor shaft and intercepts the flux of a permanent magnet. As the disk rotates, eddy currents are induced in it by the flux that it cuts, and the counter torque which results from the reaction between these eddy currents and the field of the magnet is proportional to the disk speed. Therefore, the speed of rotation of the motor shaft is proportional to the load power, and its total number of revolutions over a time interval is proportional to the energy consumed by the load during the interval.

2. Induction Watt-Hour Meter. — The induction watt-hour meter is used almost universally for metering A.C. energy. Its principle of operation, identical with that of the induction motor, may be understood by considering two laminated electromagnets A and B, situated on either side of an aluminum disk and displaced slightly from one another along its periphery. The alternating magnetic field of A induces eddy currents in the disk that intercept the field of electromagnet B, producing a torque on the disk. Conversely eddy currents induced in the disk by electromagnet B intercept the field of magnet A, and react to produce a torque. If the magnetic field of B lags in phase behind the field of A, the two torques are in the same direction and their sum is proportional to the product of the currents producing the fields and to the sine of their angular phase difference.

To produce a torque in the rotating disk proportional to load power, one of the electromagnets (say A) is wound with a few turns of heavy mire and is connected to carry the load current. The other electromagnet (B) is wound with many turns of fine wire and is connected between the power lines so that its current is proportional to load voltage. This electromagnet is designed to have a very large inductance and the current in its coil lags almost go" behind the voltage producing it. By using an additional shading coil, the flux of this magnet intercepted by the disk, is made to lag precisely go° behind the voltage and, since the sine of go° is unity, maximum torque is developed if the current in the series coil (electromagnet A) is in phase with the voltage, *i.e.*, for a unity power-factor load. As in the commutator meter, the aluminum disk passes between the poles of a permanent magnet to provide a braking torque proportional to speed.

A gear train drives a register whose count is proportional to total revolutions of the shaft, and thus to energy consumption, providing a basis for billing the power customer.

Fig. 3 shows a single-phase meter such as is employed to meter the energy used in the ordinary household. Other meter types have two driving elements for a three-wire distribution system, or three elements for a four-wire system. For very large currents, where huge blocks of power are metered for an industrial customer, the current coils of the watt-hour meter are connected through current transformers. When the metering must be done at high voltages, voltage transformers are also used to connect the meter to the power lines.

FIG. 3.— SINGLE-PHASEWATT-HOUR METER
(Left) schematic; (right) assembled

Because of the very large number of meters in use, and the high total value of the electrical energy consumed annually, a great deal of engineering talent has been devoted to refining watt-hour meter design. A modern meter may be expected to have an accuracy of nearly 1% over a wide range of loads and at temperatures ranging between the extremes of winter and summer, and to retain this accuracy over a period of many years with little or no maintenance.

D. Resistance Measurements

Depending on the accuracy required, it is possible to measure a resistance with a deflecting instrument called an ohmmeter, or compare its value with that of a known resistance in a ratio network such as the Wheatstone bridge.

Deflection methods generally may be expected to yield an accuracy of a few per cent, whereas bridge methods may be used with ordinary precautions for work nhich requires values to o 1% and, with care, to o.01% or better. In the national standardizing laboratories and in other laboratories having comparable equipment, nominally equal resistances can be compared in a bridge network to 1 part in 10,000,000.

1. Ohmmeter.— Ohmmeters are of two types. The series ohmmeter, which forms a part of many inexpensive multipurpose testing instruments, consists of a D.C. milliammeter in series with a small dry-cell battery and an adjustable rheostat. A gap in this circuit is provided with binding posts or test leads so that the resistance to be measured can be inserted conveniently into the circuit. With the test gap shorted out, the milliammeter is set by means of the rheostat to a reference point on its scale marked zero. The pointer position with the gap open, so that there is no current in the circuit, is marked infinity.

When a resistor is connected across the gap to complete the circuit, the instrument pointer assumes a position intermediate between the zero and infinity marks, and the scale is marked in terms of resistance.

The ratio (or crossed-coil) ohmmeter represents a substantial improvement. as its reading is nearly independent of supply voltage and it need not be set to a reference mark each time it is used. It is a permanent magnet instrument with two moving-coil systems arranged so that their torques oppose one another. The circuit, containing a voltage source, is so arranged that the current in one coil is proportional to the voltage across the resistor to be measured. The current through the other moving coil goes also through the resistor. Thus the torques resulting from the currents in the two moving coils represent respectively the voltage across the resistor and the current through it. As these torques oppose one another, the instrument pointer takes up a position representing their ratio, the quotient of rhe voltage by the current in the resistor.

The instrument scale is marked in resistance units. Such instruments, with a supply voltage ranging from 500 to 5.000 v. are used for measuring the resistance of electrical insulation. and their scales are usually marked in megohms. A somewhat similar type of crossed-coil instrument is arranged for four-terminal measurements, and its scale may be marked in microhms.

2. Wheatstone Bridge.— The Wheatstone bridge consists of two parallel branches (as shown in fig. 4), carrying currents i_1 and i_2 respectively. supplied from a common voltage source. If the individual resistors of one branch, say p and r, have a ratio of fixed value, the resistors in the other branch can be brought to the same ratio by adjusting the value of one of them. The ratios are equal when the potential drop caused by the current i_1 in resistor p is equal to the potential drop resulting from i_2 in q. Simultaneously, of course, $i_1 r = i_2 s$. Thus, when the resistance ratios are equal in the two branches, there is no potential difference across the galvanometer; and its zero indication demonstrates balance in the bridge. For this condition $p/r = q/s$ or $q = s \times p/r$. The value of the resistor q is determined from a known ratio p/r and a known resistance s. At balance it is also true that $p/q = r/s$ and it follows that the galvanometer can be interchanged with the voltage source in the network without affecting the balance condition.

This interchangeability is, in fact, characteristic of any bridge network. and can frequently be used to advantage, by placing the voltage source and the detector of unbalance to obtain best sensitivity: *i* e., larger detector response to a given proportional unbalance of the bridge and, hence an observable response to a smaller unbalance.

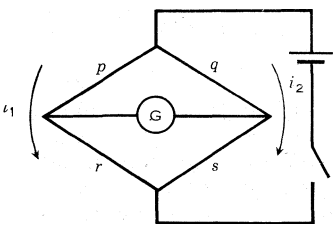

FIG. 4.— WHEATSTONE BRIDGE

If the voltage sensitivity of the galvanometer is known for the circuit resistance which it encounters in the bridge, its response to any specified proportional departure from the balance condition can be computed easily. The unbalance voltage e, acting to deflect the galvanometer, is given by the formula

$$e = E\Delta\frac{pr}{(p+r)^2} = E\Delta\frac{qs}{(q+s)^2},$$

where E is the supply voltage at the bridge terminals and Δ is the proportional unbalance. It should be noted that the alternative formulas provide for a departure of any arm from the balance condition; *i.e.*, the expression is used which includes the unbalanced arm.

The Wheatstone bridge is regularly used in a variety of forms for the precise measurement of resistance in the range from 1 ohm to 100 megohms. For a resistance less than an ohm. the resistance introduced at the terminals of the bridge when connecting it into a circuit becomes increasingly important with decreasing total resistance. For example. if the terminal resistance amount to o oor ohm and the resistor itself is o 01 ohm, the terminals contribute 10% of the whole. Hence, the precise definition and measurement of low resistances must avoid inclusion of these terminal resistances.

Low-valued resistors in the precision class have four rather than two terminals, the current being introduced through one pair and the potential drop measured between the other pair. The resistance of a four-terminal resistor is defined as the ratio of the voltage difference between the potential terminals to the current entering and leaving the current terminals. Bridges for measuring or comparing four-terminal resistors must have two pairs of ratio arms rather than one. The Kelvin bridge netnork shown in fig. 5 is such an arrangement.

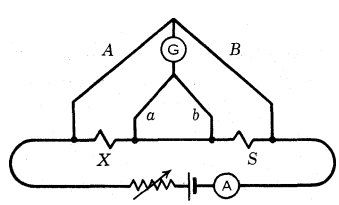

FIG 5.— KELVIN BRIDGE

E. Capacitance and Inductance Measurements

Alternating current networks similar to the Wheatstone bridge are used to measure capacitance or inductance. One of the network branches may form a ratio pair and the other branch may be used to compare one inductor with another, or one capacitor with another. The value of the unknown element is determined from a

known standard of the same kind, and the known ratio. The ratio arms of the bridge may be made up of two resistances, two inductances or two capacitances.

In any A.C. bridge, balance is possible only when there is no potential difference across the detector at every instant throughout the A.C. cycle. Thus, the ratio arms should have the same time constants, and the elements being compared should have equal phase angles. In other words, both magnitude and phase-angle balances are required in an A.C. bridge. This usually means that a resistance must be inserted in the arm containing one or the other of the elements being compared, to bring their phase angles to equality.

The Wheatstone network can also be arranged in a form known as the product-arm bridge, in contrast to the ratio-arm network just described. In this arrangement a capacitor can be compared to an inductor in the opposite arm, the remaining opposite pair of arms being resistors. Thus a capacitance can be measured in terms of an inductance and the product of two resistances, or an inductance can be measured in terms of a capacitance and a product of resistances.

To summarize the possibilities, if two capacitors (or two inductors) are to be compared in a four-arm bridge, they must be in adjacent arms. If a capacitor is to be compared with an inductor, they must be in opposite arms.

V. Recording Instruments

In industrial and laboratory operations it is often necessary to have a record of the variations of voltage, current, power or some related quantity over an extended time interval. To make such a record, moving a pen over a paper chart, requires much more power in the operating mechanism of the instrument than is needed merely to indicate with a pointer the value of an electrical quantity. Direct-writing recorders have moving systems similar to those of the corresponding indicating instruments except that the torque requirements may be a hundred or even a thousand times greater. Some kind of a clock mechanism must also be incorporated into the instrument to move the chart paper at a uniform rate.

A second type, called a servo-recorder, has a small motor which takes its power from an auxiliary source and moves the pen across the paper. Servo-recorders make use of either a bridge or a potentiometer network in which a quantity is measured in terms of the balance position of a slide-wire that forms part of the network. When the network is unbalanced, the output of a detector or sensing element is fed into an amplifier. The amplifier output is applied to the motor which drives the slide-wire and the recording pen in the proper direction to restore balance to the network. Large numbers of servo-recorders are used in industrial plants to record temperatures of furnaces or stills, using a thermocouple or resistance thermometer, or to record, by means of an electrical weighing device, the rate of flow of a material used or produced. In short, servo-recorders can be used to make a continuous record of any quantity which can, by some type of transducer be made to produce an electrical signal.

Frequently the amplifier output from the unbalance signal, or the position of the recording pen, is used to initiate controlling devices so that the entire operation is automatic except for supervision.

INSUBRES, a Celtic people of upper Italy, the most powerful in Gallia Transpadana. Their origin is obscure. Livy, whose account (v. 34) is not reliable, regards them as Aedui who came into Italy over the Mont Genèvre pass. By about 400 B.C. the Insubres were controlling a large area around their capital city Mediolanum (Milan). From 222 to 194 B.C. they were frequently at war with the Romans. In 222 B.C. they were defeated at Clastidium by M. Claudius Marcellus, who gained the *spolia opima* by slaying with his own hand their king Viridomarus; and in 194 B.C. they were finally subdued by L. Valerius Flaccus.

Thereafter their separate identity was gradually obscured. The area was given Latin rights in 89 B.C. and full Roman citizenship in 49 B.C.

INSULATING MATERIAL. The advantages of heat insulation must have been known very early in history. The comforts of fur clothing and snowhouses of the Eskimo, for example, certainly were realized hundreds of years ago. Wood was used for insulating steam boilers, engine cylinders and pipes early in the 19th century.

The extensive development of commercial insulation, however, dates from about 1900.

Purposes of Heat Insulation. — The chief use of insulation is to retard the rate of heat flow. This may reduce the heat flow outward from a building or furnace, for example, or inward to a cold-storage warehouse. Great savings in fuel and electricity are made possible by the proper installation of insulation and it is often used to prevent condensation of water vapour on the inside of factory roofs where the manufacturing process requires or develops a high relative humidity, as in cotton or paper mills. Cold-water pipes in buildings are frequently insulated solely to prevent condensation and consequent dripping on warm humid days. Working and living conditions can often be made more comfortable by the use of insulation.

Buildings can be made cooler in summer and the working conditions around furnaces, hot flues, etc., improved. The addition of insulation to buildings, bake ovens, furnaces, etc., will tend to produce a more uniform temperature distribution.

The low heat capacity of insulating firebrick is an important factor in saving fuel used by intermittently heated furnaces. The time required to reach a desired temperature may be reduced by the use of lightweight insulating firebrick to one-quarter that needed when conventional heavy firebrick is used.

Insulation is sometimes applied to structural steel in buildings to reduce the fire hazard. Underwriters' tests indicated that unprotected structural steel collapses quickly in a hot fire. The thermal expansion of concrete roof slabs can be much reduced by the use of insulation.

Proper insulation also will minimize the formation of lath patterns on walls of plaster on wood lath.

Factors Affecting the Value of Insulation. — The coefficient of thermal conductivity or K value of insulating materials increases with an increase of temperature. The loose fibre type generally increases much faster than the more solid type such as corkboard or 85% magnesia, as shown below:

Glass wool	2.1 lb/cu ft.	0 28 @ 100° F.	0.55 @ 300° F.
85% magnesia	12 lb/cu ft.	0.38 @ 100° F.	0.43 @ 300° F.

When referring to a K value of an insulating material, it is important to note the temperature corresponding. For insulating materials used at temperatures below 70° F., provision should be made to prevent moisture from entering the insulation. For water has a *K* value more than ten times that of most insulating materials, and if it is present in the insulation the effective K value is increased materially and usually other difficulties develop. In cold-storage plants as well as houses, water vapour tends to enter from the warmer side and condense in the cooler parts of the insulation. Thus every effort should be made to seal the warmer side of such walls so that they will be impervious to water vapour. This is a serious problem when extremely low temperatures are encountered. In general, for any given insulating material, the K

value will increase with density but there are notable exceptions in the case of many loose fibrous materials and some powders. Bagasse (sugar cane fibre) has a minimum K value at a density of four pounds per cubic foot, the K value increasing if the density is made greater or less than this amount. Another factor that tends to increase the K value of a few insulating materials is radiation through the material and, in special cases of loose fibrous materials. there may be convection currents of air transmitting heat from the warm side to the cool side.

Types of Insulation. — Heat insulating materials may be roughly classified as follows: (1) powders, such as diatomaceous earth, silica aerogel, sawdust, etc.; (2) loose fibrous materials similar to eelgrass, glass wool, rock wool, shredded redwood bark, etc.; (3) blanket insulation, consisting of glass wool, rock wool, wood fibres. etc.. enclosed by paper. cloth or wire mesh; (4) board or block insulation. such as corkboard. fibreboard, expanded glass block, 85% magnesia, vermiculite block, etc.; (j) insulating refractories such as diatomaceous earth and kaolin bricks; (6) heavy refractories such as fire clay, magnesite, silica bricks, etc.; (7) reflective insulation, consisting usually of aluminum foil with an adjoining air space. Reflective insulation is effective because it reflects a high percentage of the radiation striking it and also emits a small percentage of the amount of heat radiated by ordinary (nonmetallic) surfaces under the same temperature conditions.

Reflective insulation is based on entirely different principles from those of conventional insulation.

INSULATING MATERIAL (ELECTRICAL). Electrical insulation is nonconducting material used to hold electrical conductors in position, separating them from each other and from surrounding structures. Insulation forms a barrier between energized parts of an electric circuit and confines the flow of electric current to wires or other conducting paths as desired. The insulation of electric circuits is a necessary requirement for the successful operation of all electrical apparatus.

Various types of materials are used as insulation, the selection being made on the basis of the specific requirements of each application. The copper conductors used in the electrical wiring in homes are insulated from each other and from the building by rubber or by plastics. These materials are low in cost, long lived and sufficiently flexible to withstand necessary bending. Extension cords of heating appliances are usually insulated with asbestos. a material which is capable of aithstanding high temperature nithout deterioration. Overhead power lines operating at high voltage are supported on porcelain insulators which are unaffected by outdoor exposure. Paper is used to insulate the small nires of telephone cables and the conductors of high-voltage power cables; in the latter case the paper is impregnated with insulating oil to improve the quality of the insulation. Large electric generators and motors which operate at high voltages and high temperatures are insulated with mica In some applications, solid insulation is used in conjunction with liquid or gaseous insulation. For example. in high-voltage transformers. solid insulation provides mechanical rigidity while insulating oil contributes to increased insulation strength and serves to carry heat out of the structure.

Electrical insulation is ordinarily regarded as a nonconducting material, but is, in fact, better described as a poor conductor or a substance of high resistance to the flow of electric current. Different insulating and conducting materials are compared with one another in this regard by means of a material constant known as the resistivity, the resistance measured across identically dimensioned samples of the several materials. The resistivities of a number of insulating materials are shown in the table, column 2, along with the resistivity of copper, the most commonly used conductor material. As may be seen, the resistivities of the insulating materials are vastly greater than the resistivities of the metal. Nevertheless, in the normal operation of electrical equipment, minute conduction currents flow through the insulation separating the energized parts and a small amount of heat is thereby released within the insulation.

Under the influence of ordinary voltage application, insulation has extremely high resistance to current flow. However. if the voltage gradient (volts per centimetre thickness of insulation) exceeds a critical value, the resulting rearrangement of the atomic structure of the material results in a sudden decrease in the resistance of the material to such an extent that high-value currents may flow through local regions. Such a change leads to breakdown or "puncture." In the case of solid insulation, puncture represents permanent damage to the material, whereas in the case of liquid or gaseous insulation, the interruption of the current flow and the removal of the offending overvoltage restores the material to substantially original conditions. The puncture strength of several insulating materials is shown in the table.

Characteristics of Insulating Materials

Material	Resistivity ohm-cm.	Puncture strength volts per cm.	Relative permittivity
Air (20° C., 760 mm. Hg)	$V_5 \times 10^{16}$h	3×10^4	1.0
Amber			4.3-5.5
Bakelite			4.8-5.5
Glass	2×10^{13}	$0.5\text{–}3.0 \times 10^6$	5.4–9.9
Mica	2×10^{17}	$3.5\text{–}7.0 \times 10^6$	2. j–6.6
Oil	1×10^{12}	1.0×10^5	2.2–4.7
Paper		$1.0\text{–}4.0 \times 10^5$	2.0–2.6
Porcelain	3×10^{14}	1.0×10^5	5.7–6.8
Quartz	$j \times 10^{18}$	$2.0\text{–}2.5 \times 10^5$	3.5
Rubber	1×10^{13}		2.0–3.5
Copper	1.6×10^{-6}	...	...

Data from *Standard Handbook for Electrical Engineers,* 8th ed. (McGraw-Hill Book Company, Inc., New York, London, 1949). Electrical properties may vary considerably, depending on the processes of material preparation and the methods of test.

Two conducting bodies separated by insulation form a capacitor which is said to possess capacitance, the ability of the assembly to store electric charge under the application of voltage. The capacitance is influenced by the relative permittivity of the material employed as insulation. The relative permittivity of a material is defined as the ratio of the two capacitance values: (1) the capacitance between the two electrodes separated by the insulating material; and (2) the capacitance of the same electrodes with vacuum replacing the subject material. The relative permittivities of several insulating materials are shown in the table.

The insulation material separating two electrodes is stressed when normal voltage is applied to the electrodes and this stress is reversed with each reversal of the applied voltage. This change of stress involves molecular rearrangement within the insulation with the attendant release of a small amount of heat with each reversal. If the applied voltage is of low frequency (such as 60 cycles per second), this release of heat is ordinarily of little concern. At the high frequencies employed in many communications systems (millions of cycles per second), this heat release may be evident by insulation temperature rise and by a loss of energy from the electric circuit. Special plastics, ceramics and glasses, exhibiting very low loss at high frequency, have been developed for the communications industry.

Insulating materials are subject to many deteriorating influences, the most important of which are moisture absorption and chemical changes. Porous materials. such as cotton and paper, must be effectively sealed against moisture, usually by immersion in oil or by impregnation with insulating varnishes. Silicone varnishes are used extensively as they form a very effective barrier against moisture and can withstand fairly high temperatures.

Insulating materials deteriorate under influences which change their chemical structures. Chemical changes which progress very slowly at room temperatures are. in some cases, greatly accelerated at elevated temperatures. For this reason, many types of electrical apparatus have specified maximum operating temperatures.

If operated at higher temperatures, insulation life will be noticeably shortened. Some organic compounds are damaged by exposure to ultraviolet light and corona, a product of high-voltage

stress in air. *See* also ELECTRIC POWER. (J. R. E.)

INSULIN is a protein hormone secreted into the blood by cells situated in the pancreas; its chief function is to regulate sugar metabolism. Insulin. extracted from the pancreas of certain domestic animals. is administered to persons suffering from diabetes mellitus. in whom there is an absolute or relative deficiency of insulin. It is also used to some extent in the treatment of mental disease.

In the Mammalia, in which the pancreas is well defined, the insulin-secreting cells lie in scattered groups. called the isles of Langerhans, distributed among the relatively much larger groups. or acini. of pancreas cells. In certain fishes in which the pancreas does not occur as a definite gland but is spread out diffusely in the mesentery, the islet cells form compact encapsulated glands called the principal islets, which are often of considerable size and contain no pancreatic (acinar) cells.

In 1889 J. von Mering and Oscar Minkowski found that complete extirpation of the pancreas in dogs immediately caused severe diabetes, and it was not long before the hypothesis was formulated that this must be due to the withdrawal from the body of a hormone having the function of regulating the metabolism of the carbohydrates.

The name insulin was first suggested for a hypothetical internal secretion of the pancreas by J. de Meyer in 1909. Many attempts were made to extract it from the pancreas, but with little success. In 1921, however, Sir Frederick Banting and Charles H. Best, working in the laboratory of J. J. R. MacLeod, found that extracts of partially degenerated pancreas and later of normal pancreas contained the hormone.

These observations demonstrated that insulin does exist in the pancreas, and the next step was to devise a method for extracting it in more purified form and in quantity from normal pancreas. Alcohol was found to be a suitable extractive, in that it dissolved the insulin and at the same time eliminated undesirable contaminants. Crude insulin prepared in this way by Banting and Best was first administered to human patients in Jan. 1922. Later J. B. Collip succeeded in sufficiently purifying the alcoholic extracts, by a process of fractional precipitation, so that they could be injected subcutaneously in man without causing local irritation. Very potent extracts were also prepared from the principal islets of fishes. Further purification of the extracts was effected by precipitating the insulin, either by adjustment of the reaction (isoelectric precipitation) or hy means of picric acid followed by treatment with alcoholic hydrochloric acid (insulin hydrochloride).

The function of insulin is to promote the formation and storage of glycogen (a complex sugar), of fat and of protein; it increases the burning of sugar and decreases its excessive nerv formation from protein; it helps in the regulation of potassium and phosphate metabolism. Insulin counteracts the inhibitory effects of several other hormones on these processes.

When insulin is absent from the blood. as after surgical removal of the pancreas or when the islets are destroyed by disease (diabetes). less sugar is used and sugar production takes place in the liver more rapidly. The blood sugar becomes very high (hyperglycemia) and sugar appears in the urine (glycosuria). At a later staae substances known as ketone bodies also appear in the blood and urine (ketonuria) being derived from the incomplete oxidation chiefly of fatty acid but partly also of certain of the amino acids Death ultimately occurs, either because of starvation caused by the excessive using up of the available foodstuffs of the body or because of toxic effects for which the ketone bodies are believed to be largely responsible (diabetic coma). Insulin promptly removes all these symptoms when injected under the skin or into a blood vessel; it is inactive when given by mouth, because it is destroyed by the digestive ferments of the intestine The effect passes off in a few hours, so that the injections must be repeated at least twice daily unless some material is combined with the insulin to slow the rate of its absorption. There are available various forms of slow-acting insulin.

When insulin is injected into normal animals the blood sugar. which usually stands at about o 10%, rapidly diminishes; nhen it reaches a level at between o 04% and o 05%, curious symptoms supervene.

In most of the laboratory animals these hypoglycemic symptoms consist at first of nervous overexcitability leading to convulsions. and later of coma and fall of temperature. That the symptoms are related to the disappearance of free glucose from the blood is indicated by the fact that they are promptly removed by restoring glucose to the blood. either by giving sugar by mouth or by injecting solutions of glucose. Glucose is conspicuously more efficient as an antidote than any other sugar, even than mannose and laevulose which are so closely related to it chemically. The mechanism by which excess of insulin causes hypoglycemia in the normal animal is an exaggeration of its usual action; *i.e.*, it increases the burning of sugar and its storage as glycogen and fat.

There are no true substitutes for insulin, though a great variety of oral hypoglycemic agents have been tested. Some of these are related to guanidine (*q.v.*) and have produced liver injury. A series of compounds resembling the sulfonamides in chemical structure also have been tested in animals and man. One of these, called tolbutamide, produces very little toxicity in human subjects and gives very promising results in certain older mild cases of diabetes. Since tolbutamide, unlike insulin, is a substance foreign to the body, careful watch must be kept for many years to make certain that no ill effects appear. Some insulin, either natural or administered, must be available in the body for the hypoglycemic effects of tolbutamide or related drugs to be exerted. This agent is not effective in childhood diabetes or in the adult diabetic who is in acidosis or coma.

Since insulin can be prepared in crystalline form (J. J. Abel and E. M. K. Geiling) it may be weighed out for medicinal use, but it is more convenient to use it in liquid form, which keeps well in acid reaction. The strength of the liquid in actual insulin is determined by biological methods, one of which depends on the lowering of blood sugar in a normal rabbit. The strength is gauged in units, one unit of insulin being originally defined as the amount that on subcutaneous injection will lower the percentage of blood sugar to the convulsive level. 0.045%, for a period of five hours in a fasting rabbit of two-kilogram weight. In order to ensure uniformity in the strength of insulin manufactured in different countries. the health committee of the League of Nations set up a sufficient quantity of dried insulin.. Later this original "yardstick" was replaced by purer, more potent standard preparations. Testing laboratories maintain their own standards, but they can have them checked against the international standard from time to time. By such international uniformity in strength of insulin, the diabetic patient is insured against variable dosage. The present international standard contains approximately 2 j units per milligram.

INSULL, SAMUEL (1859–1938), **U.S.** public utilities executive, known for his contributions to good utility operations and his mistakes in utility financing, was born in London, Eng., Nov. 11, 1859. In 1881 he went to the United States as private secretary to Thomas A. Edison. In 1892 he was appointed manager of the Edison Co., in Chicago, Ill. He became a U.S. citizen in 1896. He formed his first holding company, Middle West Utilities, in 1912. After his ambitious holding company pyramid collapsed in 1932, Insull fled to Europe.

He was returned to Chicago in 1934, and tried three times on charges of fraud, violation of federal bankrupting laws and embezzlement, being acquitted each time.

Insull died July 16, 1938, in Paris.

INSURANCE. The present article is an introduction to the general subject of insurance (see *General Considerations,* below). For more specific information the reader is referred to the separate articles listed below.

INSURANCE, MISCELLANEOUS contains a description of certain forms of property insurance. Other important fields of property insurance are dealt with in ENGINEERING INSURANCE; FIRE INSURANCE; MARINE INSURANCE; MOTOR VEHICLE INSURANCE; RIOT AND CIVIL COMMOTION INSURANCE; and TORNADO AND WIND-

STORM INSURANCE. In all these cases the properties insured are normally tangible. Articles on the insurance of intangible property items are CREDIT INSURANCE; REINSURANCE; and TITLE INSURANCE COMPANY.

The chief articles on personal insurance are LIFE INSURANCE: GROUP INSURANCE; and CASUALTY INSURANCE, although the latter has aspects of social insurance. The article FRIENDLY SOCIETY deals partly with charitable and partly with insurance matters.

The most important articles in the field of social insurance are SOCIAL SECURITY; UNEMPLOYMENT INSURANCE; PENSIONS; and WAR PENSIONS; also the article VETERANS ADMINISTRATION, U.S., contains portions important for insurance. Some of the institutions anteceding social insurance are treated in the article POOR LAW.

Not strictly in the field of insurance but very pertinent to the field are the articles ANNUITY; SUPERANNUATION; BONUS; GUARANTEE; and LIFE EXPECTANCY. (X.)

GENERAL CONSIDERATIONS

Insurance may be described as a social device whereby a large group of individuals, through a system of equitable contributions, may reduce or eliminate certain measurable risks of economic loss common to all members of the group. Its primary function is to substitute certainty for uncertainty, as regards the economic cost resulting from the accidental occurrence of disastrous events. Its effect is to spread the cost which normally would fall upon a single individual in an equitable manner over the members of a large group exposed to the same hazard.

Throughout the history of the institution, the terms insurance and assurance have been employed more or less interchangeably. A suggestion by Charles Babbage as early as 1826 that the word assurance be reserved for contracts relating to life was never generally adopted. From the beginning. the term insurance seemed to find greater favour in the United States.

Risk and Insurance.—Not all risks are insurable, nor is insurance the sole method of dealing with economic risk. Risk itself is the result of hazard. Risk is the chance of loss; hazard, the source of the loss. Hazards may be classified as (1) physical or (2) moral, or as (1) those affecting all members of a community alike, such as business cycles and earthquakes, and (2) those affecting only particular individuals, such as fire and theft. Risks based on a moral hazard are not regarded as insurable. Many of those affecting all members of a community alike, such as unemployment arising out of the business cycle, are insurable only by the device of social insurance to be discussed later.

For insurance purposes it is important to distinguish the two broad classifications of risk, namely (1) pure risk and (a) business or speculative risk. The first is unilateral and negative. involving only the chance of loss. The second is bilateral, including the alternative possibilities of loss or gain. The latter is usually sought by those willing to incur the chance of loss as an appropriate price to pay for the prospect of a possible gain. Only pure risks are regarded as appropriate subjects for insurance. In addition, to be insurable, a risk must be measurable in quantitative terms, for which purpose the law of large numbers and the theories of probability and chance are employed. The law of large numbers is based on the observation that the larger the number of instances taken, the closer the result approaches the theoretical probability. Probability of loss may be expressed as a fraction, of which the denominator is the number of units exposed to loss and the numerator the number expected to be lost within a given period. Assuming adequate data on exposure and loss probability of loss then becomes the ratio of losses to exposed units. To convert the probability of loss into "expectation of loss" or value of the risk. the probability of loss is multiplied by the average value of the units exposed to loss. Assuming, for example, the average value to be $10,000, and probability of loss 10/10,000, the expectation of loss will be 10/10,000 × $10,000 or $10.00. This amount may be called the pure premium or the individual loss-cost-share applicable to each unit in the group. Thus, if each unit in the group contributes this amount and experience conforms to the expectation, all losses will be covered.

In addition to the requirement that risks, to be insurable, must be of the pure variety as described above, and must also lend themselves to measurement in quantitative terms, certain other conditions must be met before the institution of insurance may function. (1) The risk must be genuine, must exist for large groups of people, and its existence must be recognized by a sufficient number to warrant the establishment of an organization or organizations to insure it. (2) Persons exposed to the risk must feel a sense of responsibility for the possible loss and its consequences. (3) Those concerned must possess the resources with which to pay their pro-rata share of the cost or the premiums. (4) The magnitude of the potential loss must be sufficient to cause a real hardship for the individuals upon whom actual losses may fall (magnitude, of course, is important only relatively to the resources of the individual). (5) The events concerned must be accidental, or fortuitous in character; they must occur according to the laws of chance and not be subject to control by those seeking to insure. Finally, (6) a catastrophe hazard must not exist. The character of the risk must not be such that a single occurrence may cause the loss of a substantial proportion of the units concerned.

Risks which ordinarily meet the requirements for insurance, classified according to what may be lost, fall into two broad categories, those which involve loss of income, and those which involve losses of property. Those in the first group may be called personal risks, since they result from hazards to persons, and the forms of insurance which may be applied are called personal insurance. Loss of income to the individual or his dependents may result from death, disability from accident or illness, unemployment, or old-age. Insurance applying to those in the second group is called property insurance. Loss of property may result from damage or destruction of specific property by fire, windstorm, hazards of the sea. earthquake, water leakage, explosion, riot and civil commotion, vandalism, theft, forgery, and, in the case of vehicles and their contents, collision. In addition, loss of property may result from the liability to pay compensation to injured employees under a workmen's compensation statute, or to pay damages because of injury to the persons or property of others. because of negligence in personal conduct or in the maintenance or operation of physical property.

Voluntary or Commercial Insurance.—The modern institution of insurance is divided into the two broad categories of voluntary or commercial insurance and compulsory or social insurance, both relying on the same basic principles but differing in many details of philosophy and organization. The description of insurance as set out above applies equally to both categories. A somewhat narrower definition may be employed, however, to describe those forms falling within the voluntary or commercial category. A widely cited definition was first enunciated by the court in the case of *Lucena* v. *Crawford*, 2B & PNR 269 (H. L. 1806): "Insurance is a contract by which the one party. in consideration of a price paid to him adequate to the risk, becomes security to the other that he shall not suffer loss, damage, or prejudice by the happening of the perils specified to certain things which may be exposed to them." The document evidencing the transaction is known as a policy and the price paid is the premium. Those seeking insurance are required to have an insurable interest. *i.e.*, they must stand to lose by the happening of the event contemplated; otherwise the transaction would constitute merely a wager and would be unenforceable if not actually illegal. Where a proper insurable interest exists, payment of a loss becomes an indemnity, not a gain as would be the case with a wager. Because such interests attach to persons, and because the character of the person is an important element of the risk. the insurance contract is spoken of as a personal contract and is not transferable without the agreement of all parties.

The business of voluntary or commercial insurance as usually conducted falls into four general divisions—life, fire, marine and casualty. In England the term accident insurance is applied to the branch of insurance for which the term casualty is used in United States practice. Marine insurance, which traces its origin back

to the Italian traders of the 1 jth century or earlier, continues as a specialized branch of the business.

In England, particularly, aviation risks are usually insured by marine companies, along with other transportation risks. Life insurance, known to have existed in England as early as 1583. did not merge with other forms to any great extent and only to a limited degree do life insurance companies provide other forms of personal insurance. The sale of annuities is usually coupled with that of life insurance.

Fire insurance, originating in its modern form following the great fire of London in 1666, continued for many years to be concerned with the fire hazard exclusively. Not until the 20th century were the hazards of wind, water damage. explosion and other so-called "allied fire lines" added extensively to the list of those insured by fire companies. The expansion of this branch of fire insurance company operation was particularly marked in the United States.

There, also inland transportation hazards are usually insured by the fire companies.

Personal accident insurance, which came into being about the middle of the 19th century, is a specialized branch of the business, having expanded to include the hazards of illness, hospital and surgical expense and related costs of illness and accident. Other special forms such as steam boiler explosion, glass breakage, employer's liability, public liability, workmen's compensation. automobile insurance as well as corporate bonding are handled by specialized insurers or, in the United States, by so-called casualty carriers.

Only after 1948, in the United States, could a single company on a wide scale offer insurance of virtually all the forms mentioned above. with the exception of life insurance and annuities. This limited "multiple-line" underwriting, as long practised in the rest of the world, was, in the second half of the 20th century, permitted by the laws of nearly all of the states.

The extent to which the various property hazards are insured at different times and in different parts of the world tends to vary with the amount of property subject to loss and with general commercial and industrial development. While life insurance. which may be regarded as typical of their personal forms, depends upon the availability of income for its purchase, the extent to which income is so employed seems to depend more upon the customs and attitudes of the people.

Organization of Commercial Insurance. — The organization for the conduct of insurance on a commercial basis consists of four principal parts, as follows: (1) insurers, whose principal function is to assume and carry the risk; (2) a field organization, the principal function of which is to maintain contacts with the public for the writing of insurance and the settlement of losses; (3) intercompany organizations called associations or bureaus, with a variety of functions including the establishment of standards, the making of rates, research, institutional advertising, dissemination of information, influencing legislation, and other activities designed to promote the interest of insurers; and (4) organizations of agents, called associations or boards. performing many of the functions listed under (3), designed in general to promote the interests of agents.

Insurer organizations fall into two classes, those organized as private enterprises, including individual underwriters. syndicates of underwriters, and corporations or joint-stock companies organized on a capital stock basis; and those organized as co-operative enterprises, including mutual companies or associations, reciprocal or interinsurance exchanges. and a number of special types. Although important at one time, the practice of individual underwriting, so-called because of the practice of indicating acceptance of the risk by a signature written at the bottom of the policy, together with an indication of the fraction to be assumed, largely disappeared. except as carried out through Lloyds of London. The capital stock form of organization is employed to provide all forms of commercial insurance but dominates in the property insurance fields. In general, mutual companies dominate in the field of life insurance.

In property insurance mutuals play a minor role but are a growing factor in the various forms of liability insurance, especially in the United States.

Field Organizations are maintained through a variety of channels. The functions include selling, inspection of property, to some extent underwriting (in this sense, acceptance or rejection of applications or conditions of acceptance to be imposed), and investigation and settlement of claims. Home offices of insurers may, of course. maintain direct contact with the public through their own salaried employees. Inspection and claims are sometimes handled in this way, but sales only rarely. Branch offices, or. particularly in the United States, general agencies, usually stand between the insurer and the sales force. Only in the Cnited States did the insurance agency become a full-time business or profession. Elsewhere direct selling or the use of part-time agents remained the rule. In Great Britain. bankers, merchants and other business or professional men act as agents, and even large owners of property may receive commissions on the insurance sold, in effect, to themselves: a practice frowned upon in the United States.

Associations.—The tendency toward association is highly developed in the insurance business — partly because of the highly technical character of some phases of the business and the need for exchanging ideas, and partly the desire on the part of various groups within the business to establish and maintain standards. A desire to provide protection against damaging legislation played a part in association activities in the United States. In the United States, also, state statutes encouraged property insurers to associate for rate-making purposes.

Government Regulation.—The importance of insurance in modern economies. its technical nature and the difficulty faced by most persons in attempting to appraise contracts and the companies offering them led to some measure of government regulation in all countries. The extent of the regulation varied, however. In the United States. it is quite detailed. Until the 1940s, regulation had been regarded as coming within the exclusive province of state and local governments. In a U.S. supreme court decision in 1944 (Cnited States v. Southeastern Underwriters Association et *al.*, 322 U.S. 533) it was ruled that insurance is commerce and, since insurance transactions traverse state lines. the business falls within the regulatory powers of congress under the commerce clause of the constitution. Subsequently, congress adopted the McCarran act (Public Law 15), giving the states until Jan. 1, 1948 (later extended to June 30. 1948), to revise their regulations so as to meet certain standards laid down in the act. The system of state regulation as revised apparently proved acceptable to congress.

In contrast to extremely detailed regulation in the U.S., British insurance is subject to only a minimum. pursuant to the Companies act, 1929, and the Assurance Companies act, 1909 and 1946.

Social Insurance. — The second broad division of the insurance field, social insurance, is of much more recent origin than voluntary or commercial insurance. The shift from an agricultural and handicraft economy to modern industrial society in the western world brought with it a new type of social insecurity for which social insurance was evolved as at least a partial solution. Germany, under Prince Otto von Bismarck, was the first nation to establish a system of social insurance on a national scale. Sickness insurance, compensation for industrial injuries, old-age and invalidity insurance were included in the original program and survivors insurance was added later. The schemes initiated in Germany relied upon existing institutions for their administration in so far as possible — funds established by community, industry or occupation in sickness insurance. workmen's compensation by trade associations, and old-age and invalidity insurance by territorial institutes. All funds were mutual and costs were shared by employer and worker or borne by the employer alone.

The principle of utilizing existing institutions generally was followed in other countries. Compensation for industrial accidents, received world wide acceptance, but provision for insurance varied widely. Compulsory sickness insurance was adopted in many European countries before World War II. At the same time, a shift from noncontributory pensions to compulsory old-age insurance was well under way. Twenty-one countries. 16 of them in Europe and j in Latin America had such plans, and in many

cases survivors' insurance and invalidity coverage had been-added. Several European countries follo ed England's lead in adopting unemployment insurance.

Social insurance made its appearance in the United States during the 1930s. Following the adoption of old-age pension plans by a number of the states and an unemployment insurance law by one (Wisconsin), the Social Security Act of 1935 provided for federal financial participation in state old-age pensions. aid to dependent children and to the blind, federal old-age and survivors' insurance, and inducement to the states to adopt unemployment insurance plans. After 1935, amendments have increased benefits and extended the scope of old-age and survivors' insurance.

By 1953 the International Labour office estimated that about one-tenth of the world's population had some form of social insurance protection. Included were about 150,000,000 in 45 countries having old-age, invalidity or survivors insurance; about 125,000,000 protected against loss of income resulting from sickness or maternity; about 90,000,000 entitled to unemployment compensation: and 200,000,000 entitled to medical care. (J. E. Hs)

INSURANCE: MISCELLANEOUS. Under this head are considered various types of insurance which are not dealt with under separate heads (see INSURANCE).

Burglary, Robbery, Theft and Larceny. — Insurance against these causes of loss is written on personal property in banks, hotels, stores, offices, factories and dwellings. Each of the perils is defined by policy conditions. Briefly. burglary. requires forcible entry of which there is physical evidence, robbery requires a taking by force or violence, larceny is the unlawful taking of property by an employee with intent to defraud, and theft embraces loss by any dishonest act, including burglary, robbery and larceny.

Banks usually insure against loss by burglary and robbery, and stocks of merchandise are insured against burglary only. Residence contents are covered against burglary, theft and larceny, and! when insured under the personal property floater policy, against all risks, wherever located. Open stocks of merchandise are usually insured under conditions of average (80% coinsurance). To collect full indemnity for a partial loss the insured must have insurance for the agreed percentage of the value exposed to loss.

Messenger, paymaster, interior robbery, safe deposit box, mercantile safe, and money and securities polices cover currency, coins, bullion, uncancelled stamps and contracts representing money or other property, such as stocks. bonds, etc.

Another type of policy covers money and securities against loss through dishonesty, destruction or disappearance. This comprehensive policy, issued to commercial concerns, combines protection once available only under five separate policies.

All Risks. — Jewellery, furs and works of art- may be insured against all risks wherever located, except losses caused by deterioration, vermin and war. The personal property floater on private residence contents is an all-risk policy, excluding only coverage on aircraft, motorboats and automobiles.

Fidelity Bonds and Suretyship. — Corporate suretyship has largely replaced personal guarantees for fidelity, honesty and performance of contracts. Honesty may be insured for individual employees in specified amounts and for groups of employees subject to a limit of recovery in any one loss. The honesty of any employees holding specified positions may be covered. Public officials, court officers, trustees and other persons occupying positions of trust are usually required to furnish bond for faithful performance. The obligor who gives bond, the obligee to whom the bond runs and the surety which guarantees the performance are all parties to the bond. Building and supply contractors are usually required to furnish a surety bond. Under all bonds the surety investigates the character and past record of the obligor; and, under contract bonds, his financial and skilled ability to perform the contract to be guaranteed.

Plate Glass. — Essentially an insurance against breakage, the risk of fire is excluded from the plate-glass policy. Only glass specified in the policy is insured. and wooden framework and lettering. The latter, unless specially insured, is not covered. Premiums are calculated according to the superficial area and type of glass to be insured. Stained and other valuable glass, lettering and painting are rated on a percentage of value. Although the policy provides' that the insurance company may replace damaged glass or reimburse the insured in money. the company nearly always elects to make replacement.

Third-Party Insurance. — Indemnities in respect of the legal liability of individuals or corporations to pay compensation to third parties for personal injuries or damage to their property caused by negligence on the part of an employer or his employees, or by defects in the ways, works, machinery or plant used in the employer's business, are almost universally sought. Policies are issued to cover the insured's entire legal liability, excluding, however, liability to a member of his family or to a person in his service. or liability assumed under contract. Within the limits of indemnity selected the insured is relieved of all monetary responsibility, including law costs incurred in defending claims) fraudulent or otherwise. All claims negotiations are conducted by the insurers who may if they wish relieve themselves of all further liability at any time by paying to the insured the maximum sum for which they are liable in respect of any one accident. The limit of indemnity stated in the policy is the insurance company's limit of liability ior all damages arising out of one occurrence. Policies suitably modified may be obtained by almost every kind of business. For individuals and householders the comprehensive personal liability policy provides this protection.

Property Owners Indemnity. — Called "O. L. & T." (owner's, landlord's and tenant's) liability insurance. these policies protect the insured against claims by third parties for bodily injury and damage to property sustained on owned or occupied premises. Claims of this nature arise out of allegedly slippery floors, stairs with broken treads or without. guardrails, acts of domestic animals, falling shingles. copings or ceiling plaster and similar causes. Claims by servants and other employees are not covered. For private dwelling owners or tenants the insurance under O. L. & T. policies is included with other coverage under the comprehensive personal liability policy.

Hail. — Hail insurance is carried mostly to protect growing crops, policies being written for the principal ones. The coverage is limited to a given maximum amount per acre for each type of crop, and the rates vary with the crop and the territory. In general the liability of the insurance company applies only aiter the crop is in a healthy growing condition.

Earthquake. — Coverage against loss by earthquake or volcanic eruption in some earthquake zones is written under supplemental contracts attached to fire insurance policies. with a deductible of 5% of the value of the insured property. The "fall of building" clause in the fire policy may be deleted for an additional premium. Elsewhere such insurance is written under separate policies with average conditions (50% coinsurance). A "bridging the gap" endorsement in these policies assumes loss by fire if the fire insurance ceases when the insured building is caused to fall by earthquake. In the United States, the Pacific coast and some of the most populous eastern states are in the zones carrying the highest earthquake insurance rates.

Tourist Baggage. — This limited form of insurance against loss by fire, transportation perils and theft covers wearing apparel, travelling equipment. portable typewriters and similar personal effects. while in transit or in the custody of common carriers, hotels, or parcel check rooms. This protection is included in the personal property floater policy.

Explosion. — Damage to the insured's property and claims by third parties for bodily injury or damage to their property, when caused by explosion of power boilers. pipes. flywheels, engines, and machinery are insured by casualty insurance companies. Explosion damage caused by heating boilers with a pressure of less than 15 lb., their connections and appurtenances in dwellings, factories and office buildings is insured by fire and casualty insurance companies.

Use and Occupancy. — Known also as business interruption indemnity or net earnings insurance, this form of consequential

loss insurance is widely carried by manufacturers and by retail and wholesale merchants. It may be purchased on a gross earnings basis with coinsurance conditions or upon net earnings with a daily or weekly limit of liability. It indemnifies for loss of earnings and fixed expenses which would have been earned by the business of the insured if not interrupted by the occurrence of the peril insured against, such as fire: windstorm, explosion or earthquake.

A form of use and occupancy insurance called extra expense insurance is frequently carried by banks. newspaper publishers and laundries. to reimburse them for the extraordinary expense of carrying on their services in rented quarters. or hiring the services of competitors to prevent interruption of business, follon-ing an insured catastrophe in their own premises.

Health.—When purchased in conjunction with accident insurance. coverage is obtainable by employed men and women to pay a weekly sum while the insured is totally disabled by illness, and a lesser sum while partially disabled. Policies are issued to those between ages 16 and 49. and. at increased premium rates. to those between ages 49 and 54. Payments are usually limited to 104 weeks. The rates for women are generally about 35% to 40% higher than for men. Coverage may be added for hospital Eees. nurse hire and surgical Eees upon payment of an additional premium. Policies may be had at reduced rates when the insurance payments begin one to four weeks after the beginning of disability.

Group Insurance. — This term usually applies to life and accident and health insurance. and to pension or annuity contracts. written to cover a group of lives such as all of the employees of one employer. The rates are based upon averages without physical examinations or individual applications.

(L. E. F.)

Hospital, Medical and Surgical. — The development of nongovernmental health insurance was a phenomenon of the first half of the 20th century. Although there were earlier experimental ventures. the British hospital schemes and Blue Cross plans in the United States and Canada after 1930 first provided popular mediums suitable for widespread effectiveness. Australia developed a pattern of government subsidy to approved private programs.

In England. the voluntary schemes gave way in 1948 to national health insurance under the Labour government, although some schemes continued to provide supplementary coverage. On the European continent. universal governmental programs providing benefits at varying levels became the general pattern; programs in some countries were begun in the 19th century.

The Canadian Hospital and Diagnostic Services act of 1958 provided nearly full hospital service in public nard accommodations; the program is administered by the provinces, all of which except Quebec had elected to participate in the program by Jan. 1959. Thereafter the United States remained the only important country without some form of compulsory national health insurance.

Blue Cross plans, sponsored by hospitals and the medical profession, pioneered in coverage of dependents and such risks as maternity. and provided certain items of hospital service regardless of their actual cost, usually in semiprivate rooms.

Commercial insurance companies in the United States. which prior to 1930 concentrated their health activities on loss of income insurance, followed Blue Cross by developing indemnity coverages providing dollar amounts toward room accommodations and a multiple of that amount (frequently ten times) toward ancillary services.

Surgical and medical coverage developed later, but began to catch up with hospital coverage in the middle of the century. Proportionally, independent programs extended further in the field of medical insurance than in either hospital or surgical coverage. Their basis of operation, usually through group medical practice, facilitated this. (A. G. S.; X.)

INSURGENCY, the status of being in armed rebellion. (To distinguish insurgency from aggression and belligerency, *see* AGGRESSION; BELLIGERENCY.) The objective sought by insurgents may be either a change of government or independent statehood. Insurgency has sometimes been described as a status intermediate between tranquillity and civil war. But what degree of organized control of armed forces and territory is necessary to transform an insurgent band into a rebel government fighting a civil war cannot be precisely defined.

Illustrative of this problem was the situation in Greece following World War II, which was characterized by uncertainly delimited and transitory territorial control. Greek insurgents operated from Albanian, Bulgarian and Yugoslav territory to which they fell back when hard pressed, only to recross the Greek border at another place.

Ill-defined limits to insurgent territory are common in the earlier stages of rebellion. An example is China before the Communists had consolidated their territory and established regular and extensive battle lines.

In international law an insurrection is a rebellion that has not attained the status of belligerency. Belligerent status arises from recognition of that status by existing states at the discretion of each. States recognizing belligerency assume duties of neutrality toward both parties.

Recognition of insurgency is a recognition of fact. It may entail limited intercourse with insurgent authorities and acquiescence in some of their acts of war. It does not entail the acceptance of duties of neutrality by the foreign state. The insurgents' right of making war is restricted to the territory and forces of the legal authorities and to foreign forces actively engaged in hostilities against the insurgents. For example, no right of visit and search of neutral vessels on the high seas is admitted by a state recognizing insurgency.

The parties to the four Geneva conventions of 1949 concerning war victims *(see* GENEVA CONVENTIONS) undertook certain duties toward insurgent forces complying with the laws of war. Minimum standards were established for the treatment of persons who had taken no active part or who had surrendered or been rendered *hors de combat* during "an armed conflict not of an international nature." These standards were made applicable not just to states but to "each party to the conflict," thereby embracing insurgents. *(See* PRISONERS OF WAR.)

Several terms have been used to describe units that fight under an insurgent banner. The terms revolutionaries and rebels have been applied to insurgents generally. both civilian and military. In both internal and international war, "volunteer" has been used to describe units hastily formed at the approach of an enemy and also units of foreign personnel, including, in Communist usage, the large numbers of Chinese engaged in the Korean hostilities. The term *francs-tireurs* ("free shooters"), describing French units formed during the Franco-Prussian War. has sometimes been used to refer to guerrilla bands in general. *Guerrilla* and *partida* (partisan), Spanish terms dating at least from the Napoleonic Wars, refer to irregular forces that strike and then melt into the populace.

Because partisans often are hard to distinguish from civilians, many writers have regarded them as illegal units. However, after World War II the Allied war crimes tribunals did not treat all partisan groups as outlaws. The 1949 Geneva Convention on the Treatment of Prisoners of War accorded benefits in both internal and international conflicts to members of irregular units that conform to the Hague Regulations on Land Warfare (1907) requiring a commander, an emblem recognizable at a distance, arms carried openly and obedience to the laws and customs of war. Insurgents are violators of the national law of their country and subject to punishment under that law. The Geneva 1949 regulations require judicial procedures in trials for treason and similar offenses. Insurgents possess privileges that expire with the loss of quasi-sovereignty. Only a successful insurgent community acquires the

more enduring rights and obligations of sovereignty. *See* also WAR; GUERRILLA WARFARE; BANDITRY. (W. L. GD.)

INTEGER: see NUMBER.

INTEGRAL CALCULUS: see CALCULUS, DIFFERENTIAL AND INTEGRAL.

INTEGRAL EQUATIONS. An integral equation is one in which the unknown function $f(x)$ appears in the integrand of some integral. One of the standard forms of such equations is

$$f(x)=g(x)+m\int_a^b K(x,y)\,f(y)\,dy$$

where $f(x)$ is the unknown function, m a parameter, while $g(x)$ and $K(x,y)$ satisfy certain continuity conditions.

The equation given above is customarily called a Fredholm equation after the Swedish mathematician. E. I. Fredholm, one of the early workers in this field, while one for which $g(x)=0$ is sometimes referred to as a Volterra equation, after the Italian mathematician, Vito Volterra.

The introduction of such equations is probably due to Pierre Laplace (1782) who considered integral equations of a simple type in conjunction with his work on differential equations. J. B. Fourier also considered particular integral equations in his work on expanding functions in terms of series of trigonometric functions. N. H. Abel in 1823 proposed a generalization of the problem of determining the curve for which the time of descent of a particle is a given function of the vertical height, the solution of which involved an integral equation. After that, many problems in physics arose whose solution involved the use of integral or integrodifferential equations. the latter being equations which involve both integrals and derivatives of the unknown function.

In the early part of the 20th century, integral equations were assiduously studied by David Hilbert and his followers. Later, extensions were made by considering equations of this type which involved the newer types of integrals, such as the Lebesgue or Stielties integral. Various criteria for the existence of solutions of such equations and methods for obtaining the solutions have been developed. Generally, solutions are found in terms of series or sequences of functions by methods involving series, successive substitutions. determinants, etc.

The equation

$$f(x)=m\int_a^b f(y)\,K(x,y)\,dy$$

has the obvious solution $f(x)=0$. It can be shown that other solutions exist for suitably chosen values of m, called characteristic values, and that associated with them is a sequence of orthogonal functions, the characteristic functions. Properties of these functions and the problem of expanding arbitrary functions in terms of series of them have been studied.

Integral equations are also closely related to certain boundary value problems which arise in differential equations. In the study of problems in physics involving the flow of heat or electricity, potential theory. or the motion of a vibrating membrane, differential equations arise whose solutions must satisfy certain boundary (side) conditions.

It was early noted that the solutions of such problems mere related to the solutions of certain integral equations. These relationships have been studied, and many of their applications discussed:

INTELLECTUALISM, a term applied, sometimes in a derogatory sense. to the tendency to emphasize or overemphasize the importance of thought at the expense of feeling or volition, or even of sensation and intuition. In moral philosophy intellectualism tends to identify virtue with knowledge, evil with ignorance.

In the theory of knowledge intellectualism or rationalism attaches more importance to thought than to sensation or intuition. In ontology it conceives the ultimate nature of reality to be some kind of intelligence, or at least regards the universe as intelligible through and through.

In Psychology it treats cognition as the primary mental function, as more fundamental than feeling or volition. In *aesthetics* it stresses the importance of the ideas expressed in. or suggested by, the object of aesthetic appreciation. In the sphere of religion intellectualism tends to attach supreme importance to theological doctrine or to religious philosophy rather than to religious sentiment or intuition.

INTELLIGENCE. The word intelligence (*inter-legentia*) was introduced by Cicero as an almost literal translation of Aristotle's term dia-noesis. In the scholastic psychology derived from Aristotle, its use implied a preference for the twofold classification of mental characteristics into intellectual or cognitive (*i.e.*, discriminative and directive) characteristics, as contrasted with dynamic or orectic (*i.e.*, affective and conative), which Aristotle proposed in place of the threefold scheme favoured by Plato. "Intelligence" was thus the abstract quality common to. and peculiar to, all "intellectual" processes; *i.e.*, sensation, perception, memory. imagination, reasoning and the like (see PSYCHOLOGY).

With the decline of the scholastic faculty psychology, the term dropped out of use, but it was revived by Herbert Spencer, who gave it a biological interpretation. The conception of intelligence as an inherent characteristic of the human mind he expressed by describing it as inherited and therefore innate; and. as its distinctive behavioural manifestation, he emphasized the way in which the more intelligent type of animal adapts or adjusts its activities in the face of its complex and ever-changing environmental circumstances.

In the writings of Spencer and his successors — Sir Francis Galton, Alfred Binet, Cyril Burt and C. E. Spearman — the word intelligence therefore acquired a standard meaning as a technical term, and has usually been held to imply three basic distinctions: (1) it connotes a cognitive or intellectual capacity, as distinct from other characteristics of the total personality; (2) it implies a general quality (i e, it enters into all types of intellectual processes and is not specific to any one type of ability); (3) it is an inborn or innate quality, as distinct from those abilities that are acquired through individual experience at home, at school or elsewhere.

In the first instance this concept of an inborn, all-round, general ability was derived mainly from introspection, general observation and philosophical speculation or reason. The conclusions so reached therefore required to be more closely checked and verified by experiment and statistical analysis. The leaders in this scientific approach were Galton (*Human* Faculty, 1883, and later writings), Binet (1890–1911) and students of animal psychology such as C. Lloyd Morgan (1890), E. L. Thorndike (1910) and Wolfgang Kohler (1915). The first effective tests of intelligence (partly suggested by those of Galton) were developed by Binet and his collaborators in France, revised for other countries by Burt (Britain), W. Stern (Germany) and Lewis Terman (U.S.) and the earliest systematic studies (based on the statistical methods introduced by Galton) were those of Karl Pearson, Spearman, Burt, Thorndike and William Brown.

The method adopted by the leaders in their numerous inquiries involved a combination of experimental testing and statistical analysis. It consisted essentially in observing what mental capacities tend to go together, and it led to the theory that there does exist in human beings a single broad mental power (additional to various special abilities) which may be called general intelligence On comparing the efficiency of various types of test, it appears that intelligence is revealed particularly in good use of verbal symbols. ability to perceive analogies. capacity to abstract and classify, mathematical ability, problem solving and those capacities for understanding relations and causal connections which have been increasingly invoked in experiments on intelligence.

Some educators believe erroneously that intelligence is defined by a mere average score on whatever combination of such subtests a psychologist happens to use. But the exact weights to be given are actually fixed through intelligence's being uniquely and objectively defined by the simple structure criterion in factor analysis. The typical mental processes in such "highly g-saturated" performances can be seen by inspecting such modern tests as the

Stanford-Binet, the Murray House tests and Raven matrices in Britain, the American Bellevue-Wechsler and A.C.E., the Cattell Culture-Fair scales and the Thurstone Primary Mental Abilities battery.

Biological Conditions. — The effects of age and of inheritance as indicated by results obtained with tests of intelligence (as above defined) have become well understood through the work of such researchers as Terman, Burt and Jean Piaget. There is a rapid augmentation of reasoning and perceptual ability between 3 and 6 years of age, followed by a flattening of the development curve around 14 years of age. Indeed, after 14 there is negligible increase in the basic ability to understand the most general relations.

Nevertheless, the individual increases his actual problem-solving capacity by increased knowledge and can better perceive relations in special fields when given close acquaintance with the particular problems of those fields. After the age of about 23 there is actually a slight decline in score on speeded intelligence tests (*i.e.*, as they are usually given), but, if reasoning capacity without speed is tested, no such decline occurs. unless and until senility supervenes. Considerations of age trend. brain injury, effect of speed limits and content have lent support to a theory by R. B. Cattell that after childhood it is necessary to deal with two distinct but highly correlated general ability factors. fluid ability, which resides most in perceptual and speeded tests and shows age changes, and crystallized ability, which is invested in more specific intellectual habits and unspeeded tests, showing no age decline.

No significant differences in intelligence have been found between men and women, and it is not even certain that qualitative differences, as shown by the somewhat higher scores of men in mechanical reasoning and of women in verbal ability, may not be considered as temporary cultural effects. On the other hand, there is ample evidence from comparing the intelligence of identical twins reared in different homes with that of, for example, unrelated children reared together that intelligence is largely inherited. Burt among others presented evidence for the inheritance of differences in intelligence, the correlations and other constants agreeing closely with what mould be expected if intelligence (like stature and other graded characters) were transmitted in accordance with the Mendelian laws for multifactor inheritance.

The usually accepted figures, based on the soundest and most extensive studies (*e.g.*, of Barbara Burks in the U.S. and Burt in Britain) employing verbal intelligence tests, assign 75% to 80% of the observed test variation in the general population to genetic factors and the rest to environmental physical and mental conditions and opportunities in home and society. Later work by Cattell, G. F. Stice and N. F. Kristy, using the Culture-Fair tests and improved statistical designs, gives a value of 78:22 to the heredity: environment variance ratio in the general population. but shows that this arises from a 70:30 ratio for intelligence variation within families and a 93:7 ratio for variation *among* families. In all these researches. whatever unreliability exists in test administration and scoring tends to inflate the percentage assigned to environment. By contrast, no experimental design has been found for reliably assigning to heredity and environment the true fractions of the appreciable differences of average intelligence test score found among widely different races.

Piaget, G. D. Stoddard, G. A. Ferguson and others experimented and hypothesized on the manner in which environment produces its effects, leading to concepts, based as yet on statistically insufficient experiment, of the trial-and-error formation of "schemata" and "transferable generalizations" in the mind of the child. On the other hand there is no clear evidence of imprinting; *i.e.*, of exercise at the right maturational moment being essential to development of function. Psychologists have given insufficient attention to physical, especially uterine, environment as a source of the observed environmental, nonhereditary variance in intelligence.

Social and Educational Associations and Uses of Intelligence Measures. — Tests of intelligence are validated in a pragmatic sense by the widespread finding that what is called intelligence in social and educational evaluation turns out to be closely identified with what is measured. Thus children drafted to schools for mental defectives score very low, selective schools average above other schools, and universities above high schools. Test scores are predictive of educational success and of occupational success in most (especially complex) occupations.

Socially there is a slight tendency for higher social class (or complexity of occupation) to be associated with higher intelligence score, even on culture-free intelligence tests, and this fits the school observation that some trend exists for better mental capacity to segregate to better social status levels. Nevertheless, the greatest absolute storehouse of high mental capacity is the lower middle class — skilled and semiskilled workers — because it is the largest class in sheer numbers.

Since it has been shown that. even in the same social class, less intelligent parents tended, in the first half of the 20th century, to produce a larger fraction of the following generation, it is probable that. apart from dominant genes and a survival rate favouring the intelligent, a decline occurred in average intelligence in industrial countries in the first part of the century. However, a survey around 1950 showed that the negative correlation of intelligence with family size had been much reduced in Britain and had practically vanished in Sweden.

Surveys in the U.S. suggested that the national resources of intelligence, for supplying persons fitted for training as higher scientific, administrative and professional workers, are not so great as once had been thought. Of persons with the requisite intelligence and monetary support to obtain, for example, a medical degree, perhaps only one-fifth also have the persistence to face continuous study or the temperamental qualities to deal with the emergencies and social demands of such a profession.

Attention to resources of intelligence. particularly in regard to manpower for scientific research, led to application of intelligence tests still more widely in industry and education. Their use in selecting for military promotion and specialized training in World War II was very extensive. In the U.S. systematic surveys of community intelligence were proposed and pursued by J. B. Wolfle, R. L. Thorndike and others, while in Britain the nation-wide systematic guidance of children at 11+ years of age into different educational streams, affecting curriculums and careers, is made about equally on intelligence tests and on school achievement at the time.

Physiological Basis of Intelligence. — This is a complex matter about which only a few basic concepts receive general agreement. From a comparison of differential animal species it has long been evident that intelligence is closely correlated with the size of the cortex or that fraction of the brain which is not directly concerned with internal bodily adjustments, muscular balance, etc. Brain operations on animals show that the decline in problem-solving capacity, as well as in the ability to learn complex habits, is just about proportional to the weight of brain removed. Brain injuries in man point to the same relation. A particular habit or capacity may be lost through injury and may be relearned, but there tends to be a loss in general power of abstraction and problem solving roughly proportional to the extent of cortical damage. In the human brain certain areas appear to be definitely associated with relatively specific bodily functions; *e.g.*, the area at the back of the head with visual perception, other areas with hearing, touch, smell, etc., others again with voluntary movement.

Intelligence, however (in the technical sense), according to most anatomists, is associated with somewhat general structural qualities characterizing the brain cortex as a whole. Thus, microscopic studies of the brains of low-grade defectives show that their nerve cells are comparatively few in number and exhibit comparatively few branches, and both the cells and their branches appear to be arranged far more irregularly than those of the normal person of the same age.

No drug that significantly increases intelligence in normal persons is known. Caffeine in coffee (as well as Benzedrine and related drugs) produces increased problem-solving ability, largely by improving memory and alertness. However, in depressed mental patients such drugs have been shown also to lead to significant improvements — returns to normal — in general intelligence-test performance.

On the other hand, there are many special physiological influences that will reduce intelligence. Twenty grams of alcohol will produce, in the average person, a measurable decline in intelligence-test performance or other forms of judgment; failure of thyroid secretion produces a considerable decline, as is well known through the history of cretinism; and failures of judgment are rapidly produced by anything that interferes with the supply of oxygen to the brain.

Intelligence in Animals. — The capacity of animals, even of the higher apes, to perceive complex relationships is far below that of adult man and seldom exceeds the level of a three-year-old child, yet it is of the same nature as the intelligence of man. Blind trial-and-error behaviour, the very antithesis of intelligence, is common in animal behaviour. But if animals are presented with sufficiently simple problems, such activity is observed to give way to a thoughtful pause, followed by sudden insight and rise to a new level of adaptive but untaught behaviour. In Kohler's classical experiment a chimpanzee given two hollow sticks, each too short to reach a banana outside the cage, was observed thinking and then fitting one stick into the other to provide a new tool long enough to do the job. Similar switches from random behaviour to "insightful" solutions have been observed experimentally in dogs and even in hens. However, the majority of complex and seemingly very intelligent things that animals do represent either inherited patterns, which go mildly astray anywhere outside the natural environment, or are the result of prolonged, blind. trial-and-error learning, as in most circus animals. Most of their relation-perceiving capacity is concerned with spatial or very simple causal relations, and they conspicuously lack the ability to abstract, generalize and deal with relations between abstractions which makes possible man's use of general symbols in language, mathematics, etc. See also ANIMAL BEHAVIOUR; PSYCHOLOGY, COMPARATIVE.

Relation of Intelligence to More Specialized Abilities. — Spencer, in his account of the development of cognitive capacities in the race and the individual, held that the general cognitive capacity which he termed intelligence progressively developed into more specialized abilities. The application of factorial methods to the results obtained with mental tests provided some confirmation of this view. Between 1913 and 1917 a series of investigations among British school children of various ages provided conclusive evidence for certain special abilities (*e.g.*, verbal, numerical, manual and spatial abilities) as well as more formal capacities such as memory and imagination.

Among younger children the general factor of intelligence accounted for the greater part of the individual differences; but aith increasing age there appeared increasing specialization, most of the more specific abilities maturing before the end of the pubertal period. In the U.S. a number of researches carried out between 1930 and 1950 by Louis Thurstone and his colleagues threw further light on the number and nature of these more specialized capacities.

The primary abilities (as Thurstone termed them) include what may be labeled as verbal, numerical, spatial, reasoning, perceptual and other capacities of restricted form. A person may develop to a considerable extent in all aspects of one of the forms of ability without equivalent development in the others, though there is also some tendency for all of them to be related as different manifestations of one general intelligence. The causes of these differential developments, whether innate or depending upon interests and environment, are not known.

The measurement of intelligence and of primary abilities was first undertaken with such objectives as that of giving better guidance to pupils in school, selecting men for more complex occupations and, at the lowest levels of ability, separating children who are merely retarded in school through absence, etc., from those who are feeble-minded.

The movement which then began succeeded brilliantly in a practical sense and added greatly to the theoretical grasp of intelligence and its associations. On the practical side the separation of mental defectives became far more reliable than it had been, and the special needs of those who lack that minimum of intelligence necessary to take care of themselves came to be better understood. Bright children also can be picked out with greater reliability than by ordinary examinations, and good predictions of their rate of learning can be made. For example, future performance in such areas as essay writing, mathematics and classics, are closely associated with level of intelligence, but drawing, geography, music and athletics are less predictable, because they depend more on special aptitudes.

Intelligence Contrasted With Related Powers. — The reverse procedure from that of predicting adult accomplishment from childhood performance was carried out in Terman's studies of the childhood records of well-known men of genius. These performances, compared with those of living children of known ages, show that children who became geniuses showed intelligence decidedly above their age, though some (*e.g.*, Charles Darwin) did not do well in school. Genius, as the follow-up studies of highly intelligent children show, requires something more than intelligence — perhaps also that touch of madness of which John Dryden wrote ("Great wits are to madness near allied, and thin partitions do their bounds divide"). But intelligence is the first ingredient. Creative imagination has a considerable association with intelligence, though always some indefinable additional power is found at work.

On the other hand, though intelligence, as capacity to comprehend, must be analyzed out from the total realm of intellectual performance, it is astonishing to see how many apparently unrelated powers are actually considerably dependent upon intelligence. Though memory can be conceptually separated from intelligence. goodness of memory (in all but rote, or meaningless, memory) is highly related to goodness of intelligence. The size of the vocabulary, for example, is an excellent indication of intelligence. Again, intelligence operates not only in reasoning but in almost every act of perception, so that the ability to judge where a ball will be in a game of tennis involves intelligence. However, although it is clear from both human and animal psychology that by intelligence is meant the capacity to perceive and handle relationships, and that by higher intelligence is meant capacity to handle more complex relationships. the logician has not yet come to the psychologist's aid by indicating criteria through which the "complexity level" of a relationship, in the hierarchy of relationships, can be independently stated. Until that is done. there is some degree of circularity in the definition of higher intelligence. See also PSYCHOLOGICAL TESTS AND MEASUREMENTS; PSYCHOLOGY; THINKING AND PROBLEM SOLVING, PSYCHOLOGY OF.

INTELLIGENCE, ANIMAL: see ANIMAL BEHAVIOUR; PSYCHOLOGY, COMPARATIVE.

INTELLIGENCE, MILITARY AND POLITICAL, the acquiring of information on a national scale, usually about a rival. but sometimes about an ally or a neutral country. Counterintelligence (or security) is the safeguarding of a country's own secrets. Although mainly related to war and to defense measures in peacetime, intelligence and counterintelligence are also concerned with the collection and safeguarding of diplomatic, economic and industrial information. Clearly the acquisition and safeguarding of information are closely associated; in most countries they are both the concern of the same organization.

The effectiveness of counterintelligence measures may often depend on the amount of positive intelligence available; correspondingly. the efficient acquisition of information may hinge on adequate security. Intelligence work involves not only the collection of information, but also its collation and the estimation of its value and reliability, and the making of reasonable deductions from it.

The outstanding examples of intelligence designations in accordance with the general purpose for which the intelligence has been

produced are strategic and tactical. Strategic intelligence is designed primarily to satisfy the needs of the strategic planners and policy makers of national governments or very high-level commands.

Tactical intelligence, which is known also as both combat and operational intelligence, is intended chiefly for use by military tactical commanders and units. For example, the broad intelligence which influenced the Allied decision to attempt a major landing on the Normandy peninsula in World War II was strategic; the detailed intelligence used in the preparation of military plans for carrying out this strategic decision was tactical.

Designations of intelligence according to subject matter are numerous and continue to multiply with the increasing division of labour and specialization in large and complex intelligence organizations, especially at the government or strategic level. For example, military intelligence, which was once the comprehensive term for all intelligence relating to military matters, has been partially superseded in practice by army, air and naval intelligence. Each of the latter three, in turn, has been broken up into several fields of intelligence specialization. Order-of-battle intelligence, for instance, deals largely with the organization, strength, disposition, weapons, equipment, logistics, training and tactics of armed forces.

Geographic intelligence, the comprehensive term for land. sea and air data required for military plans and operations, includes several subdivisions of major importance, such as topographic, hydrographic, weather and meteorological intelligence. Transportation intelligence, which was once an integral part of geographic intelligence, has itself become a separate major field. Tremendous advances in the weapons and equipment of warfare have led to the emergence of technical intelligence as a field of vital importance to national security everywhere. Part and parcel of technical intelligence is scientific intelligence, which has brought forth its own progeny of intelligence specializations on nuclear fission, electronics, guided missiles, telecommunications and chemical and biological warfare.

The fields of political, economic and sociological intelligence have come to be regarded as having great importance for a nation's armed forces as well as for its foreign service. Military scientists are in general agreement that the military planner and policy maker must know the governmental structure, the political groupings, the national policies and objectives, the industrial complex and the social matrix of a potential enemy. Moreover, commanders of forces operating in foreign countries must be similarly informed if they are to deal effectively with guerrilla and resistance activities, satisfactorily administer local government on a wartime basis and conduct a sound psychological program. The fact that the Nazis either did not have or did not use adequate political, economic and sociological intelligence on the Soviet Union has often been cited as a significant factor in the failure of the World War II invasion of the U.S.S.R. by Germany.

Historical. — From earliest times, rulers and governments have attempted to acquire information about rival countries, and rival armies about their opponents and about the topography and other matters in a probable theatre of military operations. Local military information during a campaign, or before battle, was sometimes obtained from local inhabitants, but more often by means of cavalry patrols, while long-term information was obtained through agents (or spies), traitors and casual travelers.

Indeed, the history of intelligence, as distinct from military reconnaissance in the field, is very largely the story of agents and spies. To define a spy precisely is difficult and the word has slightly different meanings according to the country and conditions. A man seeking information while dressed in military uniform is generally considered not to be a spy or an agent but a scout who, if apprehended, is entitled to treatment as a prisoner of war. On the other hand, one whose role is to obtain secret information, by clandestine methods while dressed as a civilian, is an agent or spy and in most countries is liable to the death penalty if caught.

Further, an individual may be a traitor as well as a spy or an agent if he works for a foreign country against his own. Difficulties arise in interpreting these definitions in the case of irregular forces who do not wear proper or easily recognizable uniforms and with revolutionary forces. (*See* ESPIONAGE; PRISONERS OF WAR.)

From the middle ages to the late Renaissance diplomacy and intelligence were so closely bound together that foreign ambassadors were sometimes regarded as little better than spies. In particular, the Venetian republic established embassies and missions abroad and made a point of obtaining what would now be considered remarkably full intelligence reports from its ambassadors and agents. In England espionage was a serious business by Elizabeth I's reign, when an elaborate intelligence system was organized by Sir Francis Walsingham (*q.v.*) in order to obtain information from the continent. mainly from Spain. So great was Walsingham's enthusiasm for intelligence work that, in the absence of public funds, he devoted almost the whole of his considerable private fortune to furthering it.

More than a century later, in the reign of Queen Anne, the chief organizer of British intelligence was Daniel Defoe, who may be said to have been the founder of the modern British secret service — a role in which the author of *Robinson Crusoe* is not familiarly known.

Espionage flourished in the Napoleonic Wars and it is difficult to select individuals for special mention. Perhaps Napoleon's great intelligence organizers, Joseph Fouché and René Savary (duc de Rovigo), were the best known and most successful. Much of Napoleon's military success was a result of the diligence with which his famous chief of staff, Marshal Louis Alexandre Berthier. collected information in the field.

Until several years after the Napoleonic Wars intelligence activities were greatly restricted by the limitations of communications. The horse was in those times the swiftest means of travel on land and the sailing ship by sea. These were also the quickest agencies for passing information, with the exception of the carrier pigeon — popularly believed to have been used to convey the result of the battle of Waterloo to Nathan Mayer Rothschild in London. This means, however, was not practised extensively or properly understood until later, by which time it had been superseded by telegraphy.

The limitations of the times were naturally less hindrance to the collection of long-term, or strategic, information than to that of tactical or battle intelligence. Rival navies were nearly always completely in the dark about each others' movements, the first warning of the approach of an enemy squadron invariably being given by the lookout in the crow's-nest of a scouting frigate only a few miles ahead of the main fleet. On land, comparatively large armies could bivouac or maneuver within a few miles of each other in mutual ignorance. In spite of his considerable force of cavalry Napoleon was unaware of the direction of the withdrawal of Marshal Blücher's Prussian army after Ligny and Quatre-Bras and was largely surprised when it reappeared on the battlefield of Waterloo 48 hours later.

Developments Since the Mid-19th Century. — The latter half of the 19th century saw revolutionary changes in means of transport and so of passing information. Railways, the steamship, the submarine cable and the telephone, and the internal-combustion engine all played their part. Together with developments in other fields, these increased the tempo of diplomacy. Under these conditions a good intelligence service paid large dividends and in consequence the great powers tended to maintain intelligence organizations of ever-increasing size and efficiency. The 20th century was to witness the introduction and rapid development of aircraft and the universal use of wireless telegraphy — two inventions which further increased the potentialities of a good intelligence system.

Apart from new scientific aids, the general conditions of World War I favoured intelligence activities in neutral countries. In western Europe — the main theatre of war — the rival armies faced each other in static positions at close quarters for four years, on a front extending from the English channel to Switzerland. This line of battle was flanked by neutral countries — the Netherlands and the Scandinavian countries to the north and Switzerland to the south — where spies and agents of both sides could work in com-

parative safety. British intelligence earned a deservedly high reputation during the years 1914–18. Two of its earliest successes were the immediate and unobtrusive arrest on the outbreak of war of practically all enemy agents in the United Kingdom, and the acquisition of the German naval cipher, which, for some time, gave the British admiralty prior notice of all major movements by the enemy fleet. M.I.5 became a legendary organization and. it must be confessed, often got credit which was properly due to other agencies.

World War I produced many agents who worked in neutral countries as well as from belligerents. Among the best-known was the German Kapitan Franz von Rintelen who was sent to the United States in 1915 to sabotage American aid to the Allies. The security measures in neutral America at that time were lax, as the United States had up to then escaped the intensive espionage activity which Europe had experienced for centuries. In consequence von Rintelen had considerable success, until U.S. entry into the war in April 1917 put an end to his activities. Perhaps the most publicized spy of all time was the Dutch-born agent known as Mata Hari (born Margaret Gertrude Zelle) who operated in Paris, Rome, Vienna, Berlin and other continental cities, from 1905 until her execution as a spy in France in Oct. 1917.

Long before the outbreak of World War II in 1939 intelligence and counterintelligence had ceased to be solely concerned with diplomatic and military secrets; it became one of the main duties of a national intelligence service to uncover industrial and scientific data on which the war potential of its enemies, or likely enemies, increasingly relied.

After the end of hostilities in 1945 "cold warfare" conditions, and the development of nuclear weapons. further extended the scope of the work of the intelligence organizer as well as of its urgency. There was hardly a field of human activity which was not liable to be probed by the intelligence agent, or which had not taken on a security aspect.

The methods of obtaining intelligence have been largely misrepresented by fiction writers and film producers. In popular estimation intelligence is usually associated with the glamorous spy, disguise, forged passports and clandestine meetings. It is untrue to say that these methods are never employed, but they are the exception rather than the rule. A very considerable part of all useful intelligence is gained by routine methods: from the press, through travelers, businessmen and others who may pick up something in the course of their normal work; by piecing together a number of apparently trivial facts which in isolation are worthless, but together may be of considerable value. The professional agent or spy is, generally speaking, sparingly employed, or reserved for missions of special urgency. Most of those who provide information are casual agents with no professional status in the intelligence world.

The so-called international spy is, however, worthy of mention. Mostly men, but sometimes women, they may be said to be products of the 20th century. Invariably persons with little or no national loyalties, they are often of mixed race, frequently with a grievance against their own country. Many have criminal records. Their information is rarely of much value; they work for the highest bidder. but are quite prepared to double-cross their first employer if they find a better one. Nevertheless, they flourished in considerable numbers in the period between World Wars I and II. Paris, Brussels, Geneva, Cairo and other cities where communications meet and international affairs are conducted, were their clearinghouses. They were thoroughly unreliable, and their haunts were usually well known to the police and security agencies. Yet, a few of them seem to have had some success, and even standing, in the intelligence world, as was revealed by a number of arrests and trials in the 1930s.

Intelligence in World War 11.—By reason of the development of scientific equipment, and the world-wide and fluid nature of military operations, intelligence during 1939–45 reached a high pitch of activity and efficiency. In most theatres of land operations there was no continuous and heavily manned front line; sometimes the belligerents became inextricably mixed. The number of different nationalities involved and the frequent difficulty of distinguishing friend from foe made the work of the agent and military intelligence personnel profitable in countries such as Belgium and France (1939–40 and 1944–45), Norway (1940), the middle east, Burma and Malaya. Conversely, counterintelligence was much more difficult.

The means of gathering information was greatly increased by scientific developments. Aircraft, and particularly photographic reconnaissance, made it possible to unmask installations and troop dispositions in both the strategic and tactical fields. Wireless interception and ability to "break" mechanically even the most intricate cipher or code, made the acquisition of information by this means a regular feature of intelligence procedure.

In this connection it should be noted that the United States' intelligence successfully broke the Japanese cipher before Pearl Harbor. This enabled the United States government to have prior information of Japan's generally hostile intentions, although it did not give early warning of the actual time, place or manner of attack. See CRYPTOLOGY.

Deception was practised to a greater extent than ever before. Every plan of operations was masked by a skillfully prepared "cover plan"—in other words a bogus plan which the enemy was intended to discover and to regard as the real plan. Before the battle of El Alamein in Oct. 1942 a concentration of troops was simulated by means of dummy tanks, vehicles, camps and water points. Before the landings of U.S. and British troops in Normandy in June 1944 a most elaborate cover plan was designed with the object of giving the Germans the impression that a landing in the Pas-de-Calais was contemplated. Large camps and vehicle parks were established in Kent and Essex, and bogus wireless traffic was maintained in order to direct attention toward the Dover and Calais areas and away from Normandy. A possible landing in Norway from the east coast of Scotland was also simulated on the wireless.

The older intelligence methods were greatly extended in World War II. Elaborate Allied espionage systems were organized in Norway, Denmark. the Netherlands, Belgium, France, Greece, Burma, Malaya and other occupied territories. Contact was maintained by means of clandestine wireless sets and personnel dropped by parachute or landed from submarines or small craft. (In Japan a most successful spy was the German press correspondent Richard Sorge, who was a member of the Nazi party but nevertheless a convinced Communist and a Soviet spy.)

Intelligence in the Cold War.—After 1945 many new factors arose which affected intelligence work. International frontiers were redrawn; countries with centuries of independence became satellites of the U.S.S.R.; colonial and protected countries gained full independence. As an outcome of these great changes many thousands of persons became displaced and stateless and many others left their old homelands and sought sanctuary elsewhere. These conditions made infiltration by agents, and the path of the spy, comparatively easy. In addition, the division of most of the world into two sharply defined blocs—eastern Communism and western democracy—produced subversive elements of a new type. Educated men and women holding responsible positions in the west had, for what they believed to be idealistic motives, defected to Communism. Conversely, individuals from Communist countries sought and obtained political asylum in the west.

In Sept. 1945 Igor Gouzenko, an official in the Soviet embassy in Ottawa. defected to Canada and thereby uncovered the activities of Klaus Fuchs and Alan Nunn May who were employed in Britain in nuclear research work of the greatest secrecy. The extent to which these two men's subversive activities helped the U.S.S.R. is difficult to judge. but they may have assisted Russia considerably in developing the atom bomb, and thereby hastened the end of the British-U.S. monopoly.

At that time Bruno Pontecorvo was also employed in Canada on atomic research. In 1950 he disappeared from Helsinki, Fin., and went to the U.S.S.R.. where he remained.

In 1954 a Soviet agent, Vladimir Petrov, and his wife, who were both employed at the Soviet embassy in Australia, dissociated themselves from the U.S.S.R. and were given political asylum by the Australian government. This disclosed a vast network of

Soviet espionage in Australia. Not all these individuals were professional agents. With some their defection was due to genuine, if misguided, ideological beliefs.

The number of defections from one ideology to another in the years after World War II was greatest from east to west. In Berlin alone tens of thousands crossed permanently from the eastern to the western sectors each year, whereas the numbers in the opposite direction were small. Only a very few were spies; but some were, and it demonstrated the ease with which agents could be transferred to the west from eastern Europe. Nor was Berlin the only place. Similar facilities existed in many parts of Europe where east-west frontiers were contiguous, and in many parts of the world outside Europe; *e.g.*, Hong Kong. After 1945 the opportunities for '(planting" agents in research establishments, service units, government offices, docks and factories increased.

As a consequence of such conditions the security side of intelligence developed and expanded in all national intelligence organizations. Security in Great Britain was clearly easier than in most countries. Its position as an island made it possible to impose strict control over entry and exit, and its population was unusually homogeneous. This reduced the number of likely traitors and the chances of subversive activities. States with land frontiers with other countries had a much more difficult security problem. The U.S.S.R. had the additional anxiety of satellite states and a large non-Russian population of doubtful loyalty. Although otherwise favourably placed from the security point of view, the United States had a less homogeneous population than Great Britain and this is reflected in the very elaborate security organization which it maintained.

The Korean War (1950–53).—This conflict provided unique opportunities to both sides for the acquisition of tactical information. After the first few weeks, when operations had stabilized, it was very difficult for either side to make a tactical move of any significance without its opponents receiving prior warning. This was due very largely to the fact that North Koreans and South Koreans are of the same race, speak the same language and dress in a similar manner. This made the task of the native intelligence agent a relatively easy one.

Conversely, the task of those responsible for tactical security was more difficult. On the other hand, it was probably more difficult for both sides to gain useful strategic information than is customary in modern war—due to the North Korean and Chinese "volunteer" forces possessing practically no aircraft, and the strategic reconnaissance of UN aircraft being confined, for political reasons, to areas south of the Yalu river. In this connection it should be noted that the original attack by North Korea on the Republic of Korea (South Korea) in June 1950 was to a very large extent a surprise, as was the participation of Chinese troops in Oct. 1950.

Modern National Intelligence Organizations.— The general pattern of intelligence systems in all countries is very similar. In all there is a higher directing organization in the home capital which deals with political, economic and industrial intelligence, security policy and, where necessary, co-ordinates intelligence work in the separate fighting services. Intelligence organizations are represented abroad at embassies, consulates and vice-consulates. Within the fighting forces intelligence is organized, collected and sifted by the service intelligence staffs.

Although the general organization and methods of collecting information are common to most countries, there is a marked difference in security, or counterintelligence, methods. In most democracies the conduct of security measures is somewhat limited by the need to proceed according to ordinary law, which is applicable to military and police personnel engaged in security duties in the same way as to other citizens. In many other countries the secret police, who are responsible for security, have exceptional powers of arrest, detention and interrogation.

It is one of the chief duties of the security side of a national intelligence organization to safeguard the system and methods by which it operates. It is, therefore, not surprising that detailed information concerning the organization of intelligence in various countries is scanty. The following notes give in outline the organization in the four major countries: the United States, Great Britain, France and the U.S.S.R.

United States.—The United States has shown great generosity and understanding in giving asylum, and a home, to large numbers of political refugees and stateless persons from Europe. This liberal immigration policy since 1945, although it has served the country well, has placed emphasis on the security side of intelligence, since among so many foreigners, without inborn loyalty to the United States, some were almost certainly spies. The three fighting services have their own intelligence services; in addition there are many other agencies which deal with various aspects of intelligence. All intelligence is controlled by the Central Intelligence agency (CIA), which was established in 1947 to work under the National Security council. The functions of the agency are: (1) to advise the National Security council on security matters; (2) to co-ordinate all departments and agencies in relation to intelligence; (3) to correlate, evaluate and distribute intelligence information to the appropriate agencies; (4) to deal with certain matters common to all intelligence agencies; (5) to perform such other intelligence functions as the National Security council may direct.

A body known as the Operations Coordinating board is also concerned with the security side of intelligence. The director of the CIA is a member of this board, the purpose of which is to provide for the integrated implementation of national security policies by the many agencies involved.

Great Britain.—The central organization for British intelligence is the Joint Intelligence bureau which is responsible for: (1) coordinating intelligence in the three fighting services; (2) intelligence work common to all three fighting services; (3) economic and scientific intelligence; (4) intelligence relating to guided missiles and other new weapons.

Each fighting service has its own intelligence organization. Those of the Royal Navy and Royal Air Force are mostly concerned with technical matters; that of the army is of a more general nature and on a larger scale. Before the formation of the Joint Intelligence bureau after World War II, military (*i.e.*, army) intelligence was the agency mainly responsible for many items of general intelligence now within the province of the Joint Intelligence bureau.

The acquisition of intelligence overseas is to a considerable extent the responsibility of the service intelligence organizations, mainly the army. Counterintelligence at home is vested in a number of agencies. Those primarily responsible are the Joint Intelligence bureau and the three service intelligence organizations, but the civil police, through the home office, are also closely concerned. The personnel of intelligence agencies have no powers of arrest, detention or interrogation. The general procedure is that the intelligence agencies provide the information, while Scotland Yard and the various city and county police forces act on the information.

Sometimes the civil police in their normal anticrime work unearth espionage activities. The special security agencies and the civil police work in close co-operation.

France.—Each of three fighting services has its own intelligence department, known as the deuxikme bureau, which deals with various aspects of intelligence. These three service bureaux are linked to the headquarters of the deuxikme bureau at the ministry of defense. All security matters (including counterespionage) are dealt with by S.D.E.C.E. (Service de Documentation Extérieure et de Contre-Espionnage) and D.S.T. (Direction de la Surveillance du Territoire). Each ministerial department is responsible for its own security. Security within the armed forces and services is the responsibility of the *securité* militaire. As in Great Britain all security agencies work in close co-operation with the civil police.

U.S.S.R.—Before the 1917 Revolution Russian intelligence was primitive and inefficient; security was confined largely to the investigation of movements and plots against the regime. After the early 1930s a highly efficient Soviet intelligence and counterintelligence system spread its net over every phase of national life and over activities of the U.S.S.R. in foreign lands. At the

beginning of the 1960s, under the direction of the State Security committee, there were three main branches of the organization, located within the U.S.S.R.: (1) the M.V.D. or ministry of internal affairs; (2) the G.R.U. or chief intelligence directorate of the Soviet army; and (3) the intelligence set up within the secretariat of the Communist Party of the Soviet Union which is responsible for furthering Communism in foreign countries. Each of these branches handles a variety of intelligence and security matters in foreign countries, but there is much overlapping and many of the subject headings fall outside the term "intelligence" as known in non-Communist countries.

The following are among these activities: sabotage; political and military intelligence sections (including secret intelligence groups) organized by Soviet embassies in foreign capitals: guerrilla movements (actual and potential); spy groups and intelligence agents; and agitation and propaganda for the Communist parties. Contrary to the custom with most countries, where intelligence is in the hands of specialists, it can be said that every Soviet citizen in a foreign country is in some degree a Communist agent or an agent for some branch of the intelligence system of the U.S.S.R.

International Intelligence.—NATO has no intelligence organization of its own, but relies on those maintained by its member countries. The signatories of the Warsaw treaty are believed to rely very largely on the Soviet intelligence system which is known to operate extensively in the satellite countries.

INTELLIGENCE TESTS: *see* PSYCHOLOGICAL TESTS AND MEASUREMENTS.

INTEN, FERDINAND VON (1848–1918) German pianist. was born at Leipzig on Feb. 23, 1848. He attended the Leipzig conservatory between 1862 and 1866, where he studied under Moritz Hauptmann, Ernst Richter, Karl Reinecke. Ignaz Moscheles and Louis Plaidy. After leaving the conservatory he toured in Germany until 1868, when he made his debut in New York city. Inten remained in New York where he enjoyed some popularity as a teacher (Frank and Walter Damrosch were among his pupils) and performer of chamber music. In 1876–77 he again toured Germany. He died in New York in January 1918.

INTENDANT, in certain countries an official title having the same general sense as "superintendent" (from Lat. *intendere,* "to apply the mind to." "watch over"). Thus in Germany it is applied to the head of public institutions (*e.g.,* state theatres) and both in France and in Germany to certain military offices connected with the *intendance militaire* and *Intendantur* respectively (*i.e.,* approximately the equivalents of the British quartermaster general's and financial departments of the war office and of the quartermaster general and fiscal director of the U.S. army and their branch services).

In France the name was used in early times to designate a functionary invested by the king with an important and durable commission. The most famous of these functionaries. however, the intendants of provinces *(intendants das provinces)* date from the last 30 years of the 16th century. Originally used to restore order after the civil wars, their functions were at first extraordinary and temporary; but a few were retained as permanent state officials, and in time they came to be fairly generally distributed over the kingdom. The existing territorial divisions were kept, each intendant being placed over an intendancy (which usually corresponded with a *généralité*), save where slight modifications were necessary for administrative purposes. In the 13th and 14th centuries the monarchy had organized a species of inspection (*chevauchée*) over the provincial functionaries, which was performed by the masters of petitions (*maîtres des requêtes*). In the 16th century this inspectorate was revived and passed to the intendant. who became the resident supervisor of the other functionaries in his district; its connection with the old *chevauchée* is plainly shown by the fact that the intendants were almost always selected from the *maîtres des requêtes.* The early intendants had been largely concerned with the troops; eventually special military intendants (the only ones that exist in modern French law) were created, but the *intendants des provinces* retained certain military duties.

The early intendants were called indifferently *intendants de justice* or *intendants des finances.* These came to be different offices later on. however. Their powers were fixed by the commission. they received from the king, whose direct general representatives they became in each *généralité,* with authority over the other officials. whom they were empowered to censure, suspend or sometimes even replace. They were in constant touch with the king's council. with which they were connected by their original rights as *maîtres des requêtes.* In the first half of the 17th century they met with some opposition from the governors of provinces. who had formerly been the direct political representatives of the crown. and also from the *parlements,* which traditionally intervened in the administration, especially by means of *arrêts de règlement* (decisions. from which there was no appeal. regulating questions of procedure, civil law or custom). The intendants, however. were energetically supported, and so complete was their triumph that in the 18th century governors of provinces could not enter upon their duties without formai credentials *(lettres de résidence).*

The intendants had wide powers in the drawing by lot of the militia and in the royal labour service (*corvées*) for the making and repair of the highroads and were largely concerned with the administration of the tax called the *taille,* in which they effected useful reforms.

They were the sole administrators of the principal direct and indirect imposts created in the second half of the 17th century and in the 18th century and had full powers to settle disputes arising out of these taxes. Because of the vast size of the districts allotted to the intendants (there were no more than 33 intendants in 1788), they were allowed to delegate their powers to subintendants (*subdélégués*), who were, however. not royal officials, but merely mandatories of the intendant. Decisions of the intendant could be carried to the king's council, and those of the *subdélégué* to the intendant.

In the latter half of the 18th century, these royal commissions tended to become hereditary in certain families and were increasingly conferred on members of the nobility. In consequence, the intendants became more and more intermediaries between the localities and the central government rather than agents of an encroaching bureaucratic machine! as they had been under Louis I They continued, however, to share the unpopularity of the so-called "ministerial despotism" of the monarchy. Necker attempted to undermine their importance by creating experimental provincial "administrations" in Berry and Haute Guyenne in 1777–78. Though Calonne and Loménie de Brienne preserved the intendants when reforming French local government in 1787. their authority declined rapidly after that date. Their power collapsed in the provincial revolts of 1788 and the general desire in France for greater decentralization led to their abolition by the Constituent Assembly in 1789.

INTENT, in law, is a state of mind consisting of a desire that certain consequences shall result from an act. Intent, concurring with a wrongful act, is a basis for both civil and criminal responsibility.

In criminal law, the state of mind required is expressed in the maxim of *mens* rea (guilty mind), which includes reckless as well as intentional disregard of consequences. Some crimes require only negligence—a kind of legal fault akin to *mens* rea. Crimes of strict or vicarious responsibility require no state of mind (see CRIMINAL LAW). Civil liability may also rest upon either intention, recklessness, negligence or strict liability (see TORT).

INTER-ALLIED CONTROL IN WAR: see WAR CONTROL OF FOOD; WAR CONTROL OF SHIPPING.

INTER-ALLIED DEBTS. "Inter-Allied debts" is the name given the financial obligations incurred between the governments of the Allied and associated powers during and after World Wars I and II. These obligations were distinct from the internal indebtedness arising from the war in that they were incurred by borrowing abroad, and they differed from conventional foreign indebtedness in that they were the responsibility of governments rather than of individuals or private corporations. The problem of international war finance is cast in terms different from domestic fiscal problems. and international borrowings differ from internal borrowings in that they are necessitated not by an inability to tax but by limited resources.

In World War I all Allied nations except the United States —which entered 19 months before the Armistice—found it necessary to resort to foreign borrowing, and the accumulated indebtedness which emerged was one of the most troublesome problems of the peace. Together with reparations (see REPARATIONS), it was the source of more tension, friction and discussion, diplomatic and otherwise, than any single international problem, excepting the depression, of the two decades between the two world wars.

WORLD WAR I DEBTS

By its pre-eminent financial position in the world in 1914, Great Britain became banker to the Allied and associated powers and retained this function until the United States entered the war. When the United States entered the conflict on April 6, 1917, it immediately became banker to the Allies, for British resources had dwindled in the interim; in addition to its financial operations, the United States supervised all Allied purchases in the U.S. By the four Liberty Loan acts, the congress of the United States authorized the extension of loans to Allied and associated powers to an amount not exceeding in the aggregate $10,000,000,000, the terms of the loans being substantially the same as those on domestic issues. The funds placed at the disposal of the Allies nere raised by the sale of bonds to individuals in the United States.

Amount **and** Nature **of the** Loans.—From Oct. 1914, when borrowing began, to July 1921, when U.S. loans ceased, the gross total of loans extended among the Allied nations was approximately $26,000,000,000. This gross figure is reduced considerably, however, by the cancellation of mutual debts. Net indebtedness stood at somewhat more than $16,000,000,000 when the war came to an end in 1918 (this figure excludes mutual debts among the Allies). In the next 2½ years approximately $4,300,000,000 was lent, mainly by the Gnited States, bringing the grand total of inter-Allied indebtedness to $20,780,732,000. The United States was the only country to go through the war without contracting net indebtedness to any nation. Britain emerged from the war in a creditor position, having borrowed approximately $4,200,000,000 and loaned $7,500,000,000, but because it borrowed mainly from the United States and loaned to its European allies it was in a debtor position with respect to the United States.

The total inter-Allied debt was contracted in two periods, the first between Aug. 1914 and April 6, 1917, and the second between the latter date and July 1921. The first ally to encounter financial stress was Russia, to which Britain loaned in all $2,472,000,000. In addition, Russia obtained franc credits to the value of almost $1,000,000,000, sold treasury bills to individuals and financial institutions in London and Paris and obtained advances from the U.S. and neutrals before it left the war in 1917. Although France had extensive foreign investments, large gold stocks and a considerable industrial plant, it was forced by a combination of circumstances to seek loans from Britain as early as the autumn of 1914. The first of these was raised by selling treasury bills in the London market, a process mhich yielded $379,000,000 by 1917.

The first treasury bill sales were followed by drafts on Britain against French gold deposits there, yielding $937,200,000 from deposits of $260,300,000. In 1915 France shared with Britain the proceeds of the Anglo-French loan of $500,000,000 raised in the U.S. through private agencies. Despite its stringent position, France loaned its allies about $3,000,000,000 throughout the war period, of which $2,500,000,000 were net loans. Italy entered the war in May 1915, after having been assured of receiving war credits from Britain. Total sterling credits to the value of $764,000,000 were obtained by a gold deposit of $80,700,000 before April 1917, and after that additional net credits from Britain and other countries of $2,270,000,000.

In the first period of the war, Great Britain loaned $3,655,000,000 and in the second period somewhat more than $3,500,000,000. (Britain was not under the necessity of borrowing before the floating of the Anglo-French loan of 1915.) From 1915 to April 1917 Great Britain borrowed $1,394,000,000, of which $1,065,000,000 was from private agencies in the United States; from that time to the end of the war period in 1921 it borrowed about $4,000,000,000, of which $3,696,000,000 was from the United States. In the second period of the war the greatest portion of all lending was done by the United States. In the 19 months that the U.S. was in the mar, its gross loans amounted to $7,077,000,000 of the authorized $10,000,000,000. For about two years after the Armistice, the United States continued to extend loans in order that munitions in process of manufacture could be financed, war stores on the battle fronts liquidated and funds furnished for relief and rehabilitation.

By July 1921 the aggregate of loans by the U.S. government was $10,338,000,000. To this should be added loans of about $1,910,000,000 extended to the Allies by private agencies in the United States.

TABLE I.—*Net Inter-Allied Debts, 1914–IS, and Post-Armistice Debts*
(In thousands of dollars)

Borrowing nations	Lending nations						
	Great Britain	Canada	France	Italy	United States	Argentina	Total
Great Britain	—	229,663			3,696,000	93,427	4,019,090
British empire	479,301						479,301
Belgium	434,192		534,610		171,780		1,140,582

Serbia	90,715		297,413		10,605		398,733
Total at Armistice	7,244,507	229,875	2,237,517	6,972	6,686,027	93,427	16,498,325
Post-Armistice advances	224,809		289,500	115,800	3,652,298		4,282,407
Grand total	7,469,316	220,875	2,527,017	122,772	10,338,325	93,427	20,780,732

Source. Based on H. E. Fisk, *The Inter-Ally Debts*, p. 345 (New York, 1924).

The greatest part of the proceeds of inter-Allied loans was expended within the lending country. This was particularly true of the loans made by the U.S. government. Of the more than $10,000,000,000 advanced, almost all was spent within the United States, the major expenditure being on munitions and foodstuffs, each of which took about 25% of the total. A minor portion was used to liquidate some of the private loans made in the Cnited States to the European Allies.

Financial differences among the Allied powers were stilled for the length of World War I, but almost immediately after the Armistice the problem of indebtedness became a disturbing one. During the war most of the loans were freely granted as one element of military collaboration. and detailed questions relating to their ultimate settlement were deferred until after victory. In the U.S. congress the loans were freely spoken of as America's contribution to the war in lieu of the immediate dispatch of armed forces, which was impossible.

After the defeat of Germany, however, U.S. attitudes shifted, and the loans came to be considered bona fide obligations of European governments to the government of the United States, on which payment of interest and principal was expected as soon as feasible. There then began protracted negotiations looking toward a definitive settlement of the entire debt problem, including the problem of reparations. The failure of the world to make this settlement was a disturbing factor throughout most of the years between World Wars I and II.

Attempts at Settlement. — From the beginning it was generally recognized that the position of the United States! as the largest creditor nation and the only net creditor of importance with respect to all Allied nations, made it the keystone in the entire financial structure of the postwar world, and that all efforts at settlement necessarily involved it. Before the peace conference assembled at Paris in 1919, it was suggested to the United States that the debt problem be discussed concurrently with the treaty, and it was strongly intimated that a general cancellation of all inter-Allied debts would be in order. The United States countered by proposing full payment of all intergovernmental war debts, to be effected through the funding of the debt in two series of bonds, each at 5%, with payments on the principal of the debt to begin in the tenth year after funding. Although Great Britain accepted the proposal as a basis for negotiations, nothing came of it, an3 in 1920 Britain twice repeated its interest in general cancellation. A definite program of funding was finally inaugurated in 1922 when the American Foreign Debt Funding bill was signed, authorizing a refunding of the Allied debts to the extent of $11,000,000,000 with a maximum maturity of 25 years and minimum interest rate of 4.25%. Although congress once again stated its opposition to any reduction of the debt, the interest rate fixed by the bill actually constituted a reduction of about 43% on the total of all loans due the United States, for the original rate was 5%.

As Great Britain was apprised of the unalterable intentions of the United States, it made known to its debtors that under the circumstances payment would be expected of them in amounts sufficient to cover its payments to the C.S. Discussions began in 1923 with France. leading in 1929 to final approval of a settlement program whereby France was to redeem its obligations over a period of 53 years in annual payments ranging from £4,000,000 to £14,000.000, with the right to request a revision should France's receipts from Germany on reparations account fall to less than half the amount called for under the Dawes plan. Italy agreed to pay its debt in 62 annual instalments of £4,500,000. With the exception of the U.S.S.R., all other countries made agreements or paid their debts. In 1930 France signed funding agreements with its major debtors, exclusive of the U.S.S.R., to which its loans had been heaviest.

The coming of the world depression in 1929 swept away Germany'ability to meet its reparation obligations and, because receipt of reparations was one of the conditions of settlement: reopened the entire question of inter-Allied indebtedness. To avoid a financial crisis in June 1931, Pres. Herbert Hoover instituted with general approval a one-year moratorium on all intergovernmental debt payments. The following year the Lausanne conference was held, ostensibly to discuss German reparations but also to reconsider the entire problem of war debts. The conference agreed to reduce Germany's reparations to a token amount, but ratification of the agreement was subject to a new and drastic

TABLE 11.—The Repayment of U.S. War Loans Before Suspension of Payments in 1932

Country	Total of scheduled payments (000)	Per cent reduction at 4.25%	Amount repaid (000)	Per cent repaid	Balance of scheduled payments (000)

settlement of inter-Allied debts. The United States, with which the decision ultimately rested. was still averse to any such program and in the following year refused even to discuss the problem at the World Economic conference in London. After the expiration of the Hoover moratorium in July 1932, Britain. Italy and a number of smaller nations met their December payments while France and others defaulted. In 1933 token payments were made by Britain, Czechoslovakia. Italy, Latvia. Lithuania and Rumania. After that time the United States received payments only from Finland. all its other debtors having defaulted.

Amounts Repaid. — The total amount unpaid on inter-Allied debt account is given in Tables II and III. Of the total scheduled payments (throughout the entire period of repayment) of $22,220,188,000, the total amount repaid by the end of 1932 when all payments virtually ceased was $2 722,900,600, or 12.25%, leaving approximately seven-eighths of the total scheduled payments in abeyance. The discounted value of the unpaid balance is, of

course. much smaller. Table III relates inter-Allied debt payments and total inter-European payments with amounts paid to the United States. From all their major debtors the European countries received $2,692,700,000 and paid to the United States $1,415,700,000. Excess receipts over payments were $1,277,000,000. From Germany they received $2,376,300,000, the difference between this amount and that paid the United States being $960,600,000.

Obstacles to Settlement. — The failure of the world to settle the problem of intergovernmental indebtedness must be attributed ultimately to its greater failure to re-establish economic order following World War I. There are two ways in which such obligations can be met: by the shipment of gold on the part of the debtor nation, or by the shipment of goods and services, either directly to its creditor or to a third country. Only the latter is a practicable method of repayment. Because the debts had to be paid in cash (with the exception of a certain portion of German reparations), the paying countries would have had to increase their exports in order to obtain the currency of the creditor country. Had inter-

national trade taken this course, the debt problem would probably have solved itself. The debtor countries would have obtained U.S. and British exchange by increasing their sales either to these countries or to countries from which the U.S. and Britain had imported and were in debt.

That the actual course of indebtedness was quite different is attributable to three factors, one of which was the attitude of the debtors toward their obligations. From the start, the moral basis of the loans was obscure.

Although the debtor countries eventually agreed that the debts were legal, they were never wholly convinced that they were under an ethical obligation to pay. This original obscurity was not dispelled by the attitude of the U.S. government at the time it extended its loans. Once the original difficulty was eliminated and the programs of settlement completed, the ethical question again emerged, this time in the relation between inter-Allied debts and reparations. Initially imposed in order to make Germany responsible for some of the losses wrought by the war, reparations eventually became a major source of revenue out of which to make payments to the United States.

The second obstacle to settlement was provided by the condition of world trade. The expansion of foreign trade so necessary to a liquidation of the debt was stifled by a resurgence of economic nationalism throughout the world. While the United States was demanding that all its debtors come to terms, it was simultaneously raising tariff barriers that diminished the possibility of payment. Large amounts of European imports, which would have furnished means of payment, were in competition with the output of certain U.S. industries which demanded protection of their special interests, and the United States was placed in the awkward position of both demanding payment and denying its possibility. Cast over the impediments to trade was the monetary disorder that afflicted almost every nation of Europe, making both private and public settlements the more difficult. That funding agreements were actually negotiated and payments made on inter-Allied debt and reparation accounts for the period between 1922 and 1931 must not be laid to an economic miracle but to the action of private U.S. investors who extended loans to the debtor nations. These loans, which were made purely as investments, provided much of the dollar exchange with which payments on intergovernmental account could be made, and their effect was to defer the date of ultimate settlement and to transfer a part of the debtor nations' obligations from public to private creditors.

After 1930 most of these loans ceased and new obstacles to international trading were erected which made many of the barriers of the 1920s slight by comparison. Quotas and other forms of import restriction were devised, and exports were promoted with ever-greater vigour. The collapse of the gold standard after 1931 brought in its wake monetary regulations which added more obstacles. The only nation which made any effort to prevent a total strangulation of international trade was the United States, which after more than a decade of restricting its imports—culminating in the extremely high schedules of the Smoot-Hawley tariff of 1930—reversed its position and by a program of reciprocity invited a general reduction of trade barriers throughout the world. By this time, however, all but one of its debtors had in fact, if not form, defaulted on their debts.

The third factor operating against a debt settlement was the world depression that began in 1929. By its severity the depression intensified the trade and monetary disorder noted above. Yet it was not a phenomenon distinct from these.

The extreme deflation and unusual length of the economic crisis of the 1930s may be traced to the domestic and international economic policies pursued throughout the world after the war, which had the effect of making prices rigid in internal and international markets, of creating immobilities within and between nations, and, generally, of making recovery from the depression more remote and difficult. As the impediments to trade raised obstacles'to a settlement of the debt, so they gave root to the world depression.

DEBTS IN WORLD WAR II

World War II did not leave in its wake a flood of intergovernmental obligations such as had plagued the world during the interwar period. The entire amount of United States government credits utilized by other countries bet een mid-1941 and mid-1945 did not exceed the $1,100,000,000 mark, as compared with six times that much lent by the United States during World War I. A quantitatively much more important legacy of the war was close to £4,000,000,000 of sterling balances which British Commonwealth countries and dependencies of Great Britain had accumulated in London during the first half of the 1940s.

That no larger war debt to the United States mas incurred was due to two factors: the neutrality legislation, which controlled United States foreign policy in the early phases of the war, and the subsequent enactment of the Lend-Lease act of March 11, 1941, which in effect pooled the resources of the Allies and made U.S. aid available in the form of grants rather than loans.

Cash and Carry Under Neutrality.— The neutrality and related legislation which was enacted in the United States during the 1930s mirrored a strong desire to keep that country out of foreign wars. The unhappy status of the World War I debts was a disappointment to many. Disillusionment about the precarious foreign situation—Mussolini's attack on Ethiopia, the Spanish civil war, etc.—gave way to "isolationism." In connection with the entry of the country into World War I. strong resentment was felt in many quarters against bankers and munitions makers. whose business policies were scrutinized by a special senate committee on investigation of the munitions industry from 1934 to 1936.

The Johnson act of 1934 did indeed make unlawful the placement of loans in the United States by foreign governments in default of their obligations to the United States. The Neutrality act, passed in 1935, amended in the following years and again revised in 1937, called for the embargo of shipments from the United States to countries involved in war and prohibited the purchase of securities issued by such countries. These measures did not operate against the placement of orders for munitions and other materials in the United States as long as the purchasing country was not involved in actual warfare, and such orders were indeed forthcoming from Britain. France and other European nations in 1938 and 1939. In 1939, when war seemed imminent, Secretary of State Cordell Hull submitted proposals for modification of the neutrality legislation, pointing out that "no matter how much we may wish or may try to dissociate ourselves from world events, we cannot achieve disassociation." Under the Neutrality act of 1939, which became law on Nov. 4, the embargo provisions of the earlier legislation were in effect repealed. The act insisted, however, on "cash and carry": exports to the belligerents were not to involve the extension of credit or the use of U.S. vessels.

Under the cash and carry rule of the Neutrality act of 1939, Britain, which also had taken over French orders in the United States when France fell. was compelled to finance its ever-increasing purchases in the United States from its gold and dollar resources. A rapid decline of these assets ensued, and by the close of the year 1940 the gold and dollar resources of the United Kingdom had fallen to little more than $2,000,000,000, compared with $4,500,000,000 in Aug. 1939.

Transition to Lend-Lease.— Gradually, however, and especially after the beginning of the German campaign in western Europe in the spring of 1940, the neutrality legislation ceased to be a significant instrument of U.S. foreign policy. Indicative of the changing atmosphere was the transfer to Britain of surplus stocks of munitions valued at more than $43,000,000. This was arranged in June 1940, after the retreat from Dunkirk, where the British had lost large quantities of military supplies. Thereafter, the United States government continued to supply war materials from its surplus, in addition to materials purchased from private manufacturers. In Sept. 1940 arrangements were made for the transfer by the United States to Britain of 50 over-age destroyers, originally valued at $75,000,000 and recommissioned at a cost of $20,000,000, while the United States was to receive rights to establish naval and air bases in Newfoundland and in the islands of Bermuda, the Bahamas. Jamaica, St. Lucia. Trinidad and Antigua and in British Guiana. Pres. Franklin D. Roosevelt appealed to the United States to become "the great arsenal of democracy,"

pointing out that "we have furnished the British great material support and we will furnish far more in the future." The pooling of resources without attachment of financial strings, as exemplified by the destroyer agreement, was fully implemented by the Lend-Lease act of March 11, 1941. The act empowered the president of the United States, "in the interest of national defense," to make available to governments whose defense he deemed vital to the defense of the United States a widely defined range of "defense articles." not excluding essential civilian needs. Aid was to come forth on terms "which the President deems satisfactory," including "payment or repayment in kind or property, or any other direct or indirect benefit" at the discretion of the president.

Credit Extended by the United States, 1941–45.—Lend-lease aid was not exclusively forthcoming in the form of grants. For relatively small amounts, payment in cash or strict credit terms were stipulated. Such current lend-lease credits, utilized mainly by the American republics between mid-1941 and mid-1945, amounted to $112,000,000. During the same period, $237,000,000 in silver was lent for monetary and industrial use, mainly to India, the United Kingdom and the Netherlands, to be repaid in kind. Unrelated to lend-lease, there were also. during this period, loans of the Export-Import Bank of Washington, an instrumentality of the United States government, amounting to $329,000,000 and placed mainly among the American republics. China and Canada. During that period loans also were forthcoming, in an amount of $417,000,000, from the Reconstruction Finance corporation, another instrumentality of the United States government. These credits add up to $1,096,000,000, a sum dwarfed by the $50,000,000,000 of lend-lease aid. More than one-third of the credits, $380,000,000, was repaid from 1941 to 1945.

TABLE V.—*Reverse Lend-Lease Aid Received by the United States, by Supplying Countries, 1941–45*
(In millions of dollars)

Supplying country	Amount	Supplying country	Amount
Total	7,819	China	4
		France and possessions	868
Belgium and possessions	191	Netherlands and possessions	2
British Commonwealth	6,752	U.S.S.R.	2

Source: National Industrial Conference Board, Inc., *Economic Almanac for 1949–50 1951–52*, p. 431 (New York, 1948–51).

The largest amount involved in these credits was a loan commitment of $425,000,000 made by the Reconstruction Finance corporation to the United Kingdom in July 1941. This loan, of which $390,000,000 was disbursed, was obtained on the pledge as collateral of British-owned assets and their earnings in the United States. It was to carry interest of 3% and to be repaid within 15 years. Since the earnings of the pledged collateral were larger than anticipated, the loan was paid off within little more than ten years.

Lend-Lease Settlements; Postwar U.S. Loans.—New lend-lease aid came to a halt after V-J day in Sept. 1945. United States assistance continued on a large scale, but during the immediate postwar years a substantial part of it came forth in the form of loans. Only after 1948, when the European Recovery program was established, was more emphasis again placed on grants rather than loans. The ratio of grants to credits. which had been approximately 50 to 1 during 1941–45, became 2 to 1 during 1946–50. In 1947 credits actually exceeded grants by a margin of $1,500,000,000.

Altogether the United States credits utilized during the five postwar fiscal years 1946–50 added up to $10,400,000,000, an amount nearly ten times greater than the wartime credits of 1941–45. The largest single item among the credits of the postwar years was a loan to the United Kingdom of $3,750,000,000, to be repaid after Dec. 31, 1951, in 50 annual instalments. Interest was set at 2% and a waiver of interest was provided for situations of financial stringency. The loan commitment, unparalleled in its magnitude among peacetime credits, was part of a comprehensive Anglo-C.S. financial and trade agreement, signed on Dec. 6, 1945, in which Britain undertook to reorient its policy with the aim of bringing about greater freedom of trade.

Second in line were loans of the Export-Import bank. These added up to $2,700,000,000 in 1946–50, with France receiving $1,200,000,000 in 1946–48. Third in importance were the lend-lease settlements concluded after V-J day with most major recipients, in which these undertook to pay for the value of installations and for deliveries still forthcoming. The total amount of obligations thus incurred was $1,300,000,000. Another $1,300,000,000 was the purchase price of surplus property sold to foreign governments.

Intergovernmental Obligations Other Than U.S. Credits.—Apart from the sterling balances, discussed below, only relatively minor intergovernmental debts were incurred to creditors other than the United States during World War II. In the beginning of the war, France and the United Kingdom had concluded the economic agreement of Dec. 1939, under which each country was to use its own currency to acquire what it needed of the other country's currency, with no transfers of gold to become necessary. British purchases in Canada were financed by means of an interest-free loan of $700,000,000 in April 1942, which was applied to sterling balances accumulated before, and by a free gift of $1,000,000,000, which covered requirements until early in 1943. On May 20, 1943, Canada passed the War Appropriation (United Nations Mutual Aid) act, patterned after lend-lease, and subsequently thereto British wartime requirements were met chiefly on a grant basis. In 1946 Britain negotiated a loan of $1,250,000,000 from Canada.

Sterling Balances.— The principal inter-Allied debts incurred during World War II up to V-J day were the so-called sterling balances which members of the British Commonwealth (other than Canada), British dependencies and a number of other countries accumulated in London during the war. Before the war these balances, or holdings, of sterling stood at £500,000,000. They were then composed mainly of reserves which the respective countries and territories maintained in London, the financial centre of the area composed by them. By the end of 1945 the sterling balances had risen to close to £4,000.000,000, with approximately half held by India, Burma and middle eastern countries. The bulk of the accumulations then consisted of payments for supplies imported to Britain and of British disbursements abroad for military installations, troop pay and the like. As so large a part of the sterling balances resulted from disbursements made in defense of India, Burma, Egypt. the middle east and other regions, the assumption of this burden by Britain was an act of economic chivalry whose wisdom was questioned in many quarters. After the war, the liquidation of the sterling balances proceeded only slowly; requiring, as it did, "unrequited" exports to the holding countries from Britain and thereby adding to Britain's economic difficulties. Moreover, the obligations represented by the sterling balances exceeded the value of Britain's foreign investments, which had been reduced by wartime liquidation, turning that country into a debtor on international account.

INTER CAETERA, a papal bull of May 4, 1493, defining areas of sovereignty over newly discovered lands, was issued by Alexander VI after reports of the first voyage of Christopher Columbus reached the pope and the Spanish and Portuguese rulers.

Under this bull and one of May 3, a line of demarcation was drawn 100 leagues west of "the islands commonly known as the Azores and Cape Verde," and the rulers of Castile and León were confirmed as the sovereign power over all lands already discovered or to be discovered west of that line which were not "in the actual possession of any Christian king or prince."

Portugal. which held colonies along the coast of Africa, was to retain its rights and privileges east of the line. In September of the same year, the pope expressly confirmed in another bull the Spanish rulers' right to hold lands to the "eastern region and to India."

Under the treaty of Tordesillas, June 7. 1494, the Spanish crown agreed to move the line of demarcation 370 leagues west from the Cape Verde Islands, thus giving Portugal a claim to Brazil.

INTERCALARY (Lat. *intercalare,* "to proclaim"), a term applied to a month, day or days inserted between other months or days in order to adjust the reckoning of time to the revolution of the earth around the sun, the solar year *(see* CALENDAR). From the meaning, "something placed between," intercalary is also used for something which comes between two types. In botany, the term is used of growth between the apex and base of an organ, such as the growth in length of an iris leaf; or of the internode of a grass haulm.

INTERCOLUMNIATION, in architecture, the distance between the columns (*q.v.*) of a colonnade; usually defined by the number of times in which the bottom diameter of the column is included in the distance between the two closest points on adjacent columns. Thus the distance between the centre lines of two columns is one diameter more than their intercolumniation. The intercolumniation of classic columns was systematized at an early date, and the following standard intercolumniations have been listed by Vitruvius and others: (1) pycnostyle, equal to 1½ diameters; (2) systyle, 2 diameters; (3) eustyle, 2¼ diameters, so-called "well-columned," as the one most generally satisfactory; (4) diastyle, 3 diameters; (5) areostyle, 4 diameters; and (6) areosystyle, a complex form in which the columns are arranged in pairs with the distance between the pairs greater than the distance between the columns of each pair, as in the colonnade of the Louvre. Paris (by Claude Perrault, 166j). No such absolute standardization of intercolumniation as Vitruvius' list would suggest exists in classical work; frequently all the intercolumniations of a single colonnade differed, with the widest in the centre. The list must therefore be considered. like the so-called rules for the orders. merely as a summary of the averages. *See* ORDER.

INTERDICTION, in Scots law, was a process of restraint applied to prodigals and others who, "from weakness, facility or profusion," were liable to be imposed upon. The result was to prevent the person interdicted from effectively alienating his heritable property without the consent of his interdictors. It left him competent to dispose of his movables. In voluntary interdiction the prodigal himself took the initiative in binding himself not to do anything to affect his estate without the assent of the interdictors. Judicial interdiction was imposed by order of the court either at the instance of an interested party or acting in the exercise of its equitable jurisdiction or *nobile officium.* Interdiction was abolished by the Conveyancing (Scotland) act. 1924, s. 44. (A. D. G.)

INTERESSE TERMINI, in law, an executory interest. being the right of entry which the grant of lease confers upon a lessee. Actual entry on the lands by the lessee converts the right into an estate. If the lease, however. has been created by a bargain and sale, which still exist in some places, or by any other conveyance under the English Statute of Uses, not requiring an entry, the term vests in the lessee at once. This doctrine was abolished by the Law of Property act. 1925, s. 149.

INTEREST, in ordinary usage, is the price paid for the use or forebearance of money or its equivalent, or for damages for its detention, Simple interest is that computed solely on principal. Compound interest is that paid upon interest where accrued interest is added to the principal sum and the whole treated as a new principal. For a discussion of borrowing and lending and the historical development of the practice of charging interest on loans, *see* MONEY-LENDING. For a discussion of interest on investments, *see* STOCK and BOND (IN FINANCE). For the meanings of interest in economics, *see* CAPITAL AND INTEREST.

(M. R. N.)

INTERFERENCE OF LIGHT: *see* LIGHT: *Waves and Interference;* INTERFEROMETER.

INTERFEROMETER. An interferometer is an instrument which makes use of the interference of waves for the purpose of measurement. After an introduction which includes a classification of interference effects, this article is divided into the following sections:

I. Interferometers Using Division of Wave Front
  1. The Väisälä Interferometer
  2. Michelson's Stellar Interierometer
II. Interferometers Using Division of Amplitude
  1. Fizeau-Laurent Surface Interferometer
  2. The Jamin Interferometer
  3. The Michelson Interferometer
    The Structures of Spectral Lines
    Evaluation of the Metre with Light Waves
  4. The Twyman-Green Interferometer
  5. The Linnik Interference Microscope
  6. The Mach-Zehnder Interferometer
  7. The Bates Wave-Front Shearing Interferometer
  8. The Fabry-Perot Interferometer
    Analysis of Hyperfine Structures in Line Spectra
    Measurement of Line Width
    Determination of Precision Wave Lengths
    The Evaluation of the Metre
    Refractive Index of Air
  9. The Echelon and Lummer Plate Interferometers
III. Multiple-Beam Interferometry
  1. Some Applications of Multiple-Beam Interferometry
    Microtopographies of Surfaces
    Thickness of Thin Films
    Oscillations of Piezoelectric Crystal Plates
    Fringes of Equal Chromatic Order
    Studies on Opaque Objects (Metals, etc.)

This article will be devoted entirely to optical interferometers, which can be conveniently divided into two broad groups. In the first, metrical interferometers, light waves of known wave length are used for the measurement of metrical or optical lengths. In

the second group, interference spectroscopes, the objects under study are the light waves themselves (see SPECTROSCOPY). Because the wave length of visible light is only of the order of & of a millimetre, metrical interferometers can only be used for the evaluation of quite small differences in length; nevertheless it is possible to compare large lengths provided they only differ by small amounts. Thus it becomes convenient to subdivide metrical interferometers into those used for measuring quite small lengths and those which can be used for the evaluation of lengths up to as much as 100 m.

Although the existence of phenomena due to optical interference was known to Robert Boyle, Robert Hooke and Sir Isaac Newton as early as about 1665, it was not until 1802 that the fundamental mechanism was clarified by Thomas Young, who was the first to enunciate the theory that optical interference involves the principle of coherence and the principle of superposition (see LIGHT). The essential features are (1) that light beams from two independent sources, being incoherent, can only combine their intensities; but (2) light beams from any one point of a source, which may have traveled over different paths and then come together again, being coherent, can combine their amplitudes, and this can lead to stationary fluctuations of intensity in space, called interference fringes. An interferometer is essentially an optical system that divides a beam of light from a source into two (or many) beams which follow different paths and then are recombined. If there are differences in either the optical or metric paths, then each wave-length difference leads to a shift of one interference fringe. Thus small differences become measurable.

Varieties of interference fringes were discovered successively during the first half of the 19th century by Young, A. J. Fresnel, Sir John Herschel, Sir David Brewster, Humphry Lloyd. Wilhelm Haidinger. Fox Talbot, F. Billet and others. They were treated as academic curiosities until J. C. Jamin in 18j6 invented his celebrated interference type of refractometer (*q.v.*), followed in 1859 by A. H. Fizeau who carried out an ingenious interferometric test of the water-velocity-drift formula proposed by Fresnel. Then in 1862 Fizeau applied thin-film fringes to the measurement of the thermal expansions of small bodies. Following Fizeau there were many developments. leading to a great expansion of interest in the subject by the mid-20th century and increasing use of interferometers for precise physical measurement.

Classification of Interference Effects.—Interference phenomena can be conveniently classified according to (1) chromatism; (2) wave division; (3) fringe localization; (4) multiplicity.

1. Some interference phenomena can be produced with white light; others require an approximately monochromatic source. The line uidth (departure from true monochromaticity) imposes restrictive limitations in many interference experiments.

2. The condition of coherence requires the division of the wave front into separate beams. This can be done either by (a) division of the wave front by slits or apertures or (b) division of the amplitude of a wave front by the double act of partial reflection and partial transmission at a reflecting interface.

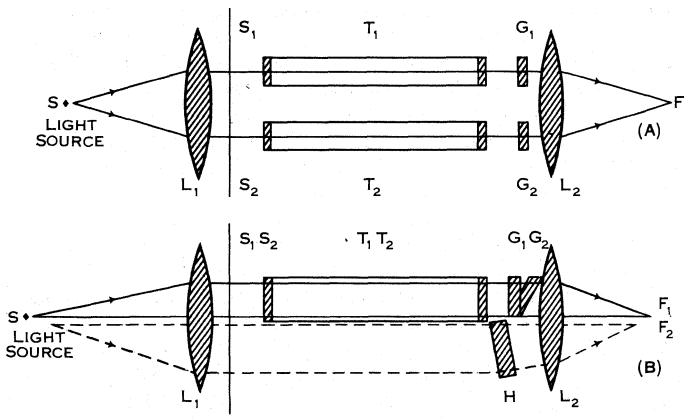

FIG. 1.—(A) PLAN AND (B) ELEVATION DIAGRAMS OF THE INTERFERENCE REFRACTOMETER

3. Fringes, according to their mode of origin, may be non-localized (*i.e.,* extend into space), localized on a surface or appear at infinity.

4. While many interference systems use two interfering light beams (two-beam interference) others use many geometrically related beams (multiple-beam interference). Correct use of multiple beams leads to a considerable reduction in the widths of the interference fringes and thus to an increase in sensitivity and accuracy.

I. INTERFEROMETERS USING DIVISION OF WAVE FRONT

In such instruments a coherent wave front is divided, usually by two parallel slits or by two separated mirrors. The Rayleigh interference refractometer, described in 1896 (see REFRACTOMETER), incorporating the modern improvements of F. Haber and F. Löwe (1910), is widely used for the determination of the refractive indices of gases and liquids. A diagram is shown in fig. 1.

Fig. 1(A) shows a plan view and fig. 1(B) an elevation view. From a slit source S, light rendered parallel by the lens L_1 falls on two fairly uide slits 1 cm. apart (S_1S_2). After passing through the tubes T_1T_2 and a compensating device G_1G_2 (invented earlier by Jamin), the beams are reunited at F by the lens L_2. Fringes appear

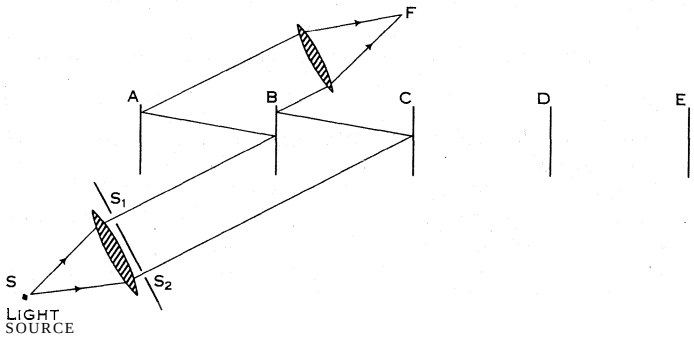

FIG. 2.— INTERFERENCESYSTEM INTRODUCED BY V. VAISALA

at the lens focus and are viewed with a high-magnification cylindrical lens.

As shown in fig. 1(B). T_1T_2 occupy only the upper half of the field of view so that similar systems of fringes appear at F_1 and F_2, the lower set at F_2 becoming a reference-fixed system, which is brought close to the movable system at F_1 with the tilted glass plate H. The Jamin compensator G_1G_2 consists of tu-o similar glass plates inclined at a small angle, the beam from the two separate slits going through separate plates. By a slight rotation, a small path difference can be introduced into either path so as to compensate any differences created in T_1 and T, by differential gas filling. The fringe displacement per degree of rotation is predetermined with light of known wave length, the final observations being made with white-light fringes; for by this means the central achromatic white-light fringe enables exact identity of path to be re-established with the compensator. If one tube is evacuated, then for a tube length L the refractive index μ is given by $nX = (\mu-1)L$ in which X is the wave length of the calibrating light and n the number of fringes which the compensator reintroduces. A shift of $\frac{1}{40}$ fringe is just measurable, and for tubes 1 m. long this corresponds to a change in refractive index of 1×10^{-8}.

1. The **Väisälä** Interferometer.—A striking adaptation of this interference system was introduced by V. Vaisala (1927) for the purpose of measuring very long paths (*e.g.,* of the order of 100 m.) for use as a base line in geodetic survey. Two arrangements were used. In the first (fig. 2), light from S, separated by the two slits S_1S_2, produces fringes at F, after reflection from mirrors A, B, C. If white light is used, then fringes are only seen if AB is equal to BC to within a light wave or two. If AB is a substandard metre then BC can be matched equal to this to within a fraction of a light wave. The length AC is now 2 m. BC can now be matched against CD by altering the inclination of the incidence of the beams on the mirrors, so an accurate length AE is secured. The system does not depend on the lengths of AB, CD, etc., but

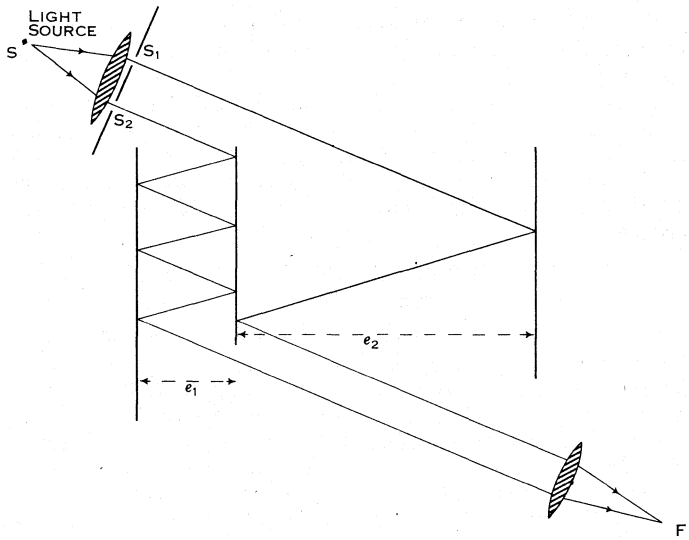

FIG. 3.— MODIFICATION OF THE VÄISÄLÄ INTERFERENCE SYSTEM

on their differences. Because of difficulties due to inclinations of beams, atmospheric disturbances and earth microtremors the method is restricted to an upper limit of roo m.

In a later modification a step-up procedure was adopted as indicated in fig. 3. In practice a step-up ratio $\frac{e_2}{e_1}$ of 5:1 was the largest that could be used. To determine 50 m. to within one wave length is a precision of one part in 10^8.

2. Michelson's Stellar Interferometer.— In 1868 Fizeau described an elegant method for measuring the angular separation between tno distant objects (slits or stars) by superposing and confusing the independent fringe patterns given from each source by a two-slit device which divided the separate wave fronts from each source. Thus. in fig. 4, let F be the fringe pattern from the one source appearing at the lens focus. Let the other source produce a similar pattern at F_1. If the F_1 fringe system is displaced from the F fringe system by half a fringe width. then maxima fall on minima, and no fringes are visible. This happens when the angular separation of the two slit sources (θ) equals $\frac{\lambda}{2a}$, or odd multiples thereof. By this technique, J. M. Stephan (1878) tried to measure the angular diameters of stars. He failed insofar as stellar distances are so great that no available telescope had an aperture big enough to give an a value sufficiently large. The first success on astronomical objects nas achieved by A A. Michelson. in 1890, who uith the large Lick telescope determined the angular diameters of Jupiter's moons (some 1 sec. of arc). Then in 1920 Michelson hit upon the ingenious device of effectively increasing a by building large girder extensions onto a massive telescope, thus constructing his celebrated stellar interferometer. The method as applied to a refracting telescope is shown in fig 5. B and C are small rectangular mirrors fixed over the telescope objective, E being a screen to cut out direct light from the star. The mirrors A and D can be moved out symmetrically. In effect the aperture of the system (a) becomes AD. Now while for two separate point sources the fringe dissonance occurs at $\theta = \frac{\lambda}{2a}$ it can be shown that a dissonance will also be produced by the separate parts from one disk-shaped source of angular diameter 8, and this occurs when $\theta = \frac{1.22\lambda}{a}$.

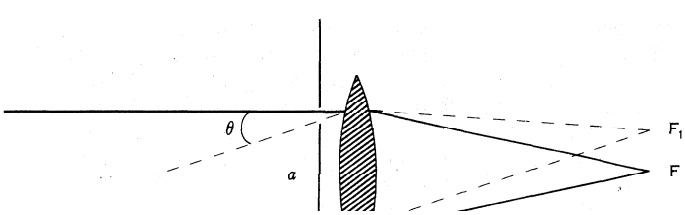

FIG. 4.—METHOD FOR MEASURING THE ANGULAR SEPARATION BETWEEN TWO DISTANT OBJECTS. DESCRIBED BY A. H. FIZEAU IN 1868

For the first star examined, Betelgeuse, the fringes vanished when a was 10 ft. 1 in., leading to an angular diameter θ of a mere 0.05 sec. of arc a quantity far too small to be detected even by the largest telescope using ordinary visual methods. An extensive program was under way in the late 1950s in several observatories, and many stellar diameters have been determined.

II. INTERFEROMETERS USING DIVISION OF AMPLITUDE

The first interference effects seriously studied, Newton's rings, involved division of amplitude. A fraction of the amplitude of an incident plane wave front is reflected from one face of a thin film and a second comparable fraction from the other face, the two recombining to give interference fringes. If very strict attention is paid to parallelism of the incident light. the two faces need not be close together and can indeed be centimetres apart. The fringes produced by division of amplitude are governed by the expression $nX = 2\mu t \cos \delta$ in which n is the order of interference, t the separation between the two surfaces in medium of refractive index μ and 6 the angle of incidence. It is often convenient to use an air medium (taking μ as unity) and parallel light of normal incidence ($\cos \theta = 1$); then with light of one wave length the fringes

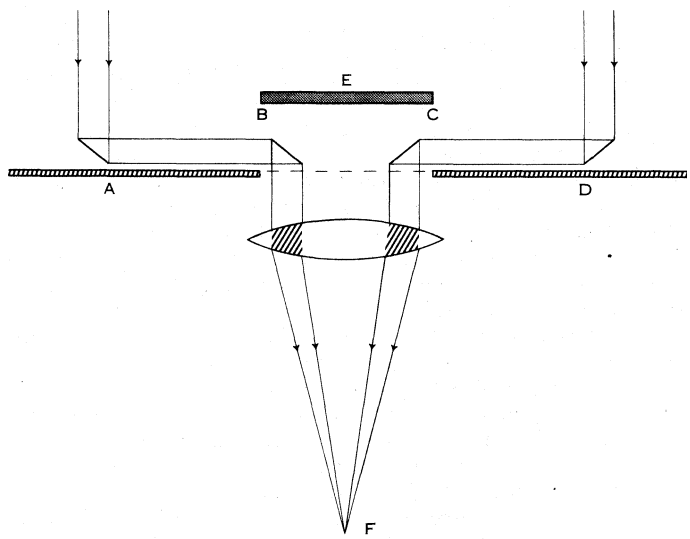

FIG. 5.— DIAGRAM OF STELLAR INTERFEROMETER DEVELOPED BY A. A. MICHELSON IN 1920

follow any variations in t. They are therefore called fringes of equal thickness. If, on the contrary, t is constant (*i.e.*, parallel-sided plates), then by using an extended range of angles of incidence (a range of 6 values) there result circular ring fringes. First discovered by Haidinger in 1849, these are called fringes of equal inclination since each arises as the envelope or locus of rays making the same inclination to the normal to the plates.

Interferometers which use fringes of equal thickness will be considered first. Fizeau's classical determinations (1861–64) of the thermal expansions of small polished crystals, using a variation of Newton's rings, introduced the first interferometer explicitly using division of amplitude for metrical determinations. A modern variant (U.S. bureau of standards) is shown in fig. 6.

A, the main surface of which is optically plane, is cut from fused quartz, which has a low thermal expansion. On a polished knife edge at B rests a quartz optical flat. The specimen C whose expansion is required is cut so that there remains a thin air film betueen A and B, with the two surfaces nearly parallel. Between these, the localized wedge fringes of equal thickness are formed with monochromatic collimated light. On heating, the relative

expansion of C to A leads to movement of the fringes. A correction for the small expansion of A is predetermined by using as C a material of known expansion.

1. Fizeau-Laurent Surface Interferometer. — An optical system. originally due to Fizeau (1862). was adapted by L. L. Laurent (1883) into an interferometer now extensively used in the optical industry. It reveals departures of polished surfaces from the plane. and enables the optical polisher to see and remove surface defects. The system is shown in fig. 7. A small pinhole A, at the focus of a well-corrected lens L. is illuminated with monochromatic light. The surfaces to be matched are a reference plane C_1 and the workpiece C_2. Incidence on C_1 is normal; and by setting a slight angle betneen the two surfaces, fringes of equal thickness are seen at E through interposition of a reflector at D. Laurent was the first to realize that these fringes constitute a contour map of the surface, being in effect contour lines which change successively in height by $\frac{A}{2}$. It is this fact which proved so valuable to the optical industry.

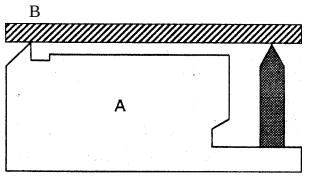

FIG. 6.—MODERN VARIANT OF AN INTERFEROMETER USING DIVISION OF AMPLITUDE

An interesting extension was proposed in 1893 by Lord Rayleigh, who pointed out that a steady liquid surface could be used as a reference plane. The workpiece can be held either above or below the surface. H. Barrell and R. S. Marriner (1940) tested the flatness of quite large plates in this way and had no difficulty in detecting errors as small as $\frac{\lambda}{10}$. Curvature of the earth causes a hillock $\frac{\lambda}{100}$ high over a 25-cm. diameter disk, and it is found that surface tension effects vanish 2.5 cm. from the disk boundary.

2. The **Jamin** Interferometer. — In 1856 Jamin described an interference refractometer which exploited the fringes of equal inclination discovered by Brewster in 1817. Brewster fringes form nhen light is reflected back from two identical thick parallel plates inclined at a slight angle to each other. Jamin used Brewster fringes formed under the special condition of 45° incidence as illustrated in fig. 8. Two thick identical glass blocks, P and Q, are set nearly parallel. The hatched faces are heavily silvered. A narrow beam of parallel light, incident at A. divides and traces the two paths XBCD and AFGD. recombining as two beams of the same intensity in the direction E, where straight line fringes of equal inclination are observed with a telescope set on infinity. Secondary reflections such as GP and DH are cut out by suitable stops. The two plates I and J constitute the Jamin compensator. Initially the two tubes T_1 and T_2 are evacuated, and with white light the central achromatic white fringe is set on the telescope cross wire. Introduction of gas into one tube leads to a fringe displacement; and the fringes are then brought back with the compensator, which has been precalibrated with monochromatic light.

3. The Michelson Interferometer. — It is probable that no single instrument has more profoundly influenced modern physics than the Michelsbn interferometer (1881). With it Michelson laid the experimental foundation to the theory of relativity. established the existence of hyperfine structure in line spectra, standardized the metre in terms of light waves and measured the tidal effect of the moon on the earth. Modifications have been used for testing lenses and prisms, as refractometers and also for the examination of surface microtopographies.

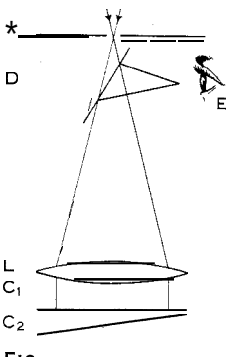

FIG. 7.—FIZEAU-LAURENT SURFACE INTERFEROMETRY SYSTEM

The instrument consists of a half-silvered mirror A (fig. 9) which divides a light beam incident at 45° into two equal parts, one of which is transmitted to the mirror M_2 and the other reflected to the mirror M_1. The beams retrace their paths and recombine in the direction B where fringes form. An observer looking along BA sees the mirror M_1 and also M_2', the image of M_2. The mirror M_2 can be moved parallel to itself with a fine-pitch screw on an accurately machined bed. Both M_1 and M_2 can be tilted with screws. The observer sees fringes formed in the air film $M_1 M_2'$. If the two planes M_1 and the virtual image M_2' are parallel. then circular fringes of equal inclination appear. If they are inclined, then fringes resembling wedge fringes are seen. If, further, the two planes intersect, then where they cross, white-light fringes are obtained (*i.e.*, in the region near to zero path difference). A means is thus available for setting AM_2 equal to AM_1 to within a small fraction of a light wave, usually estimated to be some $\frac{\lambda}{80}$.

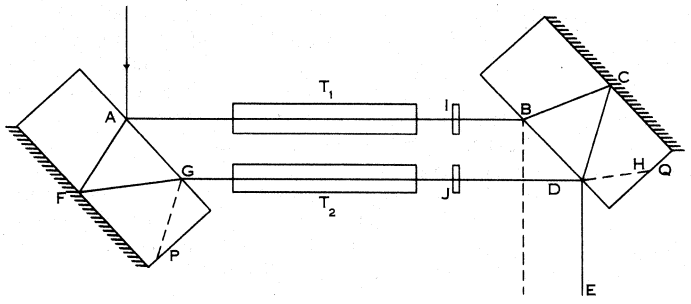

FIG. 8.— INTERFERENCE REFRACTOMETER DESCRIBED BY J. C. JAMIN IN 1856

To secure these white-light fringes, the two optical paths AM_1 and AM_2 must be the same for all wave lengths. Since the reflecting film A is on the front of a glass block, an identical compensating block is placed parallel to A in the path AM_1.

One of the first applications of this instrument was the carrying out of the celebrated Michelson-Morley experiment (see RELATIVITY and MICHELSON-MORLEY EXPERIMENT), an attempt to measure the relative motion between earth and ether. The interferometer was set up with equal arms, and rotated so that at one time light traversed AM_1 along the direction of motion of the earth and shortly after this in a contrary direction. With the particular instrumental dimensions used, computation predicted a fringe shift of 0.4 of a fringe. No shift exceeding 0.04 of a fringe was found. On this "null" result the whole superstructure of relativity physics was constructed.

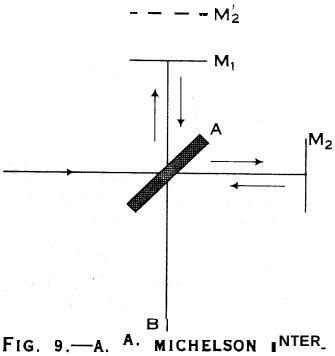

FIG. 9.—A. A. MICHELSON INTERFEROMETER (1881)

R. J. Kennedy confirmed the result in 1926, using a greatly increased sensitivity. On the mirror A and across half of it he deposited an extra silver film of thickness $\frac{\lambda}{20}$. At the boundary the fringes showed a discontinuity of $\frac{1}{10}$ of a fringe. Broad fringes were arranged to give a practically uniform tint of the illumination on either side of the step, both sides being equally off the true maximum. A very small displacement led to one side, brightening up relative to the other. Indeed. the remarkably small quantity of $\frac{1}{1000}$ of a fringe was detectable, corresponding to an optical path change of a mere 2.5 Å.

The *Structures* of Spectral Lines.--Of considerable importance to atomic nuclear physics is the study of nuclear spin and magnetic properties obtained from measurements of the hyperfine structures of spectral lines. Such structures were first detected by Michelson using his interferometer. In 1891 Michelson made a systematic study of the visibilitp of the fringes given by a range of spectroscopic lines. Defining fringe visibility from the intensity of the maxima and minima as $(I_{max} - I_{min})/(I_{max} + I_{min})$ he plotted these visibilities as a function of the separation between

the interferometer plates. The visibility is determined only by the width and complexity of the spectral line. For a theoretically monochromatic line the visibility curve is a horizontal straight line, but of course even a single line has a width due to a variety of factors. which leads to a smooth curve. If in addition the line has hyperfine structure components, then maxima and minima appear in the visibility curve.

Michelson invented a most ingenious harmonic analyzer which mechanically performed a Fourier analysis on the visibility curve. giving the original line shapes and line structures which had synthesized to produce the observed visibility curve. By this means the close structures of the lines of the hydrogen spectrum were obtained. One important observation was the finding that the red cadmium line 6438 Å was single and narrow. Thereupon Michelson adopted this narrow line as his standard in his next classical research, namely the evaluation of the standard metre interferometrically in terms of light waves.

Evaluation of the Metre with Light Waves.——The metre is internationally defined as the distance between two fine scratches on a bar of platino-iridium kept at Sèvres, near Paris. Rlichelson (1892) set himself the problem of counting the number of red cadmium light waves in this length. The line width is such that no fringes are visible with a path difference exceeding 20 cm.. and in any case there are some 1,500,000 waves to the metre. Thus a system of subdivided standards. called etalons. was adopted. The first was 10 cm.. and this was halved progressively eight times to 0.3906 mm., a length containing about 1,200 fringes and therefore reasonable for direct counting. The number of fringes in this smallest etalon A was directly counted by matching its front face against the interferometer movable mirror. retracting the latter slowly and counting until the mirror coincided with the back face. Coincidence was assured with white-light fringes. but the counting was carried out in red cadmium light. This etalon was doubled up against the next etalon B. and the only measurement which then had to be made was the difference $B \sim 2A$. This procedure was repeated until the exact length of the 10-cm. etalon was obtained. Finally this was stepped up ten times against itself. and this exactly known length then matched against the standard metre. The final result, given to 1 part in 2,000,000, was 1,553,163.5 red cadmium waves to the metre.

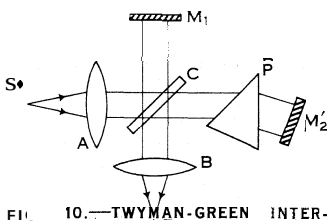

FIG. 10.—TWYMAN-GREEN INTERFEROMETER (1916) AS IT IS USED FOR TESTING A PRISM

4. The Twyman-Green Interferometer.— In 1916 F. Twyman and A. Green introduced a slight modification, adapting the Michelson interferometer for lens and prism testing and this became standard equipment in optical workshops. The essential feature is the introduction of strict Fizeau-type collimation by using a point source of monochromatic light at the focus of a well-corrected lens. The way in which the interferometer is used for testing a prism is shown in fig. 10 and for testing a lens in fig. 11. With a perfect prism P, a plane wave incident on P returns as such to D and a uniform field of illumination is seen. Local errors, either of surfacing or as knots in the glass with different refractive index, distort the wave front. The optician can then suitably correct these by working the glass until the emerging wave front is plane. For testing the lens L the plane mirror M_2 is replaced by a convex mirror M and the light strikes this normally, to retrace its path. Imperfections in the lens result in fringe distortions which can be interpreted in terms of spherical aberration, coma, astigmatism, etc.

5. The Linnik Interference Microscope.—A valuable modification was the interference microscope of W. Linnik (1926), which permits evaluation of surface microtopography to fringe accuracy in the up-down direction, and with magnifications up to 1,000 times across the surface in extension. The system is shown in fig. 12. A is the beam splitter, P the surface under examination and Q a reference flat. L_1 and L_2 are carefully matched high-power microscope objectives (usually 4-mm. lenses) so that L_1 together with lens systems L_3 L_4 constitutes a high-power microscope. One sees through this the surface P crossed with the fringes formed by P and Q so that the microtopography is contoured by fringes. Several interference microscopes were developed in which division oi amplitude takes place in a specially designed objective. An example is that of J. Dyson (1950).

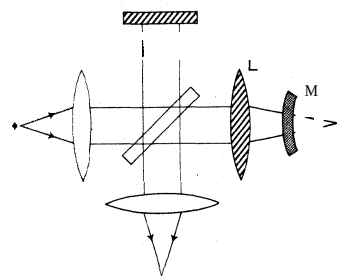

FIG. 11.—TWYMAN-GREEN INTERFEROMETER AS IT IS USED FOR TESTING A LENS

6. The Mach-Zehnder Interferometer.—Ernst Mach and L. A. Zehnder (1891) independently developed a modification of Jamin's interferometer, which though difficult to adjust has been widely used for studying air flow around models of aircraft. The svstem is shown in fir. 13. The mirrors A, and A_2 are half-silvered while B_1 and B_2 are fully silvered on the front faces. The object (aerodynamic model) is supported in the air chamber D through which a high-velocity air jet is blown. D_1 is an identical compensating chamber. Local pressure variations, due to flow. lead to local refractive index changes so that the flow pattern is revealed by fringe distortions.

There are two reasons why this instrument is better than Michelson's for aerodynamics. First, the optical circuit is such that the light traverses the observation chamber one way only. whereas in Michelson's instrument it passes and returns. Strong local refractive index variations have a prismatic action and displace the beam which would not quite retrace the same path on the return journey. Second, and more important. is the question of fringe localization. In Michelson's instrument the fringes are localized on the mirror M_1 (*see* earlier figures) whereas in the Mach-Zehnder system the fringes can be placed so as to coincide with the object in D. Thus both object and fringes can be photographed sharply in focus.

7. The Bates Wave-Front Shearing Interferometer.— W. J. Bates (1947) slightly modified the Mach-Zehnder system, with considerable advantages for the testing of large lenses or large curved mirrors. Using a collimated beam, he produced interference between two displaced parts of the same wave front by the shearing arrangement shown in fig. 14. A perfect lens gives a spherical wave which falls on the beam splitter A_1, and by tilting A, one secures two overlapping wave fronts Y and Z. The images from these wave fronts can be localized on A_2 and if these wave fronts are truly spherical, then any tilting of A, leads to no change in the field of view. If the wave front departs from the spherical, changes are seen which can be interpreted. Important is the fact that a large mirror or lens is matched against itself so that a large reference plane is not required.

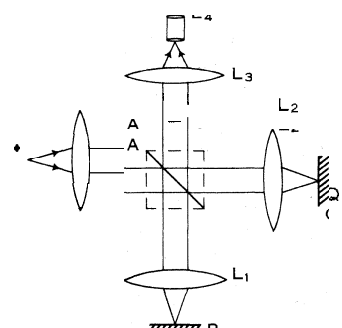

FIG. 12.—SYSTEM OF LINNIK'S INTERFERENCE MICROSCOPE (1926)

8. The **Fabry-Pérot** Interferometer. — Ranking almost in importance optically with the Michelson interferometer is that of C. Fabry and A. Pérot, which has an interesting history. In 1836 G. B. Airy had computed the effect on interference fringes of taking into account the successive multiple reflections (neglected previously because of negligible intensities). He showed that if light is incident at angle θ onto a plane parallel plate of thickness t then the transmitted intensity has the form

$$1 + \frac{4R}{(1-R)^2} \sin^2\left(\frac{2\pi\mu t}{\lambda} \cos\theta\right)$$

in which R is the reflection coefficient. This formula remained a forgotteh academic curiosity until A. Boulouch in 1893 drew at-

tention to the fact that when the reflectivity R is high (say, exceeding 80%) then this formula establishes that a profound sharpening in the fringes will take place. Indeed. Boulouch proved this to be the case experimentally.

However. it remained for Fabry and Pérot (1897) to realize the full implication of this when they produced their celebrated variable-gap interferometer. This consists of two very accurately worked planes (errors not exceeding $\frac{\lambda}{80}$ in the best instruments) maintained by optically worked spacers strictly parallel, to within a quite small fraction of a light wave. The tno plates, called an etalon. are coated with a thin transmitting film of high reflectivity (originally sputtered silver). Reflectivity should exceed 90%, and with modern techniques 95% and even 97% reflectivities are achieved with only perhaps 1.5% absorption, the rest being transmitted. Special techniques are needed to secure such low absorptions.

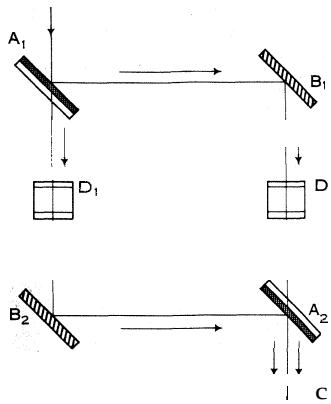

FIG. 13.—MACH-ZEHNDER INTERFEROMETRY SYSTEM, DEVELOPED IN 1891

This simple instrument is an extremely powerful optical system. Being essentially a parallel air plate, it produces Haidinger rings, localized at infinity. However. the important feature is that the successive multiple reflections, diminishing very slowly in intensity because of the high reflectivity, lead to the formation of very sharp narrow fringes. Fringes can be defined by their half width; *i.e.*, that fraction of an order occupied by the width at a region where the fringe intensity is half the peak maximum value. For reflectivity 95% the half width is about $\frac{1}{60}$ of an order separation, and as one can set to $\frac{1}{5}$ of a fringe width, this setting corresponds to $\frac{1}{600}$ of a wave length.

Only a brief resumé can be given of the many and varied uses of this admirable interferometer.

Analysis of *Hyperfine Structures* in Line Spectra.—The instrument is very widely used for the high resolution needed for revealing hyperfine structures in line spectra. At a wave length of 5,000 Å, a reflectivity of 95% and a plate separation of 10 cm. (which has been used) give a resolving power of some 20,000,000, so that one can resolve components separated by a mere 0.0002j A. Compare this with the resolving power of 100,000 available in the first order of a typical high-quality large diffraction grating.

Measurement of Line Width.—The high resolution and high dispersion enable the instrument to be used for evaluation of the widths of even quite narrow spectral lines. For example, interesting conclusions have been drawn about the temperatures in the upper atmosphere from measured line widths of auroral spectral lines.

Determination of Precision *Wave* Lengths.—The Fabry-Pérot interferometer is the standard instrument for accurate determination of the wave lengths of spectroscopic lines. By the use of three standard wave lengths (the cadmium lines 6,438.4916 Å, 5,085.8220 A, 4,799.9088 Å), each of which has been directly interferometrically evaluated against the standard metre, the spacing of the interferometer plates can. be derived with high accuracy. Then, from the measurement of the diameters of the fringes of the spectral lines under study, their wave lengths can be computed from the knowledge of this spacing, with an accuracy. in the best cases, of ± 0.001 A.

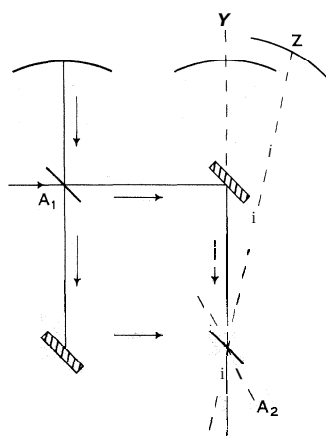

FIG. 14.— ARRANGEMENT OF W. J. BATES'S WAVE-FRONT SHEARING INTERFEROMETER (1947)

The *Evaluation of* the *Metre*.—J. R. Benôit, Fabry and Pérot (1913), combining the principles of the Brewster fringes with that of the Fabry-Pérot interferometer, redetermined the metre.

Multiple-beam Brewster fringes are produced in transmitted light by two Fabry-Pérot interferometers in series behind each other, their lengths being in the ratio 2:1. First the exact spacing in terms of the red cadmium line is found interferometrically for an interferometer with as near as possible a 6.25-cm. spacing. This is then matched, by Brewster fringes, against a 12.5-cm. etalon, then this against a 2j-cm., then this against a 50-cm. and finally the last is matched against an approximate 1-m. etalon. This etalon. the length of which is exactly known in wave lengths, can be compared with the standard metre quite rapidly, since only the difference is required.

Between Michelson's 1892 experiment and 1940, nine precision determinations were made by different laboratories; and the mean wave length for red cadmium was found to be 6.438 4696 ± 0.0010 Å, which by chance was exactly the value adopted by international agreement in 1907.

Refractive Index of Air.—The etalon gives the best values for the refractive indices and dispersions of gases. The exact metrical spacing of an enclosed interferometer is first found in *vacuo*. Then the new optical path is measured when air (or gas) is introduced. As typical of modern precision the refractive index for air (at 760 mm.. temperature 15° C. and 0.03% CO_2 content) for the red cadmium line is given by H. Barrel1 and J. E. Sears (1939) as 1.000276380.

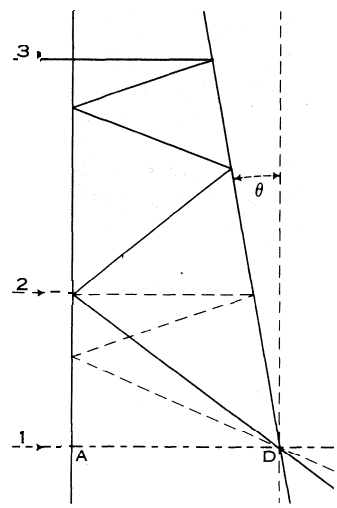

FIG. 15.—MULTIPLE-BEAM INTERFEROMETRY AS DEVELOPED BY S. TOLANSKY IN 1946

9. The Echelon and Lummer Plate Interferometers.—The echelon interferometer of Michelson and the Lummer plate interferometer, both species of multiple-beam interference instruments used specifically in spectroscopy, are discussed elsewhere (see SPECTROSCOPY) and need only be mentioned here.

III. MULTIPLE-BEAM INTERFEROMETRY

What is called multiple-beam interferometry is an important extension made by S. Tolansky (1946) of Boulouch's multiple-beam principle to include the case of wedge interference systems. The Fabry-Pérot interferometer was concerned with the circular fringes given by thick parallel plates. Such fringes arise from integration of light across the interferometer plates, hence the necessity for extreme flatness and extreme parallelism. Tolansky showed how the multiple-beam principle could be applied to thin-film localized wedge fringes; and thus succeeded in securing for topographical studies that same increase in power and sensitivity which the Fabry-Pérot interferometer had given to metrological and spectroscopic studies.

With highly reflecting plane surfaces inclined at a small angle, multiple reflections can lead to highly sharpened wedge fringes in accordance with the mechanism shown in fig. 1j.

Three successive beams. 1, 2. 3, are shown meeting at the point D. The beams are not in arithmetical phase behind each other, for the nth beam lags behind the arithmetical progression by an amount $X = \frac{4n^3\theta^2 t}{3}$ in which AD = t. Only if X is appreciably less than $\frac{\lambda}{5}$ will the necessary condition for Airy summation hold, to produce very sharp fringes. Since effective values of n up to some 80 are involved, sharpening takes place only if t is very small, indeed of the order of one or two light wave lengths.

FIG. 16.— SOME APPLICATIONS OF MULTIPLE-BEAM INTERFEROMETRY (see TEXT)

In the Fabry-Pérot-type fringes the fringe shape is determined by the term $\frac{4R}{(1-R)^2}\sin^2\left(\frac{2\pi\mu t}{\lambda}\cos\theta\right)$ in which the only variable is t. In multiple-beam localized wedge fringes the same formula holds, but θ is constant and the variable is t. The fringe widths in the two systems obey a similar relation.

The surfaces to be studied are coated with a high reflector, placed very close together and illuminated from a small pinhole with strictly collimated monochromatic light at normal incidence. The resulting considerable improvement in fringe sharpness is shown in fig. 16. In (A) are shown Newton's rings obtained with two beams and in (B) the same secured with multiple beams. In the sections which follow, a selection is given from some of the studies made by Tolansky employing multiple-beam methods.

1. Some Applications of Multiple-Beam Interferometry.—*Microtopographies* of *Surfaces.*—A new high order of accuracy has been achieved in the study of surface microtopography. The fringes are contour lines of 2,500 Å height. Fringes are of the order of some $\frac{1}{50}$ wide, and displacements of $\frac{1}{5}$ of a fringe width are clearly measurable. Thus step heights of 10 Å can be recorded, a quantity of molecular dimensions. Indeed crystal lattice spacings of from 12 to 20 Å have been measured to within 1 Å.

Fig. 16(C) shows the fringe pattern at a cleavage step on mica; such pictures establish that the steps are small integral multiples of the lattice spacing. Many crystals reveal beautiful topographies; fig. 16(D) shows a complex microtopography on the octahedral face of a diamond.

Experimentation has established that vacuum deposition of silver by thermal evaporation leads to strict contouring by the silver of the surface features, even down to molecular dimensions.

Thickness of *Thin* Films.—The multiple-beam interferometer is widely used for the precise measurement of the thicknesses of thin films. The film is coated with an opaque layer of silver. extending over the film boundary so that a step appears in this thick silver film equal in height to the original film being measured. This step is then measured against a silvered optical flat with multiple-beam fringes in reflection. Film thicknesses as small as only 25 Å can be measured. Fig. 16(E) shows the fringe pattern given by a film 550 Å in thickness. The fringes are very narrow and the accuracy in the step measurement is high.

Oscillations of Piezoelectric Crystal Plates.—Quartz plate oscillators play an important part in precision electronic circuitry as frequency stabilizers and precision clocks. A most interesting application reveals the distribution of nodes and antinodes and the exact local values of amplitudes on such oscillators. The crystal surface, polished and silvered for interferometry, is one electrode! and a wire meshwork is the other. The silvered crystal rests on a silvered optical flat. When set into oscillation the initially straight line fringes take on a stationary pattern which reveals the distribution of the vibration, and the local fringe shape gives an exact measure of the amplitude. Fig. 16(F) snows a vibrating bar and fig. 16(G) a vibrating disk. Frequencies in both cases are several kilocycles. yet the patterns are completely stationary.

Fringes of Equal Chromatic Order.—Tolansky in 1946 developed a system of white-light multiple-beam fringes which have considerable power and are advantageous in specific instances. Their formation is shown in fig. 17. A white-light source A is imaged on a small aperture C and a parallel beam directed at normal incidence onto the silvered pair of interferometer surfaces E. The two surfaces must be very close together. but it is advantageous if they are near parallelism rather than wedged. With the achromatic lens F an image of E is projected onto G, the slit of a spectrograph, which thus selects a very narrow section of the surface under examination. Sharp multiple-beam white-light fringes form at H, each fringe being the locus of points for which $\frac{t}{\lambda}$ is constant. They have been named fringes of equal chromatic order.

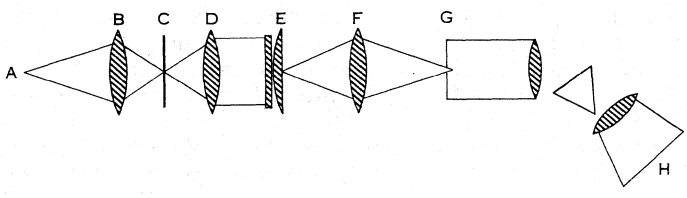

FIG. 17.— FORMATION OF WHITE-LIGHT MULTIPLE-BEAM FRINGES

For discontinuous steps, these fringes offer advantages. Examples are shown in fig. 16(H) which illustrates the fringes of equal chromatic order given by a silvered Newton's rings lens-plate combination. Fig. 16(I) illustrates the fringe pattern given by a very small surface depression with a depth of 4×10^{-6} cm. Each fringe is a contour line-profile over the same region on the object, but of different wave length. The separation between fringe pairs can be made very great. Magnifications of 500,000 times, with resolution of 10 Å, can readily be obtained. These great powers are in the up-down direction only.

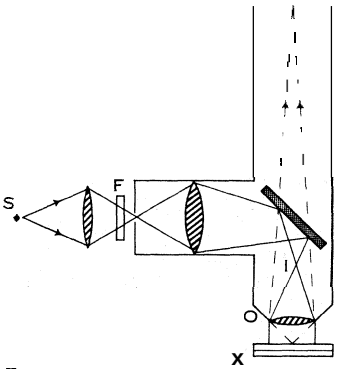

FIG. 18.—ARRANGEMENT WHEN A METALLURGICAL TYPE OF MICROSCOPE IS USED TO STUDY OPAQUE OBJECTS

Studies on *Opaque* Objects (Metals, *etc.*).—Many problems connected with surface flow, hardness indentation testing, crystal dislocation movements. electrodeposition, etc.. on metal surfaces have been studied with the multiple-beam interferometer. A metallurgical-type microscope must be employed with the arrangement shown in fig. 18. From a source S a point image I is formed at the back focal plane of the microscope objective O. The objective must illuminate the interferometer system with strictly parallel light at normal incidence and at the same time give a good microscopic image of the object X. As an example, fig 16(J) shows the distortions produced on a metal surface which has received a small micro-indent from a diamond pyramid, a procedure used in testing metal hardness. The distorted pattern is of crystallographic interest; for this indentation has been made on the surface of a single crystal of tin. The interference pattern indicates the character of the surface-flow distortion which results from the indentation. The asymmetry is even more marked than at first appears; for the extended horizontal lobes are elevations, while the smaller lobes at right angles to these are depressions. This shows that in one direction the surface "piles up." while at right angles to this it "sinks in." In fact, X-ray examination shows that these lobes lie along crystallographic axis directions. They reveal a differential directional hardness variation in the tin crystal. Such interferometric studies have already revealed much new information about surface-flow phenomena when materials are distorted.

BIBLIOGRAPHY.—The long article on interferometry by W. Feussner and L. Janicki in E. Gehrcke's Handhuch der Physikalischen *Optik,* 2 vol. (1927) is detailed and learned. C. Fabry's Les Applications des *interférences lumineuses* (1923) contains a great deal of value, especially on applications of the Fabry-Pérot interferometer. A. A. Michelson's *Studies* in Optics (1927) is a delightful exposition of Michelson's personal fundamental contributions. C. Candler's *Interferometers* (1951) contains much useful detail on instrumentation. An elementary introduction to the whole subject of interferometry is given in S. Tolansky, *Introduction* to *Interferometry* (1955). Spectroscopic interferometers are discussed in detail in S. Tolansky, High Resolution Spectroscopy (1942). The theory and practice of multiple-beam interferometry is given in S. Tolansky, *Multiple-Beam Interferometry* of *Surfaces* hnd *Films* (1948). (S. TY)

INTERGLACIAL STAGES, a series of comparatively warm and mild intervals, each several thousand years, between the equally prolonged times of extreme cold in the Pleistocene glacial period (see PLEISTOCENE EPOCH). For the stages of extreme cold the geologist A. Penck chose names from representative districts in the Alps: Günz, Mindel, Riss and Würm; of these, the Günz stage is the earliest; the Würm stage, the most recent. Penck chose these names because their order in

the alphabet corresponds to the chronological order of the four stages. while space is left between them for additional names, should additional stages of cold be defined.

The same names are conveniently used to indicate the intervening warmer stages. Thus the first mild interglacial stage is called the Günz-Mindel stage; the second, the Mindel-Riss stage; the third, the Riss-Wiirm. This cyclic alternation of climate through the Pleistocene period is accompanied by alternating arctic and temperate fauna and flora, while there is a further change, particularly of the fauna, due to the steady evolution of forms throughout the Pleistocene period. Thus in Europe during the colder stages the woolly mammoth and reindeer reached the south of France. while one of the interglacial stages was so warm that the lion and hippopotamus flourished in England.

In Sorth America there was a similar cyclic alternation of climatic conditions throughout the Pleistocene glacial period. but there are difficulties in the way of drawing definite parallels between the old world and the American stages. It is likely, however, that the earliest glacial stage in North America. which includes the pre-Kansan, Nebraskan and Albertan drifts, and which is called sub-Aftonian by American geologists, coincided with the Giinz of Penck. The earliest, or Xftonian. interglacial stage of North America would thus correspond with Penck's Günz-Mindel interval. In Sorth America, the Aftonian interglacial stage was marked by the presence of mastodons, three species of elephants, six species of horses, and the sabre-toothed tiger.

The second, or Kansan glacial stage in North America, corresponding to the Mindel ot Europe saw the extinction of some American camels and horses. It was followed by the Yarmouth interglacial stage. parallel to Penck's Mindel-Kiss, when the fauna included mastodons, mammoths, horses, tapirs, bison, deer and sabre-toothed tigers.

The third, or Illinoian, glacial stage in North America, corresponds to Penck's Riss. It was followed by the Sangamon interglacial stage; this was in its turn fourth, or Iowan, glacial stage. the record of which is not well defined. The fourth, or Peorian, interglacial stage followed; it presents similar difficulties.

The fifth. or Wisconsin, glacial stage appears to correspond to the European Würm. It was followed by the postglacial stage. which gradually merges into the present time. Elephants, mastodons, horses and the great sloths disappeared! the exact cause of their disappearance being unknown.

In the earlier or preglacial stage, Pleistocene vegetation was characterized by a commingling of warm temperate and cool temperate forms. During the alternating interglacial periods the record of plant life in the more northern regions indicates a succession of forest, barren ground, steppe, tundra and arctic types with each increase of glaciation. Upon the retreat of the glaciers this succession of plant types recurred but in reversed order. In some interglacial periods the climate was milder for the same latitudes than at the present time, so that numerous trees, for example, extended some hundreds of miles north of their present range. In the postglacial or late Pleistocene stage, which blends into the Recent, plant life assumed substantially the present status and distribution. Many arguments may be advanced supporting the view that the postglacial and recent constitute a part of an interglacial stage, as the time that has elapsed since the disappearance of the last great ice sheets from Europe and northeastern Sorth America is less than the duration of some of the former interglacial stages. The effect of glaciation upon the vegetation of Europe and North America, especially the former. was profound! not only with reference to the present distribution of the flora, but also as regards the extinction of old and the evolution of new types. In Europe the high mountain chains, which extend in an east-and-\vest direction, together with the Mediterranean, Black and Caspian seas, prevented the migration of the flora southward. In consequence an immense number of plants formerly components of the European flora, particularly that north of the Alps. was obliterated by glaciation. Numerous types of trees now found only in Sorth America and Asia were abundant in Europe in pre-Pleistocene and part of Pleistocene times. Among these were such important trees as the black walnut, butternut, hickory, magnolia, bald cypress and sassafras (*qq.v.*).

In North America the back-and-forth movement of plant life was not impeded, as in Europe, by high mountains and inland seas. The presence of the larch *(Larix laricina)* in Georgia, of the black spruce *(Picea mariana)* in Kansas and of the white spruce *(Picea glauca)* in Iowa, all far south of their present range, has been demonstrated. Likewise, the presence during a mild interglacial stage of a fig in fruit in British Columbia, and of the redbud *(Cercis)*, the Osage orange (*Maclura*), the papaw (*Asimina triloba*) and other warm temperate types as far north as Toronto. Ont., has been proved.

INTER-GOVERNMENTAL MARITIME CONSULTATIVE ORGANIZATION (IMCO), a specialized agency of the United Nations, came into existence on March 17, 1958, and was organized in Jan. 1959.

IMCO was established to promote international co-operation in maritime navigation and encourage the maximum use of safety measures; to encourage also the removal of discriminatory action and unnecessary restrictions by governments affecting international shipping; and to consider matters concerning unfair restrictive practices by shipping concerns.

It concentrated early on technical aspects of shipping such as safety at sea, pollution of the sea and tonnage measurement of ships. (M. H. H.)

INTERIOR, DEPARTMENT OF: see GOVERNMENT DEPARTMENTS.

INTERIOR DECORATION. In this article the history of interior decoration is arranged chronologically under the following headings: Egypt, Greece and Rome, Japan, India, Europe and United States. If it is read together with the article FURNITURE, arranged on similar lines, a picture can be obtained of the interiors of houses through the ages in different parts of the world.

ANCIENT CIVILIZATIONS

Egypt. — In Egypt the invariable material for houses was sun-dried brick. The roof was of reed-thatch and the floors of beaten earth. The interior walls were smoothed down with fine mud plaster and often covered with a white or coloured wash.

At the beginning of the historic period (1st dynasty, *c.* 4500 B.C.) rush or palm-leaf mats, woven in coloured patterns, were hung on horizontal rods across doorways to serve as doors or were hung on walls as decorations. They appear to have been used also as blinds at windows to keep the sun out, but the mechanism by which they were raised and lowered does not appear; it was probably of the simplest. Green-glazed tiles, 9 in. square, were used as a dado in an important building, perhaps a royal palace; they represent reed matting. Possibly the custom of decorating chambers in the tombs which were supposed to be frequented by the dead arose from the custom of decorating the rooms of the living.

In the 12th dynasty (*c.* 2500 B.C.) in the workmen's town of Kahun, the better-class houses had rooms decorated with a foot-high band of dark brown paint all round the bottom of the walls, not unlike a skirting board of modern times; above this was a dado, 4 ft. high, of vertical stripes in black, white and red. The upper part of the wall was colour-washed in a light shade of buff, on which, in a few cases, were brightly coloured frescoes.

In the palaces at Tell el Amarna (1375–58 B.C.) the interior walls were highly decorated with paintings of flowers and vines in their natural colours, with here and there scenes of animals, and the endless representations of Ikhnaton, Queen Nefertiti and their daughters. The decorations were in paint, often very delicate and beautiful; the naturalistic effect was enhanced by the inlay of the flowers and bunches of grapes moulded in coloured glazed ware, the grapes dark purple, the poppies red, the cornflowers bright blue and the large daisies with white petals and brilliant yellow centres.

The floors of the principal rooms were also painted, often with scenes of gardens and with ornamental ponds with lotuses in bud and blossom, fish swimming and numbers of water

birds on the banks. These painted floors are probably the origin of the mosaic pavements of later times.

As Egypt began to fall into decay after this period, the houses being of mud brick soon crumbled away and were reduced to utter ruin and their decorations perished with them.

See M. Murray, *The Splendour That Was Egypt* (London, New York, 1949). (M. A. M.)

Greece and Rome.—The Greeks and Romans delighted in colour and made effective use of it in the decoration of their houses and public buildings. Wall painting, a form of art. known to the ancient world since Mycenaean times *(see* AEGEAN CIVILIZATION; ARCHAEOLOGY: *Greek and Roman Orient (including Egypt-Indus)*. flourished in domestic contexts from the Hellenistic period onward. and many of the geometric and floral motifs developed at Pompeii and Herculaneum and in Rome itself spread throughout the empire and are found on many provincial sites. Scenes with human figures, animals, birds or fish also occur outside Italy, some of them. like the 4th-century Christian paintings from the villa at Lullingstone in Kent, Eng., obviously derived from the art of the Roman catacombs. The custom of decorating walls with thin sheets of marble and other coloured stones was also popular in Hellenistic and early imperial Greece and Italy; and, at a later date, wall decorations imitating these veneers in paint were no less widespread. In the 3rd and 4th centuries A.D. the use of actual marble for this purpose was revived, as, for instance, at Ostia, in association with floors of gaily coloured *opus sectile.*

Other methods of decoration, which became particularly fashionable in the 1st century B.C. and onward, when building in Rome was increasingly elaborate, include the use of slabs of terra cotta, either as individual plaques let into the walls or to form continuous friezes running round the rooms. These were ornamented with reliefs depicting gods, myths. pastoral scenes or episodes from the circus. Panels of fine stuccowork portraying the same themes were similarly used, and some particularly exquisite examples of Augustan work of this type were found in the Farnesine house in Rome. A house on the Palatine, probably of late republican date, shows griffins in white stucco on a red ground; while the vaults of ceilings of the early empire were often covered with small cameolike figures modelled on coloured backgrounds and occasionally gilded. Mosaics made of glass tesserae were used for vaults and apses, and decorated pavements, ranging from the early pebble mosaics of Delos to the later black-and-white or polychrome mosaics found all over the Roman empire, also formed part of these elaborate colour schemes *(see* MOSAIC).

Further touches of colour were added to a room by the curtains and furniture coverings. Mattresses. cushions and pillows were used with couches and chairs from the earliest times. No actual examples of these objects have survived. but they are frequently depicted on reliefs and in vase and wall paintings, where they are shown as provided with woollen or linen covers sometimes woven in very ornamental designs; the exceptionally thick mattresses popular in the and century A.D. often had very richly figured covers. Cushions and pillows were usually square or oblong in shape, and long, round bolsters were also used. The more luxurious were decorated with tassels and a fringe, or were covered in silk or cloth of gold. The stuffing seems to have consisted of feathers. straw, other vegetable materials or wool, described by Petronius as sometimes dyed scarlet or purple. Bedclothes included rush mats. skin rugs and loose draperies, and mattresses were occasionally embellished with valances. A painted stone funerary couch carved in a Ptolemaic tomb near Alexandria shows a mattress and pillows covered in a red material with broad yellow and narrow blue stripes and figures of women in gold woven in at some points. The main valance hangs down from behind a horizontal frame adorned with a frieze of gold cupids driving chariots drawn by stags, and it has a blue centre and a red border decorated with gold figures and red tassels. It may be assumed that such sepulchral couches had domestic prototypes.

Fragments of fabrics of wool, linen: cotton and Chinese silk have been found in tombs at Palmyra and a portion of a curtain or seat cover discovered at Doura-Europos bears rows of quatrefoil roses with petals shaded in dark red and pink, all outlined in tan on a green ground. Elaborate furnishings of this kind are mentioned by Horace, Propertius. Cicero and other authors, and further illustrated by such Pompeian mall paintings as the scene of the courtship of Venus and Mars in the house of Marcus Lucius Fronto, which shows a couch covered with purple, scarlet and dark green draperies with stripes and bands. of scarlet, yellow and purple. and a stool draped in red, gold and blue material with a golden fringe.

Objets d'art such as statues or statuettes of bronze or marble, painted vases and bowls and dishes of red-glazed pottery, silver, bronze or glass of various colours further enlivened Greek and Roman interiors. Lighting was provided by pottery or bronze lamps made in a variety of shapes. Sometimes these were placed or hung on elaborate bronze lampstands; fine examples of tall candelabra survive from Pompeii.

The statues and vases were displayed on shelves or placed on tables or on elaborate folding bronze tripods, the legs of which were decorated with busts and animal feet. When the tripod supported a tray or table top, the latter might be covered with a fringed tablecloth. Sometimes, however, the tops of the legs were provided with hooks which fitted under the rim of a bronze bowl or brazier; larger braziers and water heaters of bronze have come to light at Pompeii. These beautiful objects, when offset by the gaily coloured furniture and draperies and by the brilliant wall paintings and marble or mosaic floors, must have turned the interior of the dwelling of a well-to-do Hellenistic Greek or Roman into a truly gorgeous spectacle.

THE ORIENT

Japan.—The interior of a Japanese house has probably changed much less than most in the course of 1,000 years. Almost the only difference is that the rooms are now divided by sliding doors, whereas in mediaeval times there were only single-leaf screens and curtains, and the wooden floors are pou entirely covered by mats. In these earlier buildings there were pivoted doors in the Chinese manner and windows of wooden grating that pushed outward instead of the sliding shōji, such as may still be seen in shrines and temples. There was a curtained dais for the most important person and separate mats on the wooden floor for others. Then as now there was a connecting corridor outside the rooms. The *Seiryoden,* or ordinary residence of the sovereign in the Kyoto palace, a simple suite in ancient style with its walls and standing screens decorated with pictures in the Chinese classic manner, is a surviving example of a 10th-century interior in which a present-day family could live quite comfortably.

It was in the late 15th century that the interior began to assume its present form. This was the result of the blending of the older court style with the more austere type of house favoured by the military caste, which was much influenced by Zen Buddhist architecture. Then in the later 16th century under the aesthetic autocrats Nobunaga and Hideyoshi came the rise of the tea masters. These connoisseurs of the "Way of Tea," which comprises the construction of the tearoom and its garden and the correct deportment in them, established hereditary families and schools and have ever since remained the established aesthetic advisers on most aspects of domestic architecture, interior decoration and garden planning. Their principles emphasized beauty with cheapness, asymmetry and economy of movement. Much of the simple grace of these interiors is due to them.

A survey of the interiors of a number of Japanese houses would probably convey the following impressions: that they all had a quiet harmonious and unostentatious delicacy, that any decoration was almost entirely constructional and that the residences of all classes were equally neat and pleasant and lacking in disorder

and vulgarity. Their decorative qualities derive from an infinite variety of detail in a setting that is completely standardized, for the ordinary rooms are multiples of the floor-mat unit of 6 ft. by 3 ft., the sliding doors 5 ft. 8 in. high by 3 ft. wide, the supporting pillars 33 in. to 4 in. square, set at 6 ft. intervals, and the ceiling boards 1 ft. to 1.5 ft. wide. All woodwork is unpainted and rarely lacquered. But there is a great variety in the fusuma or sliding doors which divide the rooms and which are covered with paper of many patterns or decorated with paintings or calligraphy. Thus the whole side of a room may present a landscape either in black and white or in colours, often on a silver or gold background, while a change of these fusuma will completely alter its appearance, and their removal throw two or more rooms into one. All rooms may be used as bedrooms, since the bedding is kept in spacious cupboards with other utensils, but the reception rooms provide more scope for decoration than the others, for there one end of the room is occupied by a tokonoma, an alcove with a canopy above it supported by a pillar of fine or uncommon wood, in which is hung the picture or set of pictures which, with the flower arrangement that usually accompanies it, is the only ornament. Both are changed frequently according to the season or taste. Next to it a writing table is often built in. Beside the tokonoma is usually a *chigai-dana,* an asymmetric arrangement of cupboards and shelves somewhat like a sideboard. Between the top of the fusuma and the ceiling is often a *ramma* or openwork frieze carved with patterns or landscapes in wood or bamboo. A framed tablet with a poem or painting on it may sometimes find a place there. Other walls are of plain plaster in subdued shades, mostly of gray or brown. The ceilings are usually of thin boards, slightly overlapping, upheld by bars about an inch square, the whole suspended from the roof or floor beams. In large apartments as in shrines and temples the coved and coffered "Chinese ceiling" with lacquered woodwork and pictures and patterns in the coffers is sometimes found. Fancy varieties made of bamboo and reeds and plaited wood are not uncommon. Occasional articles in these rooms, which otherwise have no furniture, may be a cabinet of blackwood or lacquer, a low writing table or a screen, either twofold or sixfold, the latter generally in pairs, decorated with landscapes on a gold or silver background and mounted in brocade, while a single-leaf screen sometimes stands in the entrance hall. These with other valuables such as scroll pictures, braziers, pottery, spare fusuma, books and curios are kept in a detached fireproof storehouse by the well-to-do and produced only occasionally to ensure a constant variety in the rooms. It is a principle that rooms that are only occasionally occupied may be more showy and fanciful than ordinary living rooms, and these are most often met with in hotels and restaurants and other places of entertainment. Just as much care is taken with the interiors of the bathroom and privy as with the other rooms, and the doors and windows and walls of these are usually of excellent workmanship. Those in famous restaurants are often wonderfully decorative. Bamboo has many uses in the Japanese house as pillars and window bars and ceiling material, and when split and flattened may take the place of boards. Some idea of the variety of the fitments may be obtained from the series of volumes of Illustrations of Architectural Details by Kenchiku Shashin Ruiju (Tokyo, 1916) that give 150 different examples of tokonoma and chigaidana arrangements, 100 of *ramma,* 100 of sliding doors, about 20 of ceilings and 50 of windows. These latter are of many shapes, round, square, bell-shaped, jar-shaped, gourd-shaped, diamond- and fan-shaped and purely asymmetric, and make a happy diversion in a blank wall.

There is little interior decoration in Chinese houses. The principal feature is the furniture, and the reader will find this treated in the article FURNITURE.

See also *A. L.* Sadler, *A Short History of Japanese Architecture* (Sydney, London, 1941); R. T. Paine and A. Soper, *The Art and Architecture of Japan* (Harmondsworth, 1955). (A. L. SR.)

India. — Words of Indian origin such as calico, chintz, palampore are in themselves an indication of India's importance in the history of interior decoration. Yet, Indians themselves have never been very conscious of this role, their own domestic interiors being of the utmost simplicity, with hardly more than a carpet or prayer mat to offset stone floors and plain white walls.

In fact it can be shown that India's role, although of great importance, was less revolutionary than is generally supposed. The painted calico hangings and bedspreads exported to Europe in bulk during the 17th and 18th centuries were mostly inspired by western examples in the first place. The usual practice was that the directors of the East India company in London sent out sample patterns to their agents in India with instructions that Indian calico painters and embroiderers should be commissioned to produce designs "after the same manner." It is even arguable that the well-known "tree of life" type of design was ultimately of English origin, for in 1669 (when this type first appeared in Indo-European textiles) the London directors of the company were writing to India: "Now of late, they are here in England come to a great practize of printing large branches for hangings of Romes, and we do believe that some of our calicoes painted after that manner might vent well, and therefore have sent you some patterns. . . ." The sample patterns were probably sent in a form similar to the many contemporary pattern books published in England for domestic embroiderers — in other words, as black and white drawings in quarto or smaller. Therefore, in making freehand enlargements, the Indian draftsman would have been compelled to elaborate according to his own imagination details of the flora and fauna with which he was not familiar. This perhaps explains why common European motifs appear in a very distorted form in many of the Indian designs — for example, the oak leaf, which the Indian copyist renders with exaggerated dentations, or the strawberry fruit, with unduly large seeds. In both cases the effect is exotic, and such motifs are hardly recognizable as European without prior knowledge of how they came into being. It was precisely this element of exoticism which gave Indian hangings and bedspreads such a wide appeal in Europe.

The demand for such goods reached its peak in the last quarter of the 17th century. In 1683 the directors of the East India company wrote enthusiastically to their agents in India that "you cannot imagine what a vast number of them [chintz] would sell here to content . . . 200,000 of all sorts in a year will not be too much for this markett, if our directions be punctually observed in the providing of them."

Competition with home industries led to agitation for stopping imports. In 1686 France introduced a ban, and England followed with the restrictive acts of 1701 and 1720. But in both countries the law was a dead letter and ways were found of evading it. Throughout the 18th century, Indian fabrics found their way into every fashionable English household, and it would be difficult to discuss the interior decoration of the period without them.

Toward the end of the 18th century, the traditional Indian methods of calico painting by resist and mordant processes gradually gave way to the cheaper print-block technique. This was accompanied by artistic degeneration, and in the 19th century Indian hangings and bedspreads were a poor shadow of the earlier tradition.

Two fine collections of the 17th- and 18th-century fabrics were preserved at the Victoria and Albert museum, London, and the Royal Ontario Museum of Archaeology, Toronto — the original private collections of G. P. Baker and Harry Wearne, respectively.

See G. P. Baker, *Calico Painting and Printing in the East Indies* (London, 1921); H. Clouzot, *Painted and Printed Fabrics* (New York, 1927). The latest research on the subject is mostly scattered in the form of articles. (J. C. I.)

EUROPE

Early Middle Ages. — In the earliest middle ages, after the collapse of the Roman empire, when nearly all the amenities of domestic life so highly developed by the Romans were lost to western Europe, interior decoration, as it is now understood, can hardly be said to have existed at all. They were times of incessant war and general insecurity, and above all else it was necessary for the owner of a house to be able to defend what he owned, and therefore in these times, and late into the mediaeval period, the larger and more important houses were strongholds rather than dwellings and were designed accordingly. For the same rea-

sons, a man who owned more than one house or castle and moved from one to the other found it necessary to take all his possessions with him, and so the interior fittings were limited in number and were as simple as possible.

The principal living apartment was a large hall with bare walls. open-beamed roof. narrow windows, at this period unglazed. and a floor of stone slabs, tiles or beaten earth. There was practically no furniture. Window curtains. if used, were suspended on hinged rods, swung away from the windows during the daytime. The doorways might have similar curtains. In earlier times the log fire burned in the middle of the floor, the smoke, somewhat uncertainly, finding its escape through a hole in the roof or left to disperse among the rafters. Later, large hooded stone fireplaces uere built into the wall; early English examples still exist at Stokesay castle in Shropshire, dating from the 13th century. Metal braziers on wheels, for local heating, were used during the late middle ages.

In the earliest times the whole community often lived and slept in the one hall, but slomly the house became divided up and separate rooms were provided for members of the family and for the use of important guests. At first one or more spaces in the hall mere curtained off by movable hangings, suspended from the rafters or from iron rods projecting from the walls. and separate apartments were thus temporarily provided

When recesses in the hall were curtained off, a first approach to separate sleeping rooms was made which eventually led to the building of proper bedrooms. Solars and cabinets or bowers for women's work and recreation were developed in this way. The kitchen was a low apartment with a depression in the middle of the floor for the fire, covered with a great iron grid for cooking upon.

The houses of those other than the nobility and wealthy classes, and particularly those of the serfs and peasantry, were far more primitively constructed and equipped. They were small, often circular, huts. lined with wattles, the floor being of bare earth, and with no interior decoration or fittings worthy of the name.

Later **Middle** Ages.—Such conditions, varying according to local circumstances, were generally prevalent in western Europe down to the close of the 12th century. Where eastern habits of life had already penetrated, as in Spain or Sicily, magnificent buildings were erected. A room in the palace at Palermo, Sic., is still known as that of the Norman king, Roger II. The walls are lined with marble; the lunettes and ceiling are encrusted with elaborate mosaics.

Changes were gradual and progressive, but a definite step forward was made about the 12th century. Most of the military leaders in France, and many in neighbouring countries, had by then taken part in the crusades, and they had learned something of the more luxurious mode of living in the middle east. Also during the folloaing centuries life gradually became more secure and the castle slowly evolved into the unfortified manor house. The accumulation of more elaborate household equipment, both decoration and furniture, began. and at the same time women began to take a more prominent share in the regulation of the household and the provision of daily needs. Curtains brought back from the east would be of thinner texture and were drawn back in folds rather than swung away on rods. Tapestries and various hangings relieved the bareness of the walls and gave additional uarmth to rooms; similar textiles were often draped over chairs and tables, and brightly coloured cushions were used. The wooden ceilings might be coffered, and sometimes painted in bright colours and gold. Where shutters nere provided for windows, glazing was not so necessary, though glass became commoner as the middle ages progressed. Many of the mediaeval rooms that still exist today give a falsely austere and stark impression of nhat they were like originally. In the later part of this period a certain degree of comfort, though crude by present-day standards, was attained, and the appearance of rooms, nith their hangings and painted decorations, their painted furniture and brightly woven cushions, would have been gay and cheerful.

Throughout this period the breaking up of houses into separate rooms, serving special purposes and providing greater privacy, continued slotily, though the hall still remained the hub of the life of any house. As time went on the hall continued to serve many purposes, but gradually the house became divided into an antechamber, hall and withdrawing chamber. There might also be a special guest room, as the one described in the 14th-century English poem, *Sir Gawayne and the Grene Knight*.

In the later middle ages the wardrobe was a separate room, with deep presses lining the walls. having cupboards above and lockers below. Here were stored the hangings, floor coverings, curtains, tapestries and linen of the establishment. besides the garments and other materials necessary for a large household. With the lack of shops this was the place to replenish supplies. It was also the workroom with tables and other provisions for tailors and needlewomen.

The kitchen was now provided with vast, low arched recesses in the walls, where the fire could be better regulated than in the middle of the floor. Rotating spits in stages. for roasting, had dripping pans below and there were adjustable hooks for suspending cooking pots over the fire. The floor, of stone or earthenware tiles in large houses, of bare earth in others, was covered with sawdust, as it was until recently in large kitchens. In time it became usual to spread the floor with rushes and with fragrant herbs, and later still the rushes were plaited into mats. Plain woollen cloth or furs were sometimes laid down. For ceremonial occasions. rich fabrics were spread before the royal throne. Oriental pile carpets were not used before the 15th century, and were rare in western Europe before the 17th.

Torches at first provided the principal lighting, and the fire gave light as well as heat. There might be a few sconces fixed to the walls, with prickets for candles. Standing candelabra of iron for many candles came into use, as well as small portable pricket candlesticks, and occasionally chandeliers, or lustres, hung from the rafters.

The use of ornaments and various articles of luxury grew during the times of the crusades, increasing in subsequent centuries as commercial relations with the near east became closer. The household plate, of gold or silver, was frequently displayed for decorative purposes and to impress visitors, on sideboards and cupboards. It was not unknown for these to be roped off to prevent the near approach of the acquisitive hand. Indoor provisions for washing and bathing must also be included among luxuries. A long trough with a row of taps in the courtyard served for most of the household. At times there was a tank or cistern with water continually running. A metal bowl, flat-sided, was sometimes fixed to the wall of a living room, with a swinging ewer or a small cistern with a tap over it and a towel on a hinged rod. Small convex mirrors were hung on the walls as early as the 15th century, such as the famous one in the portrait of Jan Arnolfini and his wife by Jan van Eyck in the National gallery, London, but hand mirrors, usually of polished metal, were the only sort in general use before that time.

An illustration in the celebrated manuscript in the museum at Chantilly. Fr., the *Très riches Heures du duc de Berry*, shows a striking picture of seignurial life in the first half of the 15th century. It represents King René seated at table. Behind him is a large hooded fireplace and he is protected from its heat by a circular screen of plaited rushes. The wall is covered with tapestry hung on hooks. The table is covered with a white cloth and there is rush matting on the floor.

In the Alpine lands, such as Switzerland, the Tirol and south Germany, the use of fir, pine and other soft local woods determined the form and ornamentation of much of the interior of houses there. Floors, walls and ceilings would be made entirely of wood, as they often are today. A bedroom from the Landesfürstliche Burg at Meran (Merano), south Tirol, is a remarkably well-preserved example of an interior in a house of some standing in the latter half of the 15th century. The old Swiss furnished interiors exhibited at the Historical museum in Basle, though only in one case dating back to the mediaeval period, illustrate much that has been said about earlier times. There are others in the museums of Berne and Zurich, covering the period from the 15th to the 17th centuries. Floors are of wood, walls

and ceilings are panelled and moulded. Sometimes there is inlay of harder and more ornamental woods. The mouldings are bold, but any carving is usually in slight relief because of the nature of the wood; the inlay is generally simple and geometrical.

The Castello d'Issogne, in the Val d'Aosta in northern Italy, is remarkable among surviving examples of the adaptation of the mediaeval domestic interior to the mild climate south of the Alps, where the Gothic style never took such firm roots as in northern Europe. It was built about 1490 by a member of the Challant family who held the post of governor of the Val d'Aosta. Though mediaeval in structure and appearance, it is not a stronghold, but a summer resort. It is built in a square with a tower at each corner. There is an inner courtyard, alongside of which is a kind of vaulted portico supported by pillars and open to the courtyard. This is used as a hall, with wooden linen-fold panelling and a fixed bench running along the wall. The lunettes above the panelling are filled with fresco paintings of scenes of daily life—the shops of a provision merchant, an apothecary, a tailor and a draper, and an outdoor market and soldiers in a guardroom. There is also a dining room, an armoury, a kitchen, a servants' hall and a chapel. The coffered ceilings are carved and painted.

Stokesay castle in Shropshire is one of the most complete remaining early domestic dwellings in England, a fortified manor dating in part from the 13th century. The large hall has a high open-beamed roof, the unglazed windows have wide stone seats and the floor is of beaten earth. An outside flight of stone steps leads to the solar, a private room for the owner of the manor, where there is a built-in fireplace. The house has other separate rooms and is an early example of the development of some form of privacy in the domestic arrangements of the English interior.

A notable early specialist in house decoration in England was Henry III, who rebuilt Westminster abbey. The Liberate rolls of his reign preserve all the orders he gave for the adornment of his various castles and manor houses. Larger windows, and especially rose windows, were built in halls, their painted glass adding to the rich colour decoration that the king liked and obtained at other times by painting "histories" on his walls, as in his Great chamber at Westminster. His queen had a figure of winter painted over her fireplace there and springlike flowers painted on the whitewash of her room at the Tower of London. Walls were frescoed with histories, including both biblical and classical scenes, and below them often was wainscoting with painted and decorated boarding. Wrought roofs or painted ceilings completed a rich domestic treatment, which was rare in 13th-century England, when walls were bare and hangings were the usual means of decoration used by the wealthier classes.

Flanders tapestries, known by the generic name of arras, were then the most favoured hangings. Solidly woven, they resisted the wear and tear of being moved frequently from one house to another. Tapestries were hung curtainwise from wood quartering set with tenterhooks, and such have been renovated at Tattershall castle where, except for such hangings, the brick structure of the walls was visible, as is also seen in a picture from an illuminated manuscript produced in Flanders for Edward IV (*c.* 1475) of Richard II feasting. There is no arras, but the king sits under a rich textile canopy, similar material also hanging in front of the musicians' stand. It was not as yet customary to have the walls lined with panelling, but wood was used for structural purposes as hall screens and room partitions. Also noteworthy is the great heraldically carved chimney piece at Tattershall, dating from about 1436.

In most features of interior decoration in the later middle ages England was strongly influenced by and followed the fashions of France and, through it, the Low Countries; and development both in furnishing and interior decoration lagged behind the more sophisticated French interiors and the solid comforts of houses in the Low Countries.

RENAISSANCE

The Renaissance, originating in Italy in the early years of the 15th century, provided a new style of interior decoration. This was created both by the new humanist approach to the world, and in this particular case to man's domestic background, and in practice by a new interest in the classical tradition, which had never been entirely lost in Italy and which now provided inspiration both for design and ornament. Traces of Roman greatness were to be seen in many places, though excavation was only undertaken with the aim of obtaining building materials from the ancient ruins. When a deliberate return to the classical style was made, the borrowing of the classical orders for example, it was not merely copied, but was adapted and enriched and used in novel arrangements.

The Italian Renaissance interior is characterized by the use of classical architectural features, which besides being incorporated in the more structural elements of the room, such as doorways, fireplaces and windows, were also used in other decorative mediums such as plasterwork, wood panelling and painted decorations. Besides the pillars, entablatures and heavy mouldings, a wealth of other ornament inspired by classical sources was employed in every decorative technique. Among the most familiar are the reclining *amorini*, floral garlands, caryatids, grotesque and lion masks, scrollwork, floral arabesques, cornucopia and trophies of arms.

The number of rooms increased and the larger palaces and houses achieved a richness of treatment and a spatial grandeur hitherto unknown in western Europe. Windows became larger, fine staircases were introduced and fireplaces and doorways were elaborately decorated, becoming key features in the scheme of a room. The fireplace by Benedetto da Rovezzano, now in the National museum, Florence, is characteristic, with its architectural design and its finely sculptured decoration.

The walls of great houses were often pictorially painted, the cornice and ceiling enriched with elaborate painted and gilded plasterwork. Subjects were drawn from classical mythology and from religious sources. In the Sala del Credo, one of the rooms in the Borgia apartments in the Vatican, the lunettes are decorated with paintings of the apostles, while benches of coloured marble fill the window embrasures. Sometimes, as in the Hall of Exchange in the Collegio del Cambio with its painted decorations by Perugino, the lower part of the wall is lined with wood panelling, frequently carved with pilasters and painted and gilded. Panelling decorated with intarsia, often reproducing startling effects of perspective, is found in Italy, a celebrated example being the room at the Palazzo Ducale, Urbino, where the effect of open cupboards full of books is created.

The interior decoration of France was first influenced by the Italian Renaissance in the reign of Francis I (1515–47). The French monarchs of the 16th century invited Italian artists to the court; they were employed in extensive undertakings and the forms that they introduced were generally followed. The chimney piece from Fontainebleau, with its elaborate arrangement of Renaissance motifs and its over-all imposing features, gives some idea of the dominance of Italian influence at this time. The same influence can be seen in the grander Renaissance interiors of Germany and Austria.

In the Low Countries and north Germany during the 16th century the ornament of the Italian Renaissance was borrowed and adapted to form an entirely individual style, such as may be seen in the pattern books of Vredeman de Vries and Wendel Dietterlin. Strapwork and raised faceted ornament were widely used, together with muscular, grotesque masked caryatids and distorted architectural features arranged in undisciplined designs. Chimney pieces, with overmantels carried to the ceiling, were embellished with marble columns and elaborate strapwork patterns, while similar ornaments flanked the doorways and enriched the ceilings. The great tapestries, for which the Netherlands had long been famous, afforded protection from the cold air, and oriental carpets were used as table covers, though not at this time spread on the floor.

In many areas of Europe the Italian Renaissance had little effect on interior decoration. In the Alpine lands, where wood was cheap and plentiful. traditional methods continued for a long time, wooden floors and ceilings and panelled walls, or partly panelled with plain plaster,.were the general rule. The mouldings

were bold, but carving was usually in slight relief. Often the woodwork was painted in bright colours.

In Scandinavian countries much domestic architecture continued to be of wood. Relief was afforded by painted linen hangings, sometimes depicting biblical scenes, and by brightly coloured cushions.

England.— The Italian style of decoration began to affect the English interior in about 1520. For the next 40 years or so English craftsmen borrowed from the repertoire of Italian ornament, at first inspired by and imitating the Italian artists and craftsmen employed by Henry VIII on royal works at Hampton court and Westminster, using such motifs as arabesque decoration, medallion heads and *amorini* on panelling and plasterwork, often mingling them with the traditional Gothic motifs. The Gothic style died hard in England, lingering in the remoter provinces and country districts well into the 17th century, in spite of Henry VIII's example and encouragement of the Italian style.

During the second half of the 16th century the individual Renaissance style of the Low Countries and Germany largely replaced the Italian style, becoming the dominant influence in the decoration of panelling and plasterwork of the English interior. Characterized by such features as intricate strapwork patterns, raised faceted ornament, grotesque masks, muscular caryatids and pilasters, the style of the north European Renaissance was fostered in England by the close religious. political and economic relations between England and the Low Countries, the influx of immigrant workmen and by the circulation of Flemish and German pattern books, which showed the full repertoire of this newly created style.

In adopting both the Italian and Flemish styles, the English craftsmen to some extent adapted and naturalized them, producing a new style peculiarly English—a style that can be seen in the plaster ceiling at Herrington, Dorchester, and in the decoration of the north drawing room at Levens hall, Westmorland.

During this period several methods mere used for covering and decorating the walls of rooms, oak panelling being one of the commonest. Until the middle of the 17th century the individual panels remained small, either regular in shape throughout a room or varying a little in shape and size. The height of the panelling also varied, sometimes covering the whole wall from floor to ceiling, sometimes only rising to about four or five feet, the rest of the wall being of plaster either covered with hangings or left plain. Both the Italian and the Flemish phases of influence can be recognized in the carved decoration of this panelling. The linen-fold ornament of the late Gothic period was at first combined with and later replaced by Italianate scrolled floral patterns, medallion busts and reclining cupids, while the areas of panelling were broken by pilasters headed by classical capitals, In the second half of the 16th century and during the Jacobean period the pilasters remained, but the carved motifs were borrowed from Germany and the Low Countries, strapwork and raised faceted ornament, like the decoration on the screens at Cuckfield place. Sussex, and Wollaton hall, Nottinghamshire, being particularly characteristic. The oak panelling mas also sometimes decorated with elaborate inlaid patterns, inspired by German work, using holly, bog oak, sycamore and other woods.

Screens continued to be used in halls even where they were only now of single-story height, as at Cuckfield where the screen is dated 1581. The majority were of oak, but in some larger houses stone was used, as at Wollaton hall and at Montacute, in Somerset. Similar decoration was used by the carver on these screens as on the wainscot of the room. During this period chimney pieces became the central decorative feature of a room. Made of wood, stone, plaster and marble, they were often the most elaborately decorated part of a room, as in the case of the plaster overmantel at Plas Mawr, Conway, Caernarvonshire, and the oak chimney piece at Levens hall. Westmorland.

The frescoing of walls still continued, and of the few remaining examples some show scenes taken from biblical and classical sources and incidents from local folklore. A good Elizabethan example depicting scenes from the story of Tobit was found at the White Swan inn at Stratford-on-Avon. Embossed, painted and gilt leather was less used in England than on the continent, but tapestries and such woven fabrics as velvet and damask for the wealthy and "sayes and bayes" for people of more modest means were widely used. These hangings still held premier place as wall coverings. The inventories of Henry VIII's palaces show the vast number of tapestries and various hangings possessed by kings and great men, as indeed does an inventory of Vyne, Hampshire, of 1541 which lists sets in almost every room of the house including the chambers of dependents. A cheaper substitute for tapestries was the painted cloth, produced in large numbers and depicting the same subjects as tapestries—histories from biblical and classical sources and decorative subjects passing from Gothic to Renaissance motifs, Nearly all of this "counterfeit arras" has perished. but a set displaying the acts of the apostles survives at Hardwick hall in Derbyshire.

Elaborate plaster ceilings were introduced during this period, consisting of narrow interlaced ribs forming geometrical patterns. There are interesting examples at Plas Mawr, where the same material forms the upper part of the chimney piece, the royal arms indicating a date in Elizabeth I's reign.

The most elaborate treatment was often found in those distinctive Elizabethan rooms, the long gallery and great chamber, which were frequently upstairs; greater height was obtained by using the roof space and forming a barrel-shaped ceiling. They exhibited not only the narrow ribbing of Elizabeth I's time, but also the broad bands with enriched soffits that came in under James I. One of the finest examples is at Herringston, near Dorchester, dating from about 1615.

The staircase developed considerably, for whereas in mediaeval times the winding newel form, sometimes of wood but more often of stone and never very wide or easy in gradient, had prevailed, under Elizabeth I it began to be placed around an ampler open space. Its decorative possibilities were recognized and it was enriched with newel posts and balusters and strings were given to it. The idea was developed during the following reign, and one of the finest, both in planning and execution, is the great stair at Hatfield, Hertfordshire, dating from 1610.

A feeling for classic reserve was now spreading and the late Renaissance period might have begun under Charles I but for the political upheaval that checked the zest for fine building. Inigo Jones (1573–1651), one of the few north European architects completely to absorb the spirit and the decorative repertoire of Italian Renaissance classicism, returned from Italy in 1615. He introduced the new style in the Banqueting house at Whitehall, London, and the Queen's house at Greenwich; and in spite of the obvious handicaps of the Civil War and the Commonwealth period his hand and that of his associate and kinsman, John Webb, are found at Wilton house, Wiltshire, and possibly at Forde abbey, Somerset. Also built under the Commonwealth was Coleshill, Berkshire, the earliest and one of the finest English country houses where classic form and Italian tendencies prevailed. Inigo Jones's principles were kept alive by a small band of followers, but his influence was not widespread in England until the beginning of the 18th century and the establishment of the Palladian school of architecture and interior decoration.

BAROQUE

Baroque, which started as an architectural development of the late Renaissance style in Rome in the late 16th century, affected interior decoration throughout Europe during the 17th and early 18th centuries. The use of painted panelling, marble, plasterwork, painted decoration and tapestries continued, and many of the Renaissance motifs were still used in the new style. But both their arrangement and execution were richer. heavier, bolder and more theatrical, reflecting a more sensual appreciation of both the spiritual and material worlds. Doorways, chimney pieces and. staircases were made more imposing than before, rooms were larger and the boldly modelled garlands, volutes, mouldings and scrollwork contained a dramatic quality that reflected the departure from the classical restraint of the Renaissance. The baroque style was borrowed by many European countries and adapted to suit national tastes, but by the second half of the 17th century France

had become the dominant influence in interior decoration, to such an extent that even Louis XIV's most violent enemies imitated the decoration of Versailles in the palaces of their own capitals.

In France the Italian influence of the 16th century was gradually assimilated, and the national style of decoration evolved soon spread its influence into neighbouring countries. The development of baroque in France can be divided into roughly three stages: the style of Louis XIII, that of Louis XIV and that of the final period of transition into the rococo style, now called the *régence* style, though in fact it began in about 1690 while Louis XIV was still on the throne.

The reign of Louis XIII. covering most of the first half of the 17th century, was itself a period of transition. The fame of his son and successor might suggest that the outlook of a great nation was then modified and enlarged by the force of a single personality, but it was the national spirit which created Louis XIV and his, times. Expansion in Asia and America and the growth in the national wealth were the causes that led to the building of Versailles and the Galerie d'Apollon of the Louvre.

The great *salon* now came into being, and the number of separate apartments was multiplied. A suite would comprise a vestibule, antechamber, dining room, *salon,* state bedroom, study and gallery. Stately and spacious staircases were provided. It was at this time too that the idea of a unified scheme of interior decoration, where the fittings of the room were designed in harmony with the furniture and vice versa, came into being. The interior economy of the modern house dates back largely to this period.

The Gobelins factory was founded in 1662 under Louis XIV for the production of fine furniture and furnishings for the royal palaces and the national buildings. Charles le Brun was appointed first director of the Gobelins. Among the many architects, artists and designers who provided designs and decorative schemes for the rooms of both Louis XIV's reign and the period of the *régence,* noteworthy for their influence are Jean Berain, Andre Charles Boulle, Jean le Pautre, Robert de Cotte and Jules Mansart.

The height of French baroque magnificence can be seen in the Galerie des Glaces at Versailles and the Galerie d'Apollon at the Louvre, both dating from the second half of the 17th century. There the vastness of the rooms combined with the lavish use of marble, plasterwork and painted ceilings, with the addition at Versailles of mirror glass, created an effect of overwhelming grandeur.

Toward the end of the 17th century, in the style known as *régence,* the heavy baroque motifs received a lighter, less geometrical and more fluent treatment, as can be seen in the work of Robert de Cotte at Versailles and the Hôtel de Toulouse. until almost imperceptibly the baroque repertoire of ornament was transformed into the delicate and refined rococo style of the mid-18th century.

England. — At the time of the Restoration the classical influence of Inigo Jones became mixed with the newly introduced continental baroque style, and the combination of these two elements can be seen in the decoration of the rooms of this period, their large simple fielded panels, which replaced the small sunken panels of the previous age, contrasting with the exuberant carved baroque decoration of the chimney pieces and doorframes, where garlands of flowers and fruit cascaded in decorative forms so closely associated with the style of the sculptor and carver, Grinling Gibbons. Plaster ceilings were enriched with similar floral decoration, such as the fine examples at Ham house, Surrey, or they were painted with allegorical scenes by such contemporary artists as James Thornhill or Antonio Verrio, who painted the ceiling in the great chamber at Chatsworth, Derbyshire. Ham house, though comparatively small, represents the height of luxurious interior decoration of the late 17th century, what John Evelyn called "the politer way of living, which was soon to turn to luxury and intolerable expense," and at Ham may still be seen many of the decorative innovations of that time, such as the practice of painting panelling in imitation of marble or wood graining and of gilding the mouldings. There also are tapestries, gilt and painted leather hangings, walls lined with silk damask and elaborate parquetry floors.

The craze for collecting blue and white oriental porcelain, Queen Mary being one of the leading collectors of her time, affected interior decoration, for many rooms were provided with carved brackets and alcoves for displaying porcelain. Designs for such rooms still exist by the refugee French architect and designer, Daniel Marot, who worked in England for William III. Imported oriental lacquer panels were also sometimes used for the panelling of rooms in accordance with the Chinese taste of the period.

In the last years of the 17th century and in the early 18th century the woodworker found his domain contracting. Through the influence of the grand tour and the establishment of the Palladian school of architecture under the patronage of Lord Burlington. Italian influence predominated, the work of Inigo Jones was studied and stone and stucco became more widely used. The influence of the architect spread from the outside of the house to the interior decoration and even, in the work of such men as William Kent. to the design of the furniture itself.

Where wooden panelling was used, it was set in a simple framework. Pine largely replaced oak, and it was painted green, blue, brown and other colours; walnut and mahogany were occasionally used for panelling. The increased use of stone, stucco and marble was begun by John Vanbrugh and continued by the Burlingtonian school of architects, as in the stone or marble halls of the new Whig palaces, such as Castle Howard, Yorkshire, and Blenheim palace, Oxfordshire, under Queen Anne, and Houghton hall and Holkham in Norfolk in the following reigns. In the large state rooms of such houses the walls were decorated with stucco garlands, masks and sporting *amorini,* often the work of Italian craftsmen, boldly modelled and painted and gilded. The doors and fireplaces were architectural in form, with elaborate entablatures and massive pediments. Walls were also hung with tapestry, velvet and damask, while hand-coloured wood-block printed papers provided an economical substitute *(see* WALLPAPER). Decorative painting also continued.

Stone treads and iron balustrades were introduced for staircases, although in this feature the joiner long retained the lead. Under Charles II the work had been solid, with heavy balusters or open panels elaborately carved under a broad handrail, as at Rolseley, Staffordshire. But in the 18th century staircases became lighter and more delicate, as at Beningbrough in Yorkshire; there in 1716 the joiner was still supreme, with the quality and quantity of the woodwork apparent in the many doorways and chimney pieces, shutters and framings, as also in George II houses like Godmersham park in Kent.

In the simpler houses of the early 18th century it was in the doorways and chimney pieces that the influence of the Palladian school was seen, for these copied the heavy architectural form of the grander houses and contrasted elegantly with the simple painted pine panelling. The proportions of rooms also improved and the large windows gave them increased lightness and a generally spacious effect.

ROCOCO AND NEOCLASSIC

In the rococo style, which quickly spread throughout the courts of Europe from Russia to Spain and from England to Italy, artists, architects, designers and craftsmen combined to create a style so light and delicate, so gay and so full of movement and colour that rooms such as those at Chantilly in France or the Amalienburg in Bavaria possess the quality of fairyland. The work of such designers as J. Meissonier and N. Pineau can be seen in mounted panelling with delicately modelled ornament of ragged C-scrolls, garlands of flowers decked with ribbons, sprays of foliage, shell motifs and leaf scrolls in asymmetrical yet subtly balanced arrangement, the background painted in soft colours, the detail gilded or silvered. Frequently the panels were painted by the best artists of the day—N. Lancret, C. Huet, F. Boucher—with imageries, scenes of the *fête champêtre* or idealized peasant life, groups and landscapes in the Chinese taste or designs of birds, flowers and foliage mingled with trophies of musical instruments, garden tools or symbols of science and the arts. Ceilings were similarly decorated with raised plaster ornament or were painted, the most famous painted ceiling perhaps being that at Würzburg by G. B. Tiepolo, who also decorated a ceiling in the royal palace at Madrid.

Tapestries were frequently used, notably Gobelin, Aubusson and Beauvais, woven after designs of such artists as Huet and Boucher. Walls were often mounted with panels of mirror glass which reflected the beauty of their panelled surrounds and the light of brilliant crystal chandeliers.

The neoclassic, known in France as the Louis XVI, style had in fact taken roots before the death of Louis XV. The tortuous and asymmetrical rococo decoration had already been severely criticized in France. Stimulated by the archaeological discoveries at Herculaneum and Pompeii and the publication of surveys of other classical remains in Greece and the near east, architects and designers in the 1750s and 1760s began to turn again to antique principles and ornament for inspiration. The sinuous forms of the rococo style were slowly replaced by a more restrained form of decoration, based on straight lines: right angles, ovals and circles, once again arranged in symmetrical design. Though the same decorating techniques were retained, new motifs culled from classical sources, and in particular from the grotesque wall paintings of Roman interiors, began to be used. Soon panelling is found decorated with a medley of palmettes, tripod stands, vases, classical figures, thyrsi, trophies of arms, lyres and arabesques. The panels are rectangular in shape and the mouldings refined. The decoration of the panels is flatter than before.

The introduction of the neoclassic style with its restraint and the preference for rectilinear design can be seen in the work of A. J. Gabriel in the Salle du Conseil at the École Militaire (1773) and in the Galerie Dorée in the Ministbre de Marine (1762–72), both in Paris.

For the fully developed style in the reign of Louis XVI, a small though outstandingly beautiful room is the boudoir of Madame de Sevilly, now in the Victoria and Albert museum. The exquisite carved, painted and gilt decorations of the panels, with classical figures and baskets of cascading flowers, are by J. S. Rousseau de la Rottière and the marble fireplace with muffled caryatids and delicate gilt bronze adornment is by C. M. Clodion. This room represents the height of French 18th-century taste and craftsmanship, providing a style that was copied with varying success in every corner of Europe.

England.— While in architecture the Palladian rule of taste continued to hold sway, during the 1740s the decorative style of the English interior began to be affected by the asymmetrical French rococo style which, in spite of strong Palladian opposition, gradually replaced the symmetrical baroque style, using the repertoire of *rocaille* motifs found in the designs of such French decorators as N. Pineau and J. Meissonier. The stucco and carved decoration became lighter and more fanciful and more tortuous in design. Though many baroque motifs were still used, they were more delicately modelled and the rococo style was characterized by elaborate patterns of interlacing C-scrolls combined with such naturalistic ornaments as flowers, foliage, shells and rocks, arranged subtly in asymmetrical yet balanced patterns. The plasterwork and carved panelling were often painted in light colours and the detail picked out in gold.

The music room from Norfolk house, St. James's square, London, now in the Victoria and Albert museum, London, designed by Mathew Brettingham and completed in 1756, is a fine example of rococo decoration in England. The carved wooden panels are enriched with delicate patterns of scrolled acanthus, shells and garlands of flowers, while the overmantel mirror and the main panels are mounted with fanciful trophies of musical instruments. The fine plaster cornice and ceiling are decorated with similar rococo devices. In smaller houses the new motifs were confined to the chimney pieces and doorcases, the remainder of the room being simply panelled or plastered.

Closely allied to the introduction of the French *rocaille* was the revival of the Chinese taste in a new rococo form, when architects and designers, in search of further novelty, turned again to the east for inspiration. An added stimulus was provided by the publication of books of travel and topography, notably J. B, du Halde's *General History of China,* published in Paris in 1736 and translated into English in 1741. In interior decoration the Chinese taste, with its bizarre ornamental repertoire of pagodas, mandarin figures, icicles and dripping water and exotic foliage and birds, reached the height of rococo invention and was particularly popular for bedrooms, where elaborate chimney pieces and doorcases were set against the background of imported or imitation Chinese wallpapers, and the beds and windows were hung with eastern textiles.

One of the most elaborate of these rooms was that at Claydon in Buckinghamshire, while a simpler version may be seen in the room from Wotton-under-Edge, Gloucestershire, now in the Victoria and Albert museum. There Chinese wallpaper combines with a delicate rococo overmantel which provides brackets for small pieces of oriental porcelain.

The Gothic taste, a further variation of the rococo, was peculiar to England at this time. The Gothic revival, starting as a literary movement in the poetry of the early 18th century, during the 1740s appeared in the more concrete forms of architecture and interior decoration. Both William Kent and Sanderson Miller had made essays in the Gothic taste before 1750, and by the middle of the century the fashion was widely popular and many houses, both large and small, were in part Gothicized, both inside and out. As with the Chinese taste, the products of this 18th-century vogue bore little resemblance to the original mediaeval models. Gothic details, originally worked in stone! were borrowed, adapted, often mingled with *rocaille* and Chinese motifs, and were executed in wood and plaster. At Strawberry Hill, Twickenham, Horatio Walpole, leader of the "true Goths," borrowed the designs of mediaeval tombs and turned them to designs for fireplaces and bookcases. Though this vogue fell out of general fashion in the 1760s, a few enthusiasts remained who carried the Gothic taste through until it was vigorously revived again in the 19th century.

About 1760 the rococo style, with all its vagaries of taste, began to give way before the neoclassic style, largely inspired and introduced by the Scottish architect, Robert Adam, whose work reflected the newly awakened interest in classical remains. Adam returned from Italy in 1758, where, strongly influenced by both Roman architecture and interior decoration, he evolved a new style based on classical precedent, composed of a medley of such classical ornaments as paterae, husk chains, the ram's head, the formalized honeysuckle and other motifs. In his interior decoration Adam was deeply influenced by the gay and delicate patterns of arabesques and grotesque ornament that he had seen in various classical remains in Rome, and which had already been copied during the Renaissance by Raphael and others. Adam strongly criticized the Burlington school for using heavy architectural features in their interiors, and replaced them with delicate ornament in plaster, wood, marble and painting. With Adam the despotism of the architect over the craftsman was complete. No detail of decoration or furnishing escaped him; his rapid and precise draftsmanship covered the whole scheme, from the over-all treatment of the walls and ceiling to the decorative details of the pelmets and grates. Even carpets were made to order, and often they repeated or echoed the design of the ceiling, bringing the whole room into harmony, as in the green drawing room at Osterley, Middlesex. Wood was never left unpainted, and although the joinery was still admirable, the enrichment was often in composition or pewter. There were specially designed temple-fronted bookcases and the plasterwork was often made a frame for the decorative paintings of such artists as Antonio Zucchi or Angelica Kauffmann. At this time cheaper and quicker methods of decoration began to be introduced; a considerable amount of the plaster decoration was cast from moulds and a composite imitation marble called scagliola was sometime3 used for floors and columns, while cheaper woods were disguised by marbling and graining.

The neoclassic style was further refined at the close of the century, the plaster relief decoration being simplified and lightened. The best of this style, strongly influenced by French decoration, can be seen in the work of the architect, Henry Holland, who enlarged Carlton house, London: for the prince regent and built Sothill in Bedfordshire. Holland, like Adam, was inspired by the classical monuments in Italy, where for some time he maintained a draftsman whose drawings of classical detail Holland incorporated in his plasterwork.

During the early years of the 19th century the neoclassic style of decoration continued, but with a strong archaeological bias which led to a more literal interpretation of classical remains. A Greek revival and an interest in the newly publicized Egyptian antiquities added new motifs to the architect's and designer's repertoire. The somewhat pedantic and archaeological style was given considerable publicity in the work of the wealthy amateur architect, Thomas Hope, who enlarged and decorated both his London home in Duchess street and his country house, Deepdene in Surrey, in the Greek and Egyptian taste, publishing in 1807 his *Household Furniture and Interior Decoration,* which further influenced contemporary taste.

19TH AND 20TH CENTURIES

In the last years of the 18th century and the early 19th century, both in France with the *directozre* and empire styles and throughout the other parts of Europe where decorative styles were influenced by France, the neoclassic taste grew more archaeological in inspiration, stimulated by a desire to imitate directly the styles of ancient Rome. Greece and Egypt. the last much publicized by the campaigns of Napoleon.

Toward 1825 the reaction came. Earlier fashions were again reverted to for a time but the original spirit was lost in the half-hearted imitation. The new wealth of industrial and trading communities gave rise to new ideas of material well-being, reflected in the comfortable Biedermeier style which arose in Germany, with thick curtains, festooned draperies, antimacassars, tassels and fringes.

Later there came a strong reaction to the fussiness and overcrowding of the 19th-century interior decoration. Particularly inspired by the work of Scandinavian designers and architects, a genuine attempt was being made in the 20th century to create an original and truly contemporary style, suited to the needs of contemporary life.

England. — During the first half of the 19th century the neoclassic style dropped out of fashion and there began a long period of imitative decoration. when past styles of all ages from all parts of the world were resuscitated and unhappily reproduced, the original spirit being lost and the detail coarsened, though on occasions the craftsmanship was highly skilled. In the continued Gothic revival, the flimsy wood, plaster and paper decoration entirely missed the Gothic spirit, also failing to capture the humour and whimsical charm of the Walpole Gothic, and these features were introduced as the trappings of houses designed to'serve entirely different habits of life. Thus, when the 19th century was reached, a plan that, in the disposition of parts, the shape of rooms, the height of ceilings, suited the habits and views of the day, might be decked out by the architect in what he pleased to think was Gothic, Tudor, Roman, Greek, French, Italian, Egyptian or Indian.

In less ambitious schemes of decoration, brightly coloured wallpapers with bold patterns were widely used, and the white plaster ceilings were relieved by modelled cornices and often some central feature, frequently in a coarsened rococo design, which made a background for the elaborate light fitting. Rooms became crowded with furniture, and fireplaces were often mounted with elaborate overmantels, fitted with mirror panels and a multitude of shelves and brackets for the display of Victorian knickknacks. Both furniture and fittings were draped in dark-coloured plush with heavy fringes.

William Morris, through his own firm, made a bold and valuable attempt to reassert some definite standards of taste and craftsmanship in interior decoration! producing, with the assistance of such artists and architects as D. G. Rossetti, Sir Edward Burne-Jones and Philip Webb, furniture, wallpapers and tapestries. But his influence was limited, for like his contemporaries he looked back, seeking inspiration from mediaeval craftsmanship, and in doing so refused to accept the possibilities of machine production, thereby failing to supply the leadership in a movement to bring together craft and the machine in his industrialized age.

In the 20th century there mas a violent reaction from the sombre and crowded interiors of the previous age. Rooms mere painted in light colours, interior features such as doors and fireplaces were flattened into the surface of the walls and furniture was reduced to the simplest minimum. Later, largely influenced by European and particularly Scandinavian taste, though simplicity and practicality still predominated, brightly painted colours and gay wallpapers were introduced, and once again the architect assumed a major responsibility in interior decoration with the necessity of built-in furniture.

U.S. INTERIOR DECORATION

The story of the domestic interior in the U.S. and its decoration is inseparable both from its own architectural development and from the story of English architecture and decoration from which it was largely derived even long after the Revolution. Any discussion of U.S. decorative design must, therefore, constantly refer to the architectural ideas which prompted change on both sides of the Atlantic ocean.

Early Settlers' Homes. — Contrary to popular legend, the log cabin was not the earliest shelter of the first English settlers on the American continent. The turfed-over dugout hut of mud-chinked saplings, not unlike the Indian wigwam with the addition of a clay-daubed wooden chimney at one end, was probably the first home of the settlers in both Jamestown and Plymouth.

These primitive dwellings were speedily replaced by frame structures, copying the traditional small house of southeast England. At first a single room in plan, flanked by a massive chimney (where brick soon replaced wood and clay), the house was later enlarged by a second room on the opposite side of the chimney. The attic, later expanded into an overhanging second story, was reached by narrow winding stairs between the central entranceway and the chimney stack.

This development in New England is well represented by such vestiges as the Capen house, Topsfield, Mass. (1683). The interior clearly reflects the structure with its massive exposed oak corner posts, girders and joists and its huge open fireplace which served as the cooking and heating centre of the household. Inside walls were usually of undecorated lath and plaster, covering the studs and their clay or brick filling. Room partitions and the face of the fireplace wall were sheathed with horizontal or vertical boarding, frequently featheredged or moulded. Windows were small and originally of casement type. with small leaded panes in a wood frame. Small windows with low ceilings were needed to conserve heat in the severe winters. Floors of wide riven boards of pine, smoothed and sanded. replaced the beaten clay of the first shelters.

The furniture. with few exceptions, was simple and sparse. Though strictly utilitarian it reflected a desire for decorative warmth and dignity in its simplified carved and turned ornament and touches of earth colours.

By the end of the century homespun textiles were supplemented by imported decorative weaves in the houses of the more affluent, and mere used for curtains, table covers, bed hangings and seat pads. Richly coloured damasks and velvets gave relief and accent to unpainted wood and plaster surfaces even in puritan New England, and probably to a greater extent among the less austere New

York Dutch and the comparatively wealthy tobacco planters of Virginia.

While utensils of crude pottery and wood served the needs of most people. pewter and. to a surprising extent, vessels of silver were among the possessions of the well-to-do. A remarkable quantity of fine silver was produced in the last half of the century by silversmiths such as John Hull, John Coney and Jeremiah Dummer of Boston and Cornelius VanderBurgh and Jacob Boelen of New York. Although based mainly on English models, the work of these craftsmen shows a distinctly individual feeling for form and proportion and a craft skill matching that of their English contemporaries.

In the early dwellings south of New England, brick and stone tended to replace wood as a building material, though much small timber construction must have been used which has now largely disappeared. In the Hudson region the traditional cottage of the Flemish and Huguenot settlers, long and low with steep pitched roof and extended eaves, became the typical farmhouse. At the same time, the narrow Dutch town house of brick with its stepped gable ends gave New Amsterdam, even after the English occupation, an appearance completely different from that of the Ehglish settlements to the north and south.

In the Dutch houses windows tended to be larger and ceilings higher. The early fireplace, with its tiled surround. surmounted with a deep hood, was flush with the wall instead of deeply recessed. Such traditional Dutch features as the horizontally divided door, the monumental cupboard or kas, the built-in bed, tiling and dishes of Delft ware gave the early New York interior an individuality which withstood English influence until well into the following century.

Similar national characteristics must have distinguished the early Swedish settlement on the Delaware, where the log cabin of pioneer tradition may have appeared for the first time later in the century. But the Snedish contribution was only temporary because the settlement was speedily absorbed by both the Dutch and the English. The early settlements of the English in east Jersey were mainly founded by migrants from New England who brought with them the typical central-chimney house and interior arrangement, but before the end of the century largely abandoned them for the Flemish type of house in the neighbouring Hudson region. The first settlers in Pennsylvania, arriving in Philadelphia at the end of the century, brought the type of town dwelling devised for the rebuilding of London after the great fire of 1666, and their story belongs to the following century.

In Virginia and the south, scant evidence remains of the early 17th-century house. Bacon's castle in Surry county, Va., with its projecting two-story porch in front and rear stair tower. built in brick about 1660, is all that remains of what must have been several such colonial versions of the small English Jacobean manor. From surviving evidence and deduction it is believed that panelled walls, carefully designed beamed ceilings and ornamental plasterwork in colour gave the larger Virginia houses interiors of much more deliberate decorative effect than those of the north. While the milder climate made loftier ceilings and larger rooms possible, it is unlikely that the ordinary early dwelling differed from its northern contemporary save in its greater use of brick and in placing chimneys at the ends instead of at the centre of the structure.

Among the wealthy the principal articles of furniture were undoubtedly English imports, but the more humble settler probably had to make shift with articles of the simplest sort. Few things survive from this period, so little is known about it. Certainly the scattered or rural character of the southern settlements and their concentration on tobacco planting failed to encourage the early development of skilled crafts found in villages and towns of the northern communities.

Pre-Revolution Homes.—During this period the late mediaeval tradition of design and decoration was gradually replaced by the formalism of the full Renaissance style. Inigo Jones (1573–1651) and Sir Christopher Wren (1632–1723) had initiated and established the new architectural mode in England in the first and second halves of the 17th century. By 1720 these innovations, as reflected in the Queen Anne style with its strong mingling of Dutch and Flemish elements, had already crossed the Atlantic.

In New England the traditional two-story "salt box" was at first modified in detail rather than size by the substitution of a double-hung sash for the casement and the replacement of sheathing by panelling and trim of more or less formal design. Houses of the 17th century were often so "modernized." The parlor of the Samuel Wentworth house, Portsmouth, N.H., now in the Metropolitan museum in New York city. is an instance.

Wren's influence is increasingly evident throughout the period in the effortto achieve symmetrical design around an accented central feature and, particularly in the interiors, in greater insistence on classic ordonnance in the positions of openings and the arrangement of panelling. Panelling, usually of pine in the north, was generally painted. Relatively deep and strong tones—red, blue, green, brown and yellow—were used either singly or in combination. producing an effective background for the walnut furniture of the period.

Additional colour was introduced by a more elaborate use of woven and embroidered textiles, in upholstery as well as draperies. Though woven carpets for floor coverings were rare even at the mid-century, their effect was frequently achieved by stretched canvas painted with allover repeat patterns.

At this time throughout the colonies furniture became more plentiful and varied. Chairs without arms took the place of stools, the cabriole largely replaced the turned leg and small drop-leaf tables replaced the fixed-frame type. Bedroom furniture became differentiated with the development of the high chest (highboy) and dressing table (lowboy), and later the case-top desk or secretary became the principal ornament of the living room. Tall mirrors with crested tops replaced the small square Jacobean looking glasses, and portraits and prints came into more general use, sharing the wall space with bracketed wall lights or sconces. Artificial light still came mainly from small wick and grease betty lamps, but tallow and wax candles held in sconces, in adjustable metal and wood floor stands or in candlesticks of brass or pewter and occasionally in brass chandeliers were used by the wealthier.

Though domestic comfort was improving, north of Virginia the large formal house or mansion remained a rarity until about 1750. In the south the wealth of the slaveholding planter permitted closer fidelity to the early Georgian manor house type. Great houses of two or threestories with side dependencies became numerous. Stratford in Westmoreland county and Westover in Charles City county, built about 1725–30 by the Lee and Byrd families, are early examples of the type. The elaborately panelled rooms of these mansions were furnished according to the latest London fashion. Probably only later in the century were these products of the London shops mingled with pieces from the cabinetmakers of Philadelphia, New York and Boston. Between 1750 and the Revolution this Georgian phase reached its highest development in the colonies. Though generally smaller and lacking the forecourt and dependencies of the southern mansion, the larger houses of the north, such as the Wentworth-Gardner house in Portsmouth, mark perhaps the most distinctive achievements of colonial design and decoration by their apt translations into wood of brick and stone Georgian forms.

In the middle Atlantic colonies, particularly in Philadelphia which by 1760 had assumed urban leadership in the colonies, a type of domestic design midway between that of New England and Virginia had developed. There the English rococo decorative style publicized by Thomas Chippendale in his Director of 1754 received its most competent and original interpretation. This is well seen in Philadelphia interiors such as those of the Powel house (1768) and in the work of cabinetmakers such as Thomas Affleck and Benjamin Randolph. By this time, mahogany, with its fine grain, receptive to carving and high finish, had largely replaced walnut as the principal cabinet wood. Inspired by this material and the challenge of London design both these Philadelphia craftsmen and their northern contemporaries, particularly John Goddard and Job Townsend of Newport, R.I., brought their art to the highest level of perfection.

During the third quarter of the 18th century. the panelled interior attained its greatest colonial elaboration. North of Virginia

a fully panelled room was exceptional; wood panelling was reserved for the chimney breast and its flanking recesses or cupboards. In Virginia and the south full panelling remained the rule. Both north and south, however, the mantel and its overmantel were emphasized as a decorative unit and the baroque broken pediment became the usual crowning feature of overmantel and doorway. Painted woodwork remained popular, but with softer and lighter tones. tending toward white and gray. Plaster wall surfaces were also painted. Block-printed and painted wallpapers were frequently used in the main rooms and there are indications that fabric wall hangings were used also.

Plaster ceilings completely concealed the floor beams by the second quarter of the century, and after 1750 these were frequently decorated with ornament in low relief in the French or rococo manner and hung with many-branched chandeliers of crystal. Floors of hardwood, occasionally parquetry, were more frequently covered with patterned rugs of European or oriental origin.

During the 18th century the textile resources of the colonists had been enlarged by imports of printed cottons or chintz in the Indian taste, and these silk brocades and damasks largely replaced the linen and woollen weaves of earlier days. Upholstered furniture, wing chairs and sofas and elaborate draperies increased still further the richness of the fashionable interior.

The craft of the silversmith continued to develop in the 1700s. North of Virginia even the smaller communities supported silversmiths of ability. Judging from the quality and amount of work that survives from Boston, New York, Newport and Philadelphia, a phenomenal amount of silver plate must have been produced and distributed among even the moderately well-to-do. Like the furniture, this silver mainly followed the Queen Anne style and depended upon elegance of form and line rather than ornament.

As in Europe, the growth of tea and coffee drinking encouraged production of suitable silverware and the import of English and oriental porcelains which required corner and wall storage cupboards. Demand was also created for a variety of small movable tables and stands for tea and coffee services.

During this century the German settlers in Pennsylvania added their traditional art style to the dominantly English tradition of the colony. The effects of this were more visible in folk arts than in formal decoration. It was to this style and its development after the Revolution that the first American decorative glass of Henry William "Baron" Stiegel and Frederick Amelung must be credited, as well as most of the decoration on early American pottery.

Classic *Movement After the Revolution,* 1785–1835.—Even after the Revolution English decorative influence remained dominant in the new republic in spite of greatly increased contacts with French thought and ideas. Although many leaders like Thomas Jefferson wished to see a complete break with the English-dominated past, the Georgian forms of colonial days persisted in common usage till 1800 or after. By 1785, however, the reaction in Europe against the rather heavy classic style called free Palladianism and its rococo and baroque elaborations began to affect design in the United States.

Jefferson, largely under French influence. became the Ieader of one aspect of the new movement in the south. This combined practical planning with a literal classicism resting on the direct study of ancient monuments. While Jefferson's interest in strict classic form was felt particularly in architecture, the decorative phase of the movement both north and south was dominated by the freer and more personal interpretation of classic motifs based on the work of the Adam brothers in England, before and during the Revolution. This was the principal influence in the designs of Charles Bulfinch of Boston and his followers and was popularized about 1800 in the builders' pattern books of William Pain and Asher Benjamin.

The houses of Boston, Salem and Portsmouth built around 1800–10 by or under the influence of Bulfinch and Samuel McIntire of Salem are the best examples of the changes wrought by rhe fine scale and delicate precision of their Adam-inspired designs. producing what has become knowp as the early federal style. In the houses of the time the circle, the ellipse and the octagon were introduced as occasional variations in the plan, and the flying or freestanding staircase became a feature of the entrance hall.

In interior decoration wood panelling was practically abandoned or was restricted to the area below the chair rail. Decorative emphasis was concentrated on the mantel and overmantel, the doors and window frames and the cornice. all usually of wood and enriched with delicate repeat ornament either carved or applied. Rich colour in draperies and upholstery was set off by wall surfaces and decoration in light tones, grayed tints or white. Block-printed wallpapers with classical motifs were frequently used or replaced by stencilled decorations in the simpler homes.

In general. geometric forms and their objective embodiment in the urn, swag, patera and wreath were favoured. The taste for lightness and attenuation which verged on dryness was reflected in the furniture. The designs of George Hepplewhite and Thomas Sheraton influenced by Louis XVI and *Directoire* forms found American versions around the turn of the century in the work of Samuel McIntire of Salem, John Seymour of Boston, Duncan Phyfe of New York, Henry Connelly of Philadelphia and the cabinet shops of Baltimore and Charleston. At first, light woods and finishes and decorative inlays were preferred, but by 1820 French empire influence substituted dark ruddy mahogany, carved and gilded ornament and heavy, often ill-proportioned forms considered more in keeping with classic taste.

The new classicism, particularly in its Adam phase, was also expressed by the silversmiths, one of whom was Paul Revere, whose patriotic activities have given him a prominence somewhat unfair to his able colleagues. This silver is identified by its general use of the urn form, relieved occasionally by the cylinder, and by a simple elegance of silhouette enriched only with surface chasing. After 1820 the early federal style waned and Jeffersonian classicism was modified by the introduction of Greek and even Egyptian detail, constituting the so-called Greek revival. Accompanied by furnishings and draperies in the heavier Sheraton-empire taste, the classic pattern established in the 1820s became the basic style in building and decorative design until about 1850, and constituted for the time a national style without parallel in Europe. In its later decorative aspect the Greek revival became a fashion rather than a style. As such it marks not only the end of the 18th-century classicism but the beginning of the romantic movement.

Romantic Movement and the Battle of the Styles, 1835–1925.—The ordered symbolism of the Roman classic style had been envisioned by Jefferson as a proper expression of the American. national ideal; but by 1835 its restraints had grown tedious. Social and economic changes already initiated by the Industrial Revolution encouraged reaction. This found more or less romantic and emotional expression in a series of style revivals ill-adapted to actual conditions.

The Greek revival, stimulated by the Greek struggle for national independence, was diluted almost immediately by the antiquarian romanticism of the "Gothic." "Tuscan" and "country cottage" fashions. These offered opportunity to the undercurrent of practical utilitarianism, repressed or thwarted by the classic formula, and also gave a fertile field for the novel or exotic in decorative taste fostered by a wealth-induced appetite for comfort and display. By the middle of the century the last vestiges of order in early Victorian romanticism had disappeared under a plethora of decorative motifs and objects easily and inexpensively produced by machine. Colour became confusedly drab or brilliant, and generally out of character as a result of the introduction of uncontrolled chemical dyes and the magic of the Jacquard loom. Increased travel and ease of communication made American styles hardly distinguishable from those of Europe.

This decorative salad of classic and mediaeval motifs was supplanted by the revival of 18th-century forms which temporarily triumphed in the "second rococo" of the 1850s when rosewood and walnut took the place of mahogany, This was succeeded by fashions based on the 17th century and the later Renaissance until the Centennial exhibition of 1876 brought to America the "craft" mediaevalism advocated and industrialized by Charles Eastlake, and a new series of more literal style revivals including that of colonial times. These were in turn infiltrated by the orientalisms of the

"aesthetic" movement of the later 19th century.

In the first quarter of the present century this confused costume ball culminated for the wealthy in the fashionable antiquarianism of the authentic period interior and, for most people, in its diluted reflection, adapted to the thinner purse, provided by the wholesale decorator and manufacturer of period reproductions. The decorative picture covering these 90 years of enormous technical and financial development is too confused and complex for further analysis here. Almost from its beginnings, however, a body of criticism and rational experiment was developing both in Europe and America which was to find effective expression in the early 1920s amid the social and economic upheavals following World War I.

Functionalism and the Contemporary Mode, After 1925. —The struggle between the symbols of a traditional past and a rational acceptance of a society based on mechanized industry came into the open in the interval between the World Wars of 1914 and 1939. 4 full acceptance of new industrial techniques and an earnest desire to reconcile their free play with the needs of a society impoverished spiritually and materially by war was the basis of the co-operative efforts of the Bauhaus group established in Dessau, Germany, in the early 1920s.

This brought to a head the numerous reform movements of the late 19th and early 20th centuries. Its philosophy was a psychological and material essentialism, cathartic and analytical in its methods. which on one hand shocked the conservative into immoderate fury and on the other converted its radical adherents into equally uncompromising iconoclasts.

Though many of the ideas used by the Bauhaus movement were inspired by the subtle simplicities of the Japanese tradition and by the innovations and writings of the Chicago architect, Louis Sullivan, German functionalism hardly affected American design until its leaders found refuge in the United States from nazi oppression. The movement was brought to public attention in the middle 1930s by the need for new stimuli in the trough of economic depression, by the educational campaigns of the Museum of Modern Art in New York city, and by the re-establishment of the Bauhaus teachings in the Institute of Design in Chicago.

In the decade following the Paris exhibition of 1925 progressive thought in American design was principally influenced by the less radical productions of the French luxury crafts, based on a modified art *nouveau,* and the Swedish success in combining and developing its craft traditions in co-operation with industry. This influence was, however, confined to a relatively small and semi-professional coterie, while the market as a whole continued to concentrate on traditional forms, producing and adapting them at various levels of quality and taste. By 1935 the functionalist movement spearheaded by the adherents of the Bauhaus program had gained a substantial following among the younger architects and designers. During and after World War II their efforts, combined with those of the museums and the more progressive schools and periodicals, had gained the interest of a considerable portion of the wealthier and the manufacturers who catered to them.

The functional or contemporary program involved a complete break with the past and its ornamental motifs and meant the reawakening of a natural response to form, proportion and line and the visual and tactile values in materials. This closely paralleled contemporary interest in abstract as opposed to representational art. It also involved a scientific study of human needs and behaviour, correlating these with psychological responses to physical stimuli of all kinds, and so co-ordinated the interests of art and science. The uncompromising application of such an intellectualized program proved immediately impracticable, but its bold challenge to the conventional resulted in a notable change in the home.

The most obvious changes in the domestic interior were: first, its rapid mechanization; second, its redistribution of interior space; and third, its elimination of formal barriers between indoors and outdoors. These developments were accompanied by radical changes in decoration and the design and use of furniture and fittings. Equipment for heating and lighting, sanitation and the preparation of food, all devised essentially during the 19th century, were brought to a high degree of mechanized efficiency taking full advantage of advanced production methods. These utility units were designed to obtrude as little as possible by an insistence on simplicity of form, colour and texture. Convenience and economy became principal considerations in fitting utility units into living space instead of hiding them in otherwise unused areas in the arbitrary traditional room arrangement. The kitchen, particularly in the modest house, received careful study for visual appeal as well as operating efficiency. In mechanical equipment the mid-20th-century house began to be an efficient machine for living. Electric power, liquid fuels, flexible controls of temperature, ventilation and lighting and countless labour-saving devices became the new household gods.

Reconsideration and correlation of the space requirements of living areas broke down traditional room divisions. Decoration became concerned with the functional requirements of a living area. Because it served more than one function, a living area was frequently irregular in plan and impossible to treat as a unit in the traditional formal manner. Changes of colour, texture and materials consequently became the chief resources of decorative design, taking the place traditionally given to ornament. The new interior was in harmony with the times through its invitation to movement, both actual and implied. Earlier attempts at the functional mode suffered from, too much anxiety over simplicity and unity, and consequently became monotonous and cold. Difficulties in the handling of such abstractions as colour and texture without formal limits are so great that the temptation to follow set formulas was all too prevalent.

The demands of space tended to keep movable pieces of furniture to a minimum and encourage the use of built-in units. An earlier overemphasis on straight lines and angles was countered by greater use of curved and moulded forms in furniture design. As the average house, usually of a single story, became smaller and more efficient in its use of enclosed space and as the desire for outdoor living grew, there was a tendency to replace at least one of the enclosing walls of both living and bedrooms with glass. With a properly oriented plan this had the advantage of providing each room with a living mural as well as better light and it also extended the apparent space. Bringing the outside in has a most liberating effect, but it also creates certain practical and psychological problems. This "international style," an outcome of the functionalist movement of the 1920s and 1930s in its direct approach to needs and materials, was in complete opposition to the concepts of the Renaissance which had dominated western design for the preceding 400 years.

BIBLIOGRAPHY.—An annotated and classified working bibliography covering the main publications in this field up to and including 1947 will be found in Meyric R. Rogers, *American Interior Design* (New York, 1947). *See* also Mary E. Gould, *The Early American House* (New York, 1949); T. T. Waterman, *The Dwellings of Colonial America* (Chapel Hill, *N.C.,* 1950); and George Nelson (ed.), *Living Spaces* (New York, 1952). (M. R. Rs.)

PRACTICAL SUGGESTIONS

Styles in interior decoration have always been influenced by those trends immediately preceding, and the decorator's main efforts therefore are devoted to interpreting them discriminately and to designing original interiors based on historical period inspiration.

Traditional Style. — There was a time when whole rooms were reproduced in their entirety from some French château or Italian villa. But the contemporary interior decorator is more likely to be concerned about the minor details of a period when planning for a particular effect.

In decorating a house or an apartment there is probably no more interesting, if difficult, style to work with than the complex and highly decorative effect loosely described as 18th century. Varying renditions of the epoch come and go, changing with the decades. In recent years 18th-century styles were interpreted with rare antiques, costly panelling or expensive fabrics as the chief identifying motif. This style was also achieved more economically but as effectively by using colourful backgrounds with simple furniture and accessories.

Good interior decoration in the traditional style expresses the

period from a contemporary viewpoint without sacrificing its gracious quality and livableness to functionalism. Yet all the rooms are modern in the sense that they have convenient and efficient arrangements of furniture, are bright and refreshing with crisp colour schemes and are finely conceived.

Modern Style.—Decoration in the contemporary or modern manner calls for the same simple lines, good proportions and well-chosen woods or other mediums of decoration that apply to selection of materials for the traditional styles. Furniture and accessories must complement and harmonize with their background. Only with the greatest care, and only by those informed in period tradition can a successful combination of traditional and modern styling be accomplished. Modern furnishings against a period background can be absurd unless the background has been treated in a free manner; but period furnishings gain in effectiveness if set against a modern background. Whether traditional or modern in style, every interior should be somewhat functional through the use of modern materials; otherwise it tends to express an anachronism.

Asymmetry, which is the outstanding characteristic of contemporary design, is likely to be prevalent in any plan. Windows do not have to be equally spaced, and if they sometimes are found that way they do not affect interior decoration materially. Design develops easily from the function and general plan, and there is generally much integrity in the decoration that is produced. The contemporary designer regards the entire project as an entity in which there should be an easy and consistent flow from one room into another, instead of having each room a distinct, separate unit for living. Partitions rarely form an obstacle to design, and many times are disregarded in the scheme altogether or are used as foils to convey contrasting colours from one room into another.

Whatever may be said of modern decoration, its merit lies in function—utilitarian, simple of line and suited to contemporary living—rather than in stylistic connotation The determining factor in its measurement is not merely architectural background, nor the furniture set against it, nor mere colour, but rather a co-ordination of all these factors.

First Steps in Decorating.—The first step in decorating is to ascertain the functions of the various rooms and apportion each, depending upon its importance in the scheme, a relative share of the allotted budget in the estimate

The second step is to formulate a plan. Interior decoration is a pictorial space conceived as a four-dimensional plenum which maintains itself with reference to any point in the interior. This means that the component parts of the room are interdependent, and the relationship is maintained not by cramming the room with objects, but by use of colour harmony and pleasing co-ordinated arrangement of furniture and decorative objects.

The plan confined solely to one floor, as in the split-level and ranch-style houses, presents a problem which necessitates meticulous care in arrangement to include living comforts and service conveniences. The plan should provide an air of spaciousness in order to relieve any feeling of crowding, and one group of furniture should not interfere with another. Much of the attractiveness of the rooms depends upon draperies and carpets—even expensive furniture and textiles lose their effectiveness in bad groupings and inharmonious colour schemes. Strive for simple, straightforward, formal groupings without pictures, sofa pillows. small mirrors and incidental furniture. Add these things later, and eschew all fussy arrangements in order to defeat any chance of crowding.

Do not neglect the decorative possibilities of halls and passageways, settees and benches and console groupings uith accompanying pictures and lamps, placed in strategic positions—either to break a long wall or to form a focal point at the end of a corridor—will contribute much charm.

Proportion.—Few rooms are perfectly proportioned, and one can seldom dictate the proportions except nhen building Therefore if a room is too long, too small and high or too narron, or with doors and windows in the wrong places. nothing can be done about it except to employ decorating tricks to correct the awkward lines. The same solution applies to too-large furniture that daarfs the rest of the furniture in the room.

A cornice and a chair rail, with dado painted a different colour from the rest of the walls, will make a room seem lower, as will a ceiling painted a darker colour than the walls. To make it seem higher, employ vertical lines in the design of the wallpaper and the curtains and continue the colour of the walls over the cornice and ceiling, or paint the ceiling white. A sheet of mirror extending to the ceiling on a long wall of the narrow room will tend to widen it; so will the ends of the room painted a darker colour than the wide walls.

If windows are too narrow, hang curtains outside the window trim so that the folds are against the wall instead of the glass. For two windows too close together, hang the curtains beyond the window trim at the ends and the inner curtains in a continuous panel, as for any other window, and they will look like a wide single window. For the too-short window, a valence can be fastened on the wall above the window, low enough to conceal the window top.

Scale.—After colour, next in importance is scale. The proper scaling of furniture is frequently overlooked in the scheme because of its subtlety. It is important not only in the relationship of one object to another. but in each group of furniture to the room as a whole. Scale can be altered by the position of objects. Thus a too-large sofa between too-small tables looks larger and the tables appear even smaller. The commonest mistake is in acquiring furniture that is too large, therefore. be doubly sure that every purchase is properly scaled for the room into which it is to go. Even the patterns on fabrics and wallpaper must be considered.

Developing the Background.—The background of an interior is comprised of the walls, ceiling and floor. Of these, the walls present more problems than any other factor in the decorative ensemble, and the manner in which a decorator employs wall coverings is evidence of his ability. As background they rate highly in every scheme because they constitute a major, decorative area.

One of the most dependable sources for colour in the room, besides paint. is wallpaper; and the prodigious number of patterns available enable the decorator to choose exactly the texture of paper and the scale and character of design required for any individual scheme. Good wallpapers last for generations, and if backed with muslin they can be taken down, stored and used again and again.

Striped wallpapers possess intrinsic style. They also add to the apparent height of the wall, and if used horizontally they tend to loner the ceiling.

Pictorial papers are of three types: panoramic scenic, foliage and figured. They derive their importance in the decorative scheme from studied design and colour distributed over large areas.

The usefulness of friezes and elaborate border papers cannot be emphasized too strongly. Effects otherwise unattainable are possible with borders, panels and architectural papers showing simulated cornices, mouldings, pilasters and panelled wainscoting. Striking results are attained by pasting them to painted walls and allowing them to contribute the only pattern in the room. Border papers can also be used to outline the windows and doors and can be placed above the baseboard and the dado and at the intersection of the wall with the ceiling.

Fabric patterns are particularly adaptable as wall coverings. especially when it is desirable to have walls and draperies match exactly. The richer examples, such as flock and brocade, are of course applicable only to formal rooms. When applied to the wall and varnished, the verisimilitude of the marble papers to actual marble is astonishing. Two colours of marbled wallpapers can be combined for a pleasing effect by having the dado one colour and the wall above divided into panels of another colour.

An essential element in the background of any interior is the floor. Wood excepted. which can be patterned in beautiful parquetry of period design, floorings can be of tile, brick. stone, rubber, linoleum, cork, asphalt and the vinyl products, to mention a few. All these materials can be developed individually in ways which are decorative in themselves or which form backgrounds for rugs.

Furniture Arrangement.—In arranging the furnishings of a

room, begin with a centre of interest—such as fireplace, window or TV set—then set up secondary groupings of furniture according to their function, and keep all traffic lanes clear. The well-planned living room will be furnished to accommodate several different centres of activity—such as a record player, a grouping of table and chairs for cards or games, a bookcase, sofa and companion upholstered chairs for conversation and a desk and chair for writing—and will mix formality and informality in a way that pleases a variety of tastes.

There are four steps to observe in arranging furniture. Start with a floor plan of the room, drawn to scale, with all deficiencies of the room indicated (such as windows too close together, doors that open in instead of out or a chimney breast that juts too far into the room). Establish a centre of interest, such as a fireplace, window or breakfront cabinet, and work out from there by placing sofas near the fireplace or window and adding chairs and accompanying tables for lamps. Add supplementary groupings, such as a table and chairs for games, or a television set. Finally, check all groupings for efficiency: a desk and chair near a nindow for writing; a television set that can be heard and seen from every angle; and end tables near chairs, coffee table at the sofa and accompanying chairs. etc. Study and game areas should have a permanent place in the living room.

In order to keep the furniture arrangement flexible, keep large items parallel with walls, never cater-cornered. Disregard corners, except in small rooms developed in the modem style, and concentrate upon furniture groupings centred around larger items, such as a sofa or break-front cabinet against the wall. Never have a chair or a picture unrelated to a grouping—a print too small to go over a sofa should be used elsewhere or not at ail, and every chair should have a table or other item of furniture beside it.

The single all-purpose room will require individual treatment. First, divide the area with the dining table at one end nearest the kitchen and sitting-sleeping area at the other; curtain off, if possible, an alcove for privacy and late desk work; and lay a bold rug to accent the seating area. Two walls can be painted white or some other light colour, the other two painted a colour to blend with the decorative scheme. Furniture should be of multiple-use types, and there should be at least one comfortable upholstered chair.

Creating Colour Schemes.—Creating a colour scheme requires much sureness in order to prevent later disappointment. Yet the use of colour need not be a complicated operation, although the creation of every successful colour scheme presupposes a thorough knowledge of the primary colours, red, blue and yellow, the secondaries, green (blue with yellow), orange (red with yellow) and purple (red with blue), and their various values. such as blue-green, yellow-green, etc., in combinations ranging from the deepest shade (made by adding black) to the palest tint (made by adding white). Interior decorators generally select a colour in a rug or fabric and plan the other colours in the room around it. This is called the basic colour. With any basic colour. different contrasting effects or harmonies are possible.

A monochromatic scheme will result with all hues keyed to a single colour, such as red with pink and rose; a related colour scheme is the result of combining hues with a single related colour, such as red with orange and yellow, or coral with peach and cream; opposite or directly contrasting colours are called complementary colours, and include red opposite green, blue opposite orange and yellow opposite purple.

Generally speaking, a predominant quantity of cool colours, such as blue, green or gray, is never specified for a room with a northern exposure; there the colours should be light and warm, such as yellow, red or orange. Nor will warm colours be specified for a room with a warm exposure; there the hues should be cool and neutralized. There are exceptions, of course, for in cities one frequently sees blue rooms. green rooms, yellow rooms and red rooms irrespective of their exposures. In such instances masses of muted hues in fabrics and accessories are employed in the decorative scheme to balance the predominating colour of the background. The cool colours have a tendency to increase the apparent size of a room, just as the warm colours seem to diminish the size. Red (warm) and blue (cool) are outstanding examples, and yellow may be considered an exception because of its diffusive light quality under all conditions.

Accenting colours, either harmonizing or contrasting ones, are most important in completing a colour scheme, because without them a scheme will be flat. They lend emphasis. Care must be exercised in their use, however, else they may become a very disturbing element. Too many accents create confusion instead of pointing up a decorative scheme.

In developing a colour scheme for a room, the following course is recommended: instead of selecting a sample of fabric or wallpaper in the customary manner, and scheming with several related colours chosen from it, reduce the number of colours to two or three, emphasizing contrasts and sharpening the decorative pitch. Thus instead of employing the usual five or six colours, one dominating colour is selected and two related colours are used. This plan is infinitely simpler and more effective, and the problem of pattern and scale are reduced to a minimum.

Small rooms seem crowded and oppressive if the walls are dark or too bright. Pale blue or green gives a feeling of spaciousness, and the ceiling in the same colour increases the roomy effect. To make a big high-ceilinged living room acquire a more intimate air, paint the walls in a bright rosy shade and the ceiling in a deeper colour. This will give the illusion of less height and provide a warmer atmosphere. Apartment dwellers can make rooms appear larger by painting walls and woodwork the same colour, and by relating colours of different rooms so they seem to flow one to the other. Painting one wall a pale shade in a different colour from the rest will add length to a room that is boxy. For the room that lacks sunshine, a generous application of yellow paint will give it a sunny effect. Red should be used sparingly in the kitchen, since it is a "hot" colour and tends to emphasize the heat of cooking.

Specify background colours which are fresh and clear, whether pale or dark, subtle or vivid hues are planned. Aim for clarity rather than depth, and colours can include watermelon pink, subtle beige, lemon yellow, emerald green, blue, gray, deep brown, black or white. Colours should express a vital quality of elegance rather than opulence, and one working in this tempo will find that fabrics, floor coverings and furniture finishes all follow the same trend.

Always include the ceiling in the colour plan. It can be in contrast with the walls or match the wallpaper or rug. If the floor is wood, have it stained dark brown, then waxed and polished. The light-oak shellacked floor is never recommended.

The most helpful element in the creation of a successful colour scheme is illumination. The colour combination which in daylight seems so beautiful can at night be utterly spoiled if the illumination is not carefully planned; and nothing is more discordant in a subtle arrangement of pastels than strong shadows which have the power of actually subordinating the colours. Correct illumination, it will be found, is indistinguishable from the use of colour.

Lamps and Lighting.—Light sources should be subordinate in visual importance to the things they are intended to illuminate, except in rare instances where the light source itself is to be the dominant decorative motif. Unless concealed or counterlighted so that they are not apparent, light sources have extremely high attention value and readily dominate the decorative scheme, thereby detracting from the background and furnishings of the room. Generally speaking, lamps used for reading and writing must be relatively tall and equipped with shades wide enough to direct light on the reading plane.

Lamps should be used sparingly. Have them mounted with rubber-insulated wire, which will not fray and tends to disappear against wood better than does silk. The variety of portable lamps is as limitless as it is interesting. They range from simple pottery units with parchment shades to expensive ones fashioned of porcelains or rare metals and semiprecious stones combined with shades of the finest workmanship. Before the lamp is decided upon, it should meet the following requirements: Is the lamp appropriate for the room in which it is to be used? Is it of the same

character in design and colour as the other furnishings in the room? Is it suitable in type for the use to which it is to be put? Finally, what is the size of the table upon which the lamp is to stand? Because a lamp is a source of light. it attracts more interest than does any other object and is therefore always placed near a wall where it can be absorbed by the background, rather than in the centre of the room.

The shade is as important as the lamp base, because it is not only a decorative feature but controls the flow of light as well. For this reason it should, like the lamp base, be studied in relation to its purpose and position in the room. Uniformity of colour and styling is always to be observed. and all conflicting shapes and colours must be assiduously avoided. It is also essential that all lamp shades be kept at the same height in the room, to prevent any jumpy effect. Shades should always be severely tailored and simple of line, with ornament confined to a border band of gold or colour or a small bow. Lamp shades should be selected so that the completed lamp looks as though it had been conceived of as a lamp rather than as a vase with a shade affixed to it.

A ceiling fixture controlled by a wall switch is sufficient in a hall, because halls usually serve merely as passageways. But more adaptable lighting is essential in other rooms of the house. Floor lamps are never advisable except where close. bright illumination is required—at a piano, bridge table or sewing stand. Indirect lighting from floor lamps, although designed to eliminate glare, is not satisfactory because light is thrown on the ceiling in a manner that is objectionable in a perfectly planned interior.

Concealed lighting is appropriately termed architectural illumination and is employed as something with which to build and decorate. This versatile lighting, capable of infinite variations with fluorescent lamps, is employed to supplement the usual fixtures and portable lamps, and its decorative possibilities are limitless because it is inexpensive and easy to use. Used directly or indirectly. it is frequently employed in a simple manner with striking results. It can be confined entirely beneath a surface of enclosed glass to emphasize an architectural plane, or it can be spread, in a similar manner, behind a cornice or a frieze to illuminate an entire room.

The Small House.—The trend toward less complicated living is marked by some of the most interesting examples of interior decoration to be seen, particularly when it comes to making the smaller house or apartment attractive.

The results, decoratively speaking, can be as effective and interesting as they are low in cost. How to evoke a setting for enjoyable living and comfort in a small area. and at a minimum cost without sacrificing either beauty or good taste is the problem. In such cases original ideas are as important as money. A new window treatment, smart use of a mirror or two, colour used in just the right way—these are the little things that will lift a small house or apartment out of the ordinary.

The value of details in the scheme is infinitely greater when there are several of them, for what makes the room successful is the cumulative effect of these essential parts. In decoration, as in mathematics, the total is the sum of its component parts. Consider the dramatic qualities of natural woods, the pleasing effect of plain areas as backgrounds for dramatic settings, the sparkling beauty contributed by mirrors and glass, the decorative value of growing plants, the dramatic effect of jet-black metal or brass in the scheme or the interest created by an antique or two set against a modern background.

In the small house or apartment the chief decorative interest can be successfully centred in vivid colour; a scheme of geranium red and white carried throughout, for example, can be a jewel of decoration in a small setting. Blue and green. apricot and white, pink and brown and lilac and green are other colour combinations that prove delightful. In any case, furnishings for the small house or apartment should be kept to an absolute minimum.

Decorating on a Budget.—There are three low-budget ways to decorate, as regularly practised by decorators. First, economize by specifying inexpensive materials of limited durability, with the expectation of either replacing them as they wear out or finally substituting better materials when the budget permits it. The second way is to consider furnishing as an investment, beginning with expensive but long-wearing materials at the outset and avoiding the redecorating expense. There is much to recommend both practices.

For example, if the house or apartment is rented or leased, or alterations in the decorative style are desired with the changing seasons, it will be expedient to recommend the first plan for draperies and wall coverings; otherwise it is seldom satisfactory unless budget limitations will permit only minimum investment. Conversely, if the background of the room is fixed in architectural style as to xoodwork, fireplace and mantel, doors and windows, the decoration should be of equally enduring character consistent with it. Only then will such anachronisms as Georgian furniture combined with modern architecture be averted.

Progressive assembling is the third method of decorating an interior with a minimum initial outlay of money. A system of discriminating purchasing is recommended for either the simple or the luxurious interior, and acquiring fine things on a gradual scale—the furniture and floor coverings one season, the draperies and accessories the next—is recommended in preference to a complete installation of mediocre furnishings.

Furniture is one of the items with which the decorator can make but few. if any, economies so far as actual construction is concerned. Buy furniture of a high standard. The only way to save is to reduce the number of pieces.

Frequently one or two important items of furniture, such as a sofa. commode or large table, can be the nucleus for incidental pieces that are added later. This economy of buying fewer items is recommended because it is not necessary to include as much furniture in a room as heretofore. It should be remembered that furniture cannot be easily discarded for a passing style, and that many items lose their decorative effect because they are not placed advantageously in the room.

Above all, provision should be made for adequate floor coverings, although this item does not lend itself easily to the budget. Floor coverings should be submitted to many tests for quality and viewed with an eye to their wear and future adaptability to changing styles.

Textiles supply vitality to the decorative scheme, and the most effective may to achieve a desired effect with the minimum outlay of money is with drapery and upholstery fabrics. These can be changed from time to time to meet the exigencies of the season, and such transformations do not require much money if the fabrics are selected for enduring qualities of weave and design.

To lay the foundation for future enjoyment of a decorative scheme, spend money for decoration which is basically worthwhile and of permanent value. Economize on the things that can be replaced in a scheme: hang unlined curtains, use slip covers instead of upholstery coverings which can be supplied later. **A** sofa can be selected, for example. in a temporary sateen covering and be made the dominant note of the colour scheme. Maple or limed-oak wood finishes look well with simple curtains and no draperies, and nith upholstery and rugs of moderate cost. These relatively inexpensive woods permit use of accessories scaled correspondingly low in price.

Decorative Window Treatments.—Any attractive room can be made more attractive with appropriate curtains and draperies for its windows, and window shades can also add to the decorative effect in many instances. The variety of window treatments is legion, drawing upon every period of interior decoration.

The three periods of early American artistic expression—from the earliest New England styles through the first quarter of the 18th century; from 1725 to the early republic; and the Federal, 1785 to 1830—are exemplified chronologically by the series of decorative curtain treatments exhibited in the American wing of the Metropolitan Museum of Art in New York city. They clearly delineate the changing styles of window curtains in interiors of the respective periods and are valuable for use in traditional schemes.

The earliest example introduces a style of window treatment that was already in fashion in England when the first permanent

settlements were made in New England. The valence of worsted embroidery on linen marked a transition beta een the use of heavy, solid needlenork and the use of lighter, printed fabrics. Later examples of this latter phase are the curtains printed in a Jacobean pattern, those nith the pattern outlined in one colour and the remainder printed in by hand; and the toiles de *Jouy* The development of draperies in richer fabrics, including plain silks, damasks and brocades. began about 1756. The shaped valance, or pelmet, appeared at the same time, and this charming style was never abandoned for the various festooned adaptations that were so greatly esteemed during the first years of the 19th century.

A note of individuality is often given the roller shade by substituting glazed chintz or gaily striped awning material for the customary fabric. With shaped or plain end it is a perennial favourite for small houses, and affords a source of much colour. This type of shade is lovely with ruffled sheer curtains, and no draperies are needed nith it; an individual trick is to use a shaped valance, made of the same material as the shade. with sheer curtains and a plain coloured or white fabric for the side curtains, or no side curtains at all. A cool summery effect can be obtained with sheer starched or nylon curtains that are edged with a bright binding or with deep pleated ruffles, a treatment that is sufficient for informal sitting rooms. A more sophisticated window treatment for the formal room can be realized with bouffant Austrian shades that may be raised or lowered by traverse cords attached to the shades.

Contemporary enough for any modern whim, Venetian blinds—either vertical or horizontal—are equally correct in rooms of either English or French late-18th-century derivation. They form an ideal accompaniment to the formal French empire, English regency or early American interior, and are informal enough to be used in French provincial and colonial treatments. The advantages of Venetian blinds are many. Not only are they smart and trim, but, uhen made of plastic, are durable as well and can be easily detached for cleaning.

In informal settings, or on stair landings and in halls where wall space is less of a problem than it is in the more lived-in rooms of the house, the use of indoor shutters, both louvered and panelled. is of definite value. The panels are often painted in attractive motifs or decorated with applied flower prints. This type of decoration is by no means confined to small-house interiors; painted antique doors in the rococo style used at French windows offer as great an effect of richness and formality as could be desired.

Terraces and Outdoor Rooms.—A sunroom or breezeway in the smaller house—a transition room between the house and the garden—must have about it a suggestion of fresh air and the outdoors, an atmosphere of both garden and interior, yet also appear gayer and less formal than the inside.

This room, detached from the main part of the house, and its many windows with light streaming in will permit a freedom in decorative treatment inappropriate to any other room. This atmosphere can be emphasized by bringing in things from the outdoors: small trees, flowers, vines and water. However, the interior decoration should be related to that in the other rooms as concerns style and the type of furniture.

A terrace need not necessarily be joined to the house to be an outdoor room. Any pleasant spot or area of turf can constitute the location, because furniture is available to withstand the vagaries of weather. Provided there is a view—if not of a garden or trees, then of a high trellis with vines—the first consideration for any terrace is an awning to offer shade and to make the terrace livable at all hours of the day. It may be a portable device or be fastened directly to the house, or shade can be effected aith decorated fabric roller shades, bamboo curtains or Venetian blinds.

The fact that so many meals are served on the terrace means that the outdoor room must have chairs and tables that can be shifted to give the appearance of a well-set dining table at night. For out-of-door use. furniture must be either weatherproof or easy to move about and take up or down steps; it must not fall over or blow away in a breeze, nor be too heavy for a woman to move. Cushions must either be waterproof or easily carted indoors. And ash trays must be windproof, the best being deep ones filled with sand.

A small copper-lined cabinet is useful on the terrace to hold an electric hot-water heater for preparing tea; and it might also have a compartment in which to dump cushions, books and magazines to keep them dry. There should be a little wall fountain, also, from which to rinse teacups and to obtain fresh water. Or a little house, part of a grape arbour or tool house, might have a closet for bottles and glasses and even a small electric refrigerator. A portable screen might also prove useful, and there should be a chest for garden tools. If benches are located some distance from the house it is well to have a box for brushes and rags to flick away any dirt.

Floors for terraces and open porches are usually of bare stone, linoleum (if indoors) or tile; and if of plain cement, they are frequently coloured.

Kitchens.—The actual layout of a kitchen depends on the room itself. but if three sides of it are properly equipped the sink will be at one end under a window, flanked by two work surfaces; the stove will be on one side with additional work space, all equal in height; and across from it will be the refrigerator. Cabinets should be fitted in, above and below the various units, completing the compact arrangement.

Ignoring the universal black and white stove and refrigerator is an impossibility, therefore colour and decorative schemes must be worked out from the cabinets, wall and floor coverings and ceiling. Even wood cabinets lend an atmosphere of attractiveness when used in natural grains or when painted. Walls can have any decorative treatment, since numerous wall coverings are washable, and paints offer an excellent chance to unify a particular colour scheme; steel and other tiles can be installed that contribute sparkling brilliancy. and glass is a favourite. Linoleum, vinyl, rubber and asphalt tiles are favoured floor coverings because of their resiliency and sound-deadening effect, as well as easy cleaning.

Paint the kitchen ceiling either dark or light to contrast with the walls. Lighting fixtures can be used in such flexible mays that a kitchen can be planned in terms of the best light for efficient work. Steel domes over recessed windows can contain indirect light bulbs, for example, to give reflected illumination; cabinets can light up indirectly from within when the doors are opened; and lights can be placed under shelves to prevent glare. Daylight can flow in through glass bricks, which let in more light than windows.

Trim lines. air, light and sunshine should be part of the decoration of the kitchen. A snack bar with leather-covered high stools can be set before a long window or about a counter-table partition, or one-arm lunch chairs will lend a unique note. Decorative accessories on glass shelves set in front of the light will enhance the general scheme.

Children's Rooms.—Because few people can afford to replace furniture every few years, it is sensible to buy children's furniture with an eye to the future. The pieces should be selected with emphasis on adaptability as well as charm and comfort. Cribs are available that can later be transformed into beds, while chests can be fitted together to make cabinets and desks to fit the needs of the older child.

Because the furniture is for the child's use, it should be designed and scaled proportionately. Much of the infant's and younger child's furniture is painted or enamelled in the somewhat lifeless pinks and blues, and stencils of the familiar nursery rhyme characters are found on many pieces as well as on the walls of the room. Such designs are all right if the furniture can be scraped and refinished when the child outgrows his nursery fancies. A better choice would be vivid, primary colours which, child psychologists claim, hold more interest for the very young and will later appeal also to the older child.

The needs of the child's room should not be overlooked. It must have adequate shelf space, a place for each toy; the old wooden box into which the toys were dumped in a heap is gone forever. The child's toys should be easily accessible. Furniture should be scaled to his size. There should be space enough to leave

toys where they are when the play hour is ended; there should also be plenty of table space for drawing and a sandbox for constructing model villages. etc. Action toys are of little value if there is insufficient space in which to manipulate them.

The wall colour of the child's room should be light, and decoration should not be used to the detriment of space that can be utilized for maps, bookshelves, a blackboard and cases to house small collections of shells and stones. Washable wallpapers are not only practical. but ha e decorative, charming designs as well. A small blackboard installed on one of the walls will ward off any tendency toward infant mural decoration. Linoleum, in appropriate colours and patterns, is always good for the floor in a child's room; if rugs are used, small washable throw rugs are practical.

Accessories deserve careful consideration. Vases with fresh flowers. china animals and lamps may enhance the attractiveness of the child's room, but they are hazardous and so have no place in the scheme. Wall brackets can take the place of vases, and pictures are better than china animals. A clock in the nursery is a necessity. and indirect wall lighting is more practical than lamps (which can be pulled off tables).

Bathrooms.— In the selection and arrangement of bathroom fixtures much depends upon the size and shape of the room. Where small space or unusual design makes the use of a conventional tub impractical. a receptor bath which is more or less square in shape makes an ideal installation. Developments in tubs stress low height, straight sides and large flat bottoms, all in the interest of saiety as well as structural beauty. Wide. comfortable seats on the rims on some of the tubs make them ideal for foot-bathing. Lavatory and toilet units can match the style of the tub. Some lavatories are very sleek with their slender chromium legs; others emphasize practicality with cabinet bases for storing towels or medicines. Bathroom fixtures are available in a wide range of colours and. where space permits, the installation of the small basin for oral hygiene or shaving is a great convenience.

Because bathroom fixtures can be had in various sizes and shapes. decoration is largely a matter of arrangement. In cases where one bathroom must serve an entire family, effective partitioning can be done with walls of glass blocks or tiles to separate the toilet from the rest of the room. Separate shower units with watertight walls and doors of laminated plastics, tile or glass and with a vent at the top of the door to permit steam and heat to escape are extremely practical and easily installed.

Although the bathroom has emerged from its "laboratory" garb of austere white, there is one essential item that must be retained: adequate lighting. At the lavatory or dressing-table mirror, over the tub or in the shower unit, good lighting is necessary. Manufacturers of cabinets and dressing-table mirrors have incorporated frosted tubular lighting fixtures in their units to ensure compact design and proper illumination. Of paramount importance are the electrical outlets for the bathroom; there should be a sufficient number conveniently located for using the electric razor, vibrator and other appliances.

Besides tile, linoleum and rubber composition wall coverings, there are various types of glass bricks and panels, opaque or translucent. or glass may be used in the form of large mirrored surfaces which tend to increase the apparent size of the room. Water-repellent fabrics for curtains and washable wallpapers, figured or plain. are not only beautiiul but their use is advisable in cases where the over-all cost must be kept at a minimum.

Closets.—The closet composed entirely of sections of drawers, cabinets, shelves and sliding trays is extremely practical and smart. This kind of closet is not only suited for linens but can be used for wearing apparel. The ideally lighted closet has automatic lights that go on when the door is opened and off when it is shut. In choosing backgrounds for closets, painted walls to match the colour of the room are the simplest and most durable. Sometimes, to give a smart bandbox effect, a striped wallpaper or one with small nosegays or allover pattern makes an attractive background for hangers, hat stands, boxes and dress bags in plain colours. Colours in the wallpaper design may be effectively brought out in the colour of fabric and binding used in closet accessories.

There are all sorts of bags for use in the closet: garment bags for dresses: suits or fur coats, shoe bags with a pocket for each shoe and laundry bags. Ctility boxes come in all sizes and shapes, and are made to harmonize with other accessories of the closet ensemble. Racks, too, are an important part of the closet and it is important to note whether rods and bars are placed at a proper distance from the floor. These can be had in chromium?stainless steel, brass or painted wood. Various types of tie holders are also available in metal or plastic materials.

Hatstands are a convenience and lengthen the life of the hats by decreasing cleaning and blocking bills. The stubby or short stands with a rather broad base and top are the most practical because they do not topple over when one removes a hat. Hangers are of wood, metal or plastics. sometimes covered with velvet, satin or other fabric and often scented. Size and shape of the hanger are important considerations, in order to give proper support to the garment.

Pictures.— Pictures can be valuable in securing an atmosphere of repose if they are hung in a balanced scheme and any unbalanced arrangement, restless to the eye, is avoided. The fundamental rule—hang pictures at eye level and' at a fairly uniform height around the room—still holds, for it creates an effect of order and repose. But any variation that gives a fresh and harmonious effect will still be in good taste.

The fashion for pictures hung in groups, frequently covering an entire wall. is enjoying a revival in interest. When pictures of different sizes are hung in a line, they should be hung so that the centres are all on a line regardless of the tops and bottoms of their frames. Small pictures are always grouped together, the supporting nails concealed behind the frames; larger pictures should be hung from two parallel wires when support is necessary, and not from a single wire forming a triangle above the picture.

Pictures are wall decoration; forming an architectural part of the wall, and should not be scattered aimlessly about; for this reason the only place where pictures may be placed stepwise is the stairway wall. And pictures are always hung flat, never tipping forward.

Many a good painting has been ruined by the wrong type of frame. Be certain that the frame does not attract more attention than the picture; this can be the guide for successful framing.

(H. V. A.)

INTERLAKEN, a Swiss town (1,864 ft.) in the canton of Bern. situated on the flat plain (Bodeli) between the lakes of Brienz (east) and of Thun (west). It is built on the left bank of the Aar, and grew up around the religious house of Austin canons, founded about 1130 and suppressed in 1528.

Interlaken is much frequented in summer, partly because of the glorious view of the Jungfrau (13,642 ft.) which it commands to the south, and partly because it is the best starting point for many excursions, as to Schynige Platte, Lauterbrunnen, Grindelwald, Mürren and Jungfraujoch. The lines serving these places all start from the eastern railway station (that from Thun reaches the western or main railway station), whence steamers depart for the Giessbach falls, Brienz and Meiringen, on the way to Lucerne or to the Grimsel pass. In 1950 the population of Interlaken was 4,368 (mainly Protestant and German speaking). Opposite Interlaken is Cnterseen (population 3,448), which was built in 1280 by Berthold von Eschenbach.

INTERLUDES. Early Tudor dramas, performed indoors and before a select circle by professional minstrels (lusores) or amateurs (such as Thomas More in his youth) in the pauses of some other entertainment (banquet). Interlude may also mean simply a "play between persons" (ludus inter personas), hence stage play in general. Most interludes were of a nonreligious and even farcical nature. However, in the 15th and 16th centuries some plays were called interludes which are today classed with the morality genre. Allegorical machinery such as associated with the moralities is not absent in *A* Goodly Interlude of *Nature* by Henry Medwall (*q.v.*) and in his revival of the old *débat,* Fulgens and Lucres (c. 1497). Medieval abstractions prevailed in *A* New Interlude and a Mery of the Nature of the *IIII* Elements (*c.* 1517) attributed to John Rastell (*q.v.*) and in John Redford's

Wyt and Science (ante 1548). Rastell's son-in-law, John Heywood (*q.v.*) brought the interlude genre to perfection in his "newe and very mery interludes" called *The Play* of *the Weather* and *The Foure PP (c.* 1520).

INTERMETALLIC COMPOUNDS. The formation of intermetallic compounds cannot in general be interpreted according to the laws of ordinary chemistry; progress in the theory of the solid state and the structure of crystals, however. enables the main factors involved to be understood. During the period following the application of microscopic techniques to metallurgical problems and the application of phase-rule principles to metallic equilibrium. much research was devoted to systems consisting of two or more metals. The phase rule, which was based on thermodynamics, enabled the number of distinct phases or types of material which could coexist in such systems to be related to the temperature and pressure at which the systems were studied (see THERMODYNAMICS). It became possible to construct for these systems "equilibrium diagrams." that is, diagrams summarizing the temperature ranges and composition ranges over which various metallic phases of the systems were stable at atmospheric pressure. It was quickly realized that metals were able to dissolve in each other, not only in the liquid state but also in the solid state, particularly at high temperatures. Further. it was found that many metals formed well-defined solid compounds with each other. For example. magnesium will dissolve tin to a maximum of about 15% by weight in the solid state. Magnesium and tin also form a stable intermetallic compound, which is of substantially fixed composition and has the formula Mg_2Sn. The melting point of this compound is higher than those of either of the component metals, and its properties are very different from those of either magnesium or tin. The data available for this metallic system may be summarized in the form of the equilibrium diagram shown in fig. 1. At temperatures above the curve ABCDE. all compositions consist of a homogeneous liquid mixture of the two metals. At compositions and temperatures within the. area AFG, the system consists of a homogeneous solid solution of tin in magnesium. At temperatures and compositions within the area GFHI, however. the alloys consist of two phases—the solid solution of tin in magnesium and the compound Mg_2Sn. Similarly: alloys in the area KIJL consist of two phases—the compound and the solid solution of magnesium in tin. Only at the precise composition represented by the line CHIK do the alloys consist entirely of the intcrmetallic compound. The areas ABF and BCH represent compositions and temperatures at which the homogeneous liquid is in equilibrium with the solid solution and the compound respectively. while in areas CDI and DJE the liquid is in equilibrium with the compound and the tin-rich solid solution respectively.

Naturally the attempt was made to interpret compound formation between metals in terms of the valency conceptions of chemistry (see VALENCE). This met. however. with only partial success. Although the iormation of Mg_2Sn. for example. could be explained in terms of ionic attraction between doubly charged positive magnesium ions and tetravalent negative tin ions, other cases. such as Cu_2Mg and $CuMg_2$, defied such an interpretation. The accumulation of data with respect to intermetallic compounds showed that it is only in a comparatively limited number of cases that the laws of ordinary chemistry can be applied. In the greater number of cases. factors other than chemical bond iormation are dominant. Advances in the theory of the solid state, and particularly of the metallic state. have elucidated some of these factors. In addition, the application of X-ray crystal structure determination techniques has revealed the ways in which atoms may be arranged in solid crystals and a satisiactory classification of intermetallic compounds became possible. At the same time, theoretical work tended to emphasize that there is no sharp dividing line between the various types; the problem of fitting unlike atoms together in such a way that the assembly forms a regular three-dimensional framework in space (or space lattice) must be viewed as a whole. The stability of the arrangement will depend on a number of factors. Where these factors oppose each other. classification is difficult, and many cases of behaviour intermediate between those of the well-defined compound types are known.

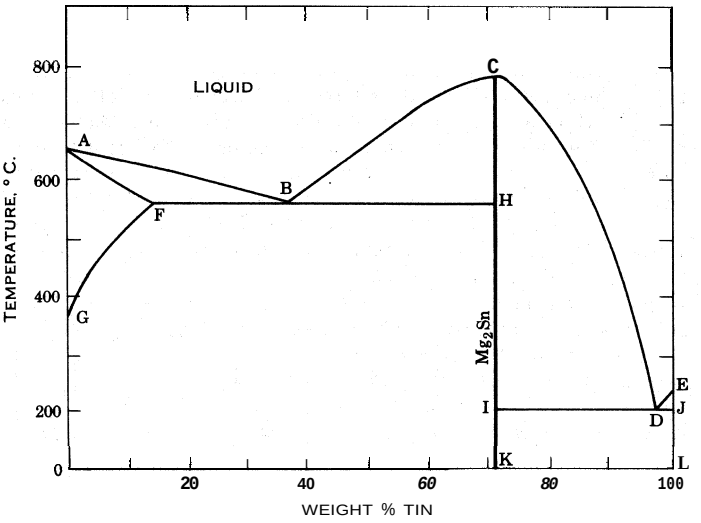

FIG. 1.— EQUILIBRIUM DIAGRAM OF THE MAGNESIUM-TIN SYSTEM

The discussion of the main types of intermetallic compounds observed may well begin with the compounds in which the normal valencies of the component metals are satisfied. These are only found when the electrochemical characteristics of the metals differ considerably. Just as the electropositive metals of the alkali and alkaline earth groups of the periodic table form stable compounds (salts) with the electronegative elements of the halogen group, they tend to form stable intermetallic compounds with the more electronegative of the metallic elements. There is a general tendency. therefore. for metals of the alkali and alkaline earth groups (*e.g.,* sodium, potassium, rubidium, beryllium, magnesium, calcium) to form stable compounds with silicon, germanium, tin and lead in the fourth group of the periodic table, and arsenic, antimony and bismuth in the fifth group. Selenium and tellurium also form the electronegative component in such compounds. In general, in compounds of this type, the normal valencies of the component metals are satisfied. A typical selection of compounds is found in the alloys of magnesium. With silicon. germanium; tin and lead, one stable compound is found in each case.

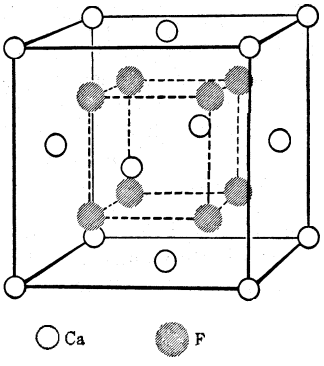

FIG 2 —FLUORSPAR STRUCTURE

Alternatively, in the case of alloys with arsenic, antimony and bismuth. the compounds Mg_3As_2, Mg_3Sb_2 and Mg_3Bi_2 are formed, while with selenium and tellurium, the compounds MgSe and MgTe occur. In each case the normal valencies of the components are satisfied. The compounds have very limited ranges of homogeneity (a reflection of the high affinity between the metals), are very brittle and tend to have high melting points. They are. if not insulators. very poor conductors of electricity. The stability decreases as the atomic number of the electronegative element increases within any one group of the periodic table. in agreement nith the usual tendency for the elements of any one group to become progressively more positive in character as the number of the period to which they belong increases. This is reflected in the progressive decrease in melting point on passing from Mg_2Si (melting point

1,102° C.) to Mg_2Pb (m.p. 553° C.), and from Mg_3Sb_2 (m.p. 1,228° C.) to Mg_3Bi_2 (m.p. 823° C.). These compounds are also characterized by high heats of formation, which are of the order of several kilocalories per gram atom. In general, the greater the stability and the heat of formation, the greater also the electropositive nature of the first metal, and the greater the electronegative nature of the elements of the fourth, fifth or sixth group of the periodic table.

It is significant that compounds of this type have crystal structures which are very closely related to those of true salts. Thus Mg_2Si, Mg_2Ge, Mg_2Sn and Mg_2Pb are anti-isomorphous with calcium fluoride, the arrangement of atoms in the structure of which is shown in fig. 2; the term "anti-isomorphous" means that the crystal structures of the compounds are such that the positive component (Mg) occupies the type of position in the framework or lattice which is occupied by the negative component in the salt. Similarly, the compounds with arsenic, antimony and bismuth are anti-isomorphous with certain of the oxides of the rare-earth elements, while MgS and MgSe and many other tellurides and selenides possess the same type of structure as sodium chloride.

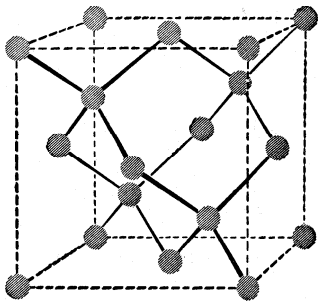

FIG. 3.—DIAMOND STRUCTURE

These compounds may thus be regarded, from one point of view, as the extension of the ordinary ionic structure into the realm of intermetallic structures where one component is electropositive and the other electronegative.

There are examples of a somewhat analogous type of compound to be found among the sulfides! selenides, tellurides and arsenides of metals such as zinc, cadmium and mercury, where the electrochemical differences are less marked than in the systems previously considered. Many of these compounds crystallize in the lattices characteristic of the two naturally occurring forms of zinc sulfide, which are both simply related to the lattice of diamond (fig. 3). Each atom in these compound structures is tetrahedrally surrounded by four atoms of the other component. Diamond takes up this structure by each carbon atom sharing one of its four valency electrons with each of four neighbouring atoms; the bonding force is covalent (electrons shared), and there are four valency electrons per atom in the structure. In the intermctallic compounds which have the zinc sulfide structures, there are again four electrons per atom, as, for example, in CdS, AlP and MgTe. It is very probable that such compounds are not essentially ionic in nature, but are held together by covalent bonds.

There is. houever, another large class of intermetallic structures which cannot be simply related to ordinary chemistry. These tend to occur in cases where the electrochemical characters of the components do not differ greatly. They often have considerable ranges of homogeneity. are metallic in their general properties and are metallic conductors of electricity. The compositions over which they are stable frequently include compositions corresponding to simple atomic ratios, but these ratios rarely bear any relation to the usually accepted valencies of the components. Thus, intermediate phases occur in the copper-tin alloys at compositions in the region of Cu_5Sn, $Cu_{31}Sn_8$ and Cu_3Sn. At first sight. there appears to be little reason why such peculiar atomic ratios represent stable structures. Systematic work on many alloy systems formed by copper, silver and gold uith elements of various valencies, however, enabled phases of this type to be classified. with striking results. In many of these systems, the primary solid solution is followed, as the concentration of the solute is increased, by a phase the structure of which is body-centred cubic (see fig. 4); the phase may be stable at room temperature or only at high temperatures. Taking copper as a typical solvent metal, and zinc, aluminum and tin as solutes of valencies 2. 3 and 4 respectively. there are body-centred cubic phases in the regions of the compositions CuZn, Cu_3Al and Cu_5Sn respectively. The common characteristic in each case is a ratio of three valency electrons to two atoms. Both the compositions of the phases and the structure they assume are therefore governed by the valency electron/atom ratio. The same principle holds for many other body-centred cubic phases in this class of alloy. In the alloys of copper and silver with elements of various valencies. homogeneous phases with a complex structure (the "y" structure) based on a deformed body-centred cube are very frequently found at a ratio of valency electrons to atoms of 21/13. Examples of this type, which tend to be brittle and silvery in colour, are Cu_5Zn_8, Cu_9Al_4 and $Cu_{31}Sn_8$. A further class, all members of which possess a close-packed hexagonal structure, tends to occur at a valency electron to atom ratio of 7/4, as. for instance, in the cases of $CuZn_3$, Cu_3Sn and Ag_5Al_3. It is of interest to note that alloys of transitional metal solvents with similar solute metals also form intermediate phases of the same type. Thus, the phases which occur close to the compositions CoAl, NiAl and FeAl are body-centred cubic in structure! while the phases Co_5Zn_{21}, Fe_5An_{21} and Ni_5Zn_{21} have the "γ" structure. It will be noted that the electron/atom ratios for these phases are the same as in the corresponding copper alloys if the transitional metal atoms are regarded as contributing no valency electrons to the structure, a behaviour which is connected with their peculiar electronic structure. This class of intermediate phase, the formation of which is governed by the number of valency electrons per atom, is usually known as the electron compound class, and occurs in the absence of any marked electrochemical difference between the components and where the atomic sizes of the components do not differ too widely. This class is of great theoretical interest, and its occurrence has been interpreted in terms of the modern electron theory of metals. Broadly speaking, the occurrence of electron compounds is caused by the tendency of a metallic structure to assume such an arrangement that the relatively free (*i.e.*, nonionic) electrons possess the lowest possible energy; this condition is satisfied at electron/atom ratios of 3/2, 21/13 and 7/4 by the body-centred cubic, "γ" and close-packed hexagonal structures respectively. As stated above, these phases frequently have considerable homogeneity ranges, unlike normal valency compounds, and the precise details of the way in which a phase of the fundamental electron/atom ratio can tolerate an excess or deficit of one kind of atom depends on subsidiary factors, such as the atomic size difference involved. It is clear, however, that, in agreement with theoretical expectations, the homogeneity ranges decrease as the valency of the solute increases.

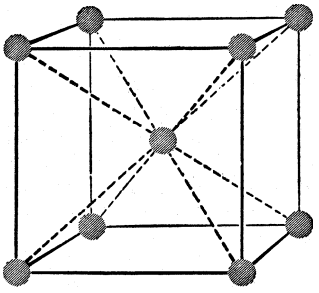

FIG. 4.— BODY-CENTRED CUBIC STRUCTURE

It is important to note that electron compounds are found in ternary alloy systems. Thus the typical "γ" structure is obtained in copper-zinc-aluminum alloys if the composition is so adjusted as to maintain the required electron/atom ratio of 21/13. A further point of interest is that, although the arrangement of the atoms on the lattice points in many electron compounds is entirely at random, in others an ordered arrangement exists. The copper-zinc β phase shows both types of behaviour. At high temperatures, the copper and zinc atoms are distributed quite at random on the lattice points, and there is no distinction between the atoms at the cube corners and the cube centre of fig. 4. At low temperatures, however, the zinc atoms occupy the cube centres and the copper atoms the cube corners (or vice versa). This behaviour depends on factors, such as atomic size, which are distinct from electronic considerations.

The two types of intermediate phases so far considered indicate that, where size and electrochemical differences are not marked, electronic factors tend to control the occurrence of compounds, while a pronounced electrochemical difference leads to the formation of normal valency compounds. Certain details of the occurrence of the electron compounds, such as the existence of ordered arrangements, show that atomic size differences must be considered as another factor which may become predominant

in certain cases. It is known. for instance. that several intermetallic compounds crystallize in the body-centred cubic structure (*e.g.*, NaTl. LiIn. LiZn) without any possibility of an electron/atom ratio of 3/2 being established. In these cases, the effect of size relationship is predominant, and the formation of a large and interesting group of phases is governed primarily by this factor. Among the most interesting are the interstitial compounds, in which it is possible to fit very small atoms into the interstices of a metal lattice. which may be deformed but is left otherwise essentially unchanged. Compounds of this type are met with in the hard. high-melting horides, carbides, nitrides and hydrides of many metals, and the skeleton of the metallic structure accounts for the metallic properties shown by many of these compounds. 4 large number are based on the face-centred cubic structure (fig. 5). Very small atoms, such as hydrogen. may he inserted into the centres of the small cubes of fig. j, so that each is surrounded by four symmetrically suited metal atoms: several hydrides possess this structure. The somewhat larger nitrogen and carbon atoms are in general too large to form stable structures of this type with most metals. Such atoms, however. can be inserted into the spaces between metal atoms which occupy the corners of the large cube in fig. 5, and are then symmetrically surrounded by six metal atoms; this type of structure is often observed in carbides and nitrides. Other types of interstitial compounds are known, but in most cases can be understood in terms of the insertion of a small atom into spaces in the metallic lattice which are large enough to accommodate them without too much strain, but not so large that the small atom would be loose in a hole too large for it. The structures are thus determined essentially by the atomic size relationships.

Analogous behaviour is often shown in cases where the atomic size difference is considerable, but not large enough for interstitial compound formation. For instance, the compounds $NaPb_3$, $CaPb_3$, $SrPb_3$, $CaTl_3$, $CaSn_3$ and $CeSn_3$ all crystallize in the structure of fig. 6. In each case the relationship between the sizes of the larger and smaller atoms is similar and the structure appears to be based on geometrical convenience — the structure of fig. 6 is a stable manner in which atoms. the sizes of which differ in a particular way, can be packed together. This clearly suggests that other structures will be found to be characteristic of different size ratios, and this is fully borne out in practice. Thus an approximately constant atomic size ratio is shown in the series of compounds Cu_2Mg, W_2Zr, KBi_2 and Au_2Bi, all of which crystallize in the same type of structure; and it may be noted, in confirmation of the principle that the relative atomic size is the main factor, that the structure of KBi_2, where the bismuth atom is the smaller, is the same as that of Au_2Bi, where the bismuth atom is the larger. The class of body-centred cubic structures quoted above (NaTl, LiIn, LiZn) are also governed primarily by size relationships. Where, in the systems XB and CD. the ratio of the atomic sizes of A and B is closely similar to that of C and D, compounds of the same general type and crystal structure may be expected. Such compounds have narrow ranges of homogeneity because of the difficulty of satisfying the geometrical conditions except at one, particular, simple atomic ratio. For the same reason, ternary cornpounds of a corresponding type are relatively scarce. Some, however, are known.

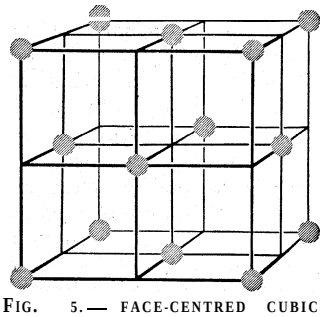

FIG. 5.— FACE-CENTRED CUBIC STRUCTURE

A particularly interesting group of compounds, in which both size and electronic factors are involved. is illustrated by certain compounds formed between magnesium and zinc. copper or nickel. Thus, in $MgZn_2$, $MgCu_2$ and $MgNi_2$ the ratio of atomic diameters lies between 1.13 and 1.1j, and in each case the smaller atoms may be regarded as situated on a close-packed lattice from which each large Mg atom has replaced two small atoms. There is a close similarity between the three lattices, which are built up from similar atomic planes arranged in a different order. As a consequence of the arrangement of planes. $MgCu_2$ has cubic symmetry, while $MgZn_2$ and $MgNi_2$ are hexagonal. the axial ratio of the latter being twice that of the former. Which of these structures is taken up depends on the number of valency electrons per atom. This is seen most clearly by considering the ternary phases which are isomorphous with these binary structures. Thus, the addition of aluminum to $MgCu_2$ increases the electron/atom ratio and leads to the appearance of a compound with the $MgZn_2$ type of structure, while the addition of silver to $MgZn_2$, which decreases the electron/atom ratio! gives a compound with the $MgCu_2$ type of lattice. These compounds form examples of a type in which the occurrence and general structure are decided by the size and number of electrons per atom.

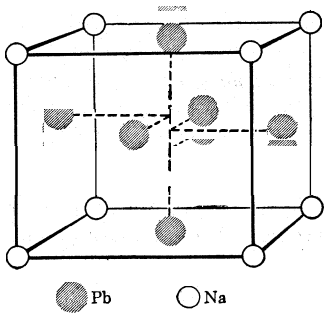

FIG. 6.—$NaPb_3$ STRUCTURE

It is possible, therefore, to interpret the formation and nature of intermetallic compounds in terms of three main factors: atomic size relationships, normal valency of components and the ratio of valency electrons to atoms. Although, in this article, only the main types which occur when one or another of these factors predominates have been considered, it will be realized that there must be cases where two or more of the factors are of equal importance. In such cases: more complex compounds may occur, but a discussion of these is beyond the scope of the present article.

Similarly, cases exist where intermetallic compounds of different characteristics crystallize in structures which are essentially the same, or vary only slightly. Thus cobalt sulfide, CoS, crystallizes in a structure in which the metal atoms may be regarded as occupying, in a regular manner, interstices in a close-packed hexagonal arrangement of nonmetal atoms.

The compound AuSn adopts the same type of structure, but with a much smaller axial ratio; it is considered that direct interactions between the gold atoms may be responsible for the difference.

The existence of intermediate types, which can be considered from different points of view, does, however, emphasize that the problem of intermetallic compounds must be considered as a whole, without too rigid an insistence on subdivision into types. The classification is a matter of convenience rather than a consequence of the existence of completely different types of compound.

INTERMEZZO. An interlude or entr'acte of a light and pleasing character serving as a contrast between the acts of a more serious drama or tragedy, and, in its developed form, continuing as an independent piece in this manner throughout the whole work, two entirely independent works, one serious and one light, being thus presented in alternate instalments. Giovanni Battista Pergolesi's famous La *serva padrona* mas such an intermezzo as originally produced. Nowadays the term is more generally applied to a short piece introduced between the larger movements of a symphony or sonata or to an independent short composition.

INTERNAL-COMBUSTION ENGINES. In an internal-combustion engine a fuel-air mixture is burned in such manner that the hot gaseous products of combustion exert a force on moving parts of the machine, thereby doing useful work and generating power. These engines comprise one group of what are known as heat engines, so named because they derive their power either

directly or indirectly from a thermal-energy-releasing reaction, such as combustion.

In the internal-combustion engine the products of combustion act directly on pistons or turbine rotor blades, whereas the external-combustion engine employs a secondary working fluid that is interposed between the combustion chamber and the power-producing elements. All heat engines other than the internal-conibustion engine are similar in principle to the steam engine and boiler combination in that the fuel with which they operate is burned in a furnace that is external to the engine; a portion of the energy liberated by combustion is transferred through boiler or heat-exchanger walls to a secondary working fluid, such as water; and the liquid is converted into steam under a high pressure that is created by the expansion accompanying vaporization. The steam is then conveyed through pipes to an engine or turbine in which the pressure of the steam acts upon pistons or turbine runners whose motion causes a shaft to rotate and produce power.

The fundamental principle of the steam engine is to produce a high-pressure working medium by utilizing the expansion accompanying the vaporization of a liquid; the internal-combustion engine utilizes the large volume of high-temperature combustion products which, when confined, become a high-pressure gaseous medium.

History. — Attempts to devise engines of various types were made in pre-Christian times. The steam engine. however. became the first successful power plant when James Watt carried the ideas of earlier experimenters to a satisfactory degree of practicability during the 18th century. The internal-combustidn engine followed as an improvement over the steam engine.

Unlike many products of the mechanical age, the internal-combustion engine cannot be attributed to any one inventor. The piston, for example, is thought to have originated about 150 B.C., and mas used by metalworkers in pumps for blowing air. The problem of preventing leakage between the piston and cylinder wall led Watt to employ rope yarn impregnated with mutton tallow as a packing in 1764. Brass sealing rings were fitted to steam-engine pistons in Scotland several years later. thus originating the metal piston rings with which internal-combustion engine pistons have aln-ays been equipped.

The internal-combustion engine of the mid-20th century was the outgrowth of more than 100 years of study and experiment. It was made possible by a gradual accumulation of knowledge of thermodynamic principles. mechanical skill! availability of materials and experience. The development was inspired by an early recognition of the inherent disadvantages of steam power plants, their low thermal efficiency, great weight and bulk and inconvenience of operation, all of which defects are largely traceable to burning the fuel in a furnace separate from the engine. The greater desirability of a self-contained power unit was evident. A remarkable development resulted from the application of engines to automobiles and aeroplanes. (This development is even more remarkable in that the gasoline engine is inherently poorly suited for vehicle propulsion and must have intricate clutch and transmission devices to adapt it to this application. The steam engine can be started under full load, but the internal-combustion must be set in motion by a cranking device before any load can be applied to it, and its performance is greatly affected by the speed at which it runs.)

The events leading to the development of a practical internal-combustion engine probably start with the attempt of the Abbé Jean de Hautefeuille in 1677 to pump water to a higher level by the combustion of gunpowder in direct contact with the water. The vacuum formed by cooling the hot gaseous products of combustion was used to lift the water. Christian Huygens in 1680 and Denis Papin in 1690 experimented unsuccessfully with similar devices. Robert Street obtained a patent in England in 1794 describing an internal-combustion engine employing a piston and a system of levers. In 1801 Lebon proposed in France that the charge be compressed before burning. but he did not build an engine. W. Cecil experimented in England with an engine operated by exploding hydrogen-air mixtures and employing the vacuum acting on a piston as the products of combustion were cooled. Tests of this engine as reported in 1820 provide the first record of operation of a gas engine.

Actual production and sale of the gas engine began in 1823 when Samuel Brown started to build a vacuum-type gas-burning engine. The role of Brown in the development of the internal-combustion engine was similar to that of Newcomen in the steam-engine field. Their engines were heavy and crude but contained many of the essential elements of later more successful engines.

The most competent early study of the thermodynamic aspects of the internal-combustion engine was that of Sadi Carnot in France. He published a pamphlet in 1824 in which he outlined not only the fundamental internal-combustion engine theory. but even that of the diesel engine. Although he did not experiment with actual engines, his *Reflections on the Motive Power of Heat* undoubtedly influenced the thinking of many other experimenters.

One of the first engines to use pressure resulting from combustion rather than vacuum from cooling of the products was built by W. L. Wright in 1833. The first engine in which the charge mas compressed before burning was built by William Barnett in 1838 and he was granted a patent which included this idea. He also built an engine of the two-stroke-cycle type with an external charging pump, an arrangement that was adopted many years later for diesel engines. By a two-stroke cycle is meant that the cycle necessary to operate the engine is completed in one up- and one downstroke of the piston or one turn of the crankshaft, in contrast with the four-stroke cycle that requires two full turns of the crankshaft. All machines have operating cycles consisting of a series of events which, when repeated over and over again, periodically return all of their parts to their exact original condition.

Barnett also devised an ingenious igniting cock that provided a pilot flame for igniting the charge and a relighter to rekindle the pilot light after it was extinguished when the oxygen in the cylinder was consumed in burning the charge. This method of ignition was applied to many engines before electrical ignition was developed. Another method of ignition, the hot plug, was introduced by Alfred Drake in 1843.

Until 1860 most of the contributions made were in the form of ideas. Few engines mere built, and not many of those ever ran; but practical difficulties were gradually overcome and production facilities improved until it was possible to combine the various accomplishments into a practical engine. In 1860 J. J. E. Lenoir, a Frenchman, placed an engine on the market that gave reasonably satisfactory service operating on illuminating gas. There was nothing new or original in the Lenoir engine; in fact it was essentially a converted double-acting steam engine with slide valves to admit gas and air and to discharge exhaust products. It operated on a two-stroke cycle and, although it developed very little power and utilized only about 4% of the energy in the gas, several hundred were sold over a period of years.

In 1861 G. Schmidt proposed that the fresh charge be compressed by pumps to a pressure of three atmospheres before introduction to the engine cylinder. He stated that this would lead to a great expansion of the products of combustion and permit a greater transformation of heat energy. Schmidt was, therefore, one of the early proponents of the theory that compression should precede combustion. although his method of accomplishing the increase in pressure pointed toward the idea of supercharge rather than to the compression-type cycle.

The operating cycle of the modern automobile engine originated with Alphonse Beau de Rochas, who published his theory in Paris in 1862. He first stated the conditions necessary for maximum economy as: (1) maximum cylinder volume with a minimum cooling surface; (2) maximum rapidity of expansion; (3) maximum ratio of expansion; and (4) maximum pressure of the ignited charge. He then described the sequence of operations whereby this maximum economy could be attained as: (1) suction during an entire outstroke of the piston; (2) compression during the following instroke; (3) ignition of the charge at dead centre and expansion during the next outstroke (the power stroke); and (4) forcing out the burned gases during the next instroke.

Although he did no practical experimental work and never built an engine, Beau de Rochas's statement of factors affecting

economy and performance appears as one of the most significant steps in the development of the internal-combustion engine. The four-stroke cycle that he described is the same as that used in modern automobile engines. Because his work mas entirely theoretical. Beau de Rochas has not been given the credit for originating the basic principle of the four-stroke-cycle engine; the name of Nikolaus Otto is commonly associated with that achievement.

The firm of Otto and Langen started production of a free-piston engine in Deutz, Ger.. in 1867. Engines of this type had previously been built by Barsanti and Matteucci, but the Otto and Langen engine was superior in mechanical design and workmanship. It employed a vertical cylinder. open at the top and fitted with a heavy piston, below which the combustion chamber was formed. The gas and air charge mas drawn into the cylinder during the first half of the upstroke. The charge was then ignited electrically and the piston lifted by the explosion. The velocity attained by the piston and the fact that upward motion mas opposed only by friction caused the piston to continue its upward travel after the pressure on its underside had been reduced to a partial vacuum. Atmospheric pressure acting on the top of the piston. the vacuum underneath and the weight of the piston caused it to descend immediately. The motion of the piston was transmitted to the engine shaft and heavy flywheel by a toothed rack extending downward and meshing the teeth of a gear on the shaft. This gear turned freely on the shaft during the upward piston stroke, but a free-wheeling clutch engaged on the downward stroke and applied a turning effort to the shaft. The engine was very noisy, of small power capacity, and the rack-and-pinion mechanism unsound mechanically. but it consumed less than half as much fuel per unit of power produced as did the Lenoir engine and succeeded commercially because of this greater economy.

In 1876 Otto and Langen applied the Beau de Rochas principle in the design of a new engine that became known as the Otto silent engine. This was the first four-stroke-cycle engine employing compression and operating on the basic principle of the modern automobile engine. In spite of its great weight and low economy by modern standards, nearly 50,000 engines with a capacity of about 200,000 h.p. were reportedly sold in 17 years. Its immediate success led to the rapid development of a wide variety of engines of the same basic type. Manufacture of the Otto engine in the United States began in 1878, following the granting of a U.S. patent to Otto in 1877.

FIG. 1 — THE STROKES OF THE FOUR-STROKE CYCLE

The four-stroke-cycle principle. as introduced by Otto and followed by a majority of the internal-combustion engines built since, is illustrated in fig. 1. The piston first descends on the intake stroke, during which the inlet valve is held open by the valve mechanism. The valves shown in the figure are of the commonly used poppet or mushroom type. The fresh charge is inducted into the cylinder by the partial vacuum created in the cylinder by the descent of the piston. The piston then ascends on the compression stroke with both valves closed and forces the charge into the smaller space of the combustion chamber where it is ignited by an electric spark as the end of the stroke is approached. The power stroke follows with both valves still closed and gas pressure acting on the piston crown because of the expansion of the burned charge. The exhaust stroke then completes the cycle with the ascending piston forcing the spent products of combustion past the exhaust valve that is now held open by the valve train. The cycle then starts to repeat itself with the closure of the exhaust valve, opening of the inlet valve and descent of the piston. The cycle thus requires four strokes of the piston — intake, compression, power and exhaust — and two revolutions of the crankshaft for its completion.

The disadvantage of the four-stroke cycle is that only half as many power strokes are completed as in the two-stroke cycle and only half as much power would be expected from an engine of a given size at a given operating speed. The four-stroke cycle, however, provides more positive scavenging and charging of the cylinders with less loss of fresh charge to the exhaust.

Although the two-stroke cycle was employed by all of the early noncompression engine builders, its application to the compression-type engine by a modification of the Beau de Rochas theory did not come until 1878, when Sir Dugald Clerk of Scotland produced his engine. The Clerk engine employed a second cylinder and piston connected to the power cylinder and crankshaft of the engine. This cylinder acted as a pump to precompress the air charge sufficiently to force it into the power cylinder and to drive the products of combustion of the previous charge from the cylinder through exhaust ports in the cylinder wall, so located that they were uncovered by the descending piston as it approached the end of the power stroke. The crank for the compressor piston led the power crank by 90° and began to build up air pressure at about the same time that the exhaust ports were uncovered and exhaust gases allowed to escape from the cylinder. Air transfer from the compressor cylinder through an automatic. spring-closed inlet valve in the power-cylinder head started immediately after the exhaust flow started. and the replacement of the spent products of combustion by the next fresh air charge was completed when the compressor piston ended its delivery stroke shortly after the exhaust ports were covered by the piston rising on its compression stroke in the power cylinder. Compression was followed by ignition and the expansion or power stroke. The compression and power strokes of the four-stroke cycle were thus unchanged, but a transfer process at the end of the power stroke and the beginning of the compression stroke replaced the inlet and exhaust or pumping strokes of the Beau de Rochas cycle. Every outstroke of the power piston was a working stroke in this engine and there was a power impulse in every turn of the crankshaft. If the scavenging and recharging had not been less effective than the pumping strokes of the four-stroke cycle, the engine would have developed twice the power of a four-stroke engine of similar size and speed.

The two-stroke principle was further simplified by Joseph Day, who produced an engine in 1891 employing the underside of the power piston and an enclosed crankcase as an air compressor, replacing the separate pumping cylinder for supplying charge to the engine. This type is illustrated in fig. 2. The crankcase is completely enclosed except for a passage leading to transfer or inlet ports in the cylinder wall and an automatic inlet valve permitting inward flow from the carburettor but preventing return flow from the crankcase.

During the compression stroke the ascending piston creates a partial vacuum in the crankcase which enables outside atmospheric pressure to force a fresh charge of fuel and air in through the carburettor. The charge trapped in the crankcase by the closure of the automatic inlet valve is compressed slightly by the downward movement of the piston on its power stroke. As the piston approaches the end of the stroke, the exhaust ports are first uncovered, permitting the spent products of combustion to start to leave the cylinder. Later the inlet ports communicating with the crankcase are uncovered, thus admitting the compressed fresh charge into the cylinder. A deflector on the piston crown directs the entering charge upward to minimize the possibility of its escaping from the cylinder by mingling with the exhaust gases and to cause it to sweep these gases toward the exhaust ports on the opposite side of the cylinder. The incoming charge thus scavenges the cylinder by pushing the spent products from the previous cycle ahead of it as it flows upward from the crankcase. The rising piston recovers the cylinder-wall ports and then compresses the charge into the combustion chamber, where it is ignited by the spark plug in the cylinder head. The piston moves downward under the force of the expanding products of combustion and a power

stroke is executed. The two strokes of the working cycle are compression (which is accompanied by induction of the next fresh charge into the crankcase) and the power stroke, during which the next charge is precompressed in the crankcase. The transfer of fresh charge from the crankcase to the cylinder is divided equally between the last portion of the power stroke and the initial part of the compression stroke. This modification of the Clerk engine became very popular and for many years mas the simplest and least expensive type of engine available. Later the blower-scavenged two-stroke engine superseded the crankcase-compression type in practically all fields of application except outboard marine engines and other very small portable types that still use crankcase compression for simplicity.

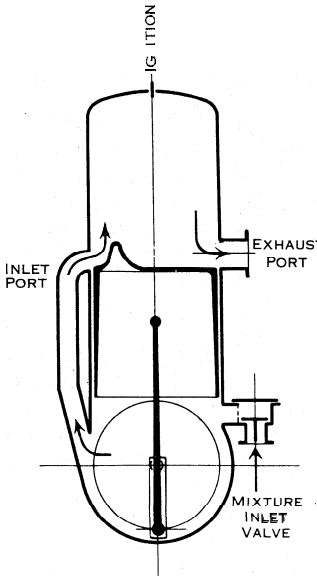

FIG. 2.— TWO-STROKE-CYCLE INTERNAL-COMBUSTION ENGINE WITH CRANKCASE COMPRESSION

Fig. 3 illustrates diagrammatically the modern two-stroke-cycle engine of the uniflow type, wherein the fresh charge is forced into the cylinder through circumferential ports by a positive-displacement rotary blower of the Roots type. The exhaust gases leave the cylinder through poppet valves in the cylinder head. thus eliminating the return flow of the previously described two-port type and reducing the loss of fresh charge by short circuiting to the exhaust outlet. The cycle of this engine differs from that of the simpler type only in the method of placing the fresh charge under pressure to cause its flow into the cylinder. All modern two-stroke diesel engines employ blowers of some type, but with a variety of port and valve combinations.

Carburettor engines operating on the two-stroke cycle lack the fuel economy of the four-stroke engines because some of the fuel escapes with the exhaust gases and does not remain in the cylinder to be used. This loss can be avoided in two-stroke spark-ignition engines only by equipping them with fuel-injection systems instead of carburettors and injecting the fuel directly into the cylinders after scavenging is completed. Such an arrangement is attractive as a means of attaining high power output from a relatively small engine. Development of the turbocharger for this application held promise of further improvement.

OF BLOWER-SCAVENGED TWO-STROKE-CYCLE ENGINE WITH UNIFLOW SCAVENGING

Ignition of the charge by the high temperature attained by very high compression, hinted at by Carnot in 1823, became a practical reality in 1897 after five years of effort by Rudolf Diesel and his associates. An original attempt to use pulverized coal as fuel was abandoned and the diesel engine, as finally developed, burned nonvolatile liquid fuels such as kerosene and heavier paraffin fuels. The diesel engine differs from spark-ignition engines in that air alone is inducted into the cylinders, compressed to such an extent that a temperature exceeding the ignition requirement of the fuel is attained. and the fuel is injected into the combustion chamber where it self-ignites and burns. The carburettor and ignition system are eliminated, and improved economy results from the use of lower-grade fuels at higher compression ratios than are attainable with spark ignition.

The **Gas** Turbine. — Continuous rotation is concededly superior to reciprocating motion in mechanical devices. and the imperfections of the reciprocating-piston-type engine are largely traceable to the noncontinuous motion of many of its parts and the cyclic interruption of combustion. The fundamental principle of the gas turbine was known before that of any other type of heat engine, historians having recorded that a toy gas turbine was built by Heron of Alexandria, Egy., in 130 B.C. Nevertheless, practical development of the gas turbine did not take place until the 20th century. John Barber had been granted a patent in 1791 on a gas turbine that was essentially similar to modern types: F. Stolze designed a unit in 1872 that comprised a multistage axial compressor and reaction turbine, devices used in modern gas-turbine plants.

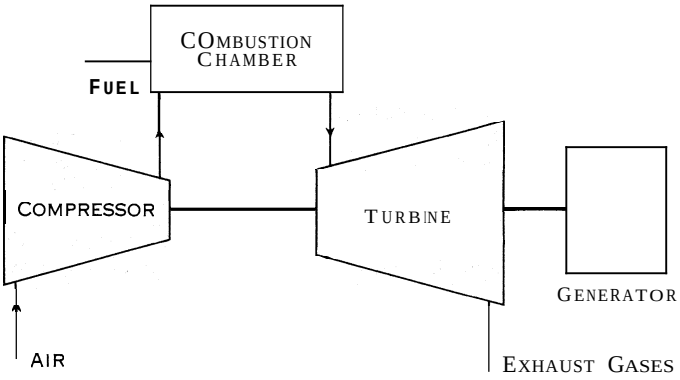

FIG. 4.— DIAGRAM OF SIMPLE GAS-TURBINE POWER PLANT

Various patents were granted during the late 19th and early 20th centuries, but no record exists of a gas turbine operating until 1902 when Sanford A. Moss converted a De Laval steam turbine during his graduate studies at Cornell university, Ithaca, N.Y. Although his turbine actually ran, it did not develop enough power to drive the air compressor which supplied the air for combustion. The large power requirement of the air compressor was to remain a problem in the development of the gas turbine.

The gas turbine is a simple power plant. An air compressor supplies air at about three to six times atmospheric pressure to a combustion chamber in which the fuel is sprayed into the air and continuous combustion maintained. The resulting large volume of high-temperature gaseous products then expands through the turbine unit to atmospheric pressure. The compressor and turbine rotors may be on the same shaft. The excess of power developed in the turbine unit over that required to turn the compressor rotor (somewhat less than half of the turbine output) is delivered to a generator. propeller or other load. The gas-turbine power plant is shown diagrammatically in fig. 4.

Continuous efforts have been made since the start of the 20th century to eliminate certain practical defects in the gas turbine. The most important barrier was the unavailability of materials to withstand the high temperatures that result if the cycle is carried out in the optimum manner dictated by theoretical considerations. Fuel and air mixtures in proportions approaching the chemical requirements of the fuel, such as are used in reciprocating-piston engines, result in combustion temperatures on the order of 4,000° F. These temperatures can be tolerated by the metal parts of the piston engine because they are maintained for only a tiny fraction of a second and the remainder of the cycle is at relatively low temperatures. Combustion in the gas turbine is continuous and the combustor walls, connecting passages and turbine blades are continuously exposed to the peak temperature of the cycle. Common practice is to supply large excesses of air so that the temperature attained by the diluted products of combustion does not exceed about 1,500° F. Efficiency is reduced in two ways by this practice: the cyclic efficiency, which is dependent upon the peak temperature attained, is lower; and the power consumed by the compressor in supplying the larger than theoretically needed amount of air is increased.

Improved compressor design increased the efficiency at which the air is supplied to the combustor, and improved metallurgy greatly increased the allowable temperature at which turbine blades and other parts may operate. Further improvements in charging efficiency may be made by multistaging the compressor and by using intercoolers between stages. 'Improvement in energy utilization may also be effected by placing a heat exchanger in the turbine exhaust line that will transfer heat from the exhaust gases to the air as it enters the combustor. This process, a feeding back of leftover energy through the system, is called regeneration. By the second half of the 20th century, it appeared to offer the greatest promise of improvement in gas-turbine economy. A further practical problem arises from the fact that, for high capacity and efficiency, the rotative speed of the turbine runner should be extremely high. on the order of 25,000 to 30.000 r.p.m. The cost and noise of gears to harness the turbine to its load at such speeds necessitates a compromise with performance by reducing runner speed. Fuel economy attained with the gas turbine is poor by comparison with that of the piston engine, but some of the more restrictive fuel specifications are eliminated. The application of the gas turbine to jet-propelled aeroplanes is a favourable one because the considerable energy in the large mass of high-temperature exhaust gases forms the propelling jet and is not wasted as it is in the simple gas turbine.

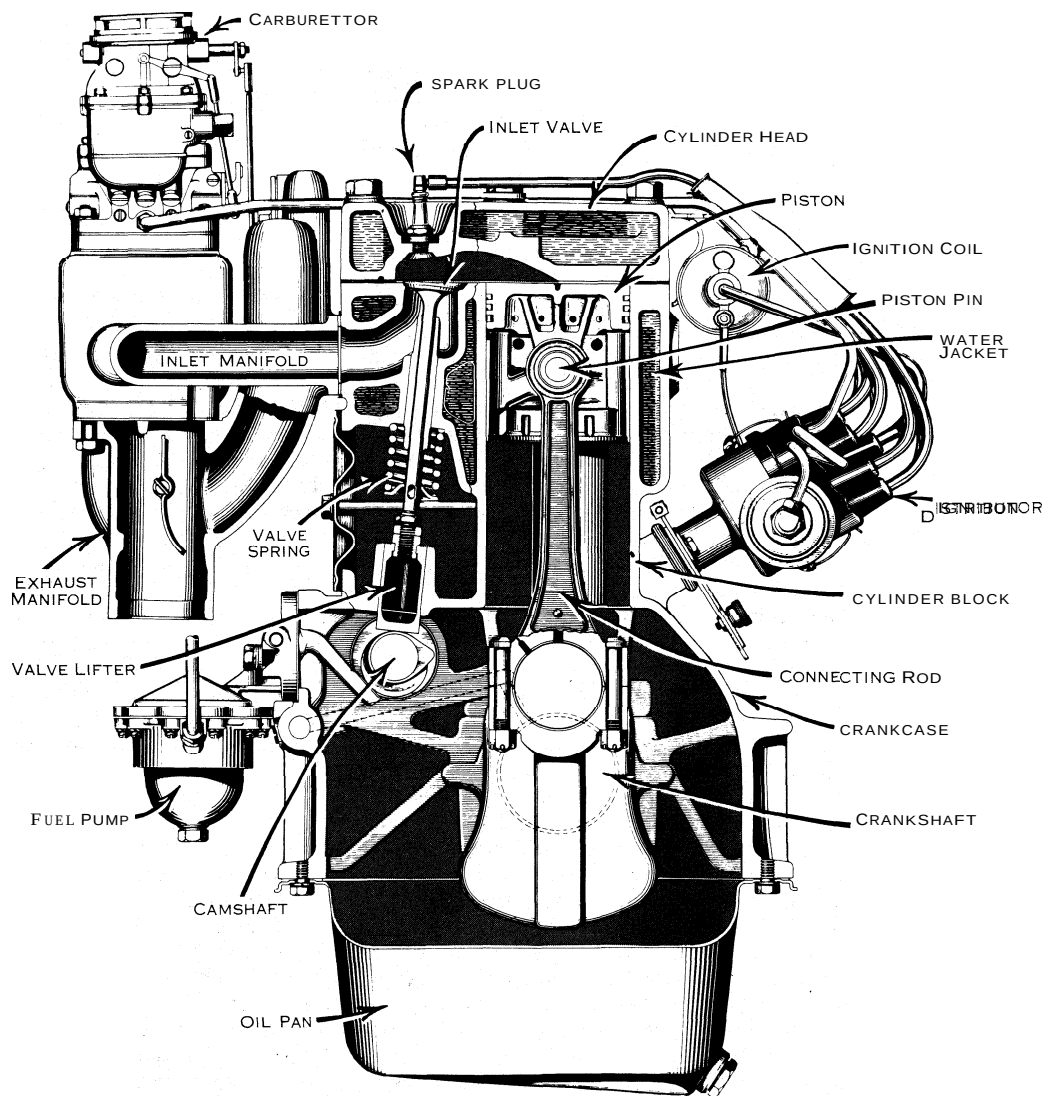
Engine Types.—A wide variety of internal-combustion engines resulted from the requirements of the extensive range of possible applications. Although these various engines differ radically in size. weight per unit of power developed, arrangement of components and details of operation! they are basically similar. The only exception is the gas turbine, which is fundamentally diiferent from the reciprocating-piston engine. The only clearly defined separation into groups having similar design and operating characteristics is consequently the classification as reciprocating-piston types and gas turbines. Classification of reciprocating engines into sharply defined groups is difficult because of overlapping of characteristics.

The greatest differences between engines are those that adapt them to various applications; *i.e.*, automotive: aviation, marine and stationary. with a wide range of special types included within each. Of these. the automotive is most important because of the number of engines in use and the total power developed. This group includes all engines used to propel land vehicles ranging from passenger automobiles to railway locomotives, with intermediate truck, tractor and bus types.

Perhaps the most striking of the differences that arise between two types of engines because of their intended applications are those that distinguish the locomotive diesel from the aeroplane engine. The most widely used locomotive diesel engine is a 16-cylinder vee-type engine weighing approximately 31,000 lb. and having a rating of 1,500 h.p. One of the best of the World War II aeroplane engines was also a 1,500-h.p. unit, a 12-cylinder, vee-type engine weighing about 1,200 lb. The locomotive engine is two and one-half times as long as the aeroplane engine and weighs more than 25 times as much—a contrast that seems to indicate inefficiency in the locomotive engine. Such, honever, is not the case. Both engines are of excellent design. The locomotive engine is a heavy-duty type designed for millions of miles of operation, much of the time at full throttle, and its crankshaft turns at less than one-third the speed of the aeroplane engine shaft, whereas the military aviation engine is designed for high specific output with a useful life of perhaps 700 hours. Both are used for transportation, but in widely differing vehicles.

The stationary power plant engine is usually even heavier than the locomotive type of the same cylinder dimensions and develops less power per unit of size and weight because of its durability and very low crankshaft speed. Intermediate between these two extreme types, aviation and stationary. are motor-vehicle engines of a wide variety, some of which are designed to operate at very high crankshaft speeds in order to reduce their size, cost and weight. It is evident that the important apparent differences between engines are largely traceable to the use for which they are intended.

Differences in operation of engines also permit grouping together certain types that have functional similarities. The most important differences result from: (1) whether the operating cycle is



REPRINTED WITH PERMISSION FROM SOLBERG, CROMER AND SPALDING, "ELEMENTARY HEAT POWER," 1952, JOHN WILEY & SONS, INC.

FIG. 5.—CROSS SECTION OF L-HEAD AUTOMOBILE ENGINE

completed in two or four strokes of the piston; (2) whether the charge is ignited by an electric spark or by compression temperature; and (3) whether the fuel burned is gas. gasoline or fuel oil. Such differences are also superimposed on those that adapt the engines to their intended use. thereby multiplying the specification items necessary to define each type. For example. a stationary power plant engine may be a diesel or compression-ignition type, operating on the two-stroke cycle, and burning a heavy fuel oil. or it might be a spark-ignition engine. burning natural gas on the four-stroke cycle. When viewed from even a short distance, these two engines appear to be very much alike because of the predominant effect of both being stationary power plant engines, but close examination reveals important mechanical and functional differences.

Engine Structure.— The following description of general engine construction is intended to indicate the essential components of an engine and to introduce and clarify the nomenclature of the various parts. The four-stroke-cycle automobile engine is used as the basic type. Fig. 5 shows a cross section of a typical cylinders-in-line automobile engine with the important parts indicated

The main structural member of all automotive-type engines is the cylinder block, which usually extends upward from the centre line of the bearings that support the crankshaft to the junction with the cylinder heads The block serves as the structural framework of the engine and carries the mounting pads by which the engine is supported in the chassis. Large stationary power plant engines and marine engines are built up from a foundation or bedplate and have upper and lower crankcases that are separate from the cylinder assemblies. The cylinder block of the automobile engine is an alloy-iron casting with appropriate machined surfaces and threaded holes for attaching the cylinder head, main bearings, oil pan and other units. The crankcase is formed by the portion of the cylinder block below the cylinder bores and the stamped metal oil pan that forms the lower enclosure of the engine and also serves as the lubricating oil reservoir or sump.

The cylinders are openings of circular cross section that extend through the upper portion of the block with interior walls bored and honed to form smooth, accurate bearing surfaces. The cylinders of heavy-duty engines are usually fitted with removable cylinder liners made of metals more wear-resistant than that used in the block casting Two arrangements of cylinders are in common automotive use—the vertical or in-line type and the vee type. The in-line engine has a single row of cylinders extending vertically upward from the crankcase and aligned with the crankshaft main bearings. The vee type has two rows of cylinders, usually forming an angle of 60° or 90° between the two banks. V-8 engines are usually of the 90° type. Fig. 6 shows a cross-sectional view of an automobile engine of the high-speed valve-in-head V-8 type. Large stationary-, marine- and locomotive-type engines with 12 cylinders commonly have 60° vees because of their firing interval, whereas 16-cyiinder engines similarly have their cylinder banks at 45°. The conventional angle between the planes of the cylinder banks is 360° divided by half the total number of cylinders.

A passage is bored lengthwise of the engine for the camshaft which operates the valves. and a gear or chain compartment for the camshaft drive from the crankshaft is formed between the front or rear extremity of the block and a cover plate. A so-called bell housing is formed at the rear of the cylinder block to enclose the flywheel and provide for attachment of a transmission housing. Water jackets are formed around the cylinders with suitable cored connecting passages for circulation of the coolant.

The design of the cylinder block is affected by the location of the valves of the four-stroke-cycle engine and by the provision of cylinder ports in the two-stroke-cycle type, The overhead-valve engine that largely replaced the L-head type has its valves entirely in the cylinder head. and no portion of the valve system is carried in the cylinder block except the camshaft and the cam followers or valve lifters that bear against the cams. The cylinder block of the L-head engine is extended to one side of the cylinder bores, as shown in fig. j, with the valve seats and passages for inlet and exhaust, together with the valve guides, formed in this extension of the block. The cylinder head then becomes merely a water-jacketed cover, providing threaded locations for the spark plugs and with its underside so profiled that a combustion chamber of the desired size and shape is formed above each cylinder bore. The depth of the combustion chamber in the L-head engine is increased above the valves and the space is thinned out above the piston at the side opposite the valves to permit control of combustion of the last portion of the charge to burn. The shape of the

FIG. 6.— TRANSVERSE SECTION OF A V-8 ENGINE

space forming the combustion chamber when the piston is at its closest approach to the cylinder head and the volume contained therein in relation to the piston displacement volume of the cylinder are extremely important in their effects upon the performance of the engine (Theoretical considerations influencing combustion-chamber design are discussed later.) The cylinder head of the valve-in-head engine is narrower and deeper. and carries the valve seats, valve guides and valve ports.

The size of the combustion chamber relative to the volume displaced by the piston establishes the compression ratio of the engine. The piston displacement of a cylinder is the volume swept by the piston during one stroke and is equal to the cross-sectional area of the cylinder multiplied by the length of the piston stroke. The larger volume above the piston at the lowest point in its stroke divided by the combustion-chamber volume when the piston is at its upper extremity of travel is called the compression ratio of the engine. The larger volume is the sum of the piston-displacement volume and the combustion-chamber volume. The compression ratio may thus be expressed as the ratio of the sum of the piston-displacement volume and the combustion-chamber volume to the combustion-chamber volume. This ratio establishes the fraction of the original volume of the charge as inducted that the charge occupies at the end of the compression stroke and also the resulting compression pressure. Compression ratio will be shown later to be the most important factor affecting the theoretical efficiency of the engine cycle. Because increased compression ratio has long been recognized as the most basic way to improve efficiency, the development of the automobile engine has followed a steady trend toward higher compression ratios.

The pistons are cup-shaped cylindrical castings of iron or aluminum alloy. The upper, closed end, called the crown, forms the lower surface of the combustion chamber and receives the force

applied by the combustion gases. The outer surface is machined to fit the cylinder bore closely and is grooved to receive several piston rings that are provided to seal the gap between the piston and the cylinder wall. The rings are larger in diameter than the cylinders and gaps are provided so that they can be compressed into the cylinder bore. The rings in the upper piston grooves are plain compression rings that prevent the combustion gases from blowing past the piston. The lower rings are vented oil rings that distribute and limit the amount of lubricant on the cylinder wall. Piston pin bosses are cast in opposite sides of the pistons and hardened steel pins fitted into these bosses pass through the upper ends of the connecting rods. The piston pins are frequently clamped in the eyes of the connecting rods although floating pins (prevented by spring clips from contacting the cylinder malls) are used by some manufacturers.

A forged steel connecting rod of I section connects the piston to the throw of the crankshaft and converts the reciprocating motion of the piston to the rotating motion of the crank. The loner. larger end of the rod is bored to take a precision bearing insert that is lined with babbitt or other bearing metal and closely fitted to the crankpin. Vee-type engines usually have opposite cylinders staggered sufficiently to permit the two conriecting rods that operate on each crank throw to be side by side. Some larger engines employ fork-and-blade rods with the rods in the same plane and cylinders exactly opposite each other

The crankshaft functions with the connecting rods in converting the up-and-down motion of the pistons to a rotary motion. Each connecting rod in an in-line engine or each pair of rods in a vee-type engine is attached to an offset portion of the crankshaft called a throm. Each throw consists of a crankpin with a bearing surface. on which the connecting rod bearing insert is fitted. and tno radial cheeks that connect it to the main journals that turn in the main bearings that are supported by the cylinder block. Sufficient throns are provided to serve all the cylinders, and the angles between them equal the angular firing intervals between the cylinders The throws of a six-cylinder. four-stroke-cycle crankshaft are thus spaced 120° apart; those of an eight-cylinder engine are go° apart because half of the cylinders fire in each turn of the crankshaft. The location of each throw in the various radial directions along the shaft depends upon the firing order of the cylinders. Firing sequence is chosen to distribute the power impulses along the length of the engine to minimize vibration. Consideration is also given to the fluid flow pattern in the manifolds. The standard firing order for a six-cylinder engine is 1–5–3–6–2–4, which illustrates the practice of alternating successive impulses between the front and rear halves of the engine whenever possible. Balancing is further improved by adding counterweights to the crankshaft to offset the eccentric masses of metal in the crank throws and thus neutralize centrifugal forces.

The crankshaft design also establishes the piston stroke because the radial offset of each throw is equal to half the stroke imparted to the piston. The ratio of the piston stroke to the cylinder bore diameter is an important design consideration. No logical basis for the establishment of this ratio existed in the early years of engine development, and a range from unity to one and one-half was used by the different manufacturers. As engine speeds increased, however, and it became apparent that friction horsepower increased with piston speed rather than nith crankshaft rotating speed a trend toward short-stroke engines started. Strokes were shortened to as much as 20% less than the bores.

Other advantages are gained by short strokes, such as providing more cylinder-head surface for valves in proportion to piston displacement and decreasing the height of the engine. Engines with lon stroke-bore ratios have showed slightly greater horsepower, principally because of reduced friction losses.

Cylinder Charging — All internal-combustion engines function by converting heat released by burning a fuel into mechanical energy or power. Certain processes must be carried out to make possible this conversion of chemical energy into power. The first is the introduction of the combustible charge to the cylinder. One hundred or more cubic feet of air must be pumped into an engine per hour for each horsepower developed in order to supply the oxygen needed for combustion. The engine must first function as an air pump as the first step in its operation. Cylinder charging includes ridding the cylinder of the spent products of combustion of the previous cycle to make room for the next charge. This is done by direct pumping on the exhaust stroke of the four-stroke-cycle engine and by pushing out the exhaust gases ahead of the fresh-air charge pumped in by the scavenging pump or blower of the two-stroke-cycle engine.

The pumping mechanism of the four-stroke engine consists of an exhaust valve that is held open during the upward stroke of the piston that follows the power stroke and an inlet valve that is held open during the next downstroke. The intake and exhaust valves remain open for longer periods than the corresponding piston strokes in order to provide time for opening and closing the valves. and to utilize the inertia effects of the high velocity at which the gases flow The opening and closing points of both valves are therefore displaced somewhat from the dead centre points at which they theoretically would occur.

The exhaust valve is timed to open at approximately 50° before the piston reaches its bottom dead centre on the power stroke. This occurs well before the power stroke is completed in order to provide a blow-doan period to release the gases from the cylinder and reduce the pressure approximately to exhaust-manifold pressure by the end of the power stroke. Some useful work near the end of the power stroke is lost by this early valve opening. but a greater amount of negative work during the exhaust stroke is avoided by not requiring the piston to ascend against back pressure.

The exhaust valve remains open about 15° after top dead centre. thus allowing the kinetic energy of the outflowing mass of exhaust gases to reduce the pressure within the combustion chamber below atmospheric pressure and thereby decrease the weight of exhaust gases remaining in the cylinder to dilute the next charge The partial vacuum created by the outrushing exhaust gases is also useful in permitting the inlet valve to be opened early and the flow of fresh charge into the cylinder started sooner.

The inlet valve opens about 15° before top dead centre to take advantage of the pulling effect at the end of the exhaust period. About 30° of valve overlap results from the early inlet opening and delayed exhaust closure. The overlap period helps to scavenge the combustion chamber and results in a larger fresh charge entering the cylinder.

The inlet valve is not closed until 50° or more after bottom dead centre to utilize the kinetic energy of the rapidly moving charge. The optimum inlet closure point depends upon the speed at which the engine is to operate. low-speed engines having much earlier closure than high-speed types. The greater the departure of ali valve events from the dead centre points, the higher the speed at which the power of the engine will reach its peak. So-called racing cams are designed with all opening events earlier than normal and all closing events, especially inlet closure, later than in conventional timing. This causes the engine to develop its maximum power at a higher speed and therefore at an increased amount. but low-speed performance is impaired.

The extent to which the cylinder is filled with fresh air depends upon the speed of the engine, the size of the flon passages. valve size. lift and timing, as well as other fluid dynamics factors. The effectiveness of the charging process of the four-stroke engine is expressed as volumetric efficiency, which is defined as the weight of fresh air inducted per cycle in per cent of the weight required to fill a volume equal to the piston displacement at outside temperature and pressure. The volumetric efficiency of an automotive engine usually rises to a peak of slightly more than 80% at about half the rated speed of the engine and then decreases considerably at higher speed. This change in air charge per cycle with engine speed is reflected in proportionate changes in the torque or turning effort applied to the crankshaft and causes the power that the engine is capable of delivering at iull throttle to reach a maximum as engine speed increases At speeds above this peaking speed the air charge inducted per cycle falls off so rapidly that less power is developed than at lower speeds. The inability of the engine to induct a full charge of fresh air for each cycle at high engine speeds is thus the factor that limits the power output of the engine.

Supercharging is resorted to because of the power limitation caused by inability of the engine to maintain its charging effectiveness at high crankshaft speeds and also at high altitudes where the lower density of the atmosphere decreases the weight of air inducted Supercharged engines differ from naturally aspirated engines in that a pump or blower is provided to raise the pressure of the air supplied to the cylinders, thus increasing the weight of charge that flows into the cylinder By this means the approximately 50% loss in power suffered by unsupercharged aeroplane engines at 20 000 ft. altitude can be largely restored It is also possible to more than double the power of an engine of given size and weight by supercharging.

Supercharging is more applicable to compression-ignition engines than to spark-ignition types because of its effect on combustion. Increased charge density and temperature, resulting from supercharge, increases the tendency for combustion knock or detonation in the spark-ignition engine and necessitates an undesirable decrease in compression ratio or the use of a fuel of higher antiknock quality. The diesel engine, however, benefits from supercharge because of improved ignition of the charge. Four-stroke-cycle diesel engines therefore are commonly supercharged as a means of increasing their specific output and improving their competitive position with the two-stroke diesel and spark-ignition engines on the horsepoaer per unit of weight basis.

The supercharging blower may be geared to the crankshaft, in which case the power consumed in driving it is added to the friction loss of the engine. The turbocharger employs a gas turbine operated by the exhaust gases from the engine to drive a centrifugal blower. thus using principally the kinetic energy of the exhaust gases that is otherwise wasted The turbocharged engine not only gains increased power capacity, but also operates at improved fuel economy. Turbochargers are used extensively to supercharge the larger four-stroke-cycle engines and have found some application on two-stroke-cycle diesel engines. Aeroplane engines are usually supercharged both by geared blowers and by turbochargers in order to provide the large pumping capacity needed to overcome the effects of high altitude.

Performance. — The performance of an engine is expressed in terms of power. speed and fuel economy relationships. The three quantities are evaluated from data taken in a dynamometer test A dynamometer is a laboratory device that applies a controllable load in the form of resistance to the turning of the engine crankshaft, and also provides a means of measuring the turning effort or torque that is exerted at the shaft coupling The resistance to turning imposed by the dynamometer may be so adjusted by the operator that the desired engine speed is established at any throttle position. It is thus possible to run the engine at the load corresponding to full throttle, or any fraction thereof, at various speeds throughout its operating range, to maintain these operating conditions continuously and to measure the precise loads and speeds at which each run is made. Additional test equipment permits measurement of the exact quantity of fuel consumed as well as the duration of the runs Certain types of dynamometers also permit the engine to be motored and the power required to drive it determined. From the data taken the power-speed-economy relationships can be calculated, performance plotted and much information regarding the suitability of the engine for its purpose derived. More thorough tests are sometimes conducted to determine the durability of the engine, quietness and smoothness of operation, accelerating ability, cooling requirements. fuel limitations, air consumption, etc.

The power produced by an engine is expressed in horsepouer, a unit established by James Watt as a means of rating his steam engines. He tested several horses to determine the rate at nhich they could work and decided that 33.000 ft. lb. per minute was a liberal unit, representing appreciably more work than an ordinary horse could do for a short time. A foot-pound of work is equivalent to lifting a mass of one pound (thereby producing a force of one pound) a distance of one foot. According to Watt's unit, a horsepower represents the work done in one minute by some force (expressed in pounds) acting through some distance (expressed in feet) such that the product is 33,000.

When the power developed by an engine is measured by means of a dynamometer or similar braking device, it is called brake horsepower or shaft horsepower. This is the power actually delivered by the engine and is therefore the capacity of the engine that the user can obtain. Engineers are also interested in the power developed in the combustion chamber of the engine, which is greater than the delivered power because of friction and other mechanical losses. This power loss, called the friction horsepower, can be evaluated by motoring the engine with a suitable dynamometer when no fuel is being burned. The power developed in the cylinders can then be found by adding the friction horsepower to the brake horsepower. This quantity is the indicated horsepower of the engine, so called from an instrument known as the engine indicator, which is used to measure the pressure acting on the pistons and thus calculate the power developed in the cylinders. The engine indicator draws a diagram of the cycle as carried out by the gases in the cylinder. It traces curves of pressures acting on the piston versus volume changes in the cylinder caused by piston motion during the strokes that correspond to one cycle.

Fig. 7 shows a pressure-volume diagram for an internal-combustion engine. From this diagram it is possible to evaluate the mean height and thus the average pressure which, if it acted constantly on the piston for one stroke. would produce a motivating force equal to that produced by the actual varying pressure during an entire cycle. It is thus possible to find the net force in pounds that would act on the piston during one power stroke if this average pressure is expressed in pounds per square inch and multiplied by the area of the piston in square inches. This pressure is called the mean effective pressure of the cylinder and is defined as the constant pressure which, if acting on the piston for one stroke, would do the same amount of work as was done by the actual varying pressure in the entire cycle. This quantity can be used to calculate the power developed in the cylinder by substituting in the equation

$$\text{indicated horsepower} = \frac{PLAN}{33{,}000}$$

where P is the mean effective pressure in pounds per square inch, L is the length of the stroke in feet, A is the piston area in square inches and N is the number of cycles completed per minute. The product PA is the force in pounds acting on the piston and, when multiplied by L, becomes the work done per cycle in foot-pounds. Multiplication by N then yields the work in foot-pounds per minute and division by 33,000 gives the horsepower.

Friction horsepower resulting from the mechanical imperfections of the engine is caused for the most part by friction between cylinder walls and pistons and by the work done in pumping the charge into and out of the cylinders. In addition to these large mechanical losses, smaller amounts of power are spent in operating the valves, driving the cooling fan, generator, ignition system and the oil and coolant pumps.

FIG. 7.— ENGINE INDICATOR DIAGRAM FOR FOUR-STROKE-CYCLE INTERNAL-COMBUSTION ENGINE (SEE TEXT FOR FURTHER EXPLANATION)

Mechanical efficiency is defined as the brake horsepower in per cent of the indicated horsepower. Friction horsepower increases rapidly with increased piston speed, but is fairly independent of load. The mechanical efficiency of an engine, therefore, increases with increased load at constant speed but decreases with increased speed at constant throttle and is usually between 70% and 90% within the normal operating speed range.

A hypothetical quantity called brake mean effective pressure (b.m.e.p.) is obtained by multiplying the indicated mean effective pressure of an engine by its mechanical efficiency. This is a commonly used index quantity expressing the ability of the engine, per unit of cylinder bore, to develop useful pressure in the cylinders and thereby deliver power. If the power delivered by an engine is increased by any change other than an increase in speed or cylinder dimensions, its b.m.e.p. increases proportionately. The

b.m.e.p., therefore. reflects any improvement in power output and permits a comparison of effectiveness of engines differing in size that cannot be made from their poner outputs alone.

Horsepower is calculated from dynamometer data by measuring the quantity known as torque that is applied to the dynamometer in restraining the rotation of the crankshaft of the engine. Torque is defined as rotating effort or the tendency to turn something about a centre and, quantitatively, is equal to the product of a force in pounds and the perpendicular distance in feet from the centre of rotation to the line of action of the force. Torque is expressed in units of pound-feet, and careful distinction must be made between this unit and the foot-pound used in measuring work. Work may or may not be done by the application of torque. If the torque applied is insufficient to overcome the resistance to turning, then no work is done, but, if the torque causes rotation, work is done per turn equal in amount to the product of the force acting and the circumference of the circle to which the force is tangent.

Dynamometer data include the length of the dynamometer arm, which is the torque arm or radius, R, in feet, of the torque circle, the reaction of the scales, W, in pounds, which is the force actmg, and the number of turns made by the crankshaft of the engine per minute. n. By Watt's definition. the brake horsepower developed may be calculated by substituting the quantities defined above in

$$\text{brake horsepower} = \frac{2\pi RWn}{33{,}000}$$

This equation may be simplified by dividing the denominator by 2π and substituting torque, t, for RW, which results in the equation

$$\text{brake horsepower} = \frac{tn}{5{,}252}$$

The brake mean effective pressure of an engine may be calculated from the dimensions of the engine and the brake horsepower as determined from dynamometer data. The equation for indicated horsepower in terms of mean effective pressure. piston area, stroke and cycles completed per minute may be converted to brake horsepower by substituting b.m.e.p. for indicated mean effective pressure. This substitution is possible because b.m.e.p. bears the same relationship to m.e.p. as brake horsepower does to indicated horsepower. If b.m.e.p. is expressed by P_b, the equation becomes

$$\text{brake horsepower} = \frac{P_b LAN}{33{,}000}$$

Transposing to get an expression for b.m.e.p.

$$\text{brake mean effective pressure} = \frac{33{,}000 \text{ b.h.p.}}{LAN}$$

The power determined by a test of an automobile engine is affected by such test conditions as atmospheric pressure, temperature and humidity; exhaust back pressure; and the number of accessories, such as the fan, generator, etc., that are attached to the engine. Automobile manufacturers in the United States adopted a standard code of rating tests for establishing the advertised horsepower of their engines. The conditions specified by this code are favourable to the engine and yield higher horsepower ratings than would be developed by the engines in normal operation. This practice establishes another, slightly smaller horsepower unit for engine rating purposes. In 1906 the Royal Automobile club in Great Britain adopted an approximate horsepower rating based upon an assumed piston speed of 1,000 ft. per minute and a b.m.e.p. 67 lb. per square inch. The rating is expressed by the equation

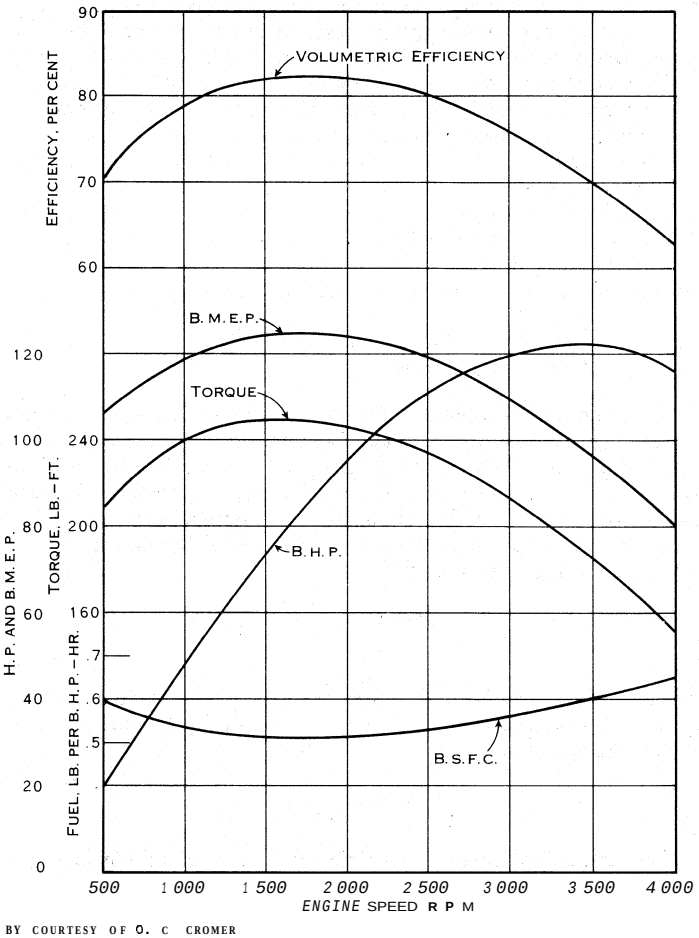
$$\text{horsepower} = \frac{B^2N}{2.5}$$

where B is the cylinder bore in inches and N is the number of cylinders. The same formula was adopted in the United States by the Association of Licensed Automobile Manufacturers and became known as the ALAM rating. Both piston speeds and brake mean effective pressures of modern engines are much higher, and it is not unusual for the manufacturer's rating to exceed the horsepower calculated by this formula by a factor as large as five. This formula is widely used as a basis for licenses and taxes.

The horsepower unit in continental Europe, where the metric system is used, is slightly smaller than Watt's unit. It evaluates a horsepower as work done at the rate of 4,500 kilogram-metres per minute and is 98.6% as large as the English and American unit.

In order to effect a comparison of engines of differing size, it is customary to divide the horsepower developed by the piston displacement, thus arriving at the power per unit of cylinder size. Either the engine speed or the mean effective pressure must be increased in order to increase the power per cubic inch of piston displacement. Because it is difficult to maintain effective cylinder charging and low friction losses at high speed, high specific power output as expressed by this unit represents a desirable design achievement. The usual range is from one-half to seven-eighths of a horsepower per cubic inch of piston displacement for automobile engines and much less for slow-speed engines.

The fuel economy of an engine is expressed in units of pounds of fuel per brake horsepower per hour. This quantity is found by weighing the fuel burned during a test run at constant operating conditions, converting the weight to pounds per hour and dividing by the brake horsepower that the engine was developing during the test. The rate of fuel consumption evaluated by this unit is called the brake specific fuel consumption of the engine (b s.f.c.). The fuel economy of an automobile engine is usually best at about half its rated speed and three-quarters or more load. Lighter or heavier



BY COURTESY OF O. C CROMER

FIG. 8.— PERFORMANCE CURVES FOR TYPICAL AUTOMOBILE ENGINE

loads and higher or lower speeds cause the specific fuel consumption to increase.

Performance curves are drawn from test data for a variable-speed engine by plotting power and economy against engine revolutions per minute. Fig. 8 is a set of such performance curves for a typical automobile engine. These curves show that both the torque and the b.m.e.p, curves follow the changes in cylinder-charging ef-

fectiveness that are reflected in the volumetric efficiency curve. The brake horsepower curve is also seen to reach a peak at the speed above which the torque and b.m.e.p. are decreasing more rapidly than the speed is increasing.

Theoretical Cycles.—Improvements in engine performance were brought about by studying and analyzing the results of tests. The engine indicator diagram is capable of theoretical analysis when simplified by substituting conventional standard processes of thermodynamics for its irregular and unsystematic curves. The indicator diagram of fig. 7 then appears as a summation of four processes as shown in fig. 9, the diagram of the ideal Otto style.

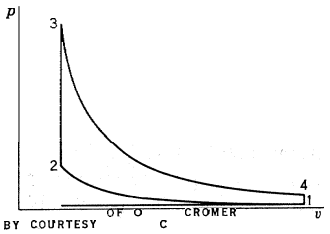


FIG 9 — THEORETICAL OTTO-CYCLE PRESSURE-VOLUME DIAGRAM (SEE TEXT FOR FURTHER EXPLANATION)

The lower loop of the indicator diagram found by the intake and exhaust strokes is eliminated by the assumption that, ideally, both of these strokes are carried out at atmospheric pressure. Further simplifying assumptions are that air is the working fluid throughout the cycle and its properties are those of atmospheric air. The cycle then starts with atmospheric conditions at the point 1. The processes 1–2 and 3–4 both follow the theoretical paths for adiabatic compression and expansion resulting from the assumption that no heat is transferred to or from the working fluid during the process. The pressure at each point along these curves is established by the perfect gas relationship PV^K, a constant, wherein P is the absolute pressure of the air, V the volume occupied by a unit mass of air and K is the ratio of the specific heat at constant pressure to that at constant volume. which may be taken as 1.4 for atmospheric air. The process 2–3 and 4–1 are carried out at constant volume, since it is assumed that energy is gained by combustion from 2 to 3 instantaneously and that rejection of energy to the exhaust from 4 to 1 is also instantaneous.

The theoretical or ideal Otto cycle may be analyzed by evaluating the energy quantities in the equation for efficiency, η :

$$\eta = \frac{\text{net work}}{\text{energy supplied}} = \frac{Q_{\text{in}} - Q_{\text{out}}}{Q_{\text{in}}} = \frac{Q_{2-3} - Q_{4-1}}{Q_{2-3}}$$

Thermodynamic relationships permit the evaluation of Q between 2 and 3 in terms of specific heat and the temperatures at the two points, and similarly for Q between 4 and 1. An expression in terms of the temperatures at the four corners of the cycle diagram is thus obtained. Further application of thermodynamics yields a simpler and more useful expression in terms of the maximum and minimum volumes of the cycle

$$\eta = 1 - \frac{1}{\left(\frac{V}{V_2}\right)^{K-1}}$$

The ratio V_1/V_2 is the compression ratio of the cycle or engine. Substituting r, the compression ratio, for V_1/V_2 makes the theoretical efficiency equation

$$\eta = 1 - \frac{1}{r^{K-1}}$$

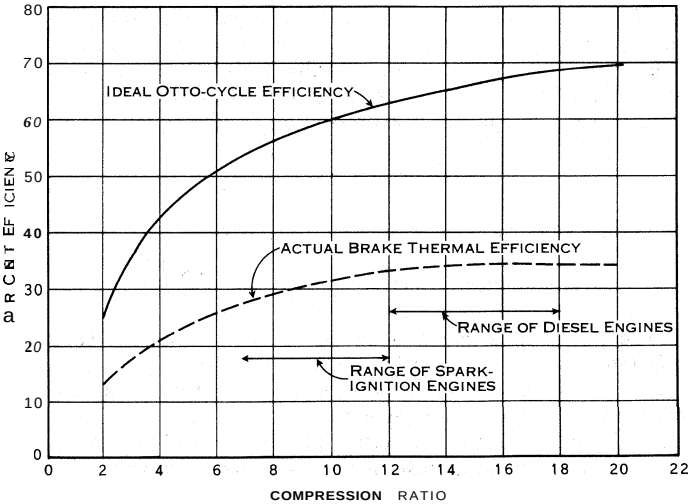
The theoretical Otto-cycle efficiency is the thermal efficiency of the cycle and is equivalent to the fraction of the energy supplied that is converted into work. No losses other than those inherent in the cycle are involved and only a perfect engine operating on that cycle could attain such high efficiency. The practical losses introduced by the imperfections of the engine include its failure to burn the fuel completely and to duplicate the cycle processes exactly; also the heat transferred from the engine, the friction losses and other ways in which energy is dissipated by the real engine. The thermal efficiency of the actual engine is calculated from test data and is much lower than the theoretical efficiency, perhaps only half as large.

The brake thermal efficiency of an engine is the fraction of the energy supplied in the fuel that is present in the brake horsepower delivered by the engine. The heating value of the fuel must be known in order to evaluate the energy supplied. Fuel is tested for heating value by burning it in a calorimeter that transfers the heat released by burning a known weight of the fuel to a known weight of water. Each degree that each pound of water is heated through 1° F. temperature rise is called a British thermal unit (B.Th.U.). The number of British thermal units released by the combustion of a pound of fuel is its heating value Q_H. For gasoline this value is about 20.000 B.Th.U. per pound. The power developed by the engine can also be expressed in British thermal units because 1 B.Th.U. has been experimentally found to be equivalent to 778 ft.lb. of work. A horsepower delivered continuously for one hour is thus equivalent to 2,545 B.Th.U. Since brake specific fuel consumption is the pounds of fuel burned in one hour to deliver one horsepower, brake thermal efficiency may be expressed as

$$\text{brake thermal efficiency} = \frac{2{,}545}{\text{b.s.f.c.} \times Q_H}$$

The curves of fig. 10 show the theoretical Otto-cycle efficiency and the approximate brake thermal efficiency of an engine operating on the Otto cycle for compression ratios from 2 to 20. The approximate ranges of the compression ratios of spark-ignition engines and diesel engines are also indicated. The upper portion of the spark-ignition engine range is attainable only by engines operating with natural gas or extremely high-octane fuels.

The cycle described by Diesel in his 1893 patent differs from the Otto cycle only in that energy is supplied more slonly, at a rate such that the increase in volume during combustion exactly compensates for the tendency for the pressure to rise. Energy is thus supplied at constant pressure instead of at constant volume as in the Otto cycle; and combustion in an engine following this cycle occurs more gradually during the early part of the power stroke instead of instantaneously at the dead centre point and the path 2–3 is horizontal instead of vertical. The analysis of the Diesel



REPRINTED WITH PERMISSION FROM SOLBERG, CROMER AND SPALDING, "ELEMENTARY HEAT POWER," 1952, JOHN WILEY & SONS, INC.

FIG. 10.— CURVESSHOWING EFFECT OF COMPRESSION RATIO ON THEORETICAL OTTO-CYCLE EFFICIENCY AND APPROXIMATE BRAKE THERMAL EFFICIENCY

cycle is not as simple as that of the Otto cycle and the expression for its efficiency is more complicated, usually being expressed as

$$\eta = 1 - \frac{1}{r^{K-1}}\left[\frac{r_c^K - 1}{K(r_c - 1)}\right]$$

wherein r_c is the cutoff ratio or ratio of expansion during combustion V_3/V_2. The value of the bracketed factor is greater than unity for any practical cutoff ratio and the subtractive term is consequently greater than that of the Otto-cycle expression, $\frac{1}{r^{K-1}}$. The efficiency of the Diesel cycle is thus lower than that of the

Otto cycle for the same compression ratio by an amount that increases with the energy input. An engine operating on this cycle would then be more efficient at a light load than at a heavier load.

The value of K in theoretical efficiency expressions is higher for air than for fuel vapours. It can be shown by calculating the value of K for various air-fuel ratios that the efficiencies of both the Otto and Diesel cycles are higher when air alone is considered as the working fluid and decrease progressively as fuel is included in the charge. It is evident from this study that lean mixtures are theoretically more efficient than those containing more fuel.

A practical consideration. however. enters here because combustion in the spark-ignition engine is slowed down as the mixture is leaned beyond the maximum-economy ratio. causing the combustion process to depart from the constant-volume process of the Otto cycle and tend toward the less efficient constant-pressure process of the Diesel cycle. The compression-ignition engine is inherently a lean-mixture engine; however. and its combustion is not retarded by excess air. The higher efficiency of the diesel-type engine is attributable both to its higher compression ratio and its higher air-fuel ratio than those used with spark ignition. High-speed diesel engines follow the Otto cycle.

These theoretical analyses indicate three factors affecting efficiency. First, the compression ratio should be as high as is practical; second, combustion should be as rapid as is practical; and third! the air-fuel ratio should be high. These criteria favour the Diesel principle of compression ignition because the compression ratio of this engine is not limited by detonation and preignition as it is in the spark-ignition engine, and it can operate at high air-fuel ratios without impairing combustion. As shown by the curves of fig. 10, the important gains in efficiency from increased compression ratio were made when ratios were increased from about 4 to 7; further increases above 12 result in proportionately less theoretical improvement and very little actual gain in thermal efficiency.

Charge Requirements. — Combustion of any fuel requires that a certain amount of oxygen be made available to permit the proper chemical reaction to occur. The amount of oxygen necessary to support the combustion of fuel may be readily calculated if the chemical ingredients of the fuel are known. It is customary to assume that gasoline is a mixture composed of many hydrocarbon coinpounds that average approximately the same as octane! C_8H_{18}. With this simplifying assumption it is possible to write the combining equation for gasoline and air as

$$C_8H_{18} + 12.5\ O_2 + 47.5\ N_2 \rightarrow 8\ CO_2 + 9\ H_2O + 47.5\ N_2$$

Multiplying each term of this equation by the molecular weight of the substance results in the folloning equation in pounds

$$114\ C_8H_{18} + 400\ O_2 + 1{,}330\ N_2 \rightarrow 352\ CO_2 + 162\ H_2O + 1{,}330\ N_2$$

For one pound of fuel

$$1\text{ lb. } C_8H_{18} + 3.51\text{ lb. } O_2 + 11.66\text{ lb. } N_2 \rightarrow 3.09\text{ lb. } CO_2 + 1.42\text{ lb. } H_2O + 11.66\ N_2$$

$$1\text{ lb. } C_8H_{18} + 15.17\text{ lb. air} \rightarrow 16.17\text{ lb. products of combustion}$$

In this final form it is indicated that 1 Ib. of gasoline reacts with slightly more than 1 j lb. of air to form products of complete combustion. These equations represent the proportion for perfect combustion in which the fuel and oxygen are both entirely consumed by the reaction. The imperfections of the combustion chamber as a chemical retort. incomplete mixing of the fuel and air, insufficient time to permit the reaction to go to completion and other unfavourable factors prevent perfect combustion and cause both combustible material and oxygen to be present in the products formed.

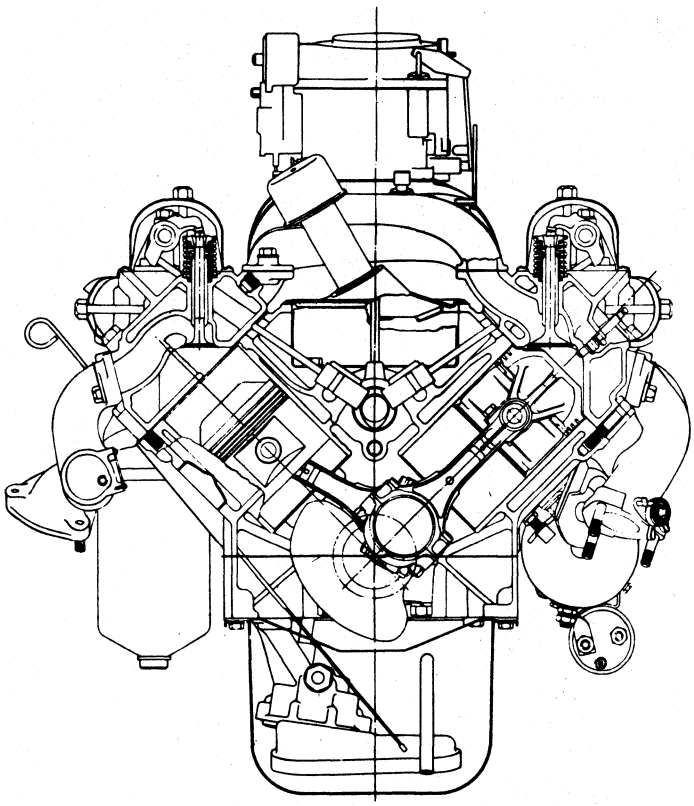
The 1 j to 1 ratio of pounds of air to pounds of gasoline. although chemically correct, is not the best proportion for a gasoline engine charge. Experiment proved that a slightly lean mixture. about 16 to 1, is more economical than the chemically correct ratio. The excess air contributes to completeness of combustion by requiring less perfect mixing in order fcr the fuel to contact sufficient oxygen, but less power is developed because less chemical energy is present in the smaller amount of fuel contained in the leaner mixture. Further leaning of the mixture is uneconomical because the burning rate of the charge is decreased. A somewhat rich mixture, about 12 to 1. is more powerful than the cheniically correct ratio. This is true because the additional fuel introduces a greater amount of chemical energy to the combustion chamber and, although the deficiency in oxygen decreases the combustion completeness slightly, the net energy release is increased. Further enrichment reduces the power output by decreasing the burning rate.

Combustion. — Combustion in the spark-ignition engine originates at the spark plug where the high temperature of the electric spark ignites the tiny portion of the charge in the immediate vicinity of the spark-plug gap. In burning, this first particle of fuel presents a somewhat spherical surface of flame to the layer of charge surrounding it, causing it to ignite and expose the next layer to an igniting flame. As the charge is exposed to this flame front, layer by layer, the inflamed sphere grows until it spans the combustion chamber. The flame front then advances radially across the chamber and, if undisturbed. progressively ignites and burns the remainder of the charge. Normal combustion, then, is a progressive burning at a rate dependent upon the density of the charge, the speed at which the flame front advances and the area of the flame surface. Although the entire process is completed in a small fraction of a second, there is no instant during the burning time when any sizable portion of the charge is burning. Energy is thus released at a uniform rate that is not violent.

As each portion of the charge burns, it releases its chemical energy; its products of combustion attain a very high temperature and the volume of space occupied by the products increases. This expansion of the burned portion of the charge compresses the unburned portion by crowding it into a smaller part of the chamber than it originally occupied. A compression of this sort is accompanied by an increase in temperature as well as in pressure and density. It is possible that the temperature and density attained by the last portion of the charge may be so great and the time of exposure be sufficient to cause the entire remaining charge to self-ignite simultaneously with explosive violence. Such almost instantaneous combustion causes a high rate of pressure rise in that part of the chamber and sets up a high-frequency pressure wave within the gases. The resulting vibration of the chamber walls produces a knock that is called detonation. When detonation occurs, the engine is noisy and the temperature of the combustion chamber rises rapidly, accompanied by a loss in power. Only the last portion of the charge, that farthest from the spark plug, is involved in this combustion irregularity, and it will not occur if the fuel is able to resist self-ignition under the conditions to which it is exposed until it is burned in the normal manner by the arrival of the flame front. Detonation can be avoided by improvements in the fuel to make it more resistent to self-ignition or by improvements in the engine that lessen the severity of the condition to which the charge is exposed before it burns. Control of combustion thus requires a knowledge of fuels and the effects of combustion-chamber design.

Fuels. — Gasoline is a mixture of many hydrocarbon compounds, each of which differs from the others in such characteristics as boiling point or volatility, inolecular structure, density and ignition behaviour. To suit the needs of a modern engine a gasoline must have the volatility, as indicated by its boiling-point range. for which the fuel system of the engine was designed, and antiknock quality, as indicated by its octane number, sufficient to avoid detonation under normal operation. Other specifications must also be met, but. volatility and octane number are the most important. Starting quality: vapour-locking tendency, rapidity of warm up, acceleration, crankcase dilution, power and completeness of combustion are some of the performance factors affected by volatility. The octane number of a gasoline determines whether knock-free operation is possible in a given engine. The size of the molecules and the structural arrangement of the carbon and hydrogen atoms within the molecules principally determine the octane number of a gasoline.

The hydrocarbon compounds of which petroleum fuels are composed have three distinct molecular patterns, straight-chain, branched-chain and ring. Larger molecules are frequently combinations of these basic forms, such as double rings or rings with side chains. Physical chemists have found that the ease with which these molecules enter into chemical reactions, such as combustion,



BY COURTESY OF GENERAL MOTORS CORP.

FIG. 11.—TRANSVERSE CROSS SECTION OF A V-8 ENGINE

is affected by both the size and structure of the molecules. Large straight-chain molecules react most readily, whereas small compact molecules are most resistant to chemical reactions. The size of the molecules and, to a lesser extent, their structure also affect the volatility of the fuel. The smallest molecule, that of methane, has the lowest boiling point, —259° F., and it is so volatile that it exists as a gas at atmospheric conditions. It is also the most inert of the hydrocarbons and therefore has the highest antiknock quality. Cetane is an example of the opposite extreme. It has a long straight chain with 16 carbon atoms, enters into reaction with oxygen at relatively low temperature and has a boiling point of 536° F. Intermediate compounds, of which gasoline is composed, have molecules with from 5 to 12 carbon atoms and a boiling point range from about 100° to 400° F.; the molecules are largely of branched-chain and ring structure that vary considerably in chemical activity.

The octane-number rating of gasolines for antiknock quality is based upon the effect of molecular structure on the knocking tendency of a fuel and the effect of increased compression ratio on the knocking tendency of an engine. A special single-cylinder test engine with adjustable compression ratio is used to compare the knock intensity of the gasoline under test with that of blends of two reference fuels that are used as a standard.

Isooctane, a branched-chain hydrocarbon of high antiknock quality, is blended with normal heptane, a straight-chain hydrocarbon that knocks severely, in varying proportions by volume. The engine is operated on the gasoline and the compression ratio adjusted until a knock of a standard intensity, as established by the test code, is indicated by a knock meter. Reference blends of octane and heptane are then successively substituted for the gasoline at the same compression ratio, in proportions that are varied until the same knock intensity is again indicated. The per cent of octane in the reference blend that causes the same knock intensity as mas caused by the gasoline is taken as the octane number of the gasoline.

A fuel that has the same knocking tendency as isooctane is a 100-octane fuel and one that behaves the same as normal heptane is a 0-octane fuel. An 80-octane fuel has the same antiknock quality as a mixture of 80% isooctane and 20% normal heptane. It should be noted that no quality of the gasoline other than its knocking tendency is indicated by its octane number.

The petroleum chemist devised refining techniques whereby gasoline molecules of compact structure and desirable antiknock characteristics are produced. In this way it became possible to improve greatly the antiknock quality of gasoline and also produce much larger amounts of gasoline from the crude oil. Additives, principally tetraethyl lead, also contribute to the knock resistance of gasoline.

For many years gasoline and other volatile portions of the crude oil were distilled off and thrown away for want of a market, but the advent of the automobile made it desirable to increase the yield of gasoline from crude oil to meet the demand. Only 20% of the crude could be made into gasoline originally and up to 1914, and its octane number was only 50. By 1922 improved refining processes and the addition of tetraethyl lead had increased the yield to 30% and the octane number to 6j. Thermal cracking, whereby large molecules too low in volatility for gasoline are broken up, came in 1925, increasing the yield to more than 40% and the octane number to 7j. In 193j the cracking process was improved by the use of catalysts to raise the octane number to 85. Higher octane ingredients are made by converting certain highly volatile constituents into gasoline, making 100-octane fuel possible and nearly 45% yield from the crude oil. *(See* also PETROLEUM)

Combustion Chambers.— While the petroleum industry was improving gasoline, the engine manufacturers were improving combustion and fuel utilization of the engines. Modern gasoline engines resulted from the mutual adaptation of fuels and engines to each other. The knowledge that higher compression ratio increases thermal efficiency and power output encouraged engine designers to increase compression ratios progressively as rapidly as the fuel limitations and the engine requirements could be matched by co-operative endeavour.

Combustion control in the spark-ignition engine is largely a matter of avoidance of preignition and detonation. Preignition is self-ignition of the charge before the spark occurs and is one of the extreme effects of increased compression ratio. Detonation is a self-ignition effect, but it occurs after most of the charge has burned normally and as an effect of the combustion and expansion of the first portion.

The tendency for a mixture of gasoline vapour and air to self-ignite increases with the temperature of the charge, its density and the length of time that it is exposed to the temperature. In high-compression engines the temperature and density attained by the charge before ignition are much higher than in low-compression engines. The problem in attaining smooth, normal combustion becomes one of burning the charge by the normal flame front before it ignites spontaneously. Much depends upon the resistance to self-ignition or octane number of the fuel, but the severity of the conditions to which the charge is exposed before and during combustion can be lessened by careful design of the combustion chamber and the induction system. as well as by improved cooling of surfaces that are contacted by the charge. The time element in self-ignition is important and can be controlled and shortened in several ways.

FIG. 12.— DIAGRAM OF SIMPLE ELEMENTARY CARBURETTOR (SEE TEXT FOR FURTHER EXPLANATION)

The more compact the combustion chamber is made the shorter the distance that the flame front must travel in order to burn all of the charge. Locating the spark plug more centrally shortens the flame travel to the most extreme boundary of the chamber. Increased engine speed causes more rapid combustion. All of these time-shortening factors are employed in reducing the octane requirements of engines.

The L-head engine was the first to which the principle of turbulence, charge concentration near the spark plug, shortened flame travel and quench area remote from the plug were applied. Sir Harry Ricardo conceived the L-head combustion chamber design shown in fig. 5 shortly after World War I, and it was widely adopted for engines of this type. The squish turbulence, created by the close approach of the far side of the piston to the cylinder head, feeds most of the charge that would otherwise have been last to burn into the flame front and permits the remainder to be kept cool by proximity to the metal walls. As compression ratios are increased, however, reduced depth of the passage from the valves in the L-head engine to the cylinder bore restricts the flow of charge between the valves and the cylinder, causing decreased power at high speeds. Manufacturers were forced to adopt the valve-in-head design, in which the charge flows directly into the cylinders from the valves, for engines with compression ratios higher than eight.

Two types of high-compression combustion chambers were developed for valve-in-head engines, the wedge type and the hemispherical type. All practical designs may be considered as modifications of these two types. The combustion chamber shown in fig. 6 is of the wedge type and employs the same basic design principles of combustion control as were expressed by Ricardo. The spark plug is located at a deep section so that as much charge as possible can be burned initially and tapers away to a region thinned out to gasket thickness as a quench area and to promote squish turbulence.

Fig. 11 shows a cross section of a V-8 engine in which a modified hemispherical-type chamber is used. The spark plug is centrally located for short flame travel and charge concentration near

FIG 13.— SECTIONAL VIEW OF A CARBURETTOR SHOWING FLOAT MECHANISM AND LOW-SPEED CIRCUIT

the plug. The piston is crowned to form shallow regions around the periphery of the chamber where combustion ends and to cause motion of the charge toward the spark plug.

Carburetion.— The gasoline carburettor is a device that proportions fuel into the air stream as it flows into the intake manifold. A simple carburettor is shown diagrammatically in fig. 12. Gasoline is maintained in the float chamber A by the float-actuated valve B at a level slightly below the outlet of the jet C. Air flows downward through the throat, past the throttle valve D and into the intake manifold. A venturi is formed by the reduced

FIG. 14.— SECTIONAL VIEW OF A CARBURETTOR SHOWING MAIN METERING SYSTEM

throat diameter at E, and acceleration of the air through this smaller passage causes a decrease in pressure below atmospheric proportional to the amount of air floaing. This decrease in throat pressure when air is flowing causes the atmospheric pressure on the surface of the gasoline in the float chamber to exceed that at E, resulting in fuel flow from jet C into the air stream. Any increase in air flow caused by change in engine speed or throttle position will increase the pressure differential acting on the fuel and cause more fuel to flow.

The volume ratio of air to fuel established by the throat and fuel jet sizes will be maintained with increased charge flow, but the weight of fuel per pound of air increases because the air expands to a lower density as the throat pressure decreases at higher rates of charge flow. This inherent enriching tendency necessitates the inclusion of a compensating device in a practical carburettor. Carburettor design is further complicated by the need for an enriching device to provide a maximum-power ratio at full throttle, a choke to facilitate starting a cold engine. an idling system to provide the special needs of light-load operation and an accelerating device to supply additional fuel while the throttle is being opened.

Fig. 13, a sectional view of a typical automobile engine carburettor, shows the throttle in the idling position and indicates the flow of fuel through the idling circuit which draws fuel from the top of the float chamber and delivers it past an idle adjusting screw to a point in the carburettor outlet just below the throttle valve. When the throttle valve is closed a high vacuum exists on the manifold side of the valve which causes the idling circuit to function.

As the throttle is opened the vacuum at the idle fuel outlet is so reduced that no fuel flows from it and it is supplied only by the main jet. The small air flow at the venturi when the throttle is closed is insufficient to cause fuel to flow from the main jet, but it comes into operation as the throttle is opened.

Fig. 14 shows the carburettor functioning normally with the throttle more fully open and fuel flowing through the main metering jet and into the air stream at the main discharge jet. The high-speed bleeder shown is a device that admits air into the fuel passage as a means of preventing enrichment at increased rates of

charge flow.

Only the idling and main-fuel circuits are shown in these two views. Accelerating, full-throttle enriching devices and other components are present but not visible.

Modern automobile carburettors are further complicated by the provision of two or four throats, commonly called barrels instead of one. as a means of improving charge distribution to the cylinders and better adapting them to the large range of quantity of charge that they must supply from idling at lon engine speed to full throttle at maximum speed. A dual carburettor has two throats, each of which supplies half of the cylinders. A four-barrel carburettor is in effect a small dual carburettor at less than half throttle and a large carburettor when the throttle is more fully opened and the other two barrels cut in.

Gasoline-injection systems were available for aeroplane engines of high power output before World M7ar II and were extensively used by the armed forces The performance of engines with this equipment was excellent. but the much greater cost of fuel-injection systems as against carburettors limited their application to large expensive engines. Efforts to simplify and cheapen fuel-injection equipment without impairing performance yielded multicylinder pumps that could compete in cost with the four-barrel carburettor Gasoline-injection equipment has been designed of a variety of types ranging from distributor systems employing a single pump for all of the cylinders to multipump types.

The principal advantages of gasoline injection over the carburettor are: (1) improved fuel economy because of more accurate fuel and air proportioning; (2) greater power because of elimination of charge heating: (3) elimination of inlet icing; and (4) more uniform distribution of charge to all of the cylinders because the fuel is delivered directly to each cylinder.

The SU fuel-injection pump, developed in England, is representative of the direct gasoline-injection systems available for engines of moderate size. An injection nozzle is located just outside each intake valve to which fuel is supplied at pressures up to zoo lb. per square inch in metred quantities while air is entering the cylinder. The basic metering principle of the system is to vary the amount of gasoline delivered to each cylinder in accordance with three functions of the engine — speed, manifold pressure and temperature of the air in the inlet manifold. This is known as speed-density metering and assumes that the rate of air flow to an engine is very nearly proportional to its speed and the density of the air as it enters the cylinders.

A cross section of the SU fuel-injection pump is shown in fig. 15 with the important parts identified. Pump bores, each with a closely fitted plunger, are spaced in a circle about the central drive shaft with their axes parallel with the shaft. The plungers are held against a wobble plate by springs and receive their reciprocating motion from the angle through which the wobble plate rocks as the main shaft rotates. This angle, in turn, depends upon the axial displacement of the servo piston and its oblique extension through the wobble plate. Upward motion of the servo piston displaces the wobble plate laterally. causing its ball-section upper surface to assume a more level position in its socket, thereby shortening the strokes of the plungers.

The axial location of the servo piston is established by the intake-manifold pressure in the capsule chamber above the piston and the gas pressure nithin the capsule created by the temperature bulb located in the manifold.

When the throttle at the entrance to the inlet manifold is opened the manifold pressure rises, compressing the capsule, moving the pin shaft upward and opening the oil supply so that pressure is applied under the servo piston. The wobble plate is then tilted at a greater angle and pumping capacity increased. Higher manifold pressure causes the piston to assume a higher position and higher air temperature lowers it, resulting in an amount of fuel delivered proportional to the air density.

There are half as many pump barrels and plungers as there are cylinders in the engine and the pump shaft turns at crankshaft speed. A distributor valve between the pump barrels and the delivery lines to the injectors is moved so that the fuel is delivered to half of the cylinders during one turn of the shaft and to the other half on the next turn. Thus each pump delivers fuel alternately to two cylinders that fire one crank turn apart. Fuel flows to each injector nozzle for 180° of crankshaft rotation. timed to occur within the period of inlet-valve opening. Fuel flow into the pump chambers on the plunger upstrokes is also controlled by the distributor valve.

Ignition. — Two types of electric ignition systems are used,

FIG. 15. — SECTIONALVIEW OF SU GASOLINE-INJECTION PUMP FOR SPARK-IGNITION ENGINES

the magneto and the battery and coil systems. They are similar in principle but the magneto is a self-contained device requiring only the spark plugs and connecting wires to complete the system, whereas the battery and coil system comprises several separate components. Fig. 16 shows the components of a six-cylinder battery, coil and distributor system and the electrical circuit. The circuit consists of a primary side, which starts with the 6- or 12-v. battery, one terminal of which is grounded while the other leads through a switch to the primary winding of the coil, comprising relatively few turns of heavy wire, and then to the circuit breaker where it is again grounded. Current flows through the primary circuit when the switch is closed and the points of the circuit breaker are in contact. Rotation of the circuit-breaker cam opens and closes the primary circuit. The secondary circuit starts with the secondary winding of the coil, comprising several thousand turns of very fine wire, one end of which is connected to the primary winding while the other leads to the rotor of the distributor which acts as a rotary switch, selecting which of the spark plugs is placed in the circuit. Each spark plug is connected to one of the outer terminals of the distributor to receive an electrical impulse in proper sequence.

When the breaker points are in contact, a current flows through the primary winding of the coil. creating a magnetic field which threads the turns of the secondary winding. Separation of the breaker points by the cam opens the circuit and causes the mag-

netic field to collapse rapidly, an action which induces a voltage across each turn of the coil. A total voltage as high as 20.000 is built up in the secondary winding at the instant that the breaker points open and applied to the rotor of the distributor. This rotor is in phase with the circuit-breaker cam so that it establishes a circuit to one of the spark plugs just before the breaker points

FIG 16.— DIAGRAM OF BATTERY AND COIL IGNITION SYSTEM FOR AUTOMOBILE ENGINES

separate and then moves on to the terminal leading to the next spark plug in firing sequence.

A considerable voltage is also induced in the turns of the primary winding when the breaker points open, causing a spark to occur at the points just as they are separating. This spark tends to burn and pit the breaker points. so a capacitor or condenser is connected across the circuit breaker to absorb the energy and protect the points from burning.

A spark plug consists of a threaded steel shell that screws into the cylinder head and an insulator that contains a central electrode. A gap of $\frac{20}{1.000}$ to $\frac{40}{1.000}$ in. is provided between the central electrode and the ground electrode attached to the shell of the plug. The central electrode extends through the insulator to receive the secondary wire from the distributor, and the circuit is completed from the ground electrode through the metal of the engine to the battery and thence to .the coil. The voltage established at the coil must be sufficient to jump the spark-plug gap against the resistance of the compressed charge.

The spark must be precisely timed to occur at the proper point in the cycle of the engine; the timing is established by the gear train connecting the breaker cam to the camshaft and thence to the crankshaft. The optimum time for the spark to occur varies both with the load on the engine and with its speed, necessitating an advance mechanism to control the timing with changes in operating conditions.

A centrifugal flyweight device advances the spark timing as the engine speed increases and a vacuum device advances the timing as the throttle is closed, utilizing the increase in intake manifold vacuum as load decreases.

Lubrication. — The purpose of lubrication is to interpose an oil film between the parts that have relative motion, thus substituting the fluid friction between the molecules of the lubricant for the mechanical friction that would quickly destroy the rubbing parts. The lubrication system must continuously replace the oil films that separate the parts.

The lubricant employed is refined from the heavy nonvolatile fractions of crude oil after the fuels are removed. The viscosity or body of the oil must be appropriate for the needs of each engine and the oil must be of a type suitable for the severity of its operating conditions. Oils are made more resistant to deterioration by additives that reduce oxidation, inhibit corrosion and act as detergents to disperse deposit-forming gums and solid contaminants.

A system of SAE numbers, from 5 to 70, is used by refiners to designate the range within which the viscosity of an oil falls; the lower the number, the lighter the body of the oil. Oils of SAE 30 and lower are classified according to their rates of flow at 130°; the higher viscosity oils are tested at 210°. The letter W after the number indicates that the oil is rated at zero temperature and is, therefore. suitable for winter use. Multi-rated oils. such as 10W-30, contain additives that oppose the tendency of the oil to thicken at low temperature. thus making the same oil satisfy both summer and winter requirements.

Automobile engine lubricants are also classified according to the severity of the operating conditions for which they are suitable by the code letters ML, MM, and MS stamped on the container. The ML grade is recommended only for light-duty service. MM for moderately severe conditions, and MS for severe conditions requiring a heavy-duty oil These oils differ principally in the types and quantities of additives included.

Oil filters, if regularly serviced, are capable of removing solid contaminants from crankcase oil. There is. however, a possihility that chemical reactions may form liquids that are corrosive and damaging to the engine. Depletion of the additives that give the oils needed properties also limits their useful life.

The lubrication system is fed by the oil sump that forms the lower enclosure of the engine. Oil is taken from the sump by a pump, usually of the gear type, and delivered under pressure to a system of passages or channels drilled through the engine parts. In some instances a full-flow filter is interposed between the pump and the main oil passage extending the length of the engine. In other engines bypass filters bleed off a small quantity of oil continuously from the system and return the filtered oil to the sump.

Oil is supplied under pressure to all of the crankshaft and camshaft main bearings. Adjacent crank throws are drilled for oil to flow from the supply at the main bearings to the crankpins. Leaking oil from all of the crankshaft bearings is sprayed on the cylinder walls, cams, and up into the pistons to lubricate the piston pins. Additional passages intersect the cam follower openings and supply oil to hydraulic valve lifters when used. A spring-loaded pressure-relief valve maintains the pressure at the design value. Fig. 17 shows the lubrication of a typical V-8 engine.

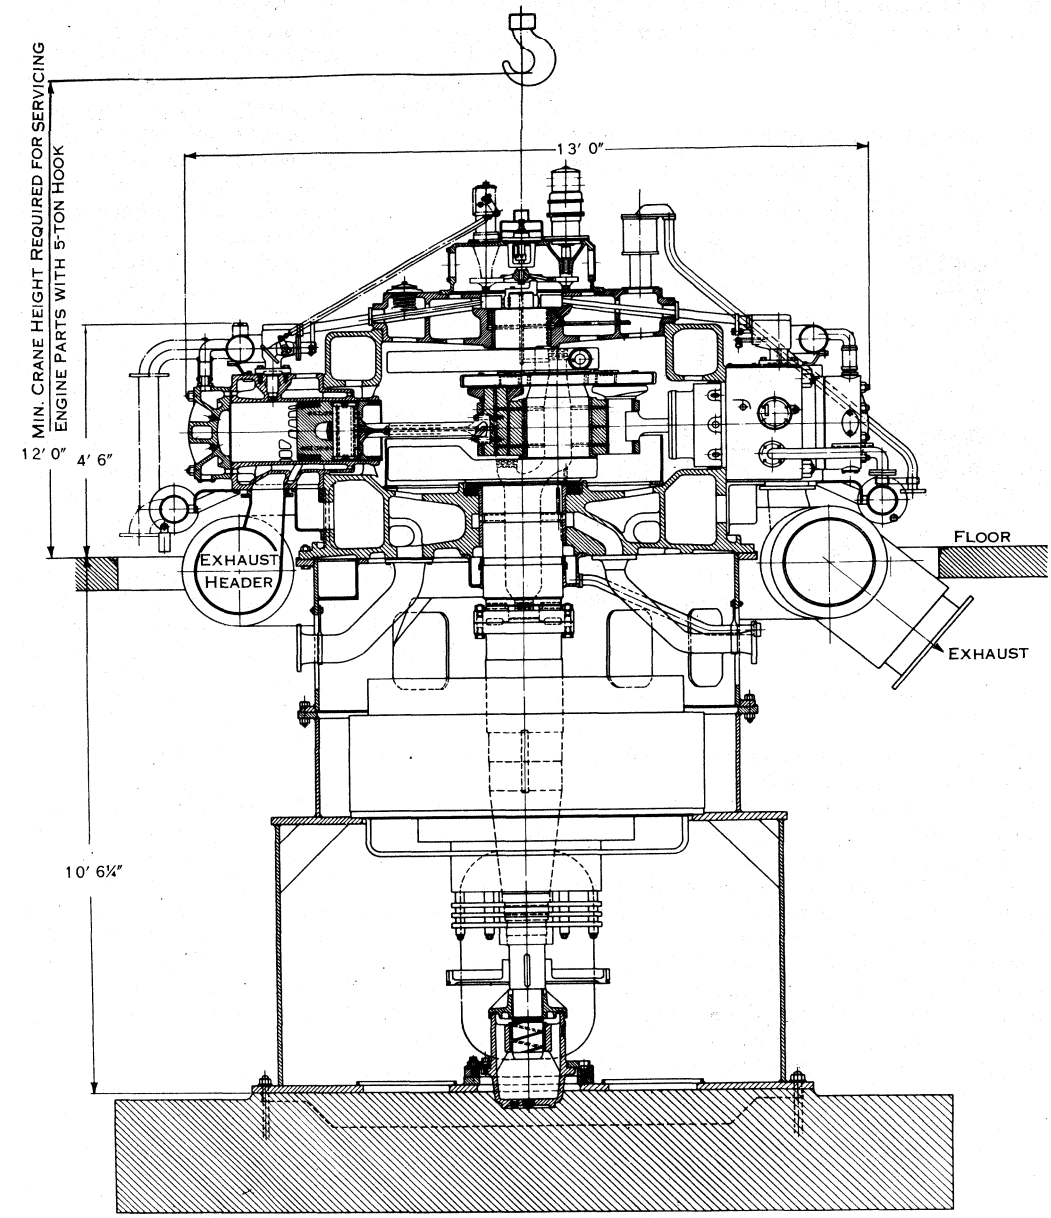
FIG. 17.— LUBRICATION SYSTEM OF AN AUTOMOBILE ENGINE

Gas Engines. — Gas is burned in two distinctly different groups of engines — large stationary power plant types and automotive types used in trucks, buses and tractors. Stationary gas engines

are used extensively in geographical regions where natural gas is available at a lower price per British thermal unit than must be paid for any other type of fuel. An additional advantage of 'natural gas used with spark-ignition engines is that it is more resistant to self-ignition than other fuels. permitting higher compression ratios to be used with higher efficiency and greater fuel economy. Low-cost power is the important factor in these engines. and brake thermal efiiciency of more than 40% is reported, more than is claimed for any other type prime mover.

Large stationary power plant engines were originally of the cylinders-in-line type, hut space requirement and engine cost considerations led to the development of vee-type and horizontal radial type engines. Two major engine manufacturers build radial gas engines in the United States.

Fig. 18 shows a cross section of a radial engine with a vertical crankshaft directly connected to a direct-current generator. The engine room is located on the floor above the ground floor where the generators are carried on the foundation which supports the entire power plant. This is a two-stroke-cycle engine with 12 cylinders of 14-in. bore and 16-in. stroke, developing up to 2,125 h.p. and 1,500 kw. at 400 r.p.m. Scavenging and charging are through two sets of ports in opposite sides of the cylinder walls and poppet valves are eliminated.



BY COURTESY OF NORDBERG MANUFACTURING CO.

FIG. 18 — SECTIONAL VIEW OF A RADIAL SPARK-IGNITION GAS-BURNING ENGINE

The salient features of the radial engine are high power output per unit of floor space, low weight, high mechanical efficiency because of few bearings. single-throw crankshaft and perfect balance. Operation on natural gas with spark-ignition at a compression pressure of 275 lb. per square inch and a maximum cylinder pressure of 650 lb. per square inch is possible because of the high antiknock quality of the fuel and the lean mixtures used. Gas is supplied at 20 lb. per square inch to mechanically actuated gas inlet valves located above the inlet ports in the top surfaces of the cylinders that admit the fuel into the stream of scavenging air brought in from headers below the floor. Two spark plugs at the top and bottom of each cylinder head fire at slightly different angles before top dead centre. A unique feature of this engine is the restraining linkage that prevents rotation of the single master bearing to which the inner ends of the connecting rods are pinned.

Automotive gas engines obviously cannot operate on natural gas because of the large volume of gas that would have to be carried. These engines burn propane-butane mixtures that are liquefied hy compression to about 185 lb. per square inch. These gases are important by-products of petroleum refinery operation and are available on the market as liquefied petroleum gases (LPG). Gases with similar liquefying characteristics also are taken from the ground at petroleum wells. The supply of these gases is large in proportion to the demand and, particularly in oil-producing regions. they are priced below the cost of gasoline.

The necessity of storing LPG in steel bottles or cylinders designed to withstand 250 lb. per square inch is a serious handicap attending its use; nevertheless its excellent combustion characteristics for spark-ignition engines make it attractive. High antiknock quality, high energy content or heating value per pound and high volatility, which facilitates mixture formation, give LPG excellent performance characteristics. The high antiknock quality permits compression ratios several units higher than are practical uith gasoline, resulting in higher thermal efficiency and fuel economy.

The fuel system that must be installed requires, in addition to the heavy steel container, pressure regulators. a vaporizer heated by the engine coolant and a gas carburettor. The fuel is supplied to the vaporizer as a liquid and is prevented from freezing because of the refrigerating effect of its vaporization by the heat received from the coolant. The LPG carburettor is simpler than the gasoline carburettor because special compensating devices are unnecessary.

INTERNATIONAL, THE. The term "international" is used by many groups with an international membership, such as the international associations of trade unions. Politically, however, the term has been fastened upon international organizations devoted to the transformation of the "capitalist" into a "socialist" world order.

The First International. — The idea of an international revolutionary association was first entertained by the French Jacobins of the 1790s. Before the revolutions of 1848 there were already several organizations, such as the French Alliance des Justes (directed by Louis Auguste Blanqui), the Italian Giovane Europa (directed by Giuseppe Mazzini) and the German Bund der Kommunisten (led by Karl Marx and Friedrich Engels), aiming at creating a revolutionary International. None of them, however, achieved that aim, though political co-operation between various national movements during the revolutions of 1848 was quite close.

The first successful attempt was made in 1864 when, under the prompting of several strong British trade unions. with the organizational and theoretical guidance of Marx and Engels, the International Working Men's association, known as the First International (1864–72), was founded. Its importance at the time was much overrated. Most of the British unions and important sections of the budding continental labour movement (the Blanquists in France, the Lassalleans in Germany) held aloof. Apart from fighting against the importation of strike breakers from abroad, the First International achieved nothing tangible and had no real influence upon the growth and ideological development of labour movements in the bigger countries. The unfolding of its banner did, however, do much in stimulating the emergence and growth of Socialist labour organizations in Spain, Italy, Belgium, the Netherlands and Scandinavia.

The International served as an important forum of debate, and its annual or biennial congresses became the platform where Marx's centralist socialism and the anarchism of the Russian Mikhail Bakunin clashed. When, in March 1871, the Paris Commune was formed, Marx. in a pamphlet written on behalf of the International, interpreted the Paris revolutionary government's policy as identical with his own principles. This raised violent objections both from the British unions, unwilling to be accomplices of violence, and from the Anarchists, uho regarded Marx's interpretation of the Commune as an usurpation. At its Hague congress in 1872 the First International split between Marxists and Bakuninists. The latter, actually controlling the majority of the membership, lost by a narrow margin because the Italian section, entirely Bakuninist, had broken with the International before the congress. The Bakuninists thereupon created their own Anarchist International. which adopted the official name of the International Working Men's association and continued to exert a fluctuating but at times considerable influence on the labour movements of southern Europe and of Latin America (also, to some extent, on those of the C.S., Australia, the Netherlands and Scandinavia) until it finally collapsed at the end of the Spanish Civil War (1936–39).

Marx moved the offices of his fragment of the First International to New York city. It expired soon after, on July 15, 1876, in Philadelphia.

The Second International, to 1920.—The Second International was formed at a congress in Paris in 1889 and at once adopted a statute leaving an ample measure of independence to the affiliated national parties, thus securing a much wider range of adherents than the First had had. Since in the meantime the labour movements of nearly all European countries had grown in size and experience and could very well stand on their own feet, the real influence of the Second International was perhaps even smaller than that of the First. Yet, since contact between Socialist and Labour movements of various countries was quite considerable during that period, membership of the International was valued by practically all European Socialist and labour parties as a certificate of their being bona fide representatives of labour interests. Thus the International, by threatening nonrecognition or expulsion of dissident groups, could prevent splits and occasionally enforce a merger of various labour groups within one country (as in France in 1904).

As the First, so the Second International became a debating platform for the various tendencies in international socialism: for orthodox Marxists such as August Bebel and Jules Guesde, for less rigid "revisionists" and "reformists" such as Jean Jaurès and Eduard Bernstein and, somewhat later, for a new extreme left represented primarily by Nicolai Lenin and by Rosa Luxemburg.

World War I.—In the decade preceding World War I the International had entertained a vigorous agitation against armaments and against the danger of war; at its Stuttgart congress of 1907, on a motion of Lenin and Luxemburg, it had even pledged itself to exploit any possible war for revolutionary purposes. These too-ambitious aspirations proved futile when, in Aug. 1914, by far the greater part of the Socialist movements in the belligerent countries supported their several governments. The attitude to the war was sharply debated in all parties throughout the years 1914–18; but only the German Social-Democratic party split over the question of supporting the war, in 1916–17. In 1915, however: the Swiss and Italian Socialist parties. which were pacifist in their majority, summoned "internationalists" from belligerent and neutral countries to a conference at Zimmerwald, Switz., which created a liaison office and issued a manifesto in favour of the class struggle and of the peace movement. Another conference of the same groups followed in 1916, at Kienthal, Switz.

Bolshevism and *the Vienna* International.—Lenin, who took part in both these conferences but failed to influence them, had before the war founded the Bolshevik group among the Russian Marxists and developed a doctrine hostile to the self-determination of the proletariat and stressing almost exclusively the need for a small group of dedicated professional revolutionaries. In 1914 he concluded that all other Socialist parties had "betrayed" their revolutionary programs and with them the proletariat and that the only safeguard against a repetition of this collapse was the extension of his concept of a revolutionary vanguard party to the whole world.

Already in Sept. 1914 he had launched the slogan of a "Third Communist International" and, in opposition to the pacifism of the Socialist left wing, the program of "transforming the imperialist war into civil war." He did not find much of an audience for these ideas until, in Nov. 1917, he had captured power in Russia; but even then the civil war in his own country at first prevented him from effectively controlling any section of the western European labour movement. The great strikes of Jan. 1918, which shook the Central Powers to their roots. were inspired by sympathy with the Soviet system but not in any sense directed from Moscow. The "Soviet republics" of Hungary (March–July 1919) and of Bavaria (April 1919), while invoking the Russian model, were not in any specific sense attached to Moscow.

When the war was over, the Socialists tried to rally, but the antagonism between patriots and pacifists could not at first be overcome. The patriots, supported by the German Socialist right wing and by the British, Belgian, Dutch, Swedish and Danish Socialist and labour parties, simply rebuilt the Second International. The pacifists, in 1920, at a congress in Vienna, Aus., founded an International mainly supported by the German left wing, by the Eritish I.L.P. (Independent Labour party) and by the Austrians, the Swiss and the French.

The Third International, or Cornintern. — The Cornintern, that is, the Communist or Third International, founded in Moscow at a conference in March 1919, was at first entirely unrepresentative of anything except the Bolshevik regime in Russia. Grigory Zinoviev, one of Lenin's oldest supporters, was elected its first president. The most important non-Russian section, the German Spartacusbund, was in ruins at the moment of the Comintern's

first congress, since its leaders, Karl Liebknecht and Rosa Luxemburg, had been murdered and its ranks shattered in consequence of an ill-timed attempt at capturing power two months before.

The Congress *of 1920.*—In 1920, however, with the Russian civil war over. the Comintern could carry through a frontal attack against the Vienna International. Continuing their old feud against the Zimmerwald majority and invoking the experience of their own victory, the Russian Communists challenged the pacifists to join the ranks of the Comintern. while at the same time laying down 21 stringent conditions for admission. These were so framed as to make access impossible to most of the pacifist leaders, in order that the masses which might join should come directly under Moscow's control. Indeed. the acceptance of control from the Executive Committee of the Comintern (E.C.C.I.), which mas itself actually controlled by the Russian Politburo, was stipulated among the 21 conditions. which also provided for periodical purges, for the creation of a secret *Apparat* side by side with the official party (even where the latter enjoyed perfect democratic freedom) and for measures to disrupt the armed forces of all "capitalist" countries; great stress moreover was laid on work in the colonial and backward areas. as Lenin expected the world revolution not to be purely proletarian,but to emerge out of an alliance of proletarian revolutionaries in the west with national revolutionaries in the east. These 21 conditions were submitted to the second world congress of the Comintern (July 1920) and there accepted. The German Independent Social-Democratic party (the pacifist left wing of the German labour movement), the French Socialist party and, as iar as possible, other Socialist parties were then split, for and against the 21 points.

The Vienna International, shattered by these divisions, was merged with the restored Second International in 1923. The Communists in many European countries, especially Germany, France, Italy, Bulgaria and Norway, had become a mass party.

Yet this favourable position could not be maintained for long. In March 1921 (only a few months after the splitting oi the German Independents), the German Communist party, by Moscow's orders. was involved in an absurd rising (interspersed with criminal acts') and collapsed amid the indignation of its own members. The French Communist party, in a slightly more protracted process. disintegrated under inner dissensions.

The Italian and Norwegian Socialist parties, originally accepted into the ranks of the Comintern without a split, were split under the 21 points soon aiter; and in both cases Moscow kept only a small fraction of its original adherents. A congress for the eastern nations, held at Baku. U.S.S.R.. in Sept. 1920 and mostly attended by Moslems. had at first seemed to hold out splendid prospects; but its effects evaporated in the unfavourable Moslem milieu almost without leaving a trace. By 1922 the Comintern found itself reduced to insignificance.

The *United* Front.— In the meantime. however, the tactics of frontal attack on western governments and Socialist parties alike had been replaced by the tactics of the United Front. endorsed by the third world congress in the middle of 1921. Under this policy any merging with the Socialist parties was to be sternly rejected, but at the same time offers of co-operation on specific points (*e.g.*, wages. taxes and the defense of democratic rights) were to be made. The Communists' suggestions were in each case framed to appear quite moderate but were in iact incompatible with the allegiance of the Socialist parties to a free democracy.

Germany became the model country for the new tactics. which were quite successful there since they involved a temporary renunciation of revolutionary verbiage and a new interest in the practical problems of working-class life. Trade-union work (also highly developed in the British Communist party) and municipal activities became the chief support of Communist propaganda, and the parties effectively adopting the new tactics again gained in membership. In the political field the tactics of the United Front led to the strengthening and radicalization of a left wing within the Social-Democratic parties (especially in central Germany) ready to co-operate with the Communists against their own party leaders. The chief drawback, at first, appeared to be that the new tactics carried disruption into the Communist parties themselves, which, while exerting pressure upon the Socialists, were now also exposed to pressure from them.

Negotiations with Socialists involved compromise. How far could a Communist go in that direction? Several parties, notably the French and the Italian, refused to apply the new tactics in earnest; in others, for example the German, a left wing grew to fight against them.

Triumph of Stalinism.— With Lenin dying. the first serious symptoms of internecine struggle within the Soviet Communist party appeared and rapidly intermingled with the antagonisms existing in the Comintern. The latter came to a head when the German Communist party, in 1923, banking on the effects of the French occupation of the Ruhr and of runaway inflation, prepared a rising which, they expected, would be supported by the left-wing Socialists. That help was refused at the last moment, the plan for a rising foundered, the Communist ministers who had joined the Socialist provincial governments of Saxony and Thuringia were ejected by the military, the party itseli was prohibited for a short period. and its influence again collapsed, dragging into limbo the prestige of the United Front tactics. The right wing of the German party was removed from leadership by the infuriated members, who replaced it with left extremists, and in Moscow every group attempted to exploit the defeat. which had shattered all hope of ending the isolation of the U.S.S.R. Zinoviev half supported the left wing, which helped him to defeat L. Trotsky; and the fifth world congress of the International, in the middle of 1924, endorsed a more extremist policy.

But Zinoviev's tactics were short-sighted, as the victorious left wing of the German and also of the French, Czechoslovakian and other Communist parties soon turned against the policy, then propounded by the rising J. V. Stalin, of "socialism in one country" —a policy that left no importance to the Comintern. Soon the left extremists turned anti-Soviet too. thus providing a splendid argument for Stalin against Zinoviev. In the summer of 1925 the German left extremists were removed from their leading positions by Moscow; in Dec. 1926 Zinoviev had to resign the presidency of the Comintern; and in 1927, when Zinoviev and Trotsky had joined hands against Stalin, almost the whole left wing was expelled in all Communist parties as "Trotskyite."

Comintern developments now ran parallel to Soviet developments. The Chinese Communist party had risen to great influence in the revolutionary Kuomintang government by tactics closely patterned on those of German communism in 1923. But the divisions between right and left. which had torn the German party, also paralyzed the Chinese. In 1927, largely through acting on orders irom Stalin (who supported the right wing), it suffered a crushing defeat. just at the time of Stalin's campaign against Trotsky and Zinoviev.

When Trotsky and Zinoviev had been expelled. however, Stalin turned against the international right wing, led by N. I. Bukharin, who had replaced Zinoviev as the Comintern's president. Bukharin had to give this position up (actually at the sixth world congress in 1928, formally in the spring of 1929) and was for a short time replaced by V. M. Molotov. The latter, however. soon ceded control to Dmitry Manuilskiy, a second-rank Bolshevik, who was appointed not president but only secretary-general. Bukharin's supporters all over the world were simultaneously expelled irom their parties, except those who, like the Italian Palmiro Togliatti and the German Gerhart Eisler, capitulated before Stalin. The Comintern was now wholly Stalinist, wholly totalitarian.

The First Five-Year-Plan.—The U.S.S.R.'s first five-year plan opened a new era of leit extremism which had to be closely copied by the Comintern. All vestiges of contact with the Socialists were now removed, the latter were denounced as "Social-Fascists," the trade unions were split and the Communists began a show of co-operation not with the Socialists but with the Nazis and other groups of the extreme right. In most countries, both west and east, these tactics almost at once reduced the Communist parties to nullity; hut in Germany, shaken as the country was by economic and political crisis, the party achieved considerable electoral successes, though far below those of the Nazis. When the Nazis came to power, the German Communists were crushed, almost

without leaving a trace of their former mass influence.

The Popular Front.—After the end of the first five-year plan a more "liberal" attitude prevailed for a short time in the U.S.S.R.; and this, combined with the failure to come to an understanding with Germany. prompted the plan to gain control over the international policy of the western democracies, beginning with France, by setting the local Communist parties on a road which would give them direct political influence. This necessitated a plausible pretense of having renounced the idea of world revolution, and this in its turn involved a return to the United Front policy of the early '20s, without any of the inhibitions, restrictions and internal feuds which had hampered it originally. Offers of co-operation were now no longer limited to the Socialists but extended also to the "bourgeois" left and centre. Thus the class struggle ceased to be the basic doctrine of international communism; and programs and slogans became strictly pragmatic, so that not infrequently the Communists appeared much more moderate than the Socialists. The bloc thus created in France was baptized the "Popular Front." The seventh and last world congress (1935) endorsed that policy and elected Georgi Dimitrov president, while Manuilskiy remained the real manager.

The basic hypocrisy of such a policy stood in the strongest possible contrast to the genuine revolutionary fanaticism of the early days and, involving an exceedingly flexible opportunist kind of manoeuvring. could only be carried out by men unquestioningly obedient to orders. Such groups of leaders of the various Communist parties were now for the first time available; the last group of convinced left extremists had been weeded out from the national leaderships in the transition from the first five-year plan to the "liberal" phase. and the remaining leaders (Maurice Thorez in France, Ernst Thalmann—until his arrest by the Gestapo—in Germany. Togliatti in Italy. etc.) were docile.

The bloc of left and centre groups formed under the Popular Front policy in France gained an ample electoral victory in June 1936 and was able to form a government. The Communists. however, who through that policy had risen from nullity to very large influence, refused to participate in the government and, from its very inception, harassed it by organizing strikes, by promoting an inflationary financial policy and by undermining the Socialist organizations. A particularly grave difficulty was created for the French Popular Front by the outbreak of the Spanish Civil War.

This war was not planned by the Communists: they were at the time quite insignificant in Spain; and any such planning would not have tallied with the long-term approach to power characteristic of the Popular Front policy. Once the war had started, however, the Communists made every effort to gain control of the Republican camp, using as a means of pressure the military help sent by the L.S.S.R.

Characteristically, once they had got hold of a large part of the police forces. they turned their efforts against the revolutionary left wing of the movement, the Anarcho-Syndicalists. left-wing Socialists and Trotskyites. whom they crushed. They played a key role in building up the new army and administration, thus securing further power; but in view of the very sharp turn to the right that simultaneously took place in the U.S.S.R. (where the "Old Guard" was exterminated) and the international complications that a Communist victory in Spain would have created, it is doubtful whether the Communists ever wanted fully to win the war. In its later stages they found themselves involved in sharp antagonisms with the moderates of the Republican camp, who resented foreign domination and a totalitarian police regime. Ultimately all other groups of that camp, together with the most important military leaders. rose against the Communists in March 1939 and enforced capitulation before Gen. Francisco Franco.

The French Communists. meanwhile, had vainly attempted to push France into direct intervention in Spain. Divergences about foreign policy and currency inflation: however, undermined the Popular Front government until, after repeated reshuffles, it collapsed in April 1938. In Nov. 1938 the Communists drove the Confédération Générale du Travail into a general strike, which failed miserably and led to the virtual collapse of the C.G.T. The Popular Front had ended in complete failure, but the French Communists had immensely enhanced their strength and influence—the first lasting success achieved by international communism.

World War II.—By this time Stalin had already lost interest in any kind of co-operation with free countries or with democratic parties and was preparing his pact with Adolf Hitler. One of the implied or, at any rate, unpublished stipulations of that pact seems to have been that the Communist parties abroad would support the Nazi cause.

This, in the case of the German Communist party in exile, went to the point of overtly anti-Semitic and almost overtly pro-Nazi propaganda, while simultaneously the British and the French Communists (the latter from underground) fiercely attacked the Allied effort in the first years of World War II. When Hitler invaded one western country after another, the Communists joined in the Nazi appeals for co-operation with the invader. Everywhere they tried to gain control of the national trade-union movement and of the largest possible section of the government machine.

That policy wore thin during the last months before Hitler's attack on the U.S.S.R. and was dramatically reversed at the moment of the Nazi invasion. The western Communists now adopted, as the Chinese under Mao Tse-tung had done since 1937, the slogan of the democratic struggle against fascism. In a repetition of the Popular Front phase, the Communists, under cover of their newly discovered "patriotism," continued trying to infiltrate governments and political parties and to undermine governments and all the non-Communist political leaderships—with, however, considerably more camouflage than ever before. These dispositions, together with the U.S.S.R.'s skilful foreign policy, undoubtedly helped to create that atmosphere of uncritical goodwill toward the Soviet regime which was a major factor in bringing about a postwar settlement very favourable to Stalin.

The main field of Communist action was, however. in territory occupied by the enemy. The Communists, almost everywhere superior to any competitors in underground organization, successfully infiltrated some of the other resistance movements (*e.g.*, in France) and defeated others in a sanguinary civil war within the war (*e.g.*, in Yugoslavia). In China they used guerrilla warfare to subdue vast territories which, at the moment of Japan's capitulation, were withheld from the recognized government's control. These tactics laid the foundations for Mao Tse-tung's later ascendancy in China and at least contributed to Tito's in Yugoslavia; and after the war it became clear that the Communists had considerably strengthened their position in France and in Italy, though in these two countries the presence of U.S. and British armies had counteracted their influence over the guerrilla warfare. In the far east, moreover, the guerrilla phase, even outside China, had greatly increased the Communists' influence and prestige.

In eastern Europe, on the other hand, the Soviet armies installed congenial governments even where no guerrilla warfare had prepared the ground.

On May 22, 1943, the Comintern, which at the beginning of the war had been removed to Ufa in the Urals, was officially dissolved. Actually, its offices continued to exert their old functions and returned to Moscow. Yet the return home of all the emigration leaders weakened the *Apparat:* in the last years of the war and in the early postwar period Moscow's control, if never absent. was weaker and more intermittent than ever before. This led to the emergence of new factions of an international character; extremists such as Tito and the Frenchman André Marty stood for immediate Communist revolution. while moderates such as Togliatti advocated a much more circuitous strategy. The extremists are supposed to have been backed by Andrei Zhdanov, second man of the Moscow Politburo, but Stalin seems to have sided with the party of caution. After attempts at direct capture of power had failed in Belgium and in Greece in 1944, the Communist parties everywhere adopted a "patriotic-democratic" line and in most continental countries joined in government coalitions.

The Corninform.—The "patriotic-democratic" policy broke down with the breakdown of co-operation between the eastern and

western powers. At a conference at Wilcza Gora in Poland in Sept. 1947, under the guidance of Zhdanov. a new official centre of international control. described as the Communist Information bureau or Cominform, was set up. Officially, it comprised only the Communist parties of the U.S.S R , of the eastern European countries and of France and Italy; in fact its jurisdiction was both farther-reaching and ampler in function than was admitted. Its formation initiated a phase of direct revolutionary aggression in many countries. The Communists everynhere left the national governments; revolutionary strikes took place in France and in Italy; in Feb 1948 a coup d'état in Prague completed the process of imposing Communist regimes on all countries originally occupied by the Soviet army: and the civil war in Greece. which had been simmering since 1946, suddenly took a grave turn. But in June 1948 the dissidence of Tito, nho had been one of the promoters of the Cominform. broke the backbone of its policy. Its offices were transferred from Belgrade, Tugos., to remote Bucharest, Rum.. and Zhdanov died in Aug. 1948. Thereafter the Cominform seemed to be confining itself to the issuing of anodyne propaganda, and Moscow's control over international communism was apparently directed from the Kremlin.

This statement, however, needs a qualification. Mao Tse-tung had risen to prominence in his own right, not, as all other Communist leaders had done, through Stalin's investiture; and it is clear that he never submitted to control of the ordinary type from Moscow. His conquest of China (1948–50) made him a world influence, and simultaneously he raised a claim to advise and control the Communist movement in all the colonial. semicolonial and backward countries. This did not eliminate Moscow's influence over any section of eastern communism, but whereas in the nest that influence was exclusive. in the east the claims of Moscow and of Peking had constantly to be adjusted behind closed doors.

In the west, on the other hand. Moscow's control was hampered by the severe internal antagonisms besetting the Kremlin leadership in the years immediately preceding Stalin's death. These antagonisms paralyzed activity and interfered with the purge of "Titoists." The sensational purge trials in Hungary, in Bulgaria and in Czechoslovakia and the less sensational purges in other Communist parties after Tito's defection may well have been connected with developments inside the Kremlin (the trial of Rudolf Slansky in Prague was clearly a signal for the anti-Semitic campaign which very shortly after resulted in the notorious case of the Jewish doctors in the U.S.S.R.). When Stalin at last died (1953). further divergences of policy seemed to be discernible among Communist parties not only in the non-Communist world but even in the U.S.S.R.'s satellite countries. (Fz. B.)

The Socialist International. — After its reconstitution the Second or Socialist International, which with the Vienna International had been merged in 1923, never again attempted to define principles for the policy of its affiliated parties within their several countries. Nonetheless, it made frequent pronouncements on international policy. backing the various peace policies between World Wars I and II. It also campaigned against the totalitarian regimes of right and left. With Hitler's victories in Europe its organization collapsed. Afterward it was reconstituted by gradual stages. The first meeting of Socialist parties, held in England in 1946, set up a Socialist information and liaison office. To this was added a consultative committee, which in 1947 developed into the Committee of the International Socialist Conference, or Comisco, comprising one representative of each member party. This organization. consisting of Comisco and periodic conferences but usually referred to simply as Comisco, continued until 1951, u-hen it was decided to reconstitute the Socialist International.

The rehirth took place at the eighth postwar international Socialist conference, held at Frankfurt-on-Main. Ger., in July 1951. A declaration of the "Aims and Tasks of Democratic Socialism" was adopted. together with a statute of the International which determined the structure of the organization. The main structure consisted of three institutions: congress. council and bureau. All member parties and associated organizations were to be represented at the congress. which should meet at least once every two years. Each member party might send six delegates to the congress, but each delegation had only one vote. In addition to making political decisions. the congress was empowered to amend the constitution of the International and to decide upon the admission or expulsion of members. This power to determine its membership was the only sanction at the International's disposal.

The council was to be as representative as the congress but a smaller body, the number of delegates being limited to two from each party. It was to meet two or three times a year and had the power to take political decisions. In both the council and the congress every effort was to be made to reach unanimity. Decisions taken by a majority vote were not binding on, the minority. Each member party of the International was to retain its autonomy. The International was thus not a supreme authority but an instrument of co-operation between Socialist parties.

The bureau was to be a small body of 12 members, which could not be fully representative of the International's membership. Its functions were therefore administrative. It was to arrange the meetings of other organs of the International and to supervise the work of the permanent secretariat in London.

Directly associated with the Socialist International mere the International Socialist \Vomen's secretariat, the International Union of Socialist Youth and the Socialist Union of Central-Eastern Europe (composed of Socialist parties in exile). all represented at meetings of congress and council with the right to speak but not to vote. A press centre established in Paris served as an agency for Socialist newspapers and convened a number of experts' conferences to examine general problems requiring specialist knowledge, such as industrial democracy or policy for the underdeveloped areas of the world.

The general rule was that there should be one vote from each country. but an exception was made for Japan. where the Socialist party split after its admission to the International. In 195j the International comprised Socialist, Social-Democratic or Labour parties from Argentina, Austria, Belgium. Bulgaria (exiles), Canada, Czechoslovakia (exiles), Denmark, Estonia (exiles), Finland. France. Germany. Great Britain. Greece, Hungary (exiles). Iceland. India. Israel, Italy, Jamaica. Japan, Latvia (exiles), Lithuania (exiles). Luxembourg, Malaya, the Netherlands. New Zealand, Norway, Poland (exiles), the Saar, Spain (exiles). Sweden. Switzerland. Trieste. the United States of America (non-voting observers), Uruguay and Yugoslavia (exiles), as well as the International Jewish Labour Bund and the World Union of Zionist Socialist Parties. In Jan. 1953 at Rangoon an Asian Socialist conference was formed, on the model of the old Comisco. comprising parties from Burma, India. Indonesia, Israel. Japan. Lebanon, Malaya and Pakistan. (S. RE.)

INTERNATIONAL BANK FOR RECONSTRUCTION AND DEVELOPMENT: see INTERNATIONAL MONETARY FUND; BANK FOR RECONSTRUCTION AND DEVELOPMENT, INTERNATIONAL.

INTERNATIONAL CHAMBER OF COMMERCE. A world forum of private enterprise, the I.C.C. was founded in 1919 by business leaders from Belgium, France, Italy, the U.K. and the C.S. The organization works for world trade expansion through advocacy of broad international economic policies, reduction of trade barriers and provisions for a central clearinghouse for the exchange of views among businessmen.

The I.C.C. engaged in the economic work of the League of Nations and in 1946 was granted the highest consultative status with the Economic and Social council of the United Nations. Permanent liaison with the United Nations was established through the international headquarters at Paris. Fr., and its special offices in New York, N.Y., and Geneva, Switz. Permanent contact also is maintained with numerous other international organizations.

The congress. or general assemhly of members, which determines the general policy of the I.C.C.. meets biennially in a major world city. Congresses have been held in Paris, Lisbon, London, Vienna. Washington and other world centres. The governing body is the council on which each national committee is represented. Usually the council meets in Paris two or three times a year. In the interval between council meetings, the president,

elected for a two-year term, has the advice of an executive committee The secretary-general heads the international secretariat, which includes specialists in leading fields of business and international relations. National committees are the essential links between international headquarters and domestic business communities.

The range of work of the I.C.C. falls into four broad categories: (1) economic and financial policy; (2) transport and communications; (3) production. distribution and advertising; (4) law and commercial practice. Major objectives in the 1950s included a campaign for return to currency convertibility; a code of fair treatment for private foreign investments; elimination of double taxation; co-ordination of transport; simplification of trade formalities; statements on tariff policy; a convention on the enforcement of international arbitration awards; a code of standards of advertising practice; and similar matters. From 1923 the I.C.C. maintained a court of arbitration which provided an inexpensive and quick method for settlement of disputes which might arise among businessmen in connection with commercial transactions.

In 1954 membership extended into 57 countries, of which 30 had organized national committees in five continents. (R M. LI.)

INTERNATIONAL CIVIL AVIATION ORGANIZATION. The ICAO was established by the Chicago Convention on International Civil Aviation in 1944 to foster development of safe, regular and efficient international civil aviation. The principal body of the organization is the assembly, meeting annually until 1956 and thereafter at longer intervals. A permanent council of 21 contracting states is elected by the assembly every three years. Subordinate to the council were the Air Navigation commission (12 technical experts nominated by states); the Air Transport committee and the Joint Support committee (limited membership from council-member states); and the Legal committee (open to all contracting states). The headquarters of the permanent bodies and secretariat were established in Montreal, Can., with five regional offices in Bangkok, Thailand, Cairo, Egy., Lima, Peru, Mexico City and Paris.

Technical activities of the ICAO comprise establishment of regional plans giving details of specific facilities and services required in each region; and of international technical specifications related to airports, air traffic, telecommunications, meteorology, charts, operations, airworthiness and personnel. Such plans and specifications originate in regional and technical meetings, convened from time to time, whose recommendations are reviewed by the Air Navigation commission and approved by the council.

Economic activities channeled through the Air Transport committee include studies and recommendations concerning international airmail; exchange of commercial rights in air transportation: charges for airports and air-route facilities; publication of statistical data; and establishment of specifications on facilitation of air transport (simplification of forms and procedure for immigration, customs, health and quarantine). Joint-support activities of the ICAO relate to agreements for joint financing of ground or water facilities (such as North Atlantic Ocean Station vessels) by member states. See also AERIAL LAW. (WR. B.)

INTERNATIONAL COURT OF JUSTICE, the principal judicial organ of the United Nations. which succeeded the Permanent Court of International Justice after World War II. For generations eminent statesmen, private persons and various organizations — national and international — have devoted much time and energy to efforts looking to the peaceful settlement of disputes between nations. Various methods of settlement have been advocated and at times resorted to. such as the use of good offices by other states, commissions of inquiry and conciliation, arbitration and judicial settlement.

Arbitration as a form of judicial settlement has been used by states over a long period of time — not generally but frequently. Many bilateral and a number of multilateral treaties and conventions providing for arbitration have been concluded from time to time, some relating to then-existing disputes and others relating to disputes or categories of disputes which might arise in the future. Of the multilateral conventions providing for arbitration those which stand out are the Conventions for the Pacific Settlement of International Disputes concluded at the first and second peace conferences held at The Hague in 1899 and 1907. The convention of 1899 contains provisions on the use of good offices and mediation. international commissions of inquiry and elaborate provisions designed to regularize arbitral procedure. It also provides for the establishment by the signatories of a panel of jurists called the Permanent Court of Arbitration (although in no sense a court) to which each state, party to the convention, should appoint four members, and from which governments desiring to arbitrate might choose competent arbitrators.

Although many international arbitrations both before and following the Hague conventions constitute landmarks in the process of peaceful settlement of disputes, and the tribunals in such cases made notable contributions to an international jurisprudence, it was recognized that with all its virtues a system in which reliance is placed on ad *hoc* tribunals, as distinguished from an established court of justice. was not all that might be desired. The situation, as visualized by him. was epitomized by Elihu Root, the U.S. secretary of state, who, in instructions to the U.S. delegation to the second Hague conference, observed that the principal objection to arbitration rested not upon the unwillingness of nations to submit their controversies to impartial arbitration, but upon an apprehension that the arbitrators would not be impartial. He instructed the delegates to try to have the Permanent Court of Arbitration developed into a permanent tribunal composed of judges "who are judicial officers and nothing else, who are paid adequate salaries, who have no other occupation and who will devote their entire time to the trial and decision of international causes by judicial methods and under a sense of judicial responsibility."

The 1899 convention was revised, but as revised it fell far short of the pattern outlined by Root. It did not provide for judges "who are judicial officers and nothing else" and who would "devote their entire time to the trial and decision of international causes." Rather it continued the system of a panel of jurists from which arbitrators might or might not be chosen for particular cases.

However, the 1907 conference prepared and recommended to the powers represented at the conference a draft convention to establish a court of arbitral justice composed of judges to be elected for fixed periods of service and on a salary basis. But the project was not adopted by the states and the court was never established. Xevertheless the draft had its influence on subsequent developments.

Permanent Court of International **Justice.**—The next notable step in the process of developing an international judiciary was taken by the League of Nations in 1920, when, pursuant to article 14 of the covenant of the League, it took steps to establish the Permanent Court of International Justice.

Article 14 provided:

> The Council shall formulate and submit to the Members of the League for adoption plans for the establishment of a Permanent Court of International Justicc. The Court shall be competent to hear and determine any dispute of an international character which the Parties thereto submit to it. The Court may also give an advisory opinion upon any dispute or question referred to it by the Council or by the Assembly.

In Feb. 1920, the council appointed a committee of jurists to prepare a plan which it could submit to members of the League for adoption. The members of the committee were: Mineitciro Adatci (Japan), Rafael Altamira Y Crevea (Spain), Raoul Fernandes (Brazil), Baron E. E. F. Descamps (Belgium), G. F. Hagerup (Norway), Albert Geouffre de la Pradelle (France), B. C. J. Loder (Netherlands). Lord Phillimore (United Kingdom), A. Ricci-Busatti (Italy) and Sen. Elihu Root accompanied by James Brown Scott (United States).

The committee, following meetings at The Hague in June and July of that year, submitted to the council a draft scheme which, with certain modifications. was adopted by the council, and with still further amendments was approved by the assembly on Dec. 13, 1920. The text was attached to a protocol of Dec. 16, 1920, for signature and ratification by the members of the League.

By Sept. 1921, the requisite number of states, a majority, had given their approval and the draft became the statute of the Permanent Court of International Justice.

The statute prescribed the qualifications for the judges, the method of election and tenure of office, the court's jurisdiction, its mode of procedure, etc. The first court. consisting of 11 judges and 4 deputy judges, was elected by the council and the assembly on Sept. 14–16, 1921. Later, in 1930, the assembly elected 15 judges and 4 deputy judges. Still later, following the coming into force in 1936 of amendments to the statute, the deputy judges were eliminated and the court was composed of 15 judges elected as theretofore by the council and the assembly.

The court held its first meeting at The Hague. its seat, on Jan. 30, 1922 It held annual meetings thereafter until its work was interrupted by World War II. Its last meeting, an administrative one, was in Oct. 1945.

During its existence it rendered 23 judgments and gave 27 advisory opinions. The court was open to members of the League and also to states mentioned in the annex to the covenant. The conditions under which it should be open to still other states were to be laid down by the council. Acceptance of the jurisdiction of the court was not compulsory. States were free to bring their disputes to the court or not as they might see fit. However, they were privileged, under the optional clause of article 36 of the statute, to declare, either when signing or ratifying the protocol to which the statute was adjoined, or at a later moment, that they recognized as compulsory ***ipso facto*** and without special agreement, in relation to any other state accepting the same obligation, the jurisdiction of the court in any or all of certain specified categories of disputes. Such declarations might be made unconditionally or on condition of reciprocity on the part of several or certain states or for a certain time. During the existence of the court some 29 states accepted the compulsory jurisdiction in varying forms and for varying periods of time. During this same period 47 states signed the protocol of 1920, to which the statute was annexed, and all but 8 ratified it.

The United States did not become a party to the statute of the Permanent court, although efforts to have it do so were made in turn by Secretaries of State Charles E. Hughes, Frank B. Kellogg and Henry L. Stimson, supported by Presidents Warren G. Harding and Herbert Hoover, as well as by many private citizens who felt that such a tribunal held great potentialities for peaceful settlement of international disputes. A senate resolution for adherence that came to a vote on Jan. 29, 1935, failed to obtain the requisite two-thirds vote, and no further action to have the United States become a party to the statute was taken. Yet throughout the period of the court a U.S. jurist was on the bench.

Judges of the Permanent Court.—During its existence, the court had on the bench the following named judges who served respectively for the periods indicated:

Rafael Altamira (Spain), 1922–45
Dionisio Anzilotti (Italy), 1922–45
Ruy Barbosa (Brazil), 1922–23
A. Sánchez de Bustamante (Cuba), 1922–45
Viscount Finlay (United Kingdom), 1922–29
Hans Max Huber (Switzerland), 1922–30
B. C. J. Loder (Netherlands), 1922–30
Mineitciro Adatci (Japan), 1931–34
W. J. M. van Eysinga (etherlands), 1931–4j
T. G. Guerrero (El Salvador), 1931–45
Demétre Negulescu (Rumania), 1931–45
E. Rolin Jacquemyns (Belgium), 1931–36
Michal Rostworowski (Poland), 1931–40
Walter Schiicking (Germany), 1931–35
John B. Moore (United States), D. G. G. Nyholm (Denmark), 1922–30
Yorozu Oda (Japan), 1922–30
C. A. Weiss (France), 1922–28
E. da Silva Pessôa (Brazil), 1923–30
Charles E. Hughes (U.S.), 1928–30
Henri Fromageot (France), 1929–45
Sir Cecil Hurst (U.K.), 1929–45
Frank B. Kellogg (U.S.), 1930–35
F. J. Urrutia (Colombia), 1931–42
Charles De Visscher (Belgium), 1937–45
Wang Chung-hui (China), 1931–36
Åke Hammarskjöld (Sweden), 1936–37
Manley O. Hudson (U.S.), 1936–45
Harukazu Nagaoka (Japan), 1935–42
Cheng Tien-hsi (China), 1936–45
R. W. Erich (Finland), 1938–45

The deputy-judges were:

F. V. N. Beichmann (Norway), 1922–30
Demétre Negulcscu (Rumania), 1922–30
Wang Chung-hui (China), 1922–30
Mihailo Yovanovich (Yugoslavia), 1922–30
R. W. Erich (Finland), 1930–36
J. Caeiro da Matta (Portugal), 1930–36
Mileta Novakovich (Yugoslavia), 1930 36
Josef Redlich (Austria), 1930–36

The court was authorized by the statute to elect its president and vice-president for three years. The presidents were: Loder (Netherlands), 1922–24; Huber (Switzerland), 1925–27; Anzilotti (Italy), 1928–30; Adatci (Japan), 1931–33; Sir Cecil Hurst (U.R.), 1934–36; Guerrero (El Salvador). 1937–45. The vice-presidents were: Weiss (France), 1922–28; Huber (Switzerland) 1928–30; Guerrero (El Salvador), 1931–36; Sir Cecil Hurst (U.K.), 1937–45.

Establishment **of** International Court of Justice.—Following World War II and the advent of the United Nations, the League of Nations mas dissolved and with it the Permanent Court of International Justice. But that court was not dissolved until the new one—the International Court of Justice—had been established. By this time the nations, including the United States, were thoroughly convinced that a court of justice must have first rank in any organization for the maintenance of peace. This explains why the court was featured in the charter of the United Nations and why the statute was unanimously approved by the U.S. senate. Article 92 of the charter states:

The International Court of Justice shall be the principal judicial organ of the United Nations. It shall function in accordance with the annexed Statute, which is based upon the Statute of the Permanent Court of International Justice and forms an integral part of the present Charter.

Article 93 states that all members of the United Nations are ***ipso facto*** parties to the statute and states not members may become parties on conditions to be determined in each case by the UN general assembly upon recommendation of the Security council. The court consists of 1j judges, no two of whom may be nationals of the same state, elected by the general assembly and the Security council. They do not have life tenure as do members of the supreme court of the United States, for example, but are elected for periods of nine years and are eligible for re-election.

The seat of the court is at The Hague, but it may hold sessions elsewhere whenever it considers it desirable. Its first session was held at The Hague in April and May 1946.

It is a continuing body. The statute provides that it shall remain permanently in session, except during judicial vacations. It is also an autonomous body. It elects its president and vice-president, appoints its registrar and provides for the appointment of such other officers and clerical staff as may be necessary. The president and the registrar are required to reside at The Hague.

The Judges.—The judges, who must possess certain specified qualifications, do not represent the states from which they are chosen. They represent the entire international community of states. They are not selected by the governments of their states or even nominated by them; they are nominated rather by the national groups in the Permanent Court of Arbitration referred to above, or. in the case of states not represented on the Permanent Court of Arbitration, by national groups appointed for that purpose by their governments, the purpose being to remove the nominations as far as possible from political considerations.

Comparable safeguards were placed around the election of the judges. The statute provides that in such elections the general assembly and the Security council shall proceed independently of each other, and that at every election the electors should bear in mind not only that the persons to be elected shall individually possess the qualifications required "but also that in the body as a whole the representation of the main forms of civilization and of the principal legal systems of the world should be assured." Those candidates who obtain an absolute majority of votes in both the general assembly and the Security council are to be considered as elected. Further procedure is provided for the situation where, after the first meeting for the purpose of the election, one or more seats remain to be filled.

The judges receive annual salaries reasonably commensurate with their status. But they must be prepared to accept certain inhibitions; *i.e.*, they must refrain from all activities incompatible with their judicial functions. Specifically, they are forbidden to exercise any political or administrative function, or to engage in any other occupation of a professional nature; they are not permitted to act as agent. counsel or advocate in any case, and no member may participate in the decision of a case in which he has previously taken part as agent, counsel or advocate for one of the parties, or as a member of a national or international court, or a commission of inquiry, "or in any other capacity."

The purpose of the statute is to have at all times a court that is entirely free from bias or any preconceived notion as to the merits of any case coming before it. Each member is required, before taking up his duties, to "make a solemn declaration in open Court that he will exercise his po ers impartially and conscientiously." In order to facilitate the proper exercise of their judicial functions the members, when engaged on the business of the court, enjoy diplomatic privileges and immunities. Members are bound to hold themselves permanently at the disposal of the court.

While nine judges constitute a quorum, the statute requires that the full court shall sit except when it is expressly provided otherwise. The court may dispense with the sitting of one or more judges "according to circumstances and in rotation," provided the number of available judges is not thereby reduced below 11. In practice, the full court sits in all cases except where a judge is disqualified by reason of some previous connection with the case or is prevented by illness or other serious reasons from attending.

No judge may be dismissed unless in the opinion of all the others he has ceased to fulfill the required conditions.

Vacancies resulting from death or otherwise must be filled by the same method as that laid don-n for the first election. A member elected to replace a member whose term of office has not expired holds office for the remainder of his predecessor's term.

Obviously, since there are only 15 judges. cases are sometimes presented by states which have no national on the court. While the statute provides that judges of the nationality of each of the parties retain their right to sit in the case before the court, it also provides that, if the court includes upon the bench a judge of the nationality of one of the parties, the other party may choose a person to sit as judge; also that if the court includes upon the bench no judge of the nationality of either party each of the parties may choose a person to sit as judge. This privilege is frequently exercised. *Ad hoc* judges receive compensation for each day on which they exercise their functions.

Competence. — Since the function of the court is to pass judgment upon disputes between states, only states may be parties in cases before the court. It is open to all states parties to the statute and to such other states as comply with conditions laid down by the Security council, which conditions must not, in any case, place the parties in a position of inequality before the court.

At the time that the statute was being drafted, there was strong sentiment on the part of certain states, particularly the smaller ones. for giving the court compulsory jurisdiction; *i.e.*, making it possible for any state to bring an action against any other state without the latter's consent. This, it was argued, was warranted by the more than 20 years of satisfactory experience with the Permanent court. The opponents of this view felt that some states were not yet ready to accept compulsory jurisdiction, and that to try to force it upon them might cause them to decline to accept the statute at all. They favoured the adoption of the optional provisions in article *36* of the statute of the Permanent court. This was agreed upon, and that article became article *36* of the new statute. Under it parties to the statute may at any time file with the secretary-general of the United Nations a declaration accepting compulsory jurisdiction. A large number of states have done so.

The declaration mentioned may be made unconditionally or on condition of reciprocity on the part of other states, or for a certain time.

It was further provided in article 36 (paragraph *5)* that declarations made under the old statute conferring jurisdiction on the Permanent court which were still in force should be deemed, as between the parties to the new statute, to be acceptances of the compulsory jurisdiction of the new court.

The Anglo-Iranian Oil company case *(Great Britain* v. *Iran)* involved a declaration by Iran in 1933 under article *36* of the statute of the Permanent court. Although the court held that it did not have jurisdiction, it was only because it found that the declaration did not cover that particular case (judgment. July *22,* 1952; I.C.J. Reports [1952] p. *93).*

The court's jurisdiction was still further extended by article 37 of the statute, which stipulates that whenever a treaty or convention in force "provides for reference of a matter to . . . the Permanent Court of International Justice, the matter shall, as between the parties to the present Statute, be referred to the International Court of Justice."

The advisory opinion given July 11, 1950 (I.C.J. Reports [1950] p. *128).* on the international status of South-West Africa, and the judgment rendered July *1,* 1952, in the Ambatielos case *(Greece* v. *Great Britain; ibid.* [1952] p. *28)* are examples involving article 37 of the statute.

States which have not accepted compulsory jurisdiction may not be sued without their consent. A state may give its consent by entering into an agreement with another state or otherwise indicating its willingness to submit the dispute to the court, *See* the judgment of March *25, 1948,* in the Corfu channel case *(Great Britain* v. *Albania; ibid.* [1948] p. 15).

In 1954, the United States filed with the court two applications instituting proceedings against the Soviet Union and Hungary, respectively, and in 1955 like action was taken against Czechoslovakia and the Soviet Union, respectively, each complaint relating to certain aircraft incidents; also in 1955 Great Britain filed two applications instituting proceedings against Argentina and Chile, respectively, concerning sovereign rights in the antarctic. None of the defendant states had accepted compulsory jurisdiction, and on being informed of these actions by the registrar of the court, each in turn specifically declined to submit the dispute to the court. In consequence, the court was under the necessity of issuing orders removing the cases from its list.

The statute declares it to be the duty of the court to decide disputes in accordance with international law. It applies: *(1)* international conventions establishing rules recognized by the contesting states; *(2)* international custom, as evidence of a general practice accepted as law; *(3)* the general principles of law recognized by civilized nations; and *(4)* it may look to judicial decisions and the teachings of the most highly qualified publicists of the various nations as subsidiary means for determining rules of law. It may also decide cases *ex aequo et bono* (that is to say, on the basis of equity), if the parties agree. In the absence of such an agreement it must apply rules of law.

Procedure. — The official languages of the court are French and English; either may be used by the parties. Written pleadings and oral arguments presented in one language are translated by the court's staff into the other. The judgments and opinions are in both languages.

Cases are brought before the court either by the notification to it of a special agreement concluded by the parties or by the unilateral action of one of them through a written application addressed to the registrar. The proceedings are in two parts, written and oral. The written proceedings usually consist of two pleadings on each side and supporting documents. Oral arguments by counsel follow the written proceedings.

The court may also hear witnesses and appoint commissions of experts to make investigations and reports when necessary. Both these procedures were followed in the Corfu channel case *(Great Britain* v. *Albania)* decided April *9,* 1949.

The deliberations of the court are in private, but the judgments, which are by a majority vote, are read in open court. Any judge may file a separate opinion if he does not agree in whole or in part with the decision. Few decisions represent the unanimous opinion of the judges. The judgment is final and without appeal.

The question is frequently asked as to how decisions of the

court are enforced. This also troubled the minds of some of the delegates at the United Nations Conference on International Organization, held at San Francisco, Calif., when the statute was under consideration. To meet their wishes there was incorporated in article 94 of the charter an undertaking on the part of each member of the United Nations "to comply with the decision of the . . . Court . . . in any case to which it is a party," and a further provision that:

If any party to a case fails to perform the obligations incumbent upon it under a judgment rendered by the Court, the other party map have recourse to the Security Council, which may, if it deems necessary, make recommendations or decide upon measures to be taken to give effect to the judgment.

It should be remarked, however, that by the late 1950s there had been no known instance of the failure of a party to a case before the court, or before its predecessor, the Permanent Court of International Justice, to carry out a decision of either court. In the case of the Anglo-Iranian Oil company, *supra,* Iran declined to observe an order issued by the court, July j, 1951, under article 41 of the statute, indicating interim measures of protection to be taken by the parties pending final decision. But this is not to be regarded as an exceptisn to what has just been stated since such orders do not amount to judgments. They merely indicate provisional measures which the court considers ought to be taken to preserve the rights of the parties.

Advisory Opinions.— The court is authorized by article 65 of the statute to give advisory opinions on any legal questions at the request of whatever body may be authorized by or in accordance with the charter of the UN to make such a request.

Article 96 of the charter provides that such opinions may be requested by the general assembly or the Security council; also that they may be requested by other organs of the United Nations and specialized agencies, when authorized by the general assembly. Such requests must be laid before the court by means of a written request containing an exact statement of the questions, accompanied by all documents likely to throw light upon them. From this point on, the procedure before the court is somewhat analogous to that followed in contentious cases; that is to say, the registrar gives notice of the request to all states entitled to appear before the court, and the court or the president of the court fixes time limits within which the states wishing to do so may submit written statements or be heard orally at a public sitting to be held for the purpose. States and organizations presenting written or oral statements are allowed, within a specified time, to comment on those submitted by others.

Advisory opinions, like judgments, are delivered in open court.

Article 13 of the statute provides that the members of the court shall be elected for nine years and may be re-elected, but in order to avoid the necessity of electing an entirely new court at the end of each nine-year period and to ensure that there shall be on the bench at all times a majority of experienced judges, it was further provided that of the judges elected at the first election, the terms of five should expire at the end of three years and the terms of five more should expire at the end of six years; also that the judges whose terms were to expire at the end of the said periods of three and six years should be chosen by lot to be drawn by the secretary-general of the United Nations immediately after the first election had been completed.

The first election was held on Feb. 6, 1946, at the London meeting of the general assembly and the Security council. Fifteen judges were elected.

The procedure provided in article 13 was applied and five judges drew three-year terms and five others drew six-year terms.

On its 12th anniversary (Feb. 6, 1958) the court was constituted as follows:

Green H. Hackworth (United States), president
Abd-el-Hamid Badawi (Egypt), vice-president
J. G. Guerrero (El Salvador)
Jules Basdevant (France)
Bohdan Winiarski (Poland)
Helge Klaestad (Norway)
E. C. Armand-Ugon (Uruguay)
Feodor I. Kozhevnikov (U.S.S.R.)
Muhammad Zafrulla Khan (Pakistan)
Sir Hersch Lauterpacht (United Kingdom)
L. M. Moreno Quintana (Argentina)
Roberto Córdova (Mexico)
V. K. Wellington Koo (China)
Ioannis Spiropoulos (Greece)
Sir Percy Spender (Australia)

Former presidents and vice-presidents were: Guerrero and Basdevant (1946–49); Basdevant and Guerrero (1949–52); Sir Arnold McNair and Guerrero (1952–55).

Former members were:

Alejandro Alvarez (Chile), 1946–55
Isidro Fabela (Mexico), 1946–52
Milovan Zoričić (Yugoslavia), 1946–58
Charles De Visscher (Belgium), 1946–52
Sir Arnold McNair (United Kingdom), 1946–55
Sergei B. Krylov (U.S.S.R.), 1946–52
John Erskine Read (Canada), 1946–58
Hsu Mo (China), 1946–56
José Philadelpho de Barros e Azevedo (Brazil), 1946–51
Levi Carneiro (Brazil), 1951–55
Benegal Rau (India), 1952–53
Sergei A. Golunski (U.S.S.R.), 1952–53

INTERNATIONAL FINANCE CORPORATION, an international investment institution, closely affiliated with the World bank (*see* BANK FOR RECONSTRUCTION AND DEVELOPMENT, INTERNATIONAL) was founded in July 1956. Its purpose was to further economic development in its member countries by investing, without government guarantee, in productive private enterprises in association with private capital and management.

Membership was opened to all members of the World bank and by the early 1960s the corporation capital amounted to nearly $1,000,000,000. The corporation's investments in more than 25 projects throughout the world, particularly in Central and South America and Asia, covered a wide range of industrial activities including manufacturing, milling, mining, smelting and refining.

INTERNATIONAL GEOPHYSICAL YEAR, commonly known as IGY, is the designation of the 18-month period July 1, 1957–Dec. 31, 1958, during which an intensified program of geophysical research was conducted throughout the world. The magnitude of the effort is suggested by the fact that it included: co-operation among more than 70 nations, participation by several thousand scientists and observers and operation of several thousand scientific stations reaching from pole to pole.

The IGY was directed toward a systematic study of the planet earth and its cosmic environment. Even as a single planetary body, the earth is far from static. Earthquakes, large and small, subject it to noticeable stresses and strains, and not only the oceans and seas but the land itself is subject to tidal pulls. Moreover, the processes at its surface are in continual flux. Energized by the sun's heat, water passes from the solid state in glaciers and snow fields to a liquid form in seas and rivers and then becomes a vapour in the atmosphere. Great atmospheric and oceanographic circulation systems transport heat energy between the tropics and the high latitudes, equalizing the energy balance of the earth: the tropics receive more energy from the sun than can be reradiated, while the polar regions radiate to space more energy than received directly from the sun.

The sun plays a critical role in the events associated with weather and climate, for it serves as the driving engine of the winds and currents in the seas and the atmosphere. But the sun also plays a dominant role in the upper atmosphere, the region from 20 to some thousand or so miles above the earth. Invisible particles and radiations stream to the earth, affecting the ionosphere and the earth's magnetic field and causing the brilliant northern and southern lights. Many of these particles and radiations come from the sun; some of them, including most cosmic rays and radio naves. come from the vast stretches of interplanetary space and distant stars and nebulae. The earth is thus an integral part of the universe whose forces, particles and radiations establish the conditions of human life and activity. These conditions are dynamic in nature as events vary in the universe and as the earth rotates about its axis. moves about the sun and is carried with the solar system in a vast trajectory about the centre of our galaxy.

To understand these phenomena and processes better, to obtain thereby a better mastery of man's planetary environment and to gain new insights into the nature of the cosmos, world-wide ob-

servations and measurements are needed. The IGY included 11 fields of geophysics: aurora and airglow, cosmic rays. geomagnetism, glaciology, gravity, ionospheric physics, longitude and latitude, meteorology, oceanography, seismology and solar activity. Each of these fields is planetary in nature and some are interplanetary. Each field requires measurement at many points on or above the earth's surface if a relatively complete view of the field is to be obtained, and because many of the fields are interrelated. simultaneous studies permit the establishment of correlations and relationships among the many phenomena and processes. Because no one nation could undertake so extensive an effort nor overcome problems of national boundaries, the IGY was necessarily a cooperative effort among scientists of many nations.

History and Organization.— The idea of international cooperation in geophysical investigations is not new, for the IGY had two antecedents in the polar years of 1882–83 and 1932–33. Both of these endeavours were largely concerned with studies of the high northern latitudes. During the first International Polar year 12 stations were established by 11 nations in the arctic for studies of surface weather conditions. geomagnetism and the aurora borealis. Perhaps the most significant result of this effort was the mapping of the auroral lights, which showed that these lights occurred most often and vividly in a circular belt about the north magnetic pole and some 1,200 mi. below it. The success of the first International Polar year led to an expanded effort 50 years later during the second International Polar year. Some 20 nations organized expeditions, and the number of observation stations in the northern latitudes was considerably increased. For example, about 90 meteorological stations were available in the arctic and 30 geomagnetic stations in latitudes above 60° N. In addition to the three fields investigated in the first International Polar year, studies of ionospheric physics were included in the second International Polar year. Using a device then relatively new, which transmitted short pulses of radio energy to the ionosphere and received the reflected signals, physicists gained new insight into the behaviour of the electrified layers between 40 and 200 mi. above the earth. Another new instrument at that time was the radiosonde, a balloon-borne instrument for measurements of pressure, temperature and humidity, which transmits its data to ground by radio. Appreciable advances were made, using radiosondes, in the understanding of arctic weather and its relationship to weather in lower latitudes.

The impetus behind the IGY had several sources. aside from the examples of the two polar years. Advances in instrumentation during the three decades following the second International Polar year had made possible sensitive and quantitative measurements. High-altitude balloons extended the range of radiosondes to some 100,000 ft. and special balloons could carry cosmic ray instruments even higher. Rockets were successfully used in the decade following World War II for direct exploration of the atmosphere up to heights of 250 mi. Automatic high-speed computers, capable of analyzing the vast quantities of data that characterize most of the fields of geophysics, were becoming available. These and many similar devices suggested that considerable progress could be made in studying geophysics on a broad basis. As early as 1950 informal discussions were held by geophysicists looking to a third polar year. Proposals to this effect were considered by two international scientific organizations: the International Scientific Radio union and the International Union of Geodesy and Geophysics.

In view of the instrumentation advances, the existence of some good networks of stations, as in meteorology, geomagnetism and ionospheric physics, and the increased recognition of the planetary nature of geophysical problems, the proposal for a third polar year was broadened to encompass the whole earth and its cosmic environs. Accordingly, the parent body of international scientific organizations—the International Council of Scientific Unions—sanctioned the broader study of the International Geophysical year and established a special committee (Comité Spécial de l'Année Géophysique Internationale) for the IGY consisting of scientific representation from the unions concerned with ionospheric and radio physics, astronomy, geodesy and geophysics, physics and geography, and the World Meteorological organization. The officers of this committee were Sydney Chapman (president), L. V. Berkner (vice-president) and Marcel Nicolet (secretary-general). The first meeting of the special committee, commonly known by its abbreviation as CSAGI, took place in Brussels. Belg., in July 1953 and was followed by a series of general assemblies and regional conferences. At the general assemblies in particular, the criteria for the IGY program were established by scientific delegates from all parts of the world.

The criteria were essentially four in number. First. fields of geophysics were to be studied where data were needed from many points on or above the surface of the earth in order to get a planetary view of a particular field—for example, meteorology, geomagnetism and ionospheric studies. Second, special projects were to be undertaken which would yield results of value to the former studies, such as rocket exploration of the upper atmosphere. Third, advantage would be taken of expeditions to remote places to conduct studies in other fields. In large part seismology and gravity measurements mere introduced into the program to capitalize upon opportunities opened up by the IGY in the antarctic, the arctic basin and at sea. Finally, epochal measurements were to be made for posterity. Such measurements, as of snow and ice in glaciers, repeated at intervals over many years, could indicate long-range trends in climate.

Within each country the pattern of planning and operations developed on somewhat similar lines. National committees were established by scientific organizations to plan, direct and execute their contributions to the over-all effort, and these groups solicited support from their governments and private institutions. In Great Britain, for example, the Royal society established an appropriate committee of experts. In the United States, the National Academy of Sciences assumed responsibilities for the United States effort, which received contributions from many public and private organizations, including the National Science foundation (through which congress appropriated $43,500,000 by Dec. 31, 1958, for research aspects) and the department of defense (which contributed extensive logistics and technical support, particularly in arctic, antarctic, rocket and satellite operations).

More than 70 nations co-operated in the IGY; 66 national groups were formal participants: Argentina, Australia, Austria, Belgium, Bolivia, Brazil, Bulgaria, Burma, Canada, Ceylon, Chile, China (Taipei), Colombia. Cuba, Czechoslovakia, Denmark, Dominican Republic, East Africa, Ecuador, Egypt, Ethiopia, Finland, France, German Democratic Republic, German Federal Republic, Ghana, Greece, Guatemala, Hungary, Iceland, India, Indonesia, Iran, Ireland, Israel, Italy, Japan, Democratic Republic of Korea, Malaya, Mexico, Mongolian Peoples Republic, Morocco. Netherlands, New Zealand, Norway, Pakistan, Panamá, Peru, Philippines, Poland, Portugal, Southern Rhodesia, Rumania, Spain, Sweden, Switzerland, Tunisia, Union of South Africa, Union of Soviet Socialist Republics, United Kingdom, United States, Uruguay, Venezuela, Democratic Republic of Vietnam, Republic of Vietnam, Yugoslavia. The committees in these nations were responsible for the operation of more than 2,500 major scientific stations as well as several thousand small or temporary stations and the participation of 10,000 scientists and technicians as well as several thousands of amateur and volunteer observers in such programs as satellite tracking, visual auroral observations and radio-wave propagation studies. It is estimated that the IGY research effort cost about $500,000,000.

IGY measurements and observations fall into three major categories: (1) physics of the upper atmosphere, which includes solar activity, and particles and radiations from the sun, other stars and the interplanetary medium; (2) the heat and water regimen, which includes meteorology, oceanography and glaciology; and (3) the earth's structure and interior, which includes seismic, gravimetric, and longitude and latitude determinations. While rockets and satellites represented appreciable efforts, they are not fields of geophysics but are powerful tools for placing instruments in space. In addition to these areas, some work in biology, environmental medicine and geology was conducted in the arctic and antarctic.

Particularly in the first two categories, measurements and observations were conducted on regular, daily schedules. Here the influence of the sun is often at play. Because the IGY period was chosen to coincide with the maximum sunspot cycle, when solar flares and disturbances are prevalent, the role of the sun was even more significant. To study these disturbances and their effects on the high atmosphere, special provisions mere made for intensifying observations in a program called World Days. Indications of unusual solar activity were flashed from any IGY station to a World Warning agency operated by the national bureau of standards at Fort Belvoir, Va. Here such reports were evaluated; if major disturbances in the upper atmosphere were anticipated, warnings were radioed to all stations in the world-wide network. These stations then increased the frequency of their regular measurements of the earth's magnetic field and of the ionosphere, sent up balloons to detect increases in cosmic ray intensities and auroral activity and launched rockets to intercept directly the particles and radiations from the sun. There were three classes of special days or periods for such intensified observation: World Meteorological Intervals, Regular World Days and Special World Intervals.

World Meteorological Intervals consisted of periods of 10 consecutive days each, in June, September, December and March. They coincided exactly with two pentads (five-day periods) of the World Meteorological organization and always included either a solstice or equinox, periods during which intensified meteorological observations are most desirable.

Regular World Days were three or four days each month selected in advance. Two were consecutive days at the time of the new moon; the others were at times of unusual meteor showers (Geminid, Perseid, Taurid, etc.) or near one of the lunar quarter phases. They also included the days of solar eclipse, with adjacent days for control purposes. For observations insensitive to lunar phase or meteoric effects and for those which could not be carried out continuously throughout the IGY period, the Regular World Days constituted a representative sample of the IGY period.

Periods of Alerts and Special World Intervals were designated on a day-to-day basis. A period of Alert was declared whenever solar activity was unusually high and significant geomagnetic, auroral, ionospheric or cosmic ray effects were probable. During the period of Alert, an Interval would be declared whenever the probability was high that an outstanding geomagnetic storm, with associated effects in other disciplines, would begin within a few hours. The periods of Alert and Interval continued in effect until terminated by the World Warning agency.

The Upper Atmosphere. — The region of space between some 20 and 300 mi. above the earth is largely dominated by particles and radiations from stars and interplanetary space. The sun, our nearest star and the source of almost all of the earth's energy, emits a broad spectrum of radiations and particles that affect the earth and its atmosphere. Solar disturbances, particularly sunspots and flares, often result in magnetic storms, heightened auroral displays, ionospheric variations that frequently disrupt long-range radio communications and sometimes intensification of cosmic rays. IGY solar investigations had several objectives: to monitor solar activity so that warnings could be issued to all IGY scientists of disturbed or unusual conditions, to make comprehensive measurements of all possible solar phenomena and to analyze solar observations both with respect to the sun itself and in relation to events in the upper atmosphere. Thirty-one nations were engaged in solar observations at 120 stations.

A world-wide flare patrol network was established. Solar flares are considered to be the most significant of all solar phenomena in their direct relation to terrestrial effects. Solar radio noise, cosmic radio noise and propagation of atmospheric noise were also observed. The life histories of the variations of the width and intensity of spectrum lines of certain major flares were recorded, and an effort was made to map the magnetic-field pattern of the entire solar disk on a day-to-day basis.

Both aurora and airglow are optical phenomena of the upper atmosphere. The aurora is the luminous trace of charged particles streaming from the sun. These particles are deflected toward the geomagnetic poles by the earth's magnetic field, penetrate the atmosphere most often at high latitudes and excite gas atoms. The radiation of energy by the atoms as they return to their normal state produces the colourful curtains of the northern and southern lights.

A variety of instruments were used in the IGY auroral studies. Twenty-nine special cameras photographed the sky from horizon to horizon on film, recording spatial distribution and changes of the aurora as it began, increased and decayed. Hundreds of amateur observers assisted in plotting the extent of auroral displays. Radar devices were used to scan the skies in cloudy weather and during daylight. Spectrographs and spectrometers analyzed the auroral variations. The objectives of these studies were to map the aurora in the north and south, to learn more about the radiations and the action of the bombarding particles, to correlate auroral events with other phenomena in the atmosphere and the sun, and to examine the amount and nature of the disruptions in radio communications caused by aurora. Aside from hundreds of visual sites, over 140 instrumented stations were in operation.

Airglow at its brightest resembles faint aurora, but its cause is chemical reactions in the upper atmosphere rather than bombarding particles. Sensitive photometers and high-speed spectrographs were in use at 50 stations to detect airglow. The nature and distribution of airglow were the principal interests of IGY scientists in this field.

Although the main source of the earth's magnetic field lies deep within its interior, the small component of the field in space which gives rise to the rapid and storm variations was the chief object of interest during the IGY because it is highly variable, solar influenced and interacts with the ionosphere, cosmic rays and the charged particles responsible for aurora. More than 250 magnetic observatories were active in the IGY, and rockets and satellites were also used to carry instruments aloft. Particular attention mas directed to rapid magnetic-field fluctuations, which are usually accompanied by disturbances in radio-wave propagation and by auroral displays. They may appear only in high latitudes or they may spread over the earth, and they increase and decrease with the number of sunspots. The main features of the fluctuations are such as might be caused by three great electrical currents, hundreds of thousands of amperes in strength, flowing through the upper atmosphere, two moving in the high latitudes and one around the equator. IGY scientists also established a basis for more accurate correlations of magnetic effects and other atmospheric and solar phenomena.

In the tenuous region between about 40 and 200 mi. above the earth lies the region known as the ionosphere, so called because ultraviolet and X-radiations from the sun eject electrons from gaseous atoms and thereby create charged ions. The region is therefore electrically active and behaves toward radio waves much like a mirror toward light waves. This feature accounts for the long-range propagation of radio waves by reflection. The ionosphere consists of several layers of varying ion density. The D-layer, ranging from about 45 to 60 mi. above the earth, has the lowest electron density. Above it in increasing electron density are the E-layer (60–90 mi.), the F1-layer (90–150 mi.) and the F2-layer (150–200 mi.). Variations in the electron density of these regions, fluctuations in their heights, relationships to magnetic storms and solar phenomena were topics of intensive PGY study in which some 250 stations were involved.

Various types of ground-based electronic devices were in use, and rockets provided a means for direct measurements of ion density. The chief instrument for ionospheric research is the ionosonde. Radarlike pulses are directed vertically to the ionosphere, and the reflections are recorded by receivers. The pulses are varied in frequency so that a broad band of the spectrum can be studied. The travel time of the pulses and their reflections provide "virtual" ionospheric heights (which are greater than the actual physical heights because of the retardation of the pulses by the ionized medium) while phase shifts and intensities yield information on the state of ionization in the charged layers. Such studies lead not only to better knowledge of the ionosphere but

provide the basis for predictions of desirable frequencies for long-range radio communications.

Cosmic rays were studied at 130 stations. These particles are atomic nuclei, and possibly some high-energy electrons, which bombard the earth continuously from every direction. One of the difficulties in studying cosmic rays is the masking influence of the lower atmosphere. The primary cosmic rays fail to reach the earth because they collide with atmospheric particles in the high atmosphere, creating secondary rays in a kind of chain reaction. In general it is "secondaries," removed several generations from the primary particles, that are observed on earth. More cosmic ray primaries enter the high atmosphere at high latitudes than at low latitudes because at high latitudes, where the magnetic field is more or less parallel to particle trajectories, fewer of the lower-energy particles are deflected away from impact with the high atmosphere: at low latitudes, where the magnetic field is more or less perpendicular to particle trajectories. most of the particles with energies less than a certain amount, which depends on the geomagnetic co-ordinates, are deflected, giving rise to the "cut-off" effect. IGY investigations were concerned with fluctuations in cosmic ray intensity near sunspot maximum and with the sunspot cycle, intensity decreases during some magnetic storms, increases shortly after the onset of solar flares and chromospheric eruptions, and mass-energy determinations. A wide variety of instruments was used: neutron and meson telescopes. cloud and ionization chambers, photographic emulsions and Geiger counters.

Heat and Water.— Weather and climate represent the end products of complicated interplay between the sun's energy and the lower atmosphere (below 20 mi. or so). the oceans, and snow and ice fields. These many and diverse relationships not only largely determine weather and climate but affect sea levels, ocean currents and the food stocks of the seas.

In meteorology. networks of 650 upper-air, 700 radiation and 100 ozone stations conducted observations and measurements. Temperature, pressure, humidity and winds were recorded around the world. Circulation of the atmosphere around the world and interchanges between the tropics and polar regions were studied. The objectives were to obtain sufficient world-wide data in order that a planetary view of weather might be had, leading to improvements in forecasting, and to provide a sounder approach to climatic trends through analysis of meteorological, glaciological and oceanographic data.

The purposes of the IGY oceanographic program were to gain an understanding of oceanic circulation, of both short- and long-duration changes in sea level, and their relationships to other oceanic and atmospheric phenomena. Thirty-five countries operated 70 research vessels and some 225 tide stations in these investigations. Measurement of the movement of deep waters occupied much attention in the IGY, for these currents are important in determining mass movements of oceanic waters and the coincident transport of large amounts of energy. Sea levels provide one key to oceanic circulation and thereby to its meteorological influences. Recording of sea-level changes was undertaken at several hundred island stations.

Glaciers, once covering 32% of the earth and now extending over 10% of it, exist on all continents except Australia. Fluctuations in glacier extent provide clues to past and coming climatic changes, while polar ice sheets have an ever-present effect on world weather as sources of cold or sinks of heat from the tropics. Projects were under way to determine the volume of ice locked in the ice sheets of Antarctica, Greenland and the arctic pack; to study the heat and water exchanges between these ice bodies and the atmosphere; and to examine snow stratigraphy. ice movement, temperature and topography. Eighty-three stations were in operation.

The Earth's Structure and Composition.— Better knowledge of the earth's interior was one of the objectives in this part of the IGY program. Seismologists of 50 nations gathered earthquake information from almost all regions, particularly those like Antarctica where data have been almost completely lacking. Man-made explosions were also used to study the propagation of seismic waves and to determine ice thickness and the structure of underlying terrain. As such waves travel through the earth, their speed and direction are altered depending upon the composition of the medium. Knowledge of wave characteristics and travel-time measurements can thus shed light on the nature of the earth. Some 240 stations co-operated in this program of simultaneous land and sea measurements.

The size and shape of the earth remain imperfectly known. Because the earth is not uniform, the pull of gravity varies from place to place, affected by the distances to the centre of the earth and by variations in the distribution of the earth's mass. Gravity measurements thus provide a tool for better determinations of the configuration of the earth, and almost 200 stations co-operated in the gravity program. Earth tides are also susceptible to gravity measurements. Similar to ocean tides but much smaller, earth tides are created by the moon and sun. Hawaii. for example, rises and falls about four inches daily. Studies of these movements by gravimetry provide a means for determining the rigidity of the earth and its internal structure.

To improve man's knowledge of distances between points and land masses, 70 stations were engaged in longitude and latitude measurements. At many of these stations. classical astronomical techniques were in use. At 20 of them a new instrument — the dual-rate moon-position camera — was used. This camera permits position determinations precise within a few hundred feet, but independent of any local gravity effects, by using the moon as a reference point. Standard astronomical techniques were also used, at locations where local gravity surveys had provided a precise knowledge of the direction of the vertical, to obtain precisions to better than five feet. Such precision is of considerable basic scientific interest — foi example, in studying possible motions of the continents — and also has applications in the making of maps.

Rockets and Satellites.— Prior to World War II knowledge of the upper atmosphere was restricted to indirect observations from or close to the ground. During the decade folloa-ing the war, research rockets were successfully developed, largely in the United States, to carry instruments as high as 250 mi. The importance of such measurements led to the inclusion of a rocket program in the IGY. Several hundred rockets were fired during the IGY by Australia. .Canada. France, Great Britain, Japan, the United States and the Soviet Union. Data about pressures, temperatures and density of the atmosphere, particles, radiations and fields were telemetered back to earth and provided new discoveries and knowledge in several fields, including meteorology and atmospheric structure, ionospheric physics, aurora and airglow, geomagnetism, cosmic rays, and solar ultraviolet light and X-rays.

Rockets are particularly useful tools in measuring the altitude variation of atmospheric phenomena — for example, the variation of temperature with height. They are restricted, however, by their brief lives of several minutes and by their essentially vertical coverage. To overcome these limitations. the IGY included satellite vehicles in the program. Satellites are important geophysical tools because they traverse vast expanses of space about the earth, permitting studies of space variations, and they last appreciable periods of time, permitting studies of the time-variation of phenomena. Several satellites were launched during the IGY, as were three probes which traveled many earth radii out into space.

Results.— The scientific products of the IGY fall into several categories. In several fields, notably meteorology and ionospheric physics, the data as taken were immediately applicable and also provided information for longer term work such as the study of ionospheric storms and atmospheric circulation. Weather observations, for example, were promptly used in weather forecasting. One of the significant achievements of the IGY was the preparation of twice-daily weather maps of Antarctica; indeed, the IGY provided the first census of Antarctic weather. Recording of temperatures to a low of at least −124° F. suggested the possible role of this vast continent of cold in world weather. Studies of temperature, pressure, humidity and winds in both the arctic and Antarctica provided data from which the influence of these regions on world weather could be examined.

In many fields and in many parts of the world, new discoveries were made. Using seismic sounding techniques, traverse parties

ranging over thousands of miles in Antarctica measured the ice thickness and thereby secured a profile of underlying land masses. One hundred miles east of IGY Byrd station, in the heart of Marie Byrd Land. the ice measured 14,000 ft. thick, resting on bedrock 8,000 ft. below sea level. This is believed to be the thickest ice ever measured. It appeared that the antarctic might be a complex of island and mountain chains, particularly certain coastal parts where a few mountains protrude above the vast ice mantle but where, even were the ice to melt, some mountain chains would lie hidden beneath sea level. Moreover, there were increasing indications of a major division between east and west Antarctica. Seismic measurements also provided a better measure of the amount of snow and ice in the world. The old figure—about 3,240,000 cu.mi.—had to be revised upward by about 40%, to some 4,500,000 cu.mi.

In the arctic, gravimetric and seismic measurements uncovered an underwater ridge, several thousand feet in height. Three major counter-currents in the oceans were found and measured. One in the Atlantic flows beneath and opposite to the Gulf stream. traveling at a rate of 8 mi. per day some 9,000 ft. beneath the surface. The second, at depths between 200 and 1,000 ft., flows against the surface equatorial current of the Pacific, transporting 1,000,000,000 cu.ft. of water per second. The third lies beneath the surface 200 mi. north of the Pacific equator, transporting 1,500,000,000 cu.ft. per second. In studying ocean bottoms. a vast mineral-rich region in the Pacific was discovered; millions of square miles of the southeast Pacific bear a surface-bottom sludge laden with nodules of manganese and iron with up to 1% of cobalt mixed with copper. The value of these minerals was estimated at about $500,000 per square mile, and the economics of dredging up the sludge appeared promising at the close of the IGY.

Both the rocket and satellite programs of the IGY yielded new knowledge of the atmosphere and the heavens. Important though these data are, however, the most significant aspect of the programs was their pioneering nature: man for the first time had created small heavenly bodies and had taken his first steps in outer space.

Several fields were studied with satellite and space probe vehicles, where the emphasis was on the environmental characteristics of space. Most important, perhaps, was the discovery of the Van Allen radiation zones, two distinct, widely separated belts of high-intensity radiation occurring about 1,400 to 3,400, and about 8,000 to 12,000, miles from the surface of the earth. A high of 25,600 counts per second was registered in these belts. These high counts are equal to about 10 roentgens per hour, if electrons, or about 100 roentgens per hour, if protons. The maximum safe weekly human dosage has been recommended to be no more than $\frac{3}{10}$ of one roentgen. At the close of the IGY, it was still too early to offer a definite appraisal of whether the more penetrating component of the radiation consists of electrons or protons. From the point of view of space travel, it remained to be seen whether acceptable means of dealing with the problem could be found. However, the area between the lower Van Allen radiation belt and the earth appeared to be safe for travelers for extended periods of time.

Through the use of sounding rockets, solar X-rays were discovered low in the ionosphere. These X-rays, rather than the ultraviolet radiation responsible for the general electrification of the ionosphere, extend downward to the lowest D-region of the ionosphere and increase its ionization to such an extent that radio blackouts occur.

The data taken during the IGY represented a major accomplishment in science and in international co-operation. The number of measurements and observations itself was remarkable, for in one project (vertical incidence soundings) of one field (ionospheric physics) alone, 10,000,000 frames of film. each containing hundreds of bits of data, were accumulated. The reduction and processing of these data were made possible by automatic computers. To ensure the safety of the data and to make them accessible, three world data centres were established—in the U.S., the U.S.S.R. and in western Europe, with branches in Australia and Japan. Each data centre gathered, indexed and archived a complete set of all IGY data. Studies of these data will occupy theoretical scientists for many years. From these studies may well come the most significant results of the IGY as the interrelationships among the phenomena in the various fields are analyzed. These results will have practical aspects, particularly in connection with weather and radio communications problems. but more importantly they will provide new and basic knowledge of the planet earth and its relationships with the universe. Finally, the IGY showed that men of all nations, of different colours, creeds and political beliefs, can work harmoniously together in an enterprise dedicated to the welfare of mankind. *See* also INTERPLANETARY EXPLORATION. (HH. O.)

INTERNATIONAL INSTITUTE OF AGRICULTURE, a clearinghouse of world agricultural information in the international sphere whose functions included the collection, analysis and publication of facts about crop and livestock production, trade, prices and related subjects "for the protection of the common interests of the farmers" of all nations. The institute was founded in Rome in May 1905. It was disbanded and its activities were transferred in 1946 to the Food and Agriculture Organization of the United Nations (*q.v.*), which superseded it.

The idea of the institute was proposed by David Lubin, a merchant of Sacramento. Calif. King Victor Emanuel III of Italy called the first conference at Rome in 1905. The convention treaty establishing the institute was later ratified by the governments of 77 nations. The convention provided for a staff of experts to be directed by a permanent committee consisting of one delegate of each country. The institute was financed by contributions of the member nations according to the class of membership chosen.

The technical staff eventually grew to about 100 men and women of more than 30 nationalities. They assembled one of the largest agricultural libraries in the world. housed in the building donated to the institute by the king of Italy; later a special library building was erected, aided by a grant of funds by the International Education board.

The institute published several series of journals, monographs, yearbooks and special reports in both French and English. The first attempt to make a world-wide agricultural census was begun for the years 1930 and 1940. Much of the work of the staff was done in connection with the biennial general assemblies held at Rome as well as hundreds of special meetings throughout Europe. The institute collaborated with the League of Nations, the International Labour organization and the economic conferences of 1927, 1933 and 1939, and participated in the organization of world congresses on forestry, wheat, poultry and dairying.

During World War II the international character of the institute was recognized by the belligerents and its work continued on a reduced scale. When the Food and Agriculture Organization of the United Nations was started in 1943, the member nations of the institute decided to dissolve it and turn its archives and staff over to the new organization, which was planned to cover the same field with more adequate resources. The staff was either retired or employed by the FAO, and the work of the institute terminated on July 31, 1946.

The library of the institute, designated as the David Lubin Memorial library, was transferred to the FAO headquarters building in Rome, which had been provided by the Italian government. (J. C. Ms.)

INTERNATIONAL LABOUR ORGANIZATION, THE. The International Labour organization, an official international institution, was originally created by the 1919 peace settlement, but later became a specialized agency of the United Nations system. Uniquely among international organizations, member states' representation is tripartite (*i.e.,* not only by each government, but also by representatives of its workers' and employers' organizations).

The ILO's chief organs are its conference (annual, as a rule), at which all members are represented; its governing body of 40 members; and the permanent secretariat, known as the International Labour office, under the direction of an appointed director-general. Its chief forms of activity are proposing international

treaties (known as conventions), recommendations, technical assistance. investigations. and research and publicity. It has concerned itself with all forms of labour and social legislation and labour law administration. with hours of work. wages, social security. welfare facilities and social services, co-operative organization, handicrafts and reform. with increasing productivity and combating unemployment and underemployment, with manpower needs and international migration. with industrial relations. freedom of association and trade union rights, and with the labour aspects of international competition.

ORIGINS AND HISTORY

During the 19th century a number of economists urged international economic agreements by governments to minimize the hardships to workers and the dangers to peace which they saw as inherent in modern industrialization and international economic competition. In 1900 a private organization. the International Association for Labour Legislation. was established. with headquarters in Basle, Switz. It succeeded in petting a diplomatic conference in 1906 to adopt two conventions, one to limit the hours of night work of women in industry. another to prohibit the use of poisonous phosphorus in the manufacture of matches. Although only a few states ratified these conventions. the association's pioneering helped prepare the way for the ILO.

Labour in the Versailles Peace Treaty. — As World War I increased its demands on workers for effort in the factories and for sacrifice on the battlefields. labour spokesmen in the Allied nations asserted claims for representation at the peace conference and for a peace settlement that would enhance social and economic justice. The Russian Revolution increased the restiveness and the demands of labour in Europe. An international trade union conference in Berne. Switz., early in 1919 demanded an "international labour parliament," with law-making powers, in which labour would have half the votes.

The peace conference set up a commission for international labour legislation, headed by Samuel Gompers, president of the American Federation of Labor. The commission put aside the more ambitious dreams of a body with legislative authority and proposed a body with powers of recommendation to national governments for action by them, in composition a tripartite body in which half the representation would be by governments, and one-fourth each by labour and by employers. The peace conference adopted these proposals and, by inserting them in the treaty of Versailles, set up the ILO.

The ILO between World Wars I and 11.—The ILO offered far less than the European or even the U.S. labour movement had asked, but as much as they seemed likely to get. The democratic labour movements of Europe (as distinct from the Communist unions which soon were competing with them, unsuccessfully, in most countries) threw their support behind the ILO, a condition indispensable for its success.

The first International Labour conierence met in Oct. 1919 in Washington. D.C. The governing body chose as the ILO's first director-general, Albert Thomas, a moderate French Socialist deputy who had been his nation's wartime minister of armaments. Under his leadership (1920–32) the ILO defined its purposes broadly. firmed up its organization, built up its staff and achieved an almost complete autonomy of policy in the League of Nations system. Upon Thomas' death. his deputy, a former British career civil servant, Harold Butler, succeeded him. When Butler resigned in 1938. John G. Winant, former Republican governor of New Hampshire and first head of the federal Social Security board. who had served as assistant director of the ILO in 1937, became director-general.

ILO after World War 11.—In 1940 the ILO moved from Geneva, Switz., to Montreal, Can.! for the duration of World War 1 Actively engaged in postwar planning, it convened one international labour conierence at Philadelphia, Pa., in 1944. Its "Philadelphia declaration" was a restatement of ILO aims—"poverty anywhere constitutes a danger to prosperity everywhere"—and a reaffirmation and amplification of the social-economic purposes of the Atlantic charter. The ILO's hopes of a major role in the postn-ar world were hardly realized, however. It was somewhat suspect to states not members of the League of Nations because of its ties with the League. The San Francisco Cnited Nations founding conference snubbed the ILO, despite British support, for the United States was lukewarm toward it and the Soviet Union definitely hostile. The UN charter made no mention of it. while giving broad powers to the U S Economic and Social council. The ILO became one of the specialized agencies by its agreement with the CS. ratified by the International Labour conference (Oct. 2, 1946) and by the UN general assembly (Dec. 14, 1946). The ILO kept most of its autonomy of policy and received a budgetary autonomy it had not had under the League.

In 1941, Edward J. Phelan, an Irishman who had been Butler's deputy, and before that a career British civil servant, had succeeded Winant. On his retirement in 1948, David A. Morse, United States undersecretary of labour, became director-general.

Changing Emphases. — In the period between World Wars I and II, the ILO had been primarily concerned with its research and '.legislative" efforts, the attempts to define and enact proper minimum standards of labour conditions by international conventions and recommendations. In the post-World War II world, although conventions and recommendations continued important, the ILO shifted its major emphasis to the programs of technical assistance to underdeveloped areas. This emphasis, dominating the period from 1949 to 1954, led it to take on, for the first time, work of an operating character.

CONSTITUTION AND STRUCTURE

The ILO brought into official intergovernmental organization the representation of functional groups. a principle which had been applied to economic and social administration within various nations. In the International Labour conference: each member state is represented by two government delegates and (normally) one employer and one worker delegate, the latter named by the government in consultation with "the most representative organizations of employers and workers" (where such exist) in each country. Not all delegations are complete, however.

To avoid the rule of unanimity, the ILO from the outset required only a two-thirds vote by its conference for the passage of a convention or a recommendation. The government delegates often cast the deciding votes in differences of opinions between the employer and worker delegates.

While the conference is the supreme authority of the ILO on most policy matters. it is the governing body which discusses and votes the ILO budget, appoints the director-general and controls the International Labour office. Tripartite, like the conference! the governing body carried out another innovation of international representation. In the conference all nations are equal, with every delegate having a single vote. In the governing body, half of the 20 government representatives must come from the 10 member states "of chief industrial importance."

Tripartism, in the 2:1:1 ratio, is firmly established in the conference and governing body. Various proposals to amend the constitution to give workers a larger representation, or to put both worker and employer delegates on a numerical par with those of government, have been rejected. Governments must be persuaded of the practical value of any proposal if it is to begin to receive implementation. The 2:1:1 ratio. however, prevails only in the phases of ILO work requiring binding votes. In conference committees and in the industrial committees (see below), representation of the three interests is equal. Thus the organization seeks the maximum contribution of specialized knowledge and the democratic participation of the major parties to industrial life—unions and employers—in its substantive work.

Two problems raised by tripartism have been troublesome, because they involve fundamental differences of national political and social structure. One is the right of governments to name as employer representatives the managers of state industries. The other is the naming of worker delegates by governments which systematically manipulate or repress labour unions within their borders. The 1954 conference, by divided votes: rejected protests

against the credentials of delegates in each of these categories.

Membership. — The ILO's ideal has been universality of membership. It admitted Germany as early as 1919, long before the League of Nations did; after World War II it admitted Italy, Japan and the German Federal Republic (west Germany). Some nations — Brazil and, for a time, Japan — remained in the ILO after quitting the League. Others became members of the ILO without joining the League or the UN. The United States, aloof to the League, joined the ILO in 1934.

Post-World War II amendments made it easier to join the ILO. Members of the UN do not have automatic membership in the ILO, as did League members, but they may become members simply by filing a declaration accepting the obligations of the ILO constitution. Nonmembers of the UN must be accepted by a vote of two-thirds of the conference, including that of two-thirds of the government delegates.

OPERATION OF ILO

Conventions and Recommendations. — The standard-setting process of the ILO, the major activity of its first two decades, uses the instruments of conventions (treaties) and recommendations. Member states are obliged to submit either a convention or a recommendation to the national "authority or authorities within whose competence the matter lies, for the enactment of legislation or other action" within a year or, under exceptional circumstances. 18 months. In the case of a federal state, the federal government must submit the convention or recommendation not only to the national legislature, but to the state or provincial authorities whenever it is, in whole or part. within their iurisdictions. A convention ratified by the nation's constitutional process becomes binding upon the nation, which makes annual reports to the ILO on the measures taken to give it effect. If it is not ratified, the state undertakes to report on its "law and practice" with regard to the subject matter of the convention.

A recommendation makes it possible to offer an international standard higher than that which at a given time may seem the maximum suitable for a convention, or to offer a general principle where a binding obligation by states is not being sought. The same problem may be dealt with by both forms, the convention setting an international minimum, and the recommendation a higher norm for more advanced countries and a level of aspiration for others.

Frequently states do not ratify conventions where their practice is as good as, or in most ways better than, the ILO's standards, because (1) governments and labour organizations are against enactment of any standards not as high as existing practices, or (2) in many federal states, national government does not have the constitutional power to ratify, as the conventions deal with matters wholly or partly within state or provincial authority. On the other hand, some states, out of a desire to be or to appear "advanced," have ratified many conventions but have done little to put them into practice. This was, for example, the case betneen World Wars I and II with some social security conventions ratified (and codes enacted) without regard for countries' limited economic possibilities or weak administrative structures.

The ILO could not, even if it wished, try to enforce the binding ratifications. Its constitution provided that it could appoint a commission of inquiry and eventually refer complaints to the International Court of Justice, whose decision mould be final. But such recourse was impractical in an international society characterized by intense national sovereignty. As of the mid-1950s there had been no commissions of inquiry and no complaints to the International Court of Justice. The. only real sanction in practice is that of public opinion, aided by the examination at the conferences of the extent of ratification and implementation of conventions, appeals to governments and education of officials, employers and labour.

Technical Assistance. — The gap between reality and law in relation to conventions was one stimulus to the new stress on technical assistance Between World Wars I and II, ILO technical assistance took the form chiefly of expert advice on legislative drafting and administrative procedures With the emphasis of the UN and the United States on technical assistance to economic and social development, beginning in 1949, the ILO amplified its services to include new techniques and operational activities. Working to raise productivity and living standards in underdeveloped countries, it also sought "to ensure that social objectives are not overlooked or sacrificed to purely economic objectives."

Fields of assistance have included vocational guidance, training and rehabilitation for workers, supervisors, teachers and administrators; methods of production — industrial, agricultural, and handicrafts; cooperative organization; aid in the selection, training, movement and reception of workers migrating from one country to another (*e.g.,* Italians going to Brazil); employment service organization and manpower utilization surveys; as well as such older areas of ILO work as wages and hours, industrial relations, social security, labour inspection and statistical procedures.

Methods have included a heavy reliance on the use of visiting experts drawn from many countries, fellowships, study tours, seminars, the supply of equipment and worker-trainees (*e.g.,* almost 400 Yugoslav skilled workers, foremen and technicians placed for training in factories in a dozen European countries).

In addition to its own programs, out of its regular budget, the ILO undertook many projects under the United Nations expanded program of technical assistance. Some were undertaken together with other UN agencies; *e.g.,* the "Andean highlands" project, for which the ILO had chief responsibility and collaborated with the UN, its Food and Agriculture organization, UNESCO and the World Health organization to help raise the living standards of the Indians of the Bolivian, Ecuadorian and Peruvian Andes, and integrate them into the economic life of each nation.

Trade Union Rights and Forced Labour. — After World War II the ILO adopted its first conventions on trade union rights (1948) and on protection of the right to organize and bargain collectively (1949). This action was overshadowed by the bitter debates over charges of violation of trade union rights, made without regard to the ratification of the conventions. The lead was taken by the Communist-dominated World Federation of Trade Unions (W.F.T.U.); its complaints, laid before the Economic and Social council, were referred to the ILO. The W.F.T.U. showed great concern for union rights in countries outside the Soviet bloc but found no occasion for complaint with conditions in the Soviet Union or its satellites. This deficiency was made up by the American Federation of Labor (A.F. of L.) and (after its formation in 1949) by the International Confederation of Free Trade Unions (I.C.F.T.U.), of which the A.F. of L. is a member. Although concentrating its fire on the Soviet bloc governments, the I.C.F.T.U. also complained of violations of labour rights by non-Communist governments.

In 1951 the governing body established a committee on freedom of association, which made a preliminary inquiry into complaints and had the power, if it found complaints warranted, to refer them to an impartial hiph-level fact-finding and conciliation commission. The ILO committee had to deal largely with complaints patently of a political motivation remote from the issues ostensibly at stake (many W.F.T.U. charges), or with issues of complete suppression of free trade unionism inherent in the whole structure of a state (many complaints against Communist governments). As the consent of the government concerned was a prerequisite to reference to the commission, no cases had gone to it (as of 1954).

Even more dramatic were the charges of forced labour levelled at the Soviet Union (and later its satellites), originally by the A.F. of L. before the UN in 1947, and then by the I.C.F.T.U. In 1951 the UN and the ILO set up a joint ad *hoc* committee on forced labour of three members, headed by Sir Ramaswami Mudaliar of India. It inquired into a welter of charges against 28 countries, for by then countercharges had been levelled at governments outside the Soviet bloc. Although facilities for inquiry within the Soviet world were denied by the governments involved, the committee made public evidence of forced labour on a vast scale. The world's public opinion, dulled by a generation of horrors, took only slight note. The committee's temperate recommendations for international consideration and action were reminders to a few consciences.

Regional Activities and Industrial Committees. — Two forms of the ILO's adaptation to the enormous differences in problems of different regions and of different industries were the intensification of regional activities and the use of industrial committees. The ILO prior to World War II, for all its official relations with other continents, had been essentially European in outlook and in support. The insistent claims of national self-consciousness and of economic and social development in other continents after World War II caused it to give weight to regional conferences, to establish field offices, to appoint more non-Europeans to responsible positions and to tackle problems (notably technical assistance) primarily, though not entirely, of interest to the near east, Africa, Asia and Latin America.

From the first (1920), the ILO had had one specialized industry committee, the joint maritime commission. In this field, the ILO achieved some of its most concrete results. The industry itself was international in operations; its workers and employers were highly organized; governments had long been accustomed to legislating on its problems. The ILO's 25 conventions and 10 recommendations made up a comprehensive and influential international seafarers' code. After 1945, the ILO set up eight new tripartite industrial committees. Although they dealt with a wide variety of problems in major industries, they did not attain the importance of the joint maritime commission.

The International Labour Office. — The office, the secretariat of the organization (and of the conferences and the governing body) consisted in the mid-1950s of more than 700 international civil servants, from more than 50 nations, and some experts on temporary assignments. Most of them work in the ILO's headquarters at Geneva; a number are, at any given time, in the field, all over the world. Substantial reports

on subjects under consideration by conferences and committees, continuing research and statistics,, publicity, a large library, technical assistance, legislative and administrative drafting, expert counsel in any field of labour and social policy are among the staff's responsibilities. Something of the ILO's manifold activities may be seen in its publications, whose extent can be gauged from its *Catalogue of Publications.* Among the most widely used are the monthly *International Labour Review* and the *Year Book of Labour Statistics.*

INTERNATIONAL LAW, PRIVATE: *see* CONFLICT OF LAWS.

INTERNATIONAL LAW, PUBLIC. International law, or the law of nations, is a body of rules and principles which states consider legally binding upon them. Its origins may in part be traced to the middle ages and antiquity; but the general body of modern international law dates from the late 16th and the early 17th centuries, when it was called into being to order the relationships and conduct of the newly appearing sovereign independent states of Europe. Clearly, a system of legal precepts binding upon sovereign states needed some prior authority. The writers of the formative period of international law—particularly the greatest of them. Hugo Grotius (Hugo de Groot), whose *De jure belli et pacis* (1625) remains one of the most important books of all time—found that authority both in the much older idea of a system of natural law discoverable by reason, and in that part of Roman law, the *jus gentium* ("law of nations"), which had always been considered to be *ratio script~*("written reason"), and to consist in rules both generally accepted and of universal validity.

Writers have always felt the need to explain and justify the legally binding nature of international law; for the notions of state sovereignty and the subjection of states to law do not easily ride together. When the idea of a system of natural law was unfashionable—particularly in the England of the 19th and early 20th centuries—an alternative basis of legal obligation was found by the so-called positivist school in the supposed consent of states to be bound; a consent, manifested sometimes expressly, as in a treaty, or sometimes tacitly, as in a rule of customary law. The positivists did a great service in emphasizing the importance of the study of actual state practice as a source of positive law; but their attempt to found obligation upon consent—though still echoed in innumerable judgments in English and United States courts—raised as many questions as it appeared to solve. It was never satisfactorily explained why, for example. a state which consented to a treaty and so became bound by it could not withdraw that consent at its discretion. It may well be a mistake to postulate some essential difference between international law and internal law in the matter of the basis of obligation. The notion that international law does not require a particular and special pleading to establish its legal nature has the advantage of being in accord with the factual situation. For while writers have sometimes found it convenient to deny the legal nature of international law, it is easily demonstrable that states do recognize their obligation to observe it.

The major difference between international law and internal law is not, as the layman often supposes, that international law is less consistently obeyed than internal law. It is true that much of the so-called law of war which used to be an important part of the system has in many ways proved both inadequate and irrelevant; this situation obtains for reasons which will be discussed later on. But the main body of the law between states in peacetime is probably more consistently applied and obeyed than many systems of internal law. Nor is the apparent lack of sanctions anything like so serious as the layman is apt to imagine. As J. L. Brierly put it in *The Basis of Obligation in International Law and Other Papers* (p. 54, Oxford University Press, London, 1958), "the regular observance of the international law of peace is explained only too easily; it is generally observed largely because there is little temptation to violate it, because its yoke lies easily—too easily—on the states, and also because to violate it habitually would invite reprisals and would not be in the interest of any state. But all that does not alter the fact that in spite of the vagueness of its sanctions, the law is very rarely broken."

Nevertheless, there are two important ways in which international law has less efficacy than internal laws. First, there are many areas of state activity, and these some of the most important, where the law reaches hardly at all. Thus, questions such as nationality, armament, immigration and fiscal and trade policies—all of which may vitally affect international relations—are traditionally within the untrammeled competence of the state itself to order and determine. It is true that there is a tendency of the law to feel its way gradually into these areas where formerly an anarchic sovereign discretion in each state was sanctioned by the law. Thus, until fairly recently, even the right to wage war was one which the law left to each state to exercise at its complete discretion but this is now no longer so. A serious qualification of the law that still remains, however, is the maxim that a court can exercise jurisdiction over a state only where the state has in some way consented to that jurisdiction; so that, for example, the International Court of Justice at The Hague has a compulsory jurisdiction, in the sense that a defendant state can be compelled to plead and to submit to judgment, only in a very limited sphere.

The second important difference between international and internal law is the comparative lack of international organizations and institutions. A developed system of internal law cannot be imagined without legislature, executive and judiciary. Yet, until about the middle of the 19th century, international law was virtually without institutional organizations, and thus dependent for action upon the separate governments of the states composing the family of nations. After the middle of the 19th century there was increasingly rapid development on the institutional side of international law, but 100 years later the machinery available was still far short of what is required for a mature and adequate system.

The Sources of International Law.—The term source is here used to connote "those agencies by which rules of conduct acquire the character of law by becoming objectively definite, uniform, and, above all, compulsory" (C. K. Allen, *Law in the Making,* 6th ed., *p.* 1, Oxford University Press, London, 1958). Obviously, every system of law must have criteria by which one can set about discovering the rule of law on a particular matter at a given time. For international law, those tests of validity have been authoritatively stated in art. 38 of the Statute of the International Court of Justice, by which it is provided:

1. The Court, who function is to decide in accordance with international law such disputes as are submitted to it, shall apply:
   a. international conventions, whether general or particular, establishing rules expressly recognized by the contesting states;
   b. international custom, as evidence of a general practice accepted as law;
   c. the general principles of law recognized by civilized nations;
   d. . . . , judicial decisions and the teachings of the most highly qualified publicists of the various nations, as subsidiary means for the determination of rules of law.

By conventions is meant what are commonly called treaties. The many thousands of treaties in force now form much the greater part of the fabric of international law. This was not always so. Treaties were formerly mainly political in content: peace treaties, alliances and the like. It was not until the 19th century that the multipartite treaty began to be used for creating law between the parties. Nowadays, the multipartite lawmaking treaty is an indispensable instrument of the society of states. It must be remembered. however, that, with very fe exceptions, treaties are contractual in the sense that they are only binding upon states parties to them.

The customary element in international law is prior to treaty law in the sense that the binding force of treaties themselves depends upon rules of customary law. To establish a rule of cus-

tomary international law it must be shown that there exists not only a practice or habit among states, but also a recognition that the practice follows a rule legally binding on them. Customary law must accordingly be distinguished from mere usage, however well established; and from the rules of international comity, which, however well observed they may be, are recognized by states as being demanded by courtesy rather than by law. Thus, the elements necessary to establish a rule of customary law are, in the words of Judge M. O. Hudson *(Permanent Court of International Justice,* p. 609), "the concordant and recurring action of numerous states in the domain of international relations, the conception in each case that such action was enjoined by law, and the failure of other states to challenge that conception at the time."

There has been some controversy over the precise meaning of the provision in the court's statute requiring it to apply general principles of law; but there can be no doubt about its importance. One general principle common to, and necessary to, all systems of law is that the law is complete in the sense that there must be some legal answer to every legal problem. The positive aspect of this principle is neatly expressed in a well-known international arbitral award: "International law, as well as domestic law, may not contain. and generally does not contain, express rules decisive of particular cases; but the function of jurisprudence is to resolve the conflict of opposing rights and interests by applying, in default of any specific provisions of law, the corollaries of general principles, and so to find . . . the solution of the problem." *(Eastern Extension, Australasia and China Telegraph Co. Ltd., Case,* 1923).

Accordingly, international law, even where relatively lacking in detailed and elaborated rules in some of its aspects, is a complete system when seen against the back cloth of the general principles of law, which are to be collected from a study of the several internal systems and of law in general. Examples of general principles nhich have been assumed by tribunals to be part of international law are the principle of unjust enrichment, that he who is unjustly enriched to another's damage must make compensation; the rule called by common lawyers estoppel, that a party may not in his assertions be allowed to blow hot and cold in the same case; and the rule of *res* judicata, that a final decision by a proper tribunal disposes of a dispute once and for all.

It should not be supposed that this provision of the court's statute was an innovation; for general principles of law have necessarily been a source since the beginnings of international law. It should be added that the general principles of law are regarded by some as being nothing more or less than the principles of natural law. At any rate. the inclusion of this source in the statute of the International Court of Justice was a rejection of extreme positivist ideas that international law rests solely upon the consent of sovereign states.

Judicial decisions are, with text writers, recognized as "subsidiary means for the determination of rules of law." Obviously there can be no rigid system of binding precedent of the kind peculiar to the common law; but argument from persuasive precedent is inevitable, for it is a natural tendency of the human mind. The International Court of Justice has shown no reluctance to refer to its own earlier decisions, nor to the awards of other international tribunals. Case law is, of course, dependent on there being a system of reports; as well as the international court's own series. there are the *International Law Reports,* published in the United Kingdom, which report not only the decisions of all international courts and tribunals but also the many decisions involving questions of international law of national courts all over the world. The transformation of international law into a case law system, which has taken place mainly since 1930, is a movement the importance of which it would be difficult to exaggerate; for it provides a resilience and a factor of growth not easily achieved in other ways.

The opinions of writers serve as evidence of what the law is. exactly as they do in other systems. Their function was well described by Justice Horace Gray in a decision of the United States supreme court on an international law question *(Paquete Habana,* 1899, *American Prize Cases,* p. 1938):

> . . . where there is no treaty, and no controlling executive or legislative act or judicial decision, resort must be had to the customs and usages of civilized nations; and as evidence of these, to the words of jurists and commentators who by pears of labour, research, and experience have made themselves peculiarly well acquainted with the subjects of which they treat. Such works are resorted to by judicial tribunals, not for the speculations of their authors concerning what the law ought to be, but for trustworthy evidence of what the law really is.

Relationship With the Internal Law of States. — To understand international law it is necessary to appreciate its close relationship to the internal law of states, or, as lawyers say, the municipal lams of states; for it is increasingly penetrating that sphere. Even the traditional international law, at a time when it was supposed to be a law only between states, had many rules which required the co-operation of municipal courts for their realization; for example, the very ancient rules whereby foreign sovereigns and their diplomatic representatives enjoy certain immunities from the municipal jurisdiction. But a very large part of modern international law is directly concerned with the activities of individuals which come before municipal courts. So that it is in municipal courts that a large and increasing part of international law is enforced.

One school of thought accepts that international law may be per se a part of the law of the land and that the municipal court therefore, in the appropriate case, applies international law directly. Another insists that a municipal court can only apply and enforce its own municipal law, and that the international law rule is binding only on the state itself, which must by legislation transform the precept into one of municipal law. The two approaches can on occasions lead to different results; *e.g.,* in a case involving a treaty which the government has omitted to transform into a municipal statute. But the second, or dualist, theory can hardly be applied in any case in those many countries *(e.g.,* the Republic of Ireland, France and the German Federal Republic) where it is by the constitution provided that international law is part of the law of the land.

The position before English courts is not so straightforward. There can be no doubt that they regard customary international law as part of the law of the land, for they take "judicial notice" of it; that is to say they assume that the court knows the law and does not require it to be proved by calling expert evidence, as in all cases involving foreign and external systems of law. The courts do in fact regard any relevant rule of customary international law as incorporated into the domestic law.

However, this statement must be understood subject to certain qualifications. First, English courts have tended to apply their doctrine of rigidly binding precedent even in cases involving customary international law. Thus, although the court may initially have applied the pure rule of international law, the rule may in the English jurisprudence have become fossilized just because the original decision has become a binding precedent; while the rule as it exists in the main stock of international law may have changed considerably in the course of its natural development. A notorious example is the rule by which a foreign sovereign state enjoys immunity from the jurisdiction of the municipal courts: in origin a simple and reasonable principle which, in the course of English case lam, has become peculiar and technical while retaining an archaic form which some consider inappropriate to modern conditions. Secondly, it must be remembered that in England a statute is paramount law and must therefore be applied even if found to be contrary to international law *(cf. Mortensen* v. *Peters, 14* S.L.R. 227). In such an impasse it is for parliament to get itself out of difficulties of its own creating by changing the law. The municipal court cannot help.

A treaty, even though binding upon the United Kingdom internationally, will not be applied as such by the courts. If the implementation of the treaty requires a change in the law it is for parliament to make that change by statute. The reason for this rule is said to be that, since the treatymaking power is a prerogative power, it would, if the treaty were binding directly on the courts, amount to a power to legislate without parliament. The position is quite different for example in the United States, where treaties are binding on the courts even if in conflict with state laws or previous federal laws; on the other hand, a subsequent federal

statute will overrule a previous treaty.

The Sphere of Operation. — Up to the end of the 19th century and even later, international law was mainly if not entirely a law governing the conduct of sovereign states. Theorists tended to erect this fact into a principle, and it used to be asserted, therefore, that international law could not bind or confer rights upon individuals, or upon entities other than sovereign states. But in truth there never was anything inherent in the law to prevent it applying to individuals. Indeed, as we have already seen, municipal courts have constantly found themselves compelled to take account of rules of international law affecting individuals appearing in cases before them. Developments during the 20th century have long outstripped the old orthodoxies. In 1928, the Permanent Court of International Justice recognized, in the case concerning the Jurisdiction of the Courts of Danzig (PCIJ, series B, no. 15) that states may expressly grant rights directly to individuals by treaty if they wish to do so, and that such rights may validly exist and be enforceable even though they have not been incorporated into the municipal law. In 1949, the International Court of Justice, in its opinion on the Reparation for Injuries *Suffered* in the Service of the *United* Nations (ICJ Reports, 1949, p. 179), expressly rejected the view that only states can be the subjects of international lam. And, of course, the laws of war were always based on the assumption that their precepts were binding not only upon sovereign states but also upon the individuals who compose them. In its judgment of Sept. 30, 1946, the Nuremberg International tribunal said this:

> It was submitted that international law is concerned with the actions of sovereign States, and provides no punishment for individuals; and further that where the act in question is an act of State, those who carry it out are not personally responsible, but are protected by the doctrine of the sovereignty of the State. In the opinion of the Tribunal, both these submissions must be rejected. . . . Crimes against international law are committed by men, not by abstract entities, and only by punishing individuals who commit such crimes can the provisions of international law be enforced.

All this is not to say of course that some parts of the law—and particularly those which developed in the 19th century—are not still coloured by the old orthodoxies. For example, the influence of dualist doctrine is still to be seen in the so-called rule of nationality of claims, by which it is assumed that a wrong to an individual committed in a foreign state is a wrong not to him but to his own state, and that there is no redress unless his own state takes up the claim, and, moreover, is qualified to do so by reason of his having been its national both at the time of the injury and continuously until the claim is brought. This cumbrous and unrealistic procedure is being changed only slowly into something more apt to the doing of justice.

Codification. — Since the middle of the 19th century it has often been suggested that international law would be strengthened by codification, on the grounds that a code would add certainty and precision to the law, besides offering an opportunity for the completion of the system. While there can be no doubt that the movement has been a salutary one, with considerable achievements to its credit, it has only been realized slowly that codification presents peculiar difficulties in the international sphere. A codification in the strict sense—*i.e.*, where existing law is put into written form but the substance remains unchanged—is, except perhaps in a very few restricted fields, practically impossible, because any attempted codification must involve the resolution of differing opinions about what the law is; so that some changes in the law in the course of codification are unavoidable. This process presents no special difficulty in an internal system where there is a legislature competent not only to promulgate the new code with authority but also to abrogate the former sources and understandings of the law. But in international law there is no legislative process as yet available. The nearest approach to it is the multilateral treaty; which, however, is still only binding on the parties to it. Consequently, unless the treaty becomes universally accepted, the former customary sources of the law remain valid for those who are not parties to the treaty. Thus it may be possible to argue that the former customary law remains in existence as the general law, and that the codification is a novel law binding only those who have subscribed. Hence, a codification attempted at the wrong moment may easily complicate rather than clarify the law.

These and other difficulties were demonstrated by the disappointing results of the Hague Codification conference of 1930 when, in spite of preparatory work of unexampled thoroughness, the conference failed to reach any agreement on two major topics of the law and produced only minor, and for the most part still unratified, conventions on a third.

A great step forward, however, was taken in the charter of the United Nations, which required the general assembly to initiate studies and make recommendations for "encouraging the progressive development of international law and its codification" (art. 13), thus recognizing that codification and development of the law are in practice inseparable companions. To carry out this task an International Law commission of experts was established in 1947 and began its studies in 1949. Its method has been to study certain major topics of the law and to report the results of its labours to the general assembly in the form of draft conventions with comment. It is then for the general assembly to decide whether the time is opportune for a diplomatic conference to use the work as a basis for an actual codifying convention. But in any case the reports of the commission and the materials they collect and publish have themselves enriched the law, thus demonstrating the force of Sir Cecil Hurst's plea for codification in the form of restatements by technical experts which might be expected to achieve the inherent authority of accurate and persuasive scholarship (see Grotius Society *Transactions*, 1946). In the first ten years of its working life, the commission produced reports on such important topics as arbitral procedure, diplomatic immunities, state responsibility and offenses against peace and security.

In its final report on the very important question of the various aspects of the law of the sea the commission recommended the calling of a general diplomatic conference. Accordingly, the representatives of 86 countries met at the Geneva Conference on the Law of the Sea in 1958. The conference failed, not unexpectedly, to agree on the crucial question of the width of territorial waters: a question which nicely illustrated the difficulty of maintaining a distinction between the question of what the law is and the question of what it might become. Some countries were doubtless still jockeying for position in the controversy and were not at that moment wishing to reach a final agreement. On other topics of maritime law, however, the conference was a very considerable success, for it achieved very wide agreement on four draft conventions ranging over almost the entire field of maritime law, comprising in all 106 articles, dealing with the territorial sea and contiguous zone, the high seas, fishing and conservation of resources on the high seas and the continental shelf. The draft conventions mere of course subject to ratification before becoming binding upon states. The Geneva experiment was a very great advance over earlier attempts at development and codification by treaty and probably showed an increasing awareness in governments of the importance of international law and the urgent need for its development.

International Organizations. — As has been already noticed, there were in quite recent times no international organs of government and administration. International law could only function through the agency of the governments of the separate states. Thus, for example, new states were admitted—and indeed still are admitted—into the international comity of nations by the process of independent recognition by each separate state. It is true, of course, that there are legal rules governing various aspects of recognition; but the act of recognition is still a function of the states and not of an international institution. Again, the claims of individuals or corporations for reparation for international wrongs such as denial of justice have to be adopted and preferred by the government of their national state before they become viable in the international sphere. Until after World War I, the final sanction of the law was accepted as being the rough and ready one of various forms and degrees of self-help by states themselves, including ultimately war.

Some international institutions began to appear, however, in

restricted and mainly technical fields in the 19th century. The first was the International Telegraph union of 1865, followed by the Universal Postal union in 1874, the Copyright union in 1886, the International Institute of Agriculture in 1905 and the Radiotelegraph union in 1906.

This development of international institutions mas greatly accelerated after World War I by the establishment of the League of Nations with its many associated agencies, including two important ones which have nith some changes, survived World War II, namely the International Court and the International Labour organization. The movement gathered pace again at the close of World War II with the establishment of the United Nations and its 12 specialized agencies, and the creation of numerous intergovernmental organizations exercising functions bearing on the development or administration of international law. Thus the middle of the 20th century saw the emergence of a large number of international agencies. some well-nigh universal, some regional and many of them now an indispensable part of the daily working of international society; *e.g.,* the International Civil Aviation organization, the World Health organization, the United Nations Educational, Scientific and Cultural organization, the Food and Agriculture organization, the International Monetary fund and the Bank for International Settlements.

These bodies are creatures not of a particular municipal law but of international law. The International Court has given its opinion that the United Nations itself is a person in the lan in the sense that it can even bring certain kinds of claims on behalf of individuals against a state. The legal problems which are common to international organizations in general, such as questions of membership, voting powers and procedures, and relations nith other organizations, with states and nith individuals, were, by the middle of the 20th century, being welded into a systematic legal discipline comparable with the constitutional law of a state.

Important. however, as this emergence of an international constitutional law undoubtedly is, its significance clearly depends in the long run on the success or failure of that central part of it which is concerned with the problem of war; for a system of lam fails in its primary function if it fails to regulate the use of physical force within the society it purports to govern.

International Law and War.—The founding fathers of modern international lam had no doubt that the control of war must be the primary function of the system. Therefore they not only devised rules governing the conduct and methods of warfare—the so-called temperaments-but also attempted to distinguish between wars which were just and lawful and those which were unjust and therefore unlawful. This attempt. however, could be of little practical significance in a society in which there mas no international authority to make the determination one way or another. Consequently, from the 18th to the early 19th century, international law abandoned the attempt to distinguish between wars and followed the cynical maxim that "war is no illegality." War, which might therefore be made at the absolute discretion of each sovereign state strong enough to wage it or desperate enough to risk it, suspended the lam of peace between the belligerents and brought into operation the rules of war intended in some measure to mitigate its severities and to protect civilian lives and property. Between the belligerents and neutrals there came into operation a highly sophisticated law of neutrality. This traditional law was codified: though not without ambiguity, at the two Hague peace conferences of 1899 and 1907. It is important to remember therefore, that during much of its existence, international law made no practical attempt to control the use of war as an instrument of policy.

World War I demonstrated the need not merely to attempt to control the conduct of war, but to prevent it; both on account of the increasingly devastating scale of modern warfare and also because even the old rules governing its conduct, except for certain fundamental principles stemming from the ordinary rules of humanity. were being rendered constantly obsolete or irrelevant as a result of the application of modern science to the methods of warfare. The rules tended always to be more appropriate to the last war than the present one.

The 20th century has therefore seen a return in a new form to the classical attempt to distinguish between the just and the unjust war: first in the League of Nations covenant, then more generally in the still important and binding general treaty for the renunciation of war of 1928, sometimes known as the Peace Pact of Paris, or the Kellogg-Briand pact. This was a well-nigh universal treaty in which states renounced war as an instrument of national policy and undertook to settle their disputes by pacific means, thus making all wars illegal except those waged in self-defense or against a state that had already violated the treaty by an illegal resort to war. It was this instrument which formed the legal basis for the abandonment of formal neutrality by the United States in the early stages of World War II and for her assistance to the Allies before she herself became belligerent. In 1946 there was added the charter and structure of the United Nations, in which members undertook to "refrain in their international relations from the threat or use of force against the territorial integrity or political independence of any state. . . ." (ch. 1, art. 2, sec 4).

Conclusions.—The experience of two world mars the failure of the League of Nations experiment and the unforeseen difficulties and frustrations of the United Nations resulted in a prevailing temper of disillusionment which contrasted strongly with the optimism of the late 19th century. Yet it is true that the 20th century has seen an unprecedented and rapid development of the main body of international law which gathered even increased momentum after the close of World War II. There is a sense in which this development was inevitable. The industrial revolution and then the technological revolution forced states closer together and greatly increased the importance and variety of crossfrontier relationships in trade, communications and culture. Though political theory continued to describe states in terms of sovereign independence, the most important fact about them became their interdependence All this was bound to produce great changes in the law For law is not created by the speculations of jurists, or even by the desire of peoples for it, but by their real needs and by the pressures of events. Accordingly, if the international law of the mid-20th century is compared with the international law of the latter part of the 19th century great differences are found. The first and most immediately striking is the increase in the sheer bulk of it Some idea of this change can be gained by comparing the slim volume of a little more than 200 pages which Sir Henry Maine found sufficient to cover the subject in his Cambridge lectures of the 1880s, with the 2,000 or more pages of a modern basic text book such as L. F. L. Oppenheim's *Ifitel-national Law,* edited by *H.* Lauterpacht (vol. i, 8th ed , 1955; vol. ii, 7th ed , 1952). But the most important difference is the change in content. At the end of the 19th century and even perhaps after the end of World War I, it was still necessary to define international law in the traditional terms of a law to order the relations of states among themselves and to delimit the territorial spheres within which their respective sovereign and independent authorities might properly be exercised. As Sir Alfred Zimmern said, in a telling criticism of it, "modern international law was developed as a means for regulating external contacts rather than as the expression of the life of a true society" *(The League of Nations end the Rule of Law,* pp 98–99, The Macmillan Company, New York and London, 1939). And indeed it was to be expected that a lam coeval with the emergence of the nation state should have been much influenced by doctrines of the fundamental rights of states, so that much of the traditional law was concerned with aspects of state separateness and independence, rather than with the problems of an international society. But by the middle of the 20th century this was no longer the position. The proliferation of modern treaty law and relationships, the development of international organizations, the increasing concern of the law with the protection of fundamental human rights of the individual even as against his own state, the necessity for detailed international regulation of technological developments such as international civil aviation: all these factors resulted in a profound transformation of the nature and content of the law nhich is admirably summarized by Wilfred Jenks:

". . . . . the emphasis of the law is increasingly shifting from the formal structure of the relationships between States and the delimitation of their jurisdiction to the development of substantive rules on matters of common concern vital to the growth of an international community and to the individual well-being of the citizens of its member States. We shall also find that as the result of this change of emphasis the subject-matter of the law increasingly includes cross-frontier relationships of individuals, or organizations, and corporate bodies which call for appropriate legal regulation on an international basis, problems of economic and technological interdependence requiring the regulation on the basis of common rules of matters which do not *per se* involve inter-State relations in any real sense, and rights designed to provide the individual, and in some cases organizations, with a measure of protection against the individual member States of the international community. This international community, which is still far from having attained any political or moral unity and is always liable to be torn asunder by disruptive forces, continues to be organized on the basis of States, but its law has long since ceased to be merely, and is rapidly ceasing to be primarily, a law between States." (C W. Jenks, *The Common Law of Mankind,* p. 17, Stevens and Sons, London, and Frederick A. Praeger, Inc., New York, 1958).

The attention of the reader is especially drawn to the following articles: ARBITRATION, INTERNATIONAL; CONFLICT OF LAWS; HAGUE CONFERENCES; INTERNATIONAL COURT OF JUSTICE; INTERNATIOXAL LABOUR ORGANIZATION, THE; LAWS OF WAR; LEAGUE OF NATIONS; NEUTRALITY; SANCTIONS AND GUARANTEES; TREATIES; UNITED NATIONS.

INTERNATIONAL MONETARY FUND, a specialized agency affiliated with the United Nations, designed to stabilize international monetary exchange rates. Together with the International Bank for Reconstruction and Development (see BANK FOR RECONSTRUCTION AND DEVELOPMENT. INTERNATIONAL) its articles of agreement were signed, after considerable prior negotiation, at Bretton Woods, N.H., in July 1944. Ratification and appropriation of funds by national governments enabled the fund to be constituted in March 1946. Initial exchange values of member currencies were accepted at the rates then current. The fund opened in March 1947 and made its first transactions in May 1947. By the late 1950s it had 67 members. No communist countries then belonged.

Organization. — Operating funds are subscribed by member governments. Each member has a quota, of which an amount equal either to 25% of the quota or 10% of the member's holdings of gold and U.S. dollars, whichever is smaller, is subscribed in gold and the remainder in national currency. By April 1958 the total quotas for 67 countries were $9,068,500,000 and the fund held gold and convertible currencies amounting to $2,506,800,000 of which $884,300,000 were subject to unutilized drawing rights under stand-by arrangements.

The fund mas designed to stabilize exchange rates by assisting members over temporary difficulties in their international balances of payments. It does so partly by consultation and technical advice, but also by allowing members to purchase from it with their own national currencies the gold or foreign exchange they need. In principle not more than 25% of the member's quota may be purchased in any one year, but in an emergency this limit may be, and often is, waived. Not more than 125% of the quota may be purchased in all Charges begin at ½% for the first 25% for the first year, rising by ½% for each additional 25% for each additional year. with a limit of 5%. Members may arrange stand-by credits to use as and if necessary. If demands for any currency outrun the fund's resources it may be declared scarce and rationed. Members may then impose discriminatory exchange controls against it. Members are required to repurchase the excess of their own currencies over their quotas within an agreed period (three to five years) and as their balances improve.

Members agree not to alter the exchange value of their currencies (except once by not more than 10%) uithout prior agreement by the fund. In 1949 Britain and many other countries secured such agreement, as did France in 1957 and other countries at different periods.

Members are pledged to the ultimate elimination of exchange control and multiple exchange rates. They must consult annually with the fund on both and it works with them toward greater freedom and uniformity of exchange rates. Such consultations offer opportunities for technical advice and assistance toward currency stabilization and the freeing of exchange transactions. Staff members also frequently visit member countries to consult with national monetary agencies.

The fund has no power to dictate national monetary policies. By providing technical assistance when asked and facilities to acquire needed reserves in emergencies, it may moderate exchange crises and minimize currency instability, but it had not by the late 1950s been able to get rid of exchange restrictions.

Policy is determined by a board of governors representing each member government. Governors cast votes weighted according to the quotas subscribed by members, ranging in the late 1950s from 25j votes for Panama to 27,750 for the United States. The 17 executive directors meet frequently. Five. representing the countries with the largest quotas (the United States. United Kingdom, China, France and India) are appointed. The remaining 12 are elected by the other members. The managing director and his staff are responsible for actual operations.

Transactions. — After years of relative inactivity, the number and amount of the fund's transactions increased sharply during the Suez crisis in 1956–57. In the organization's first ten years, ending April 30. 1957, total purchases amounted to $2,350,000,000 of which $1,114,000,000 were made in 1956–57. Another $1,212,000,000 was earmarked under stand-by arrangements in that year. Most purchases were of U.S. dollars, but there were also small purchases of German marks and Dutch guilders, as in earlier years there had been of sterling. Belgian francs and Canadian dollars. Not all stand-by arrangements were used. Up until 1958 repurchases of their national currencies by members were less than new purchases of dollars. Some national quotas were increased and there was discussion in the late 1950s of the need for a general increase to enlarge the fund's resources. It was widely recognized that the fund's action in making available large amounts of internationally acceptable currencies had eased the strain on national balances in the Suez crisis. INTERNATIONAL ORGANIZATIONS, institutions drawing their membership from two or more states, and maintaining arrangements and facilities designed to promote periodic or continuous activities by their members.

The 20th-century trend toward the creation of international organizations on a wide scale was essentially a product of circumstances stemming from advances in the technology of communication. transportation and warfare, and from the growth of industrialism. These developments gave rise to a sense of interdependence among the peoples of the world. thereby stimulating recognition of the need for systematic international co-operation to avoid the dangers, curb the evils. solve the problems and exploit the opportunities which confront the society of nations. These same developments also gave an unprecedented air of feasibility to the project of creating and operating organizations on a world-wide scale. Such institutions vary greatly in geographical scope. ranging from regional organizations to universal bodies embracing virtually the whole world. Some are concerned only with single and relatively narrow problems, while others, *e.g.,* the United Nations, deal with a great variety of substantive matters. Finally, international organizations may be designated as either intergovernmental or nongovernmental agencies.

Nongovernmental **Organizations.**—Typically, international nongovernmental organizations are associations of private groups organized separately within various states: although some are based upon the membership of individuals. The distinction between the intergovernmental and nongovernmental types is not always clear

cut. Many organizations are mixed in composition. The International Labour organization, for instance, while fundainentally an intergovernmental body, included in the 20th century spokesmen for national employers' and workers' associations along with official representatives of governments as voting delegates to the sessions of its major organs.

On the nongovernmental level, groups were organized for such purposes as the international exchange of knowledge, the promotion of religious and humanitarian causes and the development of parallel or co-ordinated practices among nations in particular areas of activity. Nongovernmental organizations also in many instances promoted the creation of intergovernmental agencies in the fields of their concern, and advised and assisted the latter bodies in their operations. While most nongovernmental organizations were designed to stimulate co-operative achievement of practical results in rather specialized fields of endeavour, some reflected a desire to cultivate internationalism as a value in itself, promoting friendly contact and habits of international co-operation as a contribution to the creation of an orderly and peaceful world.

Intergovernmental Organizations. — The intergovernmental category includes those established by agreement among governments, and maintained by states, which exercise their membership functions through governmental representatives. Public international organizations, of the mid-20th century, although less numerous than the nongovernmental agencies. generally attracted greater attention and had more adequate financial support. Their creation reflected a disposition to seek new techniques and improved facilities for coping with the tasks of government under the increasingly complex circumstances of the modern era. In particular, the ancient moral ideal of world peace and the urgent practical requirement of avoiding the devastating results of modern war produced an emphasis upon the peace-preserving function of intergovernmental organizations. Although governments formed international institutions to deal with a variety of highly technical problems, there was at mid-century a growing tendency to express the formal purpose of these agencies in terms of their potential service to international peace and security.

Accelerated 20th-Century Development. — The association of the tendency to create international organizations with the development of the complexities of modern interdependence is dramatically illustrated by statistical analysis. According to a 1957 report by the Union of International Associations, *Les 1,978 organisations internationales fondées depuis le Congrès de Vienne* ("The 1,978 international organizations founded since the Congress of Vienna"), only a handful of international organizations in existence in the late 1950s were formed before 1850; approximately 10% were established before 1900; and about 90% of the organizing activity was concentrated in the period. 1900–56. The accelerating pace of the movement was particularly notable in the decade following World War II. when more than 600 nongovernmental and over 80 official organizations were formed.

According to the 1956–57 edition of the *Annuaire des organisations internationales,* published by the Union of International Associations, there were in the late 1950s 1,116 existing international organizations. This number included 136 intergovernmental agencies, of which the most notable were the United Nations, the various specialized agencies affiliated with the United Nations, and such regional organizations as the European Coal and Steel Community, the North Atlantic Treaty organization and the Organization of American States. The variety of subjects with which intergovernmental organizations were concerned was indicated by such names as the Central Commission for the Navigation of the Rhine, the International Tin Study group, the International Patent institute, the European Organization for Nuclear Research and the International Whaling commission. Nongovernmental organizations were listed under 19 headings ranging from "Religion and Moral Improvement" to "Sport and Recreation." The largest concentrations of private international organizations fell under "Labour and Professions, Employers, Trade Unions," "Commerce and Industry" and "Medicine, General and Mental Health."

The first half of the 20th century was marked not only by the rapid multiplication of international organizations, both private and public, but also by efforts to create a pattern of orderly relationships among them. The Union of International Associations, founded at Brussels, Belg., in 1907, was an early co-ordinating body. The League of Nations, created after World War I, provided a focal point for intergovernmental organizations and also for the growing network of nongovernmental agencies. Following World War II. the United Nations became a kind of "roof organization" for the major enterprises in systematic international cooperation. In accordance with art. 57 and 63 of its charter, the UN entered into co-ordinating agreements with intergovernmental agencies operating in economic, social, cultural, educational: health and related fields. In the second half of the 20th century the roster of specialized agencies affiliated with the United Nations included: Inter-Governmental Maritime Consultative organization (IMCO); International Labour organization (ILO); United Nations Educational, Scientific and Cultural organization (UNESCO); Food and Agriculture organization (FAO): International Civil Aviation organization (ICAO); International Monetary fund; International Bank for Reconstruction and Development (World Bank); World Health organization (WHO); International Telecommunication union (ITU); Universal Postal union (CPU); World Meteorological organization (WMO); International Atomic Energy agency; and the International Finance corporation. The Economic and Social council of the United Nations, acting under art. 71 of the charter, also maintained a consultative relationship with nearly 300 nongovernmental organizations, virtually all international in scope.

The United Nations did not, however, become, nor was it intended to become, a central authority with power to control the operations of other international organizations. A great number of international agencies of all types remained outside the institutional family over which the United Nations presided. Nevertheless. the United Nations was responsible for the closest approach made to the development of a system within which the work of the great mass of international organizations might be harmonized and co-ordinated. *See* also AMERICAN STATES, ORGAXIZATION OF; BANK FOR RECONSTRUCTION AND DEVELOPMENT, INTERNATIONAL; BENELUX; CENTRAL AMERICAN FEDERATION; FOOD AND AGRICULTURE ORGAKIZATION; INTERNATIONAL CIVIL AVIATION ORGAKIZATION; INTERNATIONAL COURT OF JUSTICE; INTERNATIONAL INSTITUTE OF AGRICULTURE; INTERNATIONAL LABOUR ORGANIZATION, THE; INTERNATIONAL MONETARY FUND; INTERNATIONAL REFUGEE ORGANIZATION; INTERKATIONAL TRADE ASSOCIATIONS AND CONGRESSES; NORTH ATLANTIC TREATY ORGANIZATION; PAN-AMERICAN CONFERENCES; PAN-EUROPEAN MOVEMENT; RED CKOSS; SOUTHEAST ASIA TREATY ORGANIZATION; UNITED NATIONS; UNITED NATIONS EDUCATIONAL, SCIENTIFIC AND CULTURAL ORGANIZATION; UNITED NATIONS RELIEF AND REHABILITATION ADMINISTRATION; UNIVERSAL POSTAL UNION; WARSAW TREATY ORGANIZATION; WORLD GOVERNMENT MOVEMENTS; WORLD HEALTH ORGANIZATION.

INTERNATIONAL PAYMENTS. The main difference in the settlement of international and domestic transactions is the existence of different currencies. This, however, is not a serious obstacle as long as the currencies are freely convertible into each other. and into gold. When, for example, British importers can buy United States dollars from their banks for sterling and U.S. exporters can sell sterling to their banks for dollars, it is immaterial in what currency the transaction is settled. Banks trading in foreign exchange normally keep balances in the appropriate currencies with their branches. agents or correspondents abroad in order to facilitate the clearing process But whereas interbank credits or debits outstanding can be settled internally in terms of local currency, they are settled internationally either from ac-

cumulated balances of foreign exchange, or by loans from the creditor to the debtor. or by drawings on the International Monetary fund (q.v.) or by movements of gold. Whenever this process is multilateral rather than bilateral, it provides an additional advantage. For if, in terms of the total annual turnover of transactions between them. England is in debit to the United States and in surplus with the colonies and the latter in surplus with the United States but in debit to England, there is no net change in the foreign-exchange position of the areas concerned if the various credits and debits exactly cancel out. In practice, however, it does not work out so smoothly; there always have been considerable fluctuations in net credit and debit positions within any given year as well as between years. The way in which a country balances its international accounts is one of the most important problems of its balance of payments.

BALANCE OF PAYMENTS

The balance of payments is a systematic record of all economic transactions during a given period between residents (including the government) of one country and residents (including the governments) of other countries, referred to for convenience as foreigners. The transactions are presented in the form of double-entry bookkeeping with credit entries balanced on the debit side, and vice versa. The balance of payments of a country thus necessarily balances. There can be no surplus or deficit in a country's balance of payments as a whole.

This accounting equality of a country's total credits (receipts) and total debits (payments) may be readily illustrated. The balance of payments of the United States, for example, records the various ways in which dollars are made available to foreigners through U.S. imports, tourists' expenditures, military expenditures, donations, foreign lending activities and so forth. These expenditures are shown on the debit (payments) side of the balance. The credit (receipts) side indicates the various uses to which foreigners put their dollars. such as paying for U.S. exports, servicing of debts to the United States and the like. If foreign countries do not spend all the dollars made available to them during a given period to obtain goods and services from the United States, the balance of payments will show on the credit (receipts) side an increase of foreign-held dollar balances. foreign purchases of U.S. securities, gold exports from the United States or some similar item. If, on the other hand, the dollars made available by the United States are insufficient to pay for the exports of U.S. goods and services, additional dollars can be obtained only by liquidation of foreign holdings in the United States, by gold imports into the United States and by similar operations which would necessarily be recorded on the payments side. This must mean that for any period the receipts measured in dollars are equal to the payments measured in dollars when all the receipts and payments are included. But this equality of payments and receipts in the formal "balance sheet" conceals the reasons why countries are so concerned with their balances of payments. Hence, not whether the accounts are balanced but how they are balanced is the important question.

Operations Entering Into the Balance.—Countries are greatly concerned about the types of transactions giving rise to the receipts and payments of foreign exchange and how these compare in size with one another. The accompanying table comprises all the items in the standard schedule for reporting a country's balance of payments to the International Monetary fund (I.M.F.). It is divided into two major sections: the current account and the capital account.

The current account records all transactions other than those representing changes in the international creditor-debtor position of the reporting country and in its monetary gold holdings. It includes two distinct types of transactions: items 1 through 8, which refer to transfers of goods and services, and items 9 and 10, which cover private and official donations. The credit entries under items 1 through 8 correspond to goods and services supplied, the debit entries to goods and services received. Credits under items 9 and 10 show donations received by the country; debits show donations made.

The capital account records all transactions representing changes in the international creditor-debtor position of the reporting country and in its holdings of gold and other monetary-reserves. It does not include valuation changes (e.g., changes in the market values of securities, or revaluations of assets and liabilities because of exchange-rate adjustments) since these are not transactions. The capital movements shown do not, therefore, necessarily reflect the total change in the creditor-debtor position of the reporting country during the given period. In order to present a maximum of information compactly, the capital account is shown in terms of net changes—increases or decreases—in assets and liabilities. Increases in assets and decreases in liabilities indicate an outflow of capital (a debit); decreases in assets and increases in liabilities indicate an inflow of capital (a credit). The capital account is divided into a private sector (items 11 to 14) and an official sector (items 15 to 19).

Since economic transactions included in the balance of payments involve directly or indirectly two entries—a debit and a credit—errors and omissions apart, any net balance on account of goods, services and donations taken together is matched by an equal balance with opposite sign on capital account. Because some transactions may be inaccurately recorded or not recorded at all, the "errors and omissions" item is included to bring the statement into balance (see table).

Various Concepts of Surplus or Deficit.—To speak of a surplus or deficit in the balance of payments would appear to be a contradiction in terms. Yet much of the discussion of international economic problems following World War II concerned certain "deficits" of the war-damaged countries and the underdeveloped areas. These problems, in part, revolved about whether certain segments of a country's balance of payments were in balance or whether they were in surplus or deficit by some amount.

The discussion sometimes ran in terms of the "trade balance":

Standard Schedule for Reporting Balance of Payments to International Monetary Fund

Current transactions Reporting country——Period covered——Currency——Unit—— Exchange rate: U.S. $ per——	Credit (receipts)	Debit (payments)	Net credit (+) or (−)
Item			
A. Goods and Services			
1. Merchandise: exports f.o.b.			
Merchandise: imports f.o.b.			
2. Nonmonetary gold			
3. Foreign travel: credit			
Foreign travel: debit			
4. Transportation: credit

Official loans extended			
Official repayments			
Other			
18. Short-term assets.			
Government			
Other			
19. Monetary gold			

i.e., the net credit or debit of merchandise trade. While this is an important segment of the balance of payments, it may have very little significance by itself. An import surplus may be matched by net sales of services that are closely similar in their economic implications to sales of goods. There would then be no deficit in goods and services as a whole and this balance is a broader and more significant measure than is trade alone. Similarly, an export surplus may be reinforced by net sales of services, increasing the surplus in goods and services as a whole.

Often the balance of goods and services has been discussed as if it were the balance on current account. The current account as a whole has always had a basic importance since it is the counterpart of the capital account. A nation with a deficit on total current account is *ipso* facto decreasing its capital assets abroad (including gold) or increasing its capital liabilities to foreigners. A nation with a current-account surplus is gaining foreign assets or reducing its foreign liabilities. Manifestly a deficit or surplus on current account may be of crucial importance to a country. However, in addition to the goods and services that are sold to foreigners, there are many transactions for which no payment is made. Governments that extend grants, individuals who send goods or money to families or friends abroad, and institutions that provide charity are all engaged in such transactions. The goods, services and capital items that pass in these transactions without payment are all entered in the balance of payments as if payment were made for them. They are then simply offset by contra-entries under "donations" (which may be voluntary, automatic or semiforced) to show that, in fact, payment was not required. In many instances. to state that a country financed by foreign grants had no deficit to be met is a patent contradiction. Accordingly, while the full current account (including donations) is useful in revealing the factors that have altered the international capital position of a country, it is a seriously defective measure of balance-of-payments deficit or surplus from the standpoint of exchange problems.

Even if official donations are eliminated from the current account in arriving at a figure for deficit or surplus, the result may still be misleading as an indication of the exchange problem involved. A deficit in the balance of goods and services, for example, is not necessarily an indication of pressure on a country's exchange rate. It may be matched by an inflow of investment capital which strengthens the immediate exchange position and builds up a country's future exporting capacity. Similarly, a surplus in the balance of goods and services may be no ind cation of a strong exchange position. It may reflect the efforts of a country to pay reparations or to meet other fixed obligations abroad.

It is regrettable that in public discussions a deficit in the balance of trade is referred to as an "unfavourable trade balance" and a surplus as a "favourable trade balance." The notion that it is vitally important for a country to have an excess of exports over imports was stated as far back as the 14th century. A country that exports more commodities than it imports, so the argument runs, would receive the difference in gold and silver. This was regarded as a "favourable balance" because, for a country mith no gold or silver mines, it was the only way to increase its stock of the precious metals. But the grounds on which early writers based their beliefs in the desirability of an indefinite accumulation of the precious metals were for the most part erroneous. The mercantilists of the 16th: 17th and 18th centuries, for example, regarded any gain in the precious metals as a gain in economic power and prosperity. (See MERCANTILE SYSTEM.) Clearly, from the welfare point of view, it is goods and services that account for the economic advantages derived from foreign trade. Money is predominantly a mechanism of foreign commerce. Just as it is impossible for a country to maintain indefinitely an excess of exports over imports unless it is willing continuously to accumulate gold. invest abroad or give its goods away, so it is impossible for a country to maintain indefinitely an excess of imports over exports unless it is able continuously to obtain foreign exchange from the export of gold, from grants or investments abroad, or to default.

The terms "favourable" or "unfavourable" trade balance, when not wholly invalid, are subject to such grave limitations Chat they are rejected in modern treatments of the subject and are replaced by such terms as "active" and "passive," or "positive" and "negative," trade balance. Other terms used for the same phenomena are "export surplus" and "import surplus," or "credit" balance and "debit" balance. The more important item, net total on current account, is often designated by the terms "surplus" or "deficit" in a country's balance of current payments. The value of the net outflow of gold plus net increases in foreign holdings of a country's short-term balances has most frequently been used as a measure of a country's balance-of-payments deficit.

BRITISH BALANCE OF PAYMENTS

Britain has had a deficit in merchandise trade since before the Napoleonic Wars. Before World War II it had been able to pay for its imports of food and raw materials largely mith earnings from foreign investments built up over generations, and from services. The postwar balance-of-payments difficulties, however, which in some respects were typical of those of western Europe, were not of late origin. World War II merely hastened a great structural change in Britain's trade relations which had been going on since well before World War I.

Before World War I.—During the nation's great period of expansion—from 1780 to 1913—conditions favoured the import balance appropriate for Britain's creditor status. Its position as a pioneer in industrial development, with no tariffs or quota restrictions from 1860 to 1914, the complementary exchange of its manufactures for food and raw materials, general political stability, the large increase in overseas investment, free or "untied" lending, and stable world currencies all contributed to the relatively smooth multilateral adjustment of the British balance of payments. A fortuitous historical circumstance aided this adjustment process: Britain was able to invest much of its excess savings abroad whenever plans to invest at home declined relative to the level of total savings. But even before World War I, as Germany. the United States and Japan industrialized, world trade increased; Britain's export industries, however, were unable to keep pace with the manufactured products of the expanding industrial nations. Between 1870 and the start of World War I, world production of manufactures increased fourfold, but world trade in manufactures was a decreasing fraction of total production. In the 1870s one-third entered into international trade, in 1913 one-fifth. Nevertheless, the absolute volume of world trade in manufactures increased threefold between 1880 and 1913, and that of Britain also increased considerably although Britain's relative share of world trade declined. This trade expansion assisted the equilibration of Britain's external accounts. Even though its leadership in world trade was slowly being transferred to the United States, Britain's international accounts were not weak at the outbreak of World War I. It was the war, together with Britain's unavoidable sale of some foreign assets, that contributed to the deterioration in its balance of payments.

Between the World Wars.—Between World Wars I and II the volume of world trade in manufactures never appreciably exceeded that of 1913; the peak of 1926–30 was hardly above the 1913 level; the average of 1931–35 was only 76% of 1913; and the average of 1936–38 was 92%. The fact that Britain's share was declining rapidly within this reduced total was a significant factor in impeding adjustment of its international accounts. The external strains of the interwar period were in considerable part the result of the need for Europe—and Britain in particular—to adapt itself to this changing situation.

Furthermore, in the 1920s Britain's deficit between direct imports from. and exports to, the United States increased at the very time that invisible income (*i.e.*, shipping, insurance, banking receipts, etc.) from the United States decreased. The United States looked increasingly to the non-European world for imports, and Britain's share in U.S. trade continually declined. This decline was partially the result of a widening gap in productivity between the United States and Britain.

The gold standard, which Britain restored in 1925 following the period of currency disorder and inflation which engulfed Europe,

broke down in 1931. The great depression aggravated the external strains; comparatively free multilateral trade proved to be incompatible with mass unemployment. Multinational clearing disintegrated as restrictions on trade became ever more severe. The gains from the devaluation of sterling in 1931 proved short-lived; this action started a chain reaction that included devaluation of the U.S. dollar in 1933–34 and did not end until there had been further devaluations of the French and Belgian francs. Meanwhile, Britain (and many other countries) in the later 1930s had turned toward bilateral trade and direct controls as an effective method of relieving external strains. Despite all its efforts,Britain by 1938 was compelled to liquidate a small portion of its overseas assets to bring its international accounts into balance.

Effect of World War 11.—World War II dealt a staggering blow to Britain's balance of payments. Loss of income from overseas investments and from services impaired the nation's ability to meet the long-standing trade deficit with the Cnited States and Canada. The east-west barrier, the position of Germany and chaotic conditions in the far east and middle east increased British dependence on the dollar area. In effect, the prewar pattern of trade betueen Britain and the rest of Europe, and between Britain and the non-European world, had been practically destroyed.

Britain's postwar recovery in its balance of payments was irregular. Underlying the transitional problems was the long-term conjuncture of the great structural change in Britain's international position and the growing predominance in the world of a relatively self-contained, industrially efficient but highly unstable United States. Over the whole process of British reconstruction loomed the interrelated maladies of domestic inflation and external deficits which led to such events as the British convertibility crisis of 1547. Following that crisis, Britain made remarkable headway with the external problem, largely through a budgetary attack on inflation and, later, the European Recovery program (*q.v.*). Nevertheless, Britain suffered another reserve crisis in 1949 caused partially by a direct increase in Britain's own dollar gap (to some extent a result of "suppressed inflation"), a loss of dollar earnings by other members of the sterling area (occasioned by a recession in the United States) and an acceleration of a slow drain of gold to Belgium and Switzerland. The ominous decline in reserves compelled Britain to devalue the pound in Sept. 1949. Mass devaluations followed. Devaluation of the pound sterling, coupled with increased productivity at home and elsewhere, rapidly improved Britain's reserves. The deficit on current account with the United States and Canada was much reduced, and the surplus with the entire world was increased greatly. The over-all improvement was partly attributable to the expansion in net invisible earnings and to the continued restriction of the volume of imports. Certainly the latter could not have been accomplished without the most severe austerity in Britain.

Following the devaluations, the balance-of-payments position of the entire sterling area improved even more strikingly than did that of Britain. Actually, the sterling area raw material exporting countries had sold large quantities of wool, tin, rubber and cocoa at high prices, particularly to the United States and continental Europe, and had to a large extent "banked" the proceeds with the United Kingdom. The increase in reserves was therefore quite accidental; for the most part it was the result of the outbreak of war in Korea in 1950. Although this proved to be, with subsequent price decline of important raw materials, a temporary financial improvement, more fundamental forces were operating toward the strengthening of Britain's external accounts.

The continuing growth of British productivity during the 1950s and the more effective anti-inflationary monetary and fiscal policies helped immeasurably to reduce Britain's dollar deficit; indeed, in some years dollar surpluses were recorded. These factors, coupled with the high rates of economic growth in western Europe, Japan and the commonwealth. as well as the improvement in the United Kingdom's terms of trade, enabled it to increase its gold and dollar reserves. In 1958, with the collaboration of other western European countries, Britain consolidated the strength of its economy, which had been steadily built up in the preceding years, by establishing nonresident convertibility. As from Dec. 1958 British pounds earned by residents outside the sterling area were designated freely convertible into gold, dollars or any other currency. In effect, by 1960 the United Kingdom had achieved a workable balance in its international accounts. Despite all the stresses of World Wars I and II and their aftermaths, the pound—the international currency of the sterling area—remained one of the two leading world currencies. An important problem which remained unanswered, however, concerned the ability of the United Kingdom to maintain an appreciable rate of economic growth without rapidly encountering balance-of-payments strains. The complexity of the problems was evidenced by a recurrence of a balance-of-payments crisis in 1561. See STERLING AREA.

U.S. BALANCE OF PAYMENTS

For many years the United States had a merchandise export surplus. From 1876 to 1960 there were only three years (none after 1894) when it had a merchandise import surplus. The reasons for this development were many and varied. They included a deliberate national policy of high tariff protection; the continental character and climate of the United States; the abundance, richness and variety of its natural resources; the great distances from most foreign trading and producing centres; the protection given inland producers by high internal transportation costs; the technical skills of its people; the technological efficiency of its mass-scale production and distribution in manufacturing; the generally well-organized and mechanized agriculture; the greater tendency to generate excess capacity than other developed countries; and the nature of its commodity imports. All these factors tended to limit the expansion of American imports without heavy cost either in the production of domestic substitutes or in the deprivation of important products. Thus, compared with other important trading countries, the United States spent through the years an extremely small proportion of any dollar increases in national income on foreign products.

In the period before World War I, the United States export surplus was a sign of healthy economic development. It supplied foreign exchange for payments on foreign debt. In the 1920s, when the Cnited States became a creditor nation, it preserved its export surplus partly by making large loans to foreign countries. Other large debit items, purchases of shipping and insurance services, tourists' expenditures abroad and remittances by immigrants and charitable foundations contributed substantially to the foreign supply of dollars.

Depression and War.—The depression of the 1930s altered these conditions. Domestic investment, particularly during the spurt before the depression, tended to generate a rate of growth in income and an excess of planned saving over planned investment. With the coming of the depression, the disparity between the growth in physical capacity to produce and the growth of current demand became acute. As returns on domestic capital declined and political and economic troubles developed abroad, the excess of planned saving not only failed to be invested abroad but the flow of capital was reversed from a net outflow to a net inflow. The nation maintained a merchandise export surplus by readily importing the precious metals. From 1934 until the outbreak of World War II, rising levels of production and moderate reduction in tariffs contributed materially to a closer approach to balance in the nation's current account. On the nhole. U.S. industrial production, exports and imports moved together. During the period of U.S. participation as an active belligerent in World War II, more than 80% of total U.S. merchandise transfers represented lend-lease. In addition, for the three and one-half years following the war (from July 1, 1945, through 1948), net utilized foreign grants and credits of the U.S. government covered more than one-third of the United States total exports of goods and services.

Long-Range Trends.—What is often overlooked, however, is that powerful forces have for long been working toward international equilibration of U.S. external accounts. Thus, abstracting from the abnormal conditions of World War I and reconstruction, there has been a strong tendency since 1909 for the United States to have an excess of imports over exports of crude foodstuffs.

From 1923 to 1960 U.S. imports exceeded exports of crude foodstuffs virtually every year, despite depression conditions of the early 1930s. Similarly: since 1915. the U.S. excess of imports over exports of crude materials has been quite general, the only important exceptions being those of the years 1932–33. More noteworthy has been the long-term trend toward balance of U.S. trade in manufactured foodstuffs and in semifinished manufactures. From 1876 until 1932, U.S. exports of manufactured foodstuffs exceeded imports in every year but 1920. However, from 1932 to 1940 the trend mas reversed; and this new tendency toward net importation of manufactured foodstuffs was gradually resumed after World War II, although from 1953 to 1956 the structural maladjustments in U.S. agriculture brought about an excess of exports over imports of those products. From 1957 to 1960 imports of manufactured foodstuffs once again exceeded exports. Further. in most years from 1897 to 1921. U.S. exports of semifinished manufactures exceeded imports, but from 1922 until 1936 imports exceeded exports in every year. This trend was also resumed after World War II, although in the recession year of 1957 exports of semifinished manufactures exceeded imports. Lastly, C.S. exports of finished manufactures, the trade balance of which had been active since 1598, did not show a tendency to rise in the postwar period. whereas U.S. imports of finished manufactures continued steadily to expand.

Indeed. with one insignificant exception, throughout the 1950s U.S. total expenditures on imports of goods and services. donations and investment abroad exceeded foreign expenditures in the United States. The excess of total exports over imports in goods and services had in effect become insufficient to cover U.S. capital exports, governmental aid and expenditures. Measured in terms of gold outflow and the increase of foreign short-term balances held in the United States, from 1950 to 1957 the average annual deficit for the United States was about $1,000,000,000. In 1957 there was no such deficit, but it reached the embarrassingly large figure of over $3,000,000,000 in 1958 and 1959. The deficit in 1958 comprised a gold outflow of $2,300,000,000 and an increase of foreign short-term balances of $1,100,000,000; in 1959 it comprised a gold outflow of $776,000,000 and an increase of foreign short-term balances of $2,300,000,000. In the latter year, for the first time in the 20th century, the United States had an excess of commercial imports over exports of goods and services. It also had a deficit on total current account (items 1 through 10) and in goods and services and private donations (items 1 through 9).

During the first decade after World War II, the remarkable economic expansion in the United States and elsewhere, together with continued foreign assistance and tariff reductions, strengthened the long-term forces operating toward balance in U.S. international accounts. But at the close of the 1950s, events exhibited a "pendular" reaction. Supply conditions in western Europe had greatly improved. The high rates of economic growth at stable prices in the Federal Republic of Germany and at falling ones in Japan enabled them to expand their share of world exports of manufactures while that of the United States declined. The magnitude of the U.S deficits was aggravated by a sharp rise in U.S. imports relative to that of western Europe, an unusually prolonged steel strike. exceptionally low cotton exports, conversion to the production of commercial jet airplanes and abnormally large imports of small cars. The evidence does not disclose that U.S. prices had been rising appreciably as compared with those of most other industrial countries. With the relative expansion in Europe during 1960 the U.S. balance of payments in goods and services strongly improved. Nevertheless, the continuation of substantial deficits in 1960 and 1961 measured in terms of the outflow of gold and net increases in foreign holdings of liquid dollar assets, gave concern on both sides of the Atlantic over the long-term equilibrium of the C.S. balance of payments.

Balance-of-Payments Equilibrium.— Balances of payments are seldom in equilibrium in the theoretical sense that a small displacement of exports. imports or capital items would tend to be corrected and the original balance restored. In practice. equilibrium in a nation's balance of payments implies the absence of severe drain, or accumulation, of foreign reserves. Such drains may be the direct result of an excessive amount of domestic money being exchanged into foreign money. This may indicate that either the debtor or the creditor nation's monetary, fiscal and wage policies—and the resulting money incomes and product prices—are incompatible with the foreign-exchange rates. After World War II many countries found themselves in this situation *vis-à-vis* the United States and, by Sept. 1949, felt compelled to devalue their currencies. A persistent drain of reserves arising from an import balance in one of the selections of accounts (*e.g.*, total goods and services) may indicate that the nation in the past has been able to live partly on its foreign reserves and assets or to secure foreign loans or grants. Mounting international indebtedness may also be the result of unfulfilled or inconsistent plans with respect to domestic production and expenditures on the one hand, and imports and exports on the other. In such instances the gap between imports and exports has often been filled by foreign borrowing. Differential rates of interest may also contribute to international disequilibrium; thus the lower net-interest rates of the United States as compared with those of many other industrial countries have recently compounded the difficulty for U.S. net exports to cover capital outflows, governmental aid and expenditures.

Regardless of the source of disequilibrium, the problem of adjustment in a nation's balance of payments affects the creditor as well as the debtor. In the long term, measures appropriate to the debtor mill help solve the problems of the creditor, and measures appropriate to the creditor will help solve the problems of the debtor. But in the short term all policies are not equally acceptable, and creditors as well as debtors are tempted to resort to extreme national measures without regard for their effects on the world economy as a whole.

FOREIGN-EXCHANGE CONTROLS

As a consequence of the great depression, and attendant capital flight, from the 1930s a major complication arose in the international mechanism of adjustment, viz., the development of foreign-exchange controls. These controls restrict operations in all or specific foreign currencies on both current and capital account. They are usually administered by the central bank as the treasury's agent, and are invariably associated with trade controls. They take many forms, ranging from the licensing of all transactions involving foreign exchange to the supervision of transactions involving only specific foreign currencies or those of residents of specified countries. Nonetheless, they always constitute a method of rationing foreign currencies, particularly those which are scarce, and of ensuring that receipts of such foreign exchange are diverted into authorized channels.

The chief function of exchange controls is to prevent or redress an adverse balance of payments by limiting purchases of foreign exchange to an amount not in excess of foreign-exchange receipts. Usually, this entails setting a rate, or rates, at which exchange shall be bought and sold. When a single rate is established, it is normally higher than the rate that would prevail in a free market. Consequently, it tends to curb exports and stimulate imports. When multiple rates are established, they have the effect of differentiating between prices charged at home and abroad for specified exports and imports. The value of the currency is kept uniform for all residents with respect to their purchases of domestic products; but the multiple rates fix different prices for the same goods at home and abroad by stipulating different exchange rates for the various uses to which foreign exchange may be put. Although this practice may strengthen a country's balance of payments, it is a form of monopolistic price discrimination in international trade.

Most noncommunist countries have had occasion to adopt foreign-exchange controls out of necessity rather than preference. In periods of emergency it has often been impossible to achieve balance-of-payments equilibrium through the operation of demand and supply on the foreign-exchange market. Once adopted by some important country or countries, exchange controls have provided a source of special advantage as an instrument of trade bargaining; hence their tendency to spread. They have also been

used primarily for domestic reasons, such as to insulate an economy from external inflationary or deflationary pressures, or to assist in national economic planning and development However, in economies that are not centrally planned, exchange controls have had a tendency to direct trade into uneconomic channels, deteriorate its quality and reduce the extent of its potential contribution to the well-being of the participating countries. These factors are particularly relevant to full-employment conditions, for then exchange controls and their associated practices act as a constraint against further economic expansion. When the emergency that brought about their adoption has been removed. most noncommunist countries have tended to do away with exchange controls on trade account. They have usually been maintained on capital account, however, in order to control the flow of domestic versus foreign investment, and to deal with emergency conditions of capital flight.

Freely Fluctuating Rates.—Under normal circumstances international payments equilibrium might be achieved in a free system in which everyone is permitted to buy and sell foreign exchange in unlimited amounts. Shifts in demand and supply in foreign currencies would bring about changes in exchange rates which, in turn, would equalize the demand and supply for foreign currencies. If a country's demand for foreign exchange mere to exceed supply, the value of foreign currencies would tend to rise relative to the value of the domestic currency. Its imports would tend to fall and its exports rise, leading toward the restoration of equilibrium. This process of international equilibration, it will be observed. requires no disinflationary pressures in the country suffering from a balance-of-payments deficit; on the contrary, it tends to raise prices domestically in terms of the national currency but to lower them in terms of foreign currencies.

Despite its simplicity the system of freely fluctuating exchange rates has rarely been recommended. Almost no country for which foreign trade has been of great importance has ever been willing for long to tolerate completely uncushioned, fluctuating exchange rates. The reasons for this have been many and complex; they are grounded in the fact that fluctuating exchange rates are a powerful vehicle for disruptive speculation. A small, well-informed group customarily deals in the exchanges. In these markets there are no storage expenses. no physical deterioration or obsolescence caused by changes in tastes or wants. The asset in question is for practical purposes homogeneous, standardized and without grades Brokerage charges are minimal. the level of commissions by middlemen being lower than in any other field of speculation except national bond markets. The hedge normally earns income for the speculator and, be it foreign exchange or gold, it may be the best hedge with respect to expectations of a decline in the general price level. Lastly. there are no physical restraints. such as cost of production, on the possible extent of the swing downward in the value of a single country's currency. Exchange-rate fluctuations are often self-propelling and lead away from, rather than toward, international payments equilibrium.

It is generally recognized that once the brake of reasonably stable exchange rates is removed, the last significant obstacle to irresponsible monetary and fiscal behaviour, for a long period and for many countries, may also be removed. In addition, experience has proved that fluctuating exchange rates result in risks for foreign trade and investment which are economically costly, and for which the development of forward-exchange markets and other facilities for hedging provide only a very limited palliative. Nor is it desirable to let exchange rates fluctuate freely in response to temporary changes in demand and supply. Such fluctuations cause adjustments in production and transfers of resources which also are costly and should be avoided if the disturbance is merely of a short-term character. The crux of the matter is that changes in exchange rates are different from other price changes: they affect, directly, all prices of internationally traded commodities and, indirectly many prices in the national economy As a prerequisite for international economic stability, key trading countries must therefore maintain reasonably stable exchange rates.

Stable Rates.—Rigidly stable exchange rates also have their drawbacks, for under certain circumstances they tend to generate deflation. Between 1870 and 1914, when the gold standard was an almost universally accepted institution in the western world, gold-standard countries tied their currencies to each other in terms of gold. Residents of one gold-standard country were permitted to procure money from another gold-standard country at a rate of exchange determined by the gold-weight ratio of the two currency units and by the cost involved in sending the gold from one country to the other. Thus the price of the pound sterling in terms of dollars could not rise beyond the so-called upper or U.S. gold-export point, since at this point it would become cheaper to purchase pounds by exchanging dollars into gold in the United States and to ship the gold to Great Britain. Similarly, the price of the pound sterling could not drop below the lower or U.S. gold-import point, since at this point it would become cheaper to purchase dollars by exchanging pounds into gold in Great Britain and shipping the gold to the United States. Within limits of the gold points, the gold standard therefore directly achieved stable exchange rates. Indirectly, it contributed to the automatic operation of the international mechanism by stimulating the inflow of short-term funds to the country whose exchange rate had fallen to the lower limit and was expected soon to rise.

Should a country's demand for foreign exchange tend greatly to exceed the supply, however, the movement of short-term funds would be insufficient to re-establish equilibrium. Nevertheless, the gold-standard mechanism would still tend to produce an adjustment automatically by an outflow of gold from the country that had developed a deficit, and an inflow of gold into the country that had developed a surplus. As gold constituted the basis of the monetary system under the gold standard, a reduction in the gold base could lead to a contraction of money and credit of a country in amount several times larger than the gold export, and conversely. The outflow of gold would tend to depress prices, and if the wage-price level were not perfectly flexible, this would also tend to depress real incomes. These changes in turn would tend to reduce imports and expand exports of the country losing gold, while the opposite changes would tend to raise imports and lower exports of the country gaining gold. The monetary contraction of the country losing gold relative to the countries gaining it would have the additional effect of raising interest rates in the former and lowering them in the latter. Normally, this would aid the process of equilibration by attracting foreign capital to the country which had developed the deficit. Equilibrium would therefore tend to be restored with a minimum gold outflow, an export surplus and an inflow of foreign capital.

The gold standard clearly was conducive to the interdependent growth of free multilateral trade and large-scale private capital movements. It helped integrate the monetary and credit policies of the gold-standard countries. It also was compatible with the objectives of reasonable price level stability and satisfactory growth rates. But it could not prevent world-wide inflations or deflations. If gold-standard countries were simultaneously to go through an inflation, the gold-flow mechanism would only keep them in line by way of a gold flow from the more to the less inflationary countries. A parallel rise in prices would not set the mechanism in motion; and similarly for the case of simultaneous deflation. Furthermore, even in the 19th century, prices and costs were not flexible enough for a smooth adjustment in the event of a gold outflow. Wages were inflexible downward. Attempts to reduce prices through credit contraction often lowered profits and increased unemployment. In fact, the gold standard failed to accomplish one of the most significant aims of virtually all modern nations, the avoidance of major depressions and mass unemployment. When the gold standard was restored in the latter 1920s, its weaknesses became even more apparent. Not only had the United States replaced Britain as the pivotal country in world trade, and thus transformed the process of international equilibration, but economic rigidities had also increased: the rules, as well as objectives, of the gold standard became increasingly incompatible with the new conditions.

As an international mechanism, the gold standard failed and crumbled with the great depression. Experience and theory had shown that deflationary policies might not improve a country's

balance of payments during a world crisis. Moreover, countries suffering from external deficits could not tolerate an international mechanism which intensified unemployment. Hence, after the depressed conditions of the early 1930s, most governments eschewed financial contraction and undertook measures to increase the volume of output and employment.

A good deal of the theoretical literature of the period swept aside the classical assumptions of maintaining stable exchange rates and of relying on internal price adjustments to bear the brunt of the balancing process. Stress was laid, instead, on the equilibrating effects through income changes and on the insensitivity of internal adjustments to external forces. Emphasis was placed on greater exchange-rate variation and on trade controls as a guide to external policy; on internal stability at full employment and on effective demand as a guide to internal policy. Primarily, the equilibration of international accounts was achieved, in fact, through the adjustment of imports and exports to changes in the levels of production and income at home and abroad. When employment and production increased in one country. its imports would rise. The export industries in the countries supplying these goods would expand. Their income and employment would rise in turn, and their imports would increase. This adjustment process could readily cause a deficit in the country initiating the change, for the rise in its imports would not be followed by an immediate rise in its exports. A new balance would nevertheless tend to be established as an expansion of production, income and prices in the countries that had been stimulated would bring about an increase in their imports. On similar reasoning, a recession or depression in an important trading country could cause a contagious economic contraction. for the decline in its production would tend to result in a fall in its imports, and hence a fall in production and income abroad.

MONETARY AGREEMENT

It can readily be understood that when the representatives to the United Nations Monetary and Financial conference met in 1944 at Bretton Woods, N.H.. to establish the International Monetary fund (I.M.F.), they did not recommend a document that would have tied the hands of governments to rigidly stable exchange rates. Nor did they recommend freely fluctuating exchange rates or the complete abolition of foreign-exchange controls.

International Monetary Fund. — The main purposes of the I.M.F. were to promote international monetary co-operation; to facilitate the expansion and balanced growth of multilateral trade; to promote exchange stability and avoid competitive exchange depreciation; to assist in the establishment of free international payments and convertibility on current account without discriminatory trade or exchange restrictions; and to make international currency resources available to the contracting members. To this end. the agreement which came into force in 1945 assigned to each member a quota in the fund on which it could draw to cover a deficit in its balance of payments. The subscription of each member was equal to its quota, 25% of which was paid in gold (or, lacking this amount, 10% of its net official holdings of gold and U.S. dollars) and the balance in its own currency. Although the countries agreed to promote general stability of exchange rates, the par value of a member's currency could be changed by 10%, and the fund merely notified of such action. Changes in excess of 10% would reauire the concurrence of the fund.

The contracting members thus anticipated that exchange-rate changes would be more flexible in the postwar era than they had been under the gold standard, but that competitive exchange depreciation would be avoided. The new arrangements would give the member countries greater freedom with respect to domestic financial policies than did the gold standard. A country would be able to combat certain kinds of depressions or recessions by expanding effective demand, even though such policies might lead to an adverse balance of payments and a reduction of its exchange rate. On the other hand, if a country should suffer from a balance-of-payments deficit engendered by expansionary financial policies, the fund could withhold aid until the member adopted noninflationary policies.

After the establishment of the fund. the international mechanism of western nations consisted of arrangements lying between that of the gold standard and completely flexible exchange rates, with some measure of direct foreign-exchange controls. These arrangements have been used with a view to achieve external balance without sacrificing prevalent domestic economic objectives: a high average level of employment; avoidance of significant cyclical instability; appreciable long-run rates of growth; improvement in the average level of well-being; equity in the distribution of income; and a reasonably stable general price level. Within the limits of these objectives, most western nations have also endeavoured to keep their exchange rates stable over extended periods of time. There has thus been a general weakening in the emphasis on exchange-rate stability, although key countries have shown resolve to alter their own exchange rates only as a measure of Iast resort. All western governments have demonstrated greater determination to counteract economic fluctuations by central bank and fiscal policies. They have considered it undesirable to permit the self-regulating forces of the international mechanism to operate whenever such forces threatened the objectives of economic growth or price-level stability. In time of balance-of-payments deficit, some nations have therefore refused to follow contractionary policies; in time of surplus and full employment, others have been reluctant to follow expansionary policies. Consequently, the operation of the international mechanism of adjustment has been seriously curtailed.

In the early postwar years the I.M.F. was unable to deal effectively with the problem of international disequilibrium. Dollar deficits were inextricably interwoven with the gigantic task of European reconstruction; and the fund was never intended, nor did it possess the resources, to cope with these problems. Among other things, western European countries required larger international reserves. From 1946 to 1949 various types of monetary clearing agreements predominated in Europe. They usually involved an arrangement between the central banks of two countries; the importers of each country paid the sums they owed to the exporters of the other into an account of their own central bank. At specified intervals, the two central banks offset their mutual claims. If the imports of the two countries did not balance — as they usually did not — one country would for a considerable time accumulate claims on the other.

European Payments Union. — In 1950 these emergency arrangements were replaced in Europe by a new monetary agreement called the European Payments union (E.P.U.). The E.P.U. was a multilateral clearing agreement which allowed each country to offset a deficit in its balance of payments with any one of the member countries against surpluses with others. The clearing took place at the end of each month. If the country emerged with an over-all deficit vis-8-vis the rest of the group, the E.P.U. automatically extended credit to it either for the whole amount of the deficit or for part of it, depending on its cumulative debtor position. The difference between the deficit and the amount of credit obtained had to be paid in gold. Once the country had exhausted the quota allotted to it, the whole of the deficit had to be paid in gold. Similarly, a country that emerged with a surplus had to give credit to the E.P.U. to the extent of the whole or part of the surplus depending on its cumulative creditor position. Once it had reached the limit of its quota, the country received an agreed-upon proportion of the surplus in gold from the E.P.U. and granted the remaining credit to the E.P.U. The E.P.U. was renewed from year to year, until it was terminated in 1958.

European Monetary Agreement. — By that time western European countries felt able to make a major monetary reform to eliminate the discrimination between dollar and nondollar currencies in their formal exchange arrangements. With their adoption of nonresident convertibility in 1958, the E.P.U. was dissolved and its termination. brought into force the European Monetary agreement (E.M.A.). This agreement was signed as early as 1955 by the members of E.P.U. Under E.M.A.. the automatic credit arrangement was abolished but member countries were obliged to make available limited amounts of very short-term finance. Credits might be granted to assist in meeting temporary balance-

of-payments difficulties, the approval of each application being subject to examination of the merits of the case.

The I.M.F. had increased its quotas in 1958 and expanded its stand-by reserve arrangements. These acts were of importance in reinforcing the confidence of western Europe to establish nonresident convertibility. Even of greater significance were the deficits of the United States in improving the international liquidity position of its trading partners. These latter deficits were of great magnitude and clearly could not be continued. Hence, in 1961, the O.E.E.C. was transformed into the Organization for Economic Cooperation and Development (O.E.C.D.) with the full participation of the United States and Canada. It was established for the express purpose of achieving closer economic collaboration of the noncommunist world, and particularly to obtain larger contributions from western European countries and Japan to the development of newly independent countries. Western institutions were substantially strengthened to deal with moderate and isolated balance-of-payments strains. but they would be inadequate to meet a more severe and general international financial crisis.

In order to contribute to the defense and development of the noncommunist world, the United States is obliged to maintain an excess of exports over imports of goods and services. To achieve these ends. the United States and western Europe were faced in the early 1960s with the need to make serious adjustments. As for the United States, a substantial export surplus at appreciable rates of economic growth required the maintenance of a competitive price level. As for western Europe, it was essential to recognize that the burden of adjustment was as much the responsibility of countries with balance-of-payments surpluses as it was of countries with balance-of-payments deficits.

INTERNATIONAL REFUGEE ORGANIZATION, commonly known as the IRO, was a temporary specialized agency of the United Nations, formally established in 1946, which assisted refugees and displaced persons remaining in many countries of Europe and China after World War II who either could not return to their countries of origin or were unwilling to return for political reasons. Between July 1947 and Jan. 1952 IRO cared for over 1,500,000 persons in special camps, particularly in Germany and Austria, pending repatriation or resettlement in other countries.

Functions. — The services supplied by IRO were care and maintenance in the camps, including food and clothing, medical care, vocational training and orientation in preparation for resettlement and transportation to overseas countries of permanent resettlement. IRO also conducted an extensive tracing service in many countries to find lost relatives and to reunite families, and assisted many thousands of unaccompanied children to rejoin their parents or to find new foster homes. The aged and the ill who could not qualify for admission to countries of immigration were placed in institutions for permanent care.

Beginning operations on July 1, 1947, the IRO preparatory commission took over from its principal predecessor organization, the United Nations Relief and Rehabilitation administration (UNRRA) (*q.v.*), the administration of the refugee camps in Germany and Austria and assisted many thousands of refugees resident temporarily in other European countries and in countries of North Africa. UNRRA had previously been engaged in collaboration with the occupying military authorities in Germany and Austria in assisting the repatriation of some 7,500,000 displaced persons to their home countries immediately after the war. IRO assisted the remaining 1,500,000 refugees and displaced persons who exercised their freedom of choice, recognized by the UN, not to return to their countries of origin for political or other reasons IRO also assumed at that time the responsibilities for the legal protection of refugees and for their resettlement in other countries previously carried out by the Intergovernmental Committee on Refugees, which had been organized in London in 1939 and which terminated its activities upon the organization of IRO.

Participation. — During the five years of IRO operations, member governments contributed $400,000,000 to IRO expenditures which included over $195,000,000 for the transportation overseas of approximately 1,000,000 refugees who were accepted by Australia, Canada, the United States and the Latin American countries. Some 23,000 refugees of European origin in China were assisted to find permanent homes in other countries. When IRO terminated its activities in Jan. 1952, some 500,000 refugees remained in an unsettled state in Europe of whom 200,000 were still living in camps. Eighteen governments participated as members of IRO and contributed to its expenditures: Australia, Belgium, Brazil, Canada, China. Denmark. Dominican Republic, France, Guatemala, Iceland, Italy, Luxembourg, the Netherlands, New Zealand, Norway, the United Kingdom, the United States and Venezuela. *See* also REFUGEES; UNITED NATIOSS.

INTERNATIONAL RELATIONS (ARTICLES ON). Attempts to systematize the study of international relations date from antiquity. In the 20th century, however. the subject has acquired a new urgency. Because of the increasing destructiveness of war, the rise of new ideologies, the decline of colonialism, the establishment of universal international organizations and the increasing interdependence of all peoples through modern means of communication and transport, governments and peoples have been forced to pay primary attention to international relations. It has become an accepted field of education and research, and efforts have been made to state its principles in a unified discipline. INTERNATIONAL RELATIONS gives an introductory survey of this discipline, which has attempted to analyze the conditions, needs and aspirations influencing the foreign policies of nations; the patterns of power, interest and justification that have developed both universally and in regions; and the processes of accommodation, adjustment and change seeking to close the gap between practice and theory.

The evolution of international law, its scope, and the theoretical and practical basis of its authority are treated in INTERNATIONAL LAW, PUBLIC. The body of rules governing issues that arise between individuals belonging to different nations or between an individual and a nation other than his own, sometimes known as private international law, is discussed in CONFLICT OF LAWS.

DIPLOMACY deals with the conduct of international relations as a profession; the evolution of its traditions and methods; and the impact on these of World Wars I and II.

Major controversies of the 20th century have centred around the conditions under which a new regime is to be accepted as the legal representative of a state, or a newly established state is to be accepted in the family of nations. The factors involved in this question are discussed in RECOGNITION, DIPLOMATIC.

The varying degrees of authority exercised by fully and partially sovereign states are discussed in SOVEREIGNTY. Articles dealing with the influence of states beyond their national borders include EMPIRE; HEGEMONY; IMPERIALISM; MANDATE; PROTECTORATE; SPHERES OF INFLUENCE; SUZERAINTY.

Attempts to map a road to peace, and the methods that have been tried and proposed, are discussed in PEACE, INTERNATIONAL. Among the articles dealing with individual phases of the quest

for peace are ARBITRATION, INTERNATIONAL; DISARMAMENT; INTERNATIOKAL ORGANIZATIONS; PACIFISM; and WORLD GOVERNMENT MOVEMENTS.

SECURITY, INTERNATIONAL describes the various forms of isolationism and coalition to which states have turned to ensure their territorial and political integrity. The rise and fall of the first global organization for collective security are chronicled in LEAGUE OF NATIONS. The organization that inherited the League's problems is discussed in UNITED NATIONS, an article that describes the major executive and administrative units of the UN; its specialized agencies; and its successes and frustrations when its machinery has been called into action. Certain ideals which the UN was intended to realize are discussed in ATLANTIC CHARTER; HUMAN RIGHTS; and SELF-DETERMINATION.

INTERNATIONAL COURT OF JUSTICE describes the history, organization and administrative procedures of the chief judicial agency of the UN. Among other articles dealing with UN agencies and activities are FOOD AND AGRICULTURE ORGANIZATION; INTERNATIONAL LABOUR ORGANIZATION, THE; TRUSTEESHIP SYSTEM; UNITED NATIONS EDUCATIONAL, SCIENTIFIC AND CULTURAL ORGANIZATION; UNIVERSAL POSTAL UNION; and WORLD HEALTH ORGANIZATION.

Among many articles dealing with international economics are BANK FOR RECONSTRUCTION AKD DEYELOPMENT, INTERNATIONAL; CAPITAL. EXPORT OF; CARTEL; COMMERCIAL TREATIES; ECONOMIC UNION; INTERKATIONAL PAYMENTS; INTERNATIONAL TRADE ASSOCIATIONS AND CONGRESSES; MERCANTILE SYSTEM; SHIPPING, HISTORY OF; SHIPPING INDUSTRY (especially the section International Problems); TARIFFS; TARIFFS AND TRADE, GENERAL AGREEMENT ON; TRADE, INTERNATIONAL; TRADE ROUTES; and WATERWAYS, INTERNATIONAL.

International alignments in general are treated in ALLIANCE; those sponsored by the U.S. include NORTH ATLANTIC TREATY ORGANIZATION and SOUTHEAST ASIA TREATY ORGANIZATION. Alignments associated with the U S S.R. are discussed in COMMUNISM; INTERNATIONAL, THE; MUTUAL ECONOMIC ASSISTANCE, COUNCIL OF; and WARSAW TREATY ORGANIZATION. Economic aid programs of both the U.S. and the U.S.S.R. are discussed in FOREIGN AID PROGRAMS.

Articles on other regional groupings in international relations include MONROE DOCTRINE, THE; AMERICAN STATES, ORGANIZATION OF; and PAN-EUROPEAN MOVEMENT. Articles on ethnological and religious groupings include PAN-GERMANISM; PAN-ISLAMISM; PAN-SLAVISM; PAN-TURANIANISM; and ZIONISM.

Since international conferences and treaties made at them are usually referred to by the name of the city where they were held, articles dealing with them will be found under such headings as BAGHDAD PACT; BANDUNG CONFERENCE; GENEVA SUMMIT CONFERENCE (1955); LOCARNO, PACT OF; SAN FRANCISCO CONFERENCE (1945); YALTA CONFERENCE (194j); and, for earlier conferences, under HAGUE COKFERENCES; WASHINGTON CONFERENCE; etc. Two key articles dealing with groups of conferences are PAN-AMERICAN CONFERENCES; and WORLD WAR II CONFERENCES, ALLIED, which treats all major Allied conferences (for example, those of Casablanca and Potsdam) with the exception of Yalta, which is the subject of the separate article listed above. The procedures usually followed in gatherings for the discussion of international issues are described in CONFERENCE. TREATY deals with methods of negotiation, the various types of treaty and the place of treaties in history and in the context of international law.

FAR EAST: RELATIONS WITH THE WEST surveys the history of these relations, from the Portuguese explorations of the 16th century to the political and military chain reactions that followed the rise of Communist China. EASTERN QUESTION similarly deals with the near east and middle east.

WAR examines military policy as a branch of foreign policy; also, it reviews ancient, medieval and modern types of war, their causes and their impact on civilization. INSURGENCY deals with the activities of irregular forces, particularly with reference to international law and politics. Among other articles concerned with the repercussions of war on the international community are AGGRESSION; BLOCKADE; CONTRABAND; ECONOMIC WARFARE; ESPIONAGE; LAWS OF WAR; NEUTRALITY; PRIZE COURTS AND PRIZE LAW; PSYCHOLOGICAL WARFARE; and REFUGEES. Articles on many aspects of warfare are listed under MILITARY AFFAIRS (ARTICLES ON); NAVAL AFFAIRS (ARTICLES ON); AIR WARFARE.

The foreign policies of specific states are discussed in the general articles on those states.

A sound understanding of international relations calls for knowledge of many allied fields, the most obvious of which is covered in the survey article GEOGRAPHY. The use and misuse of geographical science in international relations are treated in GEOPOLITICS. Among other important background articles are ANTHROPOLOGY (particularly the section Applied Anthropology); ATOMIC ENERGY; FOOD SUPPLY OF THE WORLD; MIGRATION; NATIONALISM; NATURAL RESOURCES; POPULATION; PROPAGANDA; PUBLIC OPINION; PSYCHOLOGY; RACES OF MANKIND; and SOCIAL ANTHROPOLOGY.

Biographical articles summarize the work of leaders in the field, from the classical commentator GROTIUS, HUGO to such modern authorities as ANZILOTTI, DIONISIO and WILSON, GEORGE GRAFTON.

INTERNATIONAL RELATIONS. In its broadest, literal meaning, this term denotes relations among the autonomous political units which today we call nations, or among individual members of such units. On the collective level, such relations can be political, military, economic or cultural; they can comprise all kinds of individual relations involving members of different nations. Yet when we refer to international relations as a distinct object of human action and understanding, we have in mind only those collective or individual relations, transcending national boundaries, which affect the position of nations vis-à-vis each other. International relations in this sense are political relations; they comprise, aside from the foreign policy of nations, all collective and individual relations which impinge upon the political position of a nation vis-à-vis other nations. The term in this sense is a synonym for foreign relations, as used, for instance, in the name "senate foreign relations committee."

International relations are as old as political history itself and have shown throughout the ages constant patterns of relationships and policies, whether entered into by hereditary monarchs or elective governments, cities or nation-states, continental empires or tiny principalities, ecclesiastic or secular rulers. The consistency of patterns beneath the variety of historic manifestations makes both historic understanding and theoretical analysis of international relations possible. Thus we are able to understand the international relations of the Greek city-states that Thucydides describes, the international relations of the Indian states of the 4th century B.C. from which Kautilya derived his philosophy, the international relations of the ancient near east of which the Old Testament tells, as well as those of the more recent past. By detecting in the international relations of different cultures and historic periods identical responses to identical challenges, we are able to develop certain theoretical propositions about international relations that are true regardless of time and place.

Basic Patterns. — The dynamic force that molds international relations is to be found in the aspirations for power of autonomous political units. These aspirations crystallize into three basic patterns: to keep one's power, to increase one's power, to demonstrate one's power. From these patterns three basic types of policy ensue: the policy of the status quo, the policy of imperialism and the policy of prestige. The clash of these policies —A trying to maintain the status quo, B trying to change it at the expense of A—leads to an unending struggle for power which characterizes all international relations. This struggle for power can be fought by two different means: diplomacy and military force. It leads of necessity to the balance of power through which nation A, either alone or in conjunction with other nations similarly threatened, tries to maintain itself against B. When A and B pursue their goals in conjunction with other nations, they embark upon a policy of alliances. When nations carry on the struggle for power by military means, they engage in an armaments race or war. When they try to justify and rationalize their position in the power struggle by reference to universal values,

typically of a moral nature, they develop political ideologies. Continuous peaceful contacts among them lead to the development of an institutionalized diplomacy (*q.v.*).

Throughout the better part of history, several systems of international relations have existed side by side with little or no contact among them. Until the discovery of America, the American system or systems of international relations led a completely separate existence. The Chinese and Indian systems had only intermittent contacts with others.

Three different patterns of international relations can be distinguished according to the distribution of power within them: multiple, bipolar and imperial systems. The multiple system is distinguished by a number of units of approximately equal strength which combine and oppose each other in ever-changing alignments. Its main characteristics are flexibility, uncertainty as to the relative strength and future policies of its members and the propensity for limited, inconclusive wars. The European state system. from the end of the Thirty Years' War in 1648 to the beginning of World War I in 1914, with the exception of the period of the Napoleonic Wars, conformed to this pattern.

The bipolar system is characterized by the predominance of two major powers of approximately equal strength, around which the other members are grouped in different degrees of closeness. This system is rigid and stable as long as the approximately equal distribution of power between its two predominant members persists. Any marked shift in that distribution threatens the system with destruction. The structure of international relations that emerged from World War II exemplifies this pattern.

The imperial system consists of one predominant nation with a number of subordinate members clustered around it. The stability of such a system is great, and conflicts within it tend to be marginal. Its existence can be threatened by the disintegration of the predominant member, the rise of a number of subordinate members to a position from which they can challenge the predominant one, or by a challenge from outside the system. The system of international relations dominated by the Roman empire is the classic example of this pattern.

Changes in Modern Times.—International relations have undergone in modern times four drastic changes: the formerly separate systems of international relations have merged into one world-wide system; the predominance of the European system has disappeared; the possibility and actuality of total war have come to dominate the international scene; the feasibility of universal destruction with nuclear weapons has radically altered the function of force as a means to the ends of foreign policy. While the first three changes do not affect the dynamics and structure of international relations as we have known them since the beginning of history. the last constitutes a veritable revolution, the only one in recorded history, in the structure of international relations.

The expansion of the European state system into the other continents by means of colonial empires, starting early in the 16th century, broke down the barriers which had separated the different systems of international relations. They were all brought into contact with, and into some form of dependence upon, the European state system, and through it they came into contact with each other. The two world wars of the 20th century, in which most nations of the world participated, point in their very name to the transformation of a number of separate systems of international relations into one world-wide system. That process of political unification was greatly advanced and expanded to the individual sphere through the development of the technology of transportation and communications. This development started uith the great voyages at the end of the 15th century and culminated in the drastic reduction of geographic distances for transportation and the virtual obliteration of the limits of time and space for communications.

The last phase of this transformation of international relations into a world-wide system, covering roughly the period from the end of World War I to the aftermath of World War II, coincides with a radical change in the distribution of power within the system. From the beginning of the 16th century to World War I the European system provided the dynamics and the preponderant power for this transformation; now two nations, either completely or predominantly non-European—the United States and the Soviet Union—have taken its place. This decline of Europe as the political centre of the world may be said to have started with the Monroe Doctrine of 1823 declaring the mutual political independence of Europe and the western hemisphere. This declaration foreshadowed the fragmentation of the European empires which was virtually consummated after World War II in the colonial revolutions sweeping Africa and Asia. Most of the colonial possessions of European nations, one after the other, gained their national independence, and many of them either withdrew their political support from the European nations or joined their enemies. The outstanding examples of these two different forms of political emancipation are India and China.

The decline of Europe resulting from the colonial revolutions coincided with the rise to predominance of formerly backward nations such as Russia and China. The technological unification of the world gave these nations the tools to transform their superior potential in geography, population and natural resources into the actuality of national power.

Total War.—The decisive factors in the decline of Europe as the political centre of the world were the two world wars of the 20th century. At the same time that they weakened the main European nations in their human and material resources, these conflicts brought non-European nations to the fore—the United States and Japan in consequence of World War I, the United States and the Soviet Union in consequence of World War II. These two world wars differed not only in their consequences but also in their intrinsic character from other wars fought in the western world in modern times. Most of the latter were limited wars in that only a fraction of the total human and material resources of the belligerents was committed to them. Only a fraction of the total population was morally identified with these wars and suffered from them, and each war was waged only for limited objectives. The two world wars and those for which the most powerful nations continued to prepare were total in all these four respects. The actuality and threat of total war were, indeed, the most important distinctive characteristics of international relations in the mid-20th century. They were due to an unprecedented accumulation of destructive power in the hands of the most powerful nations and to the incentive to use that power for national purposes. The accumulation of power resulted from drastic changes in the distribution of political and technological power in the world; the incentive was presented by the closing of the colonial frontier and the ascendancy of a universalistic nationalism.

Throughout the modern period, with the exception of the wars of religion of the 16th and 17th centuries and of the Napoleonic Wars, wars were limited in every respect. Power was so widely dispersed among a great number of sovereign states that no single state or possible combination of states was strong enough to gain more than limited objectives against its adversaries. The drastic reduction in the number of sovereign states and the resulting concentration of power in the hands of a few nations of the first rank, which occurred between the end of the Thirty Years' War and the end of World War II, created one precondition for total war. The treaty of Westphalia of 1648, for instance, reduced the number of sovereign states of which the German empire was composed from goo to 355. The diet of Regensburg of 1803 eliminated 200 more. When the German confederation was founded in 1815, only 36 sovereign states were left to join it. The unification of Italy in 1861 and that of Germany in 1871 eliminated 31 additional sovereign states.

At the end of the Napoleonic Wars in 1815, only five nations of the first rank were left—Austria, France, Great Britain, Russia and Prussia. In the 1860s Italy and the United States joined them, followed toward the end of the century by Japan. At the beginning of World War I in 1914, eight nations were of the first rank, with Germany having replaced Prussia. After World War I the trend toward reduction of the number of sovereign states was reversed; their number about doubled because the Ottoman, Austro-Hungarian, British and French empires were broken up. Yet the trend toward concentration of more and more

power in the hands of fewer and fewer states continued. At the end of World War II the number of nations of the first rank was reduced to two: the United States and the Soviet Union.

It is not by accident that the two most powerful nations. capable of threatening each other with total war, are also most advanced technologically and industrially. The mechanization of warfare in terms of weapons, supplies, transportation and communications requires, in case of actual hostilities, the virtually total commitment of the industrial productivity of the nation. This total commitment has been made possible by the enormous increase in economic productivity brought about by a series of technological and industrial revolutions, starting in the 18th century. By contrast, in earlier periods of history, economic productivity was so low that after it had barely provided for the needs of the population, little was left for military purposes. Thus premodern technology could support only limited war, while modern industry is productive enough to allow the commitment of the lion's share of its products for military purposes.

One incentive for the great nations to use this enormous productive power for the purposes of mutual destruction was provided by a change in international relations which can be called the disappearance of the colonial frontier. The generally limited character of the means and ends of foreign policy from the end of the middle ages to World War I was in good measure due to the opportunity for the great European nations to seek satisfaction for their aspirations for power not in all-out contests with each other but through competitive expansion into Africa, the Americas and the part of Asia bordering on the eastern oceans. Colonial competition and conflict during that period provided outlets through which the European nations could compete for power without endangering their existence. But by the beginning of the 20th century the colonial frontier was, for all practical purposes, closed. Virtually all politically weak or empty spaces around the globe had been transformed into colonies or spheres of influence by one or another of the European nations. From then on, as the two world wars showed, the great European powers, deprived of the colonial safety valve, fought each other not for limited advantage but for total stakes, and they could do so with the instruments of total war.

These stakes became total not only in that total war threatened the belligerents with total destruction, but also in that the issue over which nations competed and fought had become total. That issue was no longer a limited military or territorial advantage but the universal triumph or defeat of a particular philosophy and way of life, which was supposed to be incarnate in a particular nation. While traditionally the international relations of the western world were carried on within the framework of common moral principles and of a common way of life, which imposed effective limitations upon the struggle for power, international relations in the mid-20th century were dominated by the conflict between democracy and Communism, each putting forth a universal message of salvation, each trying—with different intensity—to extend its dominion to all mankind, and each identified with one of the two great powers left in the world. Thus international relations came to be characterized not only by the traditional threat and use of military force on behalf of the aspirations of individual nations but also by a struggle for the minds of men. The proponents of the two antagonistic philosophies and ways of life, using the instruments of propaganda, foreign aid and foreign trade, endeavoured to gain the allegiance of uncommitted nations. By the same token, the traditional methods of diplomacy were in eclipse. Nations can negotiate and bargain about their interests and conclude compromises concerning them, but they feel that they cannot yield an inch where their philosophies and ways of life are at stake.

While similar situations have existed before, temporarily and on a limited scale, especially in periods of religious conflicts and wars, international relations after World Wars I and II were marked by a change in structure unprecedented in recorded history. Throughout history, there has existed a rational relationship between the threat and use of military force and the ends of foreign policy. It was rational for a nation to ask itself whether it could achieve its ends vis-à-vis another nation by peaceful means or whether it had to resort to military force to achieve them, for the risks involved in the resort to military force were generally not out of proportion to the ends sought. Great ends justified great risks, since the risks were generally not so great as to obviate the ends. Yet all-out nuclear war, likely to destroy all belligerents and thus to eliminate the very distinction between victor and vanquished, is a completely irrational undertaking. No possible end can justify it; it is an instrument of mass murder and mass suicide.

Two **Modern** Dilemmas.— International relations, then, were faced with two interconnected dilemmas upon the solution of which depended the survival of western civilization and perhaps of mankind itself. The first dilemma consisted in the contrast between the technological unification of the world and the parochial moral commitments and political institutions of the age. Moral commitments and political institutions, dating from an age which modern technology had left behind, had not kept pace with technological achievements and, hence, were incapable of controlling their destructive potentialities. The second dilemma consisted in the contrast between the need of nations to support their interests by resort to violence and the irrationality of resort to nuclear arms. If a nation cannot resort to nuclear weapons without risking its own destruction, how can it support its interests in a world of sovereign nations which is ruled by violence as the last resort?

These two dilemmas put into question the very survival of the existing system of international relations. The first dilemma suggests a higher principle of international organization, transcending the nation-state, in the form either of a universal organization, such as the United Nations, which would minimize threats to international peace, or of regional organizations, such as the European communities or a projected Atlantic union, which would eliminate local threats to peace and facilitate the rational use of regional resources. The second dilemma suggests the abolition of international relations itself through the merger of all national sovereignties into one world state which would have a monopoly of the most destructive instruments of violence. Both kinds of solutions are supported by the awareness of the unity of mankind, underlying the inevitable fragmentation of international relations. However inarticulate and submerged, this awareness never completely disappeared even in the heyday of nationalism, and it has been sharpened by the threat of nuclear destruction facing all mankind. These solutions are also supported by the longing to give that unity a viable political form, a longing which has time and again endeavoured through theoretical schemes and practical measures to transform international relations into a supranational political order. This longing, in times past mainly a spiritual or humanitarian impulse, was in the nuclear age greatly strengthened by the desire for self-preservation, innate in all men.

INTERNATIONAL TRADE: see **EXPORTS**; IMPORTS; INTERNATIONAL PAYMENTS; TRADE, INTERNATIONAL.

INTERNATIONAL TRADE ASSOCIATIONS AND CONGRESSES. The 19th century, often regarded as the age of nationalism. was characterized by the growth of private international organizations covering almost every branch of human activity and expressing the supranational extent of modern interests. These organizations continued to multiply, some 2,000 being listed by the Union of International Associations by the 1950s, as compared with 185 in the first comprehensive account in 1907.

This article is limited to permanent international associations (those representing nationals of more than one country and having a more or less continuing central office or secretariat) in the fields of commerce, industry, finance, transport, communications, agriculture and ancillary professions. Official organizations founded by intergovernmental agreement are excluded, as are also profit-making international groups such as Standard Oil and the Havas agency; these latter are better regarded as unified business concerns operating in more than one country than as

federal associations of national economic interests.

Growth and General Characteristics. — The 19th-century international fairs beginning with the great exhibition of 1851 in London provided the occasion for the first international associations. Exhibitors at these meetings not only saw the value of more permanent collaboration, but they were also able to secure such official international agreements to protect their rights when abroad as the Union for the Protection of Industrial Property of 1883 and the Berne Copyright convention and union of 1886. Some impression of the rate of growth of private organizations can be derived from statistics (World Peace Foundation, Pamphlet Series. vol. vi, no. 6, [1916]) which show that, while there were 18 meetings of these bodies in 1850–59, the number had increased to 139 in 1870–79 and to 985 in 1900–09, and that 4j8 international assemblies met in 1910–14. Corresponding figures for 1919–39 are lacking, but it was reliably estimated that in the early 1930s between 200 and 250 of these meetings took place annually. The evidence from post-1945 experience suggests that these associations possess a remarkable capacity to survive war and political changes. By 1955, for example, 118 private international organizations had passed the rigorous tests of admission to consultative status with the United Nations Economic and Social council.

As for the interests in which international organization has proved most active and viable. a gradation appears between those activities, such as railway transport, which have an obvious international significance, and those, such as agriculture, in which national organization is itself weak or which have a predominantly local area of activity. On the whole, agricultural producers' associations have been ephemeral or regional, or confined to secondary or subsidiary agrarian pursuits. It is notable here that the development of official international institutions influenced the relative grouth of various types of private organizations; the International Labour organization (ILO), for example, prompted the formation of the International Organization of Industrial Employers for the better co-ordination of the employers' point of view. Another interesting form of nongovernmental organization intermediary between the two extremes just mentioned is that dealing with international standards for industry and commerce; the International Organization for Standardization is conspicuous here. Further, since some of the most typical activities of nongovernmental organizations are joint inquiries into questions of common interest to the membership. it is not surprising that professional organizations among actuaries, accountants, architects and engineers have had an important part to play.

The spontaneous growth of these organizations has naturally meant extreme variety in structure and function. Some have highly complex constitutions, with considerable incomes and authority over their members. Others are little more than annual meetings at an accessible centre for an informal exchange of views about trade prospects with little in the way of binding understandings being reached. Generally members are not individuals but national associations, though hybrid. forms exist. A convenient form of classification is the distinction between organizations which are wholly private and those in which there is some official component. The International Institute of Refrigeration is indisputably an official body; it was founded in 1920 by a convention between governments and is governed by a general conference composed of government representatives. But uhere an organization, such as the International Federation for Housing and Town Planning, is directed by a council having at one time a majority of delegates from official agencies and at another a majority of nongovernment representatives, the case is more difficult to determine. In the marginal zone betueen the private and the semi-official, limits of the former can probably be best discovered through scrutiny of the functioning of the organization's services.

The functions and activities of international nongovernmental organizations are not essentially different from those of their national correlatives. They are intended to further the special interests of members by providing permanent machinery for exchanging views and pooling information, for public relations on an international scale, for joint studies and research, for the elaboration of standards and metric systems to facilitate international commerce, and for bringing pressure to bear upon governments. Wherever a national business or calling has something to gain by links with its opposite numbers abroad, the basis for international organization exists. Sometimes the sectional character of these groups has been masked by pacifist or internationalist ideals, but in many instances the fact that technical collaboration between private national groups seemed to be more fruitful than negotiation at the diplomatic level genuinely gave rise to the belief that in this lay the road to ultimate world order.

Business and Commerce. — The colossus among commercial organizations is the International Chamber of Commerce (I.C.C.), with a history as a forum for business interests extending back to 1869, though it was not constituted as a permanent association until 1920. The I.C.C. announced itself as a "confederation of the main economic forces of the countries included in its membership"; these forces are (a) organization members, that is, national and local associations grouped for this purpose into national committees, of which there were 30 in different countries in 1955, and (b) associate members, consisting of individual businessmen, firms and corporations in 25 more countries where no national committee is functioning. Apart from individual members, some 1,200 organizations were estimated to be affiliated to the I.C.C. in the mid-1950s. There is a supreme policy-making organ, the biennial congress, a permanent council representing each national committee, and an executive committee elected by the council. Some 40 commissions and committees for technical work handle the four main departments of the I.C.C.'s activities: economic policy, distribution and advertising, transport and communications, law and commercial practice. A court of arbitration adjudicates upon disputes arising between businessmen of different countries; there is a council to determine what constitutes unfair practice in international advertising; and a central information bureau. The I.C.C. is commonly recognized as having exercised an appreciable influence on government policy during the period between the two world wars, especially in war debt and reparation issues: it is also said to have contributed much to the establishment of the International Bank for Reconstruction and Development and of the International Monetary fund of the United Nations.

The analogous body for co-operators, the International Co-operative alliance (I.C.A.), sprang from exchanges between the British and French co-operative congresses in the 1880s, though the first international congress which formally created the alliance did not meet until 1895. The I.C.A. has among its aims "to be the universal representative of co-operative organizations of all types" and "to propagate co-operative principles and methods throughout the world." Its members by the latter 1950s included about 377,000 co-operative societies in 34 countries with a total membership of over 100,000,000, of which the Soviet Union contributed one quarter. Its structure closely resembles that of the I.C.C.. its chief policy-making organ being a triennial congress. Some indication of the scope of the alliance's interests and activities is provided by the fact that at the Copenhagen congress, which met in 1951, there were auxiliary conferences dealing with international co-operative trade, banking, assurance, co-operative agriculture, workers' co-operative production, co-operative press and education, and the role of co-operation in housing. Co-operation in the underdeveloped countries forms one of the later preoccupations of the I.C.A.

In the business field are many organizations much smaller than these two giants. Typical of the wide variety of these groups are, in order of the foundation, the Union of International Fairs, started in 1925 for the improved co-ordination of facilities for international fairs offered by public authorities; the International Association of Department Stores, a European organization which in 1928 became responsible for research on management and distribution; and the World Trade Alliance association, an international group of individuals founded in 1941 to propagate principles "for the regulation of the main export products of all countries so as to ensure a satisfactory state of general employment, avoidance of want and poverty, and a steady uplifting of the standards of living."

Manufacturing Industry. — International organization in the

manufacturing trades has generally been stronger in the secondary than in the basic industries and in the production of those commodities which play a large part in international trade. One exception to this is the International Organization of Employers (formerly Industrial Employers), which was founded in 1919 with national federations of employers as its members in order to ensure permanent liaison between employers' representatives at conferences of the ILO. The organization is, however, more of a defensive reaction to international labour pressures than a spontaneous industrial organization.

Among the secondary trades, the food, hotel management, fuel and power, building and light industries are well represented. The International Office for Cocoa and Chocolate, which functions in Antwerp, was founded by cocoa and chocolate manufacturers in 1930 and studies all questions relating to the cultivation of cocoa and subsequent manufacturing processes. The International Federation of Meat Traders' associations met annually in general assembly for similar objects beginning in 1946; it is wholly a west European organism. The European Brewery convention, established in 1947, and the Federation of Coffee Growers of Central American-Mexico-Caribbean, a foundation of 1945, are other examples of the extent and variety of these associations in the food industries. The International Hotel association in 1946 took over the functions of the International Hotelmen's association and of the International Hotel alliance, which were founded in 1869 and 1921 respectively with the object of federating all the hotel associations of the world in order to formulate a common policy on international tourist traffic. Finally in this group may be mentioned the extensive and active organizations in the fuel and power industries. The World Power conference, representing national committees in about 50 countries. normally meets in plenary session once every six years in order to study existing resources of hydroelectric power, coal, oil and other fuels and minerals, and to explore the possibility of their more efficient utilization. It has a permanent central office managed by an executive council and is powerfully supported by such organizations as the International Electrotechnical commission (founded 1906), which facilitates "the co-ordination of national electrotechnical standards not already covered by the statutes of any other recognized international organization" among 29 countries of industrial importance; the International Union of Producers and Distributors of Electric Power (founded 1925), a professional organization for the study of the production and transmission of electrical energy; and the International Conference on Large Electric Systems (founded 1921), which also has within its purview the study of all technical questions concerning electrical energy.

Textiles are the foremost internationally organized trade among the group with an important interest in the world market. The International Wool secretariat (1937) originally represented the wool boards of Australia, New Zealand and South Africa with their branches in Europe, India and Pakistan, but in 1949 the Wool Bureau, Inc., representing wool producers in North America, was admitted to associate membership. The wool secretariat defines its purposes boldly as the promotion of the interests of the producers and users of wool everywhere. The manufacture of wool and allied fibres is represented by the International Wool Textile organization which began in 1924 as an arbitration agreement between the chambers of commerce of Bradford and Roubaix Tourcoing and gradually extended in membership and scope until by the latter 1950s it covered wool organizations in 15 European countries and in Argentina, Uruguay and Japan and represented the "production, commerce and industry of wool textiles in all branches of international economic activity." Similar organizations have been promoted for cotton and silk: the International Federation of Master Cotton Spinners' and Manufacturers' Associations (1904) represents organizations in Europe, India and Egypt and offers such important services to its members as the arbitration of international disputes and, from 1922, an annual survey of the state of the U.S. cotton crop; and the International Silk association (1949) maintains liaison between representative bodies in all parts of the world. Later stages in clothing manufactdre are represented by the International Association of Clothing Designers and the International Committee for Dyeing and Cleaning, among others; the former dates from 1920 and admits only approved designers to its membership, while the latter, founded in Paris in 1950, is an association of national federations, chiefly in western Europe.

Apart from textiles and clothing, motors and rolling stock have formed the most important manufacturing trades for international organization. The International Permanent Bureau of Motor Manufacturers succeeded in 1919 the pre-World War I Union of Motor Manufacturers; its constituent bodies operate in nine European countries and there are corresponding organizations in five others. The International Association of Rolling Stock Builders. founded in Paris in 1930, was originally a cartel for the allocation of the export market; its purpose in 1934 was re-defined more generally as to "defend on the international level the general interests of the rolling stock builders' industry." It has a European membership only.

Finance.—Notwithstanding the essentially international character of modern finance. nongovernmental organizations dealing with financial business are relatively few, since international clearings between the central banks of the different countries are generally officially regulated. The most important private organization in this field is the International Credit Insurance association, with its headquarters in Zurich, Switz.; it was founded in 1946 to carry on a previous organization of the same name founded in Paris in 1928. The association acts as a clearing centre for leading insurance companies in various countries-all European with the exception of Mexico. Its evidence bureau at Amsterdam, Neth., provides different firms with opportunities for joint consultation if they are approached to insure the same risks. A similar financial organization is the International Thrift institute, an association of savings banks in European. Asian and American countries, which was formed in 1924 and was reorganized in 1948 when its office was moved from Milan, It., to Amsterdam. The Thrift institute's aims, which include helping savings banks to "enhance their influence and prestige internationally," suitably introduce another class of organizations having an interest in finance but with some financial doctrine or policy to advertise: the International Centre for Research and Information on Collective Economy, the International Interchange committee, and the International Union for Land Value Taxation and Free Trade are interesting specimens of these.

Communications.— The international agreements into which communications have entered have generally been diplomatic instruments, such as the convention of 1873 which created the Universal Postal union. In radio broadcasting, however, it was unofficial effort to eliminate the overlapping use of wave lengths which led to official intervention. The "plan of Geneva" of the unofficial International Broadcasting union. founded in 1925 for the rational allocation of European wave bands, became the basis of the intergovernmental convention adopted at Lucerne, Switz., in 1933. Thereafter the union through its technical observation post at Brussels, Belg., verified daily the accuracy with which the various stations maintained their assigned wave lengths, and assisted the League of Nations Intellectual Co-operation organization in promoting international exchanges of broadcasting material In 1950 the union was superseded by the European Broadcasting union, which by the latter 1950s consisted of broadcasting organizations in 25 European and some Asian and North African countries and associate members outside Europe. Through a biennial general assembly and an administrative council the union works to "safeguard in all fields the interests of broadcasting organizations that have adhered to the statutes and establish links with others": its technical centre in Brussels maintains the frequency control of the period before World War II and studies all questions of technical interest.

Amateur radio is represented by the International Amateur Radio union (1925), which seeks to promote and co-ordinate two-way radio communication between the amateurs of various countries. For broadcasting in the Americas the Inter-American Association of Broadcasters, created by a radio conference at Mexico City in 1946, has for its objects both the strengthening of continental solidarity in the western hemisphere and the preserva-

tion of the freedom of broadcasting through the development of private initiative. To improve wireless services at sea, the International Radio Maritime committee was set up in **1928** at San Sebastian, Sp. After its reconstruction in Brussels in 1947 its effective members became **27** radio organizations in Atlantic and Mediterranean countries. The committee's scientific centre prevents interference between ships' radios much as the E.B.U. technical centre prevents interference between stations on land, and its technical commission keeps a watching brief for maritime radio at national and international conferences.

Transport. — Among the international associations for transport, as for communications, it is not always easy to distinguish between private and official bodies; this is particularly so in railway transport since the most important railway systems in Europe are state-managed. The organizations cited here are those which are nevertheless open to private companies, provided these be of international importance. and have not been established by agreement between governments. The International Union of Railways, with its headquarters in Paris, where it was founded in **1922,** is composed of railway administrations with at least 1,000 route km. **(621** mi.) of line and having traffic relations with each other within and outside Europe; it seeks to unify and improve the construction and operation of railways engaged in international traffic. Its annual general assembly controls a system of standing committees dealing with the standardization of rolling stock, the modernization of equipment, and international timetables. A somewhat similar organization is the International Railway Congress association, first established in 1885; its membership of state railway administrations and private companies in **59** countries is geographically more extensive than the International Union of Railways, and it aims at the more general objective of "promoting railway progress by holding periodical congresses and by publications." Similar work is carried on in the American continent by the Pan-American Railway Congress association, founded in 1910 and reorganized in 1941 and **1948.** This body is composed both of public and private companies and works through a system of committees toward the unification and modernization of railway transport and the reform of legislation affecting railways. Efforts to reduce inconvenience caused by transfer from one national railway network to another were made through the European Passenger Time Table conference (1923). This is in the main an official body but includes private delegates and works on a consultative basis with the International Union of Railways. The latter is also associated with the International (Railway) Wagon union, founded in 1921 to ensure the application of the Regolamento Internazionale Veicoli which provides for the reciprocal use of railway wagons in international traffic by its 50 member railway administrations, most of whom are European.

Some international organizations for shipping are more like profit-making concerns, such as the shipping conferences which grew up in the late 19th century to eliminate price cutting. The Baltic and International Maritime conference, however, first founded 'under another name in 1905, provides for mutual consultation in all matters affecting the shipping industry, for defining and circulating news of "objectionable practices" among its members and for approving documents for the use of shipowners. Its members are in three classes — owners, ship brokers and federations of owners' and protecting associations in all parts of the world. An even more general association of shipowners is the International Chamber of Shipping (I.C.S.), founded in **1921** as the International Shipping conference, a federation of **16** national associations of private owners. Wages and conditions of labour at sea are within the purview of the International Shipping Federation Ltd., having a membership similar to that of the I.C.S.; it was dealing with strikes in the industry before 1914 but was given a permanent form with the establishment of ILO. The important role in shipping of international maritime law and maritime insurance is indicated by the International Maritime committee, a federated law society which began to promote intergovernmental maritime conventions in **1897,** and the International Union of Marine Insurance, a federal association of insurance and underwriter groups; this was established in **1874** and reorganized in **1946.**

The obvious benefits of international connections for tourists is reflected in the associations which grew up for motor transport, especially in connection with sport and recreation. The International Automobile federation is a post-World War II form of the old International Association of Recognized Automobile clubs which had existed since before World War I. It serves motoring clubs in almost every country and is closely associated with the International Touring alliance, which was founded in **1898** to bring into touch with each other the various national touring groups. Among organizations for road transport as an industry are the Permanent International Association of Road congresses (1909), a semiofficial body concerned with the general improvement of world road conditions, and the International Union of Public Transport **(1885),** a mixed public and private body dealing principally with problems of urban transport.

When the official conference met in Chicago, Ill., in 1944 to approve the convention establishing the International Civil Aviation organization (1947), the airline operators attached to the national delegations met to reconstruct the old private International Air Traffic association, founded at the end of World War I. The new body, the International Air Transport association, an agency for mutual protection of airline companies in **45** countries, claims to speak for 90% of the world's scheduled air traffic; it acts as a central bank of information on all subjects and supplies technical advice to its members. The International Aeronautical federation, established by seven European governments and the United States in 1905, has for its object the promotion of world aeronautics, including private flying, in all its forms.

Agriculture. — Since organization among sectional interests is usually as strong internationally as it is nationally, agriculture did not produce an abundance of private international associations. While the functions and assets of the official International Institute of Agriculture (1905) were transferred to the Food and Agriculture Organization of the United Nations (FAO) in **1946,** the voluntary organization, the International Commission of Agriculture (I.C.A.), though dating from **1889,** tended to lack official encouragement; its chief function was to bring together representatives of its constituent organizations **(86** in **1938)** in biennial congresses to contribute concertedly to the basic knowledge of every branch of agriculture. The I.C.A. is said to have influenced the principles of agricultural policy adopted by the 1933 International Economic conference in London and the bilateral treaties on exchange of produce concluded by certain European countries in the 1930s. The commission was reorganized in **1948** as the European Confederation of Agriculture; it speaks for **278** national and regional associations with a membership of 50,000,000 in 19 countries in Europe and the Mediterranean basin (1955). It upholds independent family farming, agricultural co-operatives and private ownership.

Representations to official international conferences on behalf of European farming are made by the confederation, the organization speaking for the agricultural world as a whole being the International Federation of Agricultural Producers, which was created at a London conference of farm organizations in **1946.** This represents general farm and agricultural co-operative organizations in all parts of the world and meets in council once yearly.

Some farm organizations are specialized by product, such as the World Poultry Science association (1912), the International Federation of Olive Growers (1934) and the International Dairy federation (1903). Some are regional: the Liaison Committee of Mediterranean Citrus Fruit Culture (1949); the American Society of Agricultural Sciences (1940); and the International Centre of Anti-parasitics **(1950),** with an exclusively European membership. Certain associations, such as the International Agricultural Credit conference (1932), represent relationships between farming and other interests.

Professional. — Activities deriving special benefits from international co-operation are those which rely upon research or standardized methods for their efficiency. Thus professions serving trade and industry are relatively well organized internationally. The International Statistical institute (1885), with its highly qualified and geographically well-distributed membership, is de-

voted to the development and improvement of statistical methods; the International Conference of Agricultural Economists (1929) publishes records of current progress in agricultural economics; among others, the Permanent Committee of the International Congresses of Actuaries (1889) links together actuaries' associations in different countries. Similar associations for engineering include the International Association for Bridge and Structural Engineering (1929) and the Union of International Engineering Organizations, which originated in an engineering conference convened by the United Nations Educational, Scientific and Cultural organization (UNESCO) in 1950. One of the most useful of these professional bodies is the International Organization for Standardization, founded in 1946 on the basis of an older organization dating back to 1926: this is a federation of national standardizing bodies seeking through the adoption of universal standards to facilitate the world exchange of goods and services.

Relations with Intergovernmental Organizations.—The League of Nations.—Article XXIV of the covenant excluded international bureaus other than those "already established by general treaties" from the provision placing existing international organizations under the aegis of the League. The private organizations, however, were not without influence on national policies within the League. Representatives of important organizations were sometimes included in national delegations to the assembly and at international conferences under League auspices nongovernmental groups were often allowed to participate in a consultative capacity: the International Chamber of Commerce played an important part in the World Economic conference of 1927 and in the League conference on international trade restrictions in 1928. These associations were active also in the work of the relevant committees and ancillary organs attached to the League. Eight of them, for example, were invited to send representatives to sessions of the Consultative Technical Commission on Communications and Transit, and not only did the ILO constitution presuppose active unofficial organizations but the organization much depended upon them for the carrying out of ratified conventions.

The United *Nations.*—The UN Conference on International Organization at San Francisco, Calif., in 1945 decided not to admit representatives of private international organizations in a consultative capacity, though consultants from 50 private national groups served unofficially in the U.S. delegation. The charter issuing from the conference, however, gave the first recognition in any multilateral agreement to these bodies; article 71 permits the Economic and Social council to make arrangements for consultation with nongovernmental organizations, with which it may negotiate directly. These arrangements were put into effect in June 1946 and reviewed at the council's tenth session (Feb. 1950), which adopted a resolution setting out the present form of consultation.

A nongovernmental organization applying for consultative status with the council must satisfy certain conditions; inter alia it must deal with matters within the competence of the council; its aims and purposes should conform with those of the UN, which it must undertake to support and publicize; it must be of recognized standing and represent a substantial proportion of the organized persons in its field. Organizations having "a basic interest in most of the activities of the Council" and "closely linked with the economic or social life of the areas which they represent" are admitted to category A consultative status. Category B includes those which have a special competence or are concerned specifically with only a few of the fields of activity covered by the council. By 1955, 109 organizations were included in category B, as compared with 9 in category A. Other organizations which "have a significant contribution to make to the work of the Council" may be entered by the secretary-general in a register established for the purpose. In general, organizations in all three categories may attend the council as observers and submit written statements relative to the work of the council. Category A organizations may also have items of special interest inserted in the provisional agenda of the council, which they may address on such items. A special committee of the council determines the manner in which consultation in the three categories is to be effected.

These arrangements provided a model for similar relations between the UN specialized agencies and the private organizations. Three of the groups mentioned above, the International Chamber of Commerce, the International Co-operative alliance. and the International Federation of Agricultural Producers, acquired consultative status with the FAO. The International Civil Aviation organization by a resolution of June 1947 authorized its council to make suitable arrangements with private international bodies whose activities affectinternational civil aviation. Article XI (4) of the constitution of UNESCO provides for co-operation with international organizations of this type in its field. The Council of Europe is only one of many official organs outside the framework of the UN which accords consultative status to qualified private organizations.

INTERPLEADER: see PRACTICE AND PROCEDURE.

INTERPOLATION, in mathematics, is the process of obtaining intermediate terms of a series of which particular terms are known. It is from the Latin *interpolare,* to insert something fresh, and is connected with *polire,* to polish. The logarithms, for instance, shown in Table I, may be regarded as terms of a series,

TABLE I

No.	Log.	1st diff. +
2.70	.4314	
		16
2.71	.4330	
		16

2.75	.4393	
.	.	.
.	.	.
.	.	

and the logarithm of any number between 2.70 and 2.75 may be found approximately by interpolation from the table. Finding the logarithm of a number lying outside these limits would be extrapolation; the formulae which apply to interpolation apply in theory to extrapolation, but in practice special precautions as to accuracy are necessary. The present article deals only with interpolation.

The term is usually limited to those cases in which there are two quantities, x and u, which are so related that when x has any arbitrary value, lying perhaps between certain limits, the value of u is determinate. There is a given series of associated values of x and of u, and interpolation consists in determining the value of u for any arbitrary value of x, or the value of x for any arbitrary value of u, lying between two of the values in the series. Either of the two quantities may be regarded as a function of the other; it is convenient to regard one, x, as the independent variable, the other, u, being treated as the dependent *variable, i.e.,* as a function of x. If. as is usually the case, the successive values of one of the quantities proceed by a constant increment, this quantity is to be regarded as the independent variable. The two series of values may be tabulated, those of x being placed in a column (or row), and those of u in a parallel column (or row); u is then said to be *tabulated* in *terms* of x.

The independent variable x is called the *argument,* and the dependent variable u is called the *entry.* Interpolation, in the ordinary sense, consists in determining the value of u for a value of x intermediate between two values appearing in the table. This may be described as *direct interpolatton,* to distinguish it from *inverse interpolation,* which consists in determining the value of x for a value of u intermediate between two in the table. Graphically. the data for interpolation are certain ordinates of the graph of u with regard to x, and direct interpolation consists in deducing the magnitude of any other ordinate whose position is given, while inverse interpolation consists in determining the position of an ordinate whose magnitude is given. The methods employed can be extended to cases in which the value of u depends on the values of two or more independent quantities x, y. . . .

The subject will be treated under three heads: I. Direct Interpolation (equal intervals), II. Direct Interpolation (unequal intervals), III. Inverse Interpolation.

I. DIRECT INTERPOLATION (EQUAL INTERVALS)

1. Notation and Arrangement. — Consider a table showing the values of a quantity u corresponding to values of a quantity x, where values of x proceed by a constant increment h. We denote the values of x by . . . x_0, x_1, x_2, . . ., so that $x_m \equiv x_0 + mh$; and the corresponding values of u are . . . u_0, u_1, u_2. . . . We want to find u_θ, which is the value of u corresponding to $x_\theta = x_0 + \theta h$; for preciseness, we can say that θ lies between -1 and $+1$.

The first step, usually, is to arrange the u's in a vertical column, followed by columns containing the successive differences. The differences of the u's are the *first differences,* those of the first differences are the *second differences,* and so on. These are also called *differences of the first, second . . . order.*

The differences, like the u's, have to be distinguished by suffixes. There are three systems, the advancing-difference, the receding-difference and the central-difference. On the *advancing-difference* system, $u_1 - u_0$ is regarded as the first difference of u_0, and is denoted by Δu_0, so that $\Delta u_1 - \Delta u_0$ is $\Delta^2 u_0$; on the receding-difference system, which is less important, $u_1 - u_0$ is the first difference of u_1. On the *central-difference* system, $u_1 - u_0$ is a difference corresponding to the interval between u_0 and u_1, and is therefore denoted by $\delta u_{\frac{1}{2}}$, so that $\Delta^2 u_{-1}$ is $\delta^2 u_0$; there is also a symbol μ for the mean of any two adjacent entries in a column, so that $\mu u_{\frac{1}{2}} \equiv \frac{1}{2}(u_0 + u_1)$, $\mu\delta u_0 \equiv \frac{1}{2}(\delta u_{-\frac{1}{2}} + \delta u_{\frac{1}{2}})$, and so on. The system is more fully set out in the article CALCULUS OF DIFFERENCES.

2. Fundamental Principle. — The methods which we are considering are, in general, applicable when the result of taking successive differences is to bring us ultimately to differences of a certain order, say the kth. which are practically constant. so that the differences of the next order. the $(k+1)$th, are zero or at any rate are negligible. The fundamental principle then is that we assume that interpolation can be performed as if these latter differences were actually zero.

3. Interpolation by First Difference. — In Table I we see that, as x increases, u increases steadily. We therefore use the *principle of proportional parts, i.e.,* we assume that for any increase in x there is a proportional increase in u.

Thus me can say that the logarithm of 2.725 is .4346 + 8 (where "+8" denotes the addition of 8 to the last figure of the tabulated entry, *i.e.,* means .0008) = ,4354; and similarly log 2.7225 = .4350.

Algebraically, we express the relation between x and u by saying that u is of the form $p + qx$. It follows that the formula for u_θ is

$$u_\theta = u_0 + \theta(u_1 - u_0) = u_0 + \theta\Delta u_0. \qquad (1)$$

To find log 2.724 we should have to add $.4 \times 16 = 6.4$. But it would be incorrect to write the result as .43524; for this would imply that we could find the logarithm to five decimal places, which the table does not enable us to do. We can do either of two things. If we only want the best value, to four places, that we can get, we must take $.4 \times 16$ to be 6. so that our answer is .4352. But a better method, if we are going to use log 2.724 for further calculation, is to retain an extra two or three figures in our work. We therefore, for the time being, write the logarithm in the form .4352 40 or $.4352^{40}$; any extra figures retained in this way are dropped at the conclusion of our work, the preceding figure being adjusted if necessary. This principle applies throughout the whole of our work.

As stated above, the table shows that as x increases u increases steadily. But this does not mean that the second differences of u are absolutely zero; it only means that when we are working to four places of decimals they are negligible. That they do exist, can be seen either by taking more correct values, as in Table II, or by taking values of x at greater intervals, as in Table III.

Similarly we could detect the existence of differences of the third or a higher order.

The sequence of differences, of whatever order, will present some irregularities. These are due to the fact that the tabulated values are necessarily not exact. Thus in Table I the occurrence of the difference 15 immediately following a series of 16's is due to the entry for 2.74 being slightly too large (as will be seen from Table 11), while the entry for 2.75 is slightly too small. A similar explanation applies to the 57 in Table II: the entry for 2.73 is too small, and that for 2.74 is too large.

4. Interpolation with Second Differences. — If we have to use second differences, but do not need third differences, the formula is

$$u_\theta = u_0 + \theta\Delta u_0 + \tfrac{1}{2}\theta(\theta - 1)\Delta^2 u, \qquad (2)$$

in which $\Delta^2 u$ may be either $\Delta^2 u_0$ or $\Delta^2 u_{-1}$. It is usually best to take the one which lies nearest in the table (see Table II or Table III); thus if θ lies between $-\frac{1}{2}$ and $+\frac{1}{2}$ we should use $\Delta^2 u_{-1}$, but if it lies between $+\frac{1}{2}$ and $+\frac{3}{2}$ we should use $\Delta^2 u_0$.

In most cases in which this formula has to be used, $A^2 u$ is small: a convenient form for calculation is then

$$u_\theta = u_0 + \theta\{\Delta u_0 - \tfrac{1}{2}(1 - \theta)\Delta^2 u\}. \qquad (3)$$

5. General Formula. — The general formula, involving differences beyond the second, may be written in terms of advancing differences or of central differences.

(i.) The advancing-difference formula is

$$u_\theta = u_0 + \theta\Delta u_0 + \frac{\theta(\theta-1)}{2!}\Delta^2 u_0 + \frac{\theta(\theta-1)(\theta-2)}{3!}\Delta^3 u_0 + \cdots, \qquad (4)$$

in which the coefficients of u_0, Δu_0, $\Delta^2 u_0$, . . ., are those of the powers of A in the expansion of $(1+\Delta)^\theta$ by the binomial theorem. If differences of order exceeding k are negligible, the series ends with a term in $\Delta^k u_0$. This is known as the *Gregory-Newton formula.*

(ii.) The central-difference formula is of two forms, but we need only consider one, viz., that which uses u_0 and the central differences on or adjoining a horizontal line through it. Thus (see §1) the differences involved are

u_0, $\mu\delta u_0 \equiv \frac{1}{2}(\delta u_{-\frac{1}{2}} + \delta u_{\frac{1}{2}})$, $\delta^2 u_0$, $\mu\delta^3 u_0 \equiv \frac{1}{2}(\delta^3 u_{-\frac{1}{2}} + \delta^3 u_{\frac{1}{2}})$, $\delta^4 u_0$ . . . .

Let us write *(see* CALCULUS OF DIFFERENCES)

$$\left.\begin{aligned} c_1 &\equiv \mu\delta u_0 - \tfrac{1}{6}\mu\delta^3 u_0 + \tfrac{1}{30}\mu\delta^5 u_0 - \tfrac{1}{140}\mu\delta^7 u_0 + \cdots \\ c_2 &\equiv \delta^2 u_0 - \tfrac{1}{12}\delta^4 u_0 + \tfrac{1}{90}\delta^6 u_0 - \tfrac{1}{560}\delta^8 u_0 + \cdots \\ c_3 &\equiv \mu\delta^3 u_0 - \tfrac{1}{4}\mu\delta^5 u_0 + \tfrac{7}{120}\mu\delta^7 u_0 - \cdots \\ c_4 &\equiv \delta^4 u_0 - \tfrac{1}{6}\delta^6 u_0 + \tfrac{7}{240}\delta^8 u_0 - \cdots \\ c_5 &\equiv \mu\delta^5 u_0 - \tfrac{1}{8}\mu\delta^7 u_0 + \cdots \\ c_6 &\equiv \delta^6 u_0 - \tfrac{1}{4}\delta^8 u_0 + \cdots \end{aligned}\right\} \quad (5)$$

Then the central-difference formula may be written as

$$u_\theta = u_0 + c_1\theta + c_2\frac{\theta^2}{2!} + c_3\frac{\theta^3}{3!} + c_4\frac{\theta^4}{4!} + \cdots \quad (6)$$

II. DIRECT INTERPOLATION (UNEQUAL INTERVALS)

6. When the differences of consecutive x's are not all equal, we use formulae analogous to ordinary interpolation-formulae, but with the differences prepared in a special way. The best-known formulae are Newton's (original) formulae and Lagrange's formula; the former uses "divided" differences.

Let the tabulated values of x be . . . , a, b, c, d, . . . , the corresponding values of u being denoted by . . . , $f(a)$, $f(b)$, $f(c)$, $f(d)$ . . . . Then our table is of the form:—

x	u	Divided Differences			
		1st	2nd	3rd	⋯
⋮	⋮				
a	$f(a)$				
		$f(a, b)$			
b	$f(b)$		$f(a, b, c)$		etc.
		$f(b, c)$		$f(a, b, c, d)$	
c	$f(c)$		$f(b, c, d)$		etc.
		$f(c, d)$			
d	$f(d)$				
⋮	⋮				

In this table

$$\left.\begin{aligned} f(a, b) &\equiv \frac{f(b)-f(a)}{b-a}, f(b, c) \equiv \frac{f(c)-f(b)}{c-b}, \cdots \\ f(a, b, c) &\equiv \frac{f(b, c)-f(a, b)}{c-a}, f(b, c, d) \equiv \frac{f(c, d)-f(b, c)}{d-b}, \cdots \\ f(a, b, c, d) &\equiv \frac{f(b, c, d)-f(a, b, c)}{d-a} \quad \cdots \end{aligned}\right\} \quad (7)$$

etc.

The quantities $f(a, b)$ . . . in the first line are called *divided differences of the first order;* those in the second line are *divided differencesof the second order;* and so on. If u is a polynomial of degree k in x, the divided differences of order k + 1 are all o. It should be observed that the value of any divided difference is independent of the order in which the u's involved in it are arranged; thus

$$f(a, b) = f(b, a), f(a, b, c) = f(a, c, b), \text{ etc.}$$

Newton's formula for unequal intervals is

$$f(x) = f(a) + (x-a)f(a, b) + (x-a)(x-b)f(a, b, c) + \cdots, \quad (8)$$

the series continuing until the differences are zero or negligible. This formula covers all those with which we have so far dealt; thus the Newton-Gauss formula, a zigzag formula involving u_0, $\delta u_{\frac{1}{2}}$, $\delta^2 u_0$, $\delta^3 u_{\frac{1}{2}}$ . . . , is obtained by taking the x's in the order o, 1, −1, 2, −2, . . .

The method was subsequently modified by Newton, in a manuscript written in 1676 but not known to the world until *1926.* Another method, similar to this modified method, but not identical with it, is that of "adjusted differences."

Lagrange's formula is

$$\left.\begin{aligned} f(x) = &\frac{(x-b)(x-c)(x-d)\cdots}{(a-b)(a-c)(a-d)\cdots} f(a) \\ &+ \frac{(x-a)(x-c)(x-d)\cdots}{(b-a)(b-c)(b-d)\cdots} f(b) \\ &+ \frac{(x-a)(x-b)(x-d)\cdots}{(c-a)(c-b)(c-d)\cdots} f(c) + \cdots. \end{aligned}\right\} \quad (9)$$

This gives exactly the same result as Newton's formula. It is not so convenient for calculation as the latter, and it does not show how many u's have to be taken into account.

III. INVERSE INTERPOLATION

7. Inverse Interpolation: Simple Cases.—In all cases of inverse interpolation we have to pay special attention to the degree of accuracy of the result. This depends largely, in ordinary cases, on the initial figure of the first difference.

If the first difference is practically constant, inverse interpolation is very simple. The direct formula

$$u_\theta = u_0 + \theta\Delta u_0$$

gives

$$\theta = (u_S - u_0)/\Delta u_0.$$

If we have to go to second differences, the direct formula is

$$\begin{aligned} u_\theta &= u_0 + \theta\Delta u_0 + \tfrac{1}{2}\theta(\theta-1)\Delta^2 u \\ &= u_0 + \theta\{\Delta u_0 + \tfrac{1}{2}(\theta-1)\Delta^2 u\}, \end{aligned}$$

where. if θ lies between o and 1, $\Delta^2 u$ may be either $\Delta^2 u_{-1}$ or $\Delta^2 u_0$. We can calculate the expression in { } by taking an approximate value of 8; and then 6 is found more accurately by dividing $u_\theta - u_0$ by this expression.

8. General Formula.— If third or higher differences have to be taken into account there are two methods.

(i) We can use the general formula (6), viz.:

$$u_\theta = u_0 + c_1\theta + c_2\frac{\theta^2}{2!} + c_3\frac{\theta^3}{3!} + c_4\frac{\theta^4}{4!} + \cdots,$$

and proceed by successive approximations. By transposition and division, we get

$$\theta = \left(u_\theta - u_0 - c_2\frac{\theta^2}{2!} - c_3\frac{\theta^3}{3!} - c_4\frac{\theta^4}{4!} - \cdots\right) \div c_1.$$

We begin with an approximate value of 8. Substituting this on the right-hand side, we get a closer approximation to θ, and so on.

(ii) The above method is only applicable when the intervals in x are equal. An alternative method, suitable for cases of unequal intervals, but not always applicable, is to invert the table (*i.e.,* to interchange the x column and the u column and find divided differences of the x's) and proceed by direct interpolation. *See* also CALCULUS OF DIFFERENCES. (W. F. S.; X.)

INTERPRETATION, in general, the action of explaining, or rendering the sense of an obscure form of words or an unknown tongue into a language comprehended by the person addressed.

In legal use the word is employed in the sense of ascertaining the meaning of the language of a document. It is usual for statutes to contain definitions and the British Interpretation act of 1889 is of general application *(see* STATUTE LAW). This term is used similarly in the United States.

INTERRACIAL RELATIONS. The great importance that has generally been attached to ideas of race, racial identity and racial differences in mentality and culture has in recent times played a major role in determining the relations between the peoples and nations of the world. A striking feature of these ideas is the fact that they have usually been based on a false conception of the meaning of race and on erroneous assumptions regarding its implications. Jacques Barzun, for example, entitled his hook on this subject *Race: a Study in Modern Superstition.* Ashley Montagu speaks of *Man's Most Dangerous Myth: the Fallacy of Race.* Gunnar Myrdal, in *An American Dilemma,* expresses the opinion

that in no other field is there so wide a gap between popular impressions and the conclusions reached by biological and social scientists. Race, in many of its aspects, exists only "in the minds of men."

The Problem of Definition.— The very term race is difficult to define. There is agreement to the effect that it is correctly applied to a subdivision of mankind which is distinguished by the possession of common characteristics, usually physical in their nature. determined by genetic or hereditary factors. Popularly. it has been confused with nation, although it is obvious that every modern nation is a mixture of inherited physical types; there is no British or Italian or German race. As a matter of fact, there is more physical or racial similarity between northern Italians and southern Germans than between the latter and Germans living in Hanover or Prussia. Similarly, there has been confusion between race and language; there is no Latin or Semitic or Aryan (Indo-European) race. since these languages are spoken by people of widely varying physical type. It follows that many of the phenomena usually included within the field of race relations have nothing to do with race as scientifically defined but rather with race as popularly, and erroneously, understood.

Difficulties of application remain even when care is taken to use race in the manner proposed by scientists. The geneticist Leslie C. Dunn, for example, believes that the word may have a valid biological meaning if applied to a group of related intermarrying individuais mhich differs from other groups in the relative commonness of certain hereditary traits. This leaves unresolved the questions of how large the group should be or which traits should be used for purposes of classification. G. Sergi, using head form as a criterion. proposes two races, the Eurasiatic or roundheaded, and the Eurafrican or longheaded; J. Deniker, relying upon a combination of features including head form, skin colour and others, concludes that there are 17 main races and 29 subraces. If the criterion of head form is preferred, this would unite in the same category the blondest Scandinavian and the darkest Negro if both are longheaded. If the more usual category of skin colour is used, differences in head form are ignored or at least relegated to the background. This means essentially that racial classification at the present stage of our knowledge is at least to some extent an arbitrary and subjective process. A group of experts consulted by the United Nations Educational, Scientific and Cultural organization (UNESCO) expressed the view that three major human divisions should be recognized, namely, the Mongoloid, Negroid and Caucasoid, and this is probably as satisfactory a classification as any now available, but it does not include all human groups, nor does it solve all the problems that have been raised. The reliance on blood properties. particularly the four blood types A. B. XB and 0, has facilitated significant genetic research, but has not as yet produced a satisfactory racial classification.

In view of these complications, it has been suggested that the term race should not be applied to existing human populations but should be replaced by the term ethnic group. which may be characterized by a particular inherited physical type, or culture, or nationality, or any combination of these. In any case, the geneticists have made it clear that the inherited similarities among all the peoples of the norld are much greater and far more common than the differences and that the distinctions that have been drawn between the so-called races of mankind are relatively unimportant.

Racialist Thinking.——This similarity among peoples has not prevented a number of influential writers, political leaders and people generally from regarding alleged racial differences as having paramount importance. It is difficult to establish definitely the origins of what has frequently been described as racialist thinking, but certainly one of the most influential of such thinkers was Count Arthur Joseph de Gobineau (*q.v.*), who published his four-volume *Essay on the Inequality of Human Races* in the middle of the 19th century. He taught the superiority of the white race over all others, and among the whites, of the Aryans as having reached the heights of civilization. This group was in fact considered to be responsible for civilization wherever it developed. The Teutons were taken to be the purest modern representatives of the Aryans. although Gobineau admitted that really "pure races" could no longer be found. As a matter of fact, he did not unequivocally favour such purity, since it was often at the point of contact and mixture between races that, in his opinion, civilization had a better chance to develop. This last point was conveniently neglected by many of his followers who. in the Gobineau societies which sprang up in Germany and elsewhere, not only glorified the Aryans and the Teutons but also insisted on keeping them "pure."

Gobineau's most important follower mas H. S. Chamberlain (*q v*). who published *The Foundations* of *the 19th Century* in German in 1899. An Englishman by birth, he spent most of his life in Germany, where he was active in the Gobineau society. and was so popular with the ruling class that he became known as the kaiser's anthropologist. He. too, insisted on the superiority of the Teutons. whom he characterized physically as being for the most part tall, fair and dolichocephalic (longheaded), that is to say. corresponding to the Nordic type. He regarded the Jews as alien in spirit to the favoured Teutons. although he admitted the difficulty of distinguishing Jews from Germans on the basis of physical characteristics alone.

Although there were many other writers who developed the racialist position, such as Ludwig Woltmann and H. F. K. Giinther in Germany. and Lothrop Stoddard and Madison Grant in the United States Gobineau and Chamberlain may be regarded as the intellectual forerunners of the racial theories of the German Nazis. Hitler himself acknowledged his indebtedness to these theorists, particularly to Chamberlain, for giving him the "scientific" basis for this aspect of his political philosophy. There were, of course, inner contradictions in the racialist approach—the fact that so many Germans did not look like Nordics and so many Jews did the alliance with the Japanese who had consequently to be exempted from the racial restrictions of the third *Reich*, the difficulty of giving any clear meaning to the concepts of German "blood" or "soul"—so that facts had to be replaced by mysticism. In spite of these and other deficiencies, racialism was used as a technique which helped to unify the Germans by identifying the "enemy." gave the people a strong sense of ego enhancement and self-confidence, justified economic exploitation and slave labour, obtained support for the war and convinced the Germans that they never could be defeated. Racialism thus functioned as one of the most effective techniques of Nazi propaganda for achieving and maintaining power over the German people.

Although colonialism cannot be compared with Naziism in terms of the violence and virulence of the human destruction it involved, it also found in racialism a helpful rationalization for conquest and expansion When the Spaniards first came to America. several of their apologists, particularly Francisco de Quevedo and Juan Ginés de Sepúlveda, supplied them with the proper excuses for taking the land away from the Indians and for treating them with complete lack of consideration. They developed the theory that the Indians had an entirely different origin from that of the Spaniards. that they were not human in the same sense and that there was therefore no need to accord to them the same treatment as to one's fellow human beings. The familiar refrain of the "white man's burden." which was mainly of British manufacture and which found its literary expression in the writings of Thomas Carlyle. James A. Froude Charles Kingsley and most strongly and clearly in those of Rudyard Kipling, made of imperialism a noble activity destined to bring civilization to the benighted members of other "races" What the British stood to gain as a result was never mentioned. Similarly the French justified the maintenance of their colonial empire on the basis of their *mission civilisatrice*, their duty to bring civilization to the backward peoples of the world.

In all of these colonizing empires, there were undoubtedly many individuals honestly convinced of the nobility of their motives and their enterprise: at the same time. the feelings of racial superiority which accompanied colonialism played an important part in developing resentments among the colonized which even the recent trend toward emancipation and independence has not always made it possible to overcome. There has even developed in some parts of the world a sort of racialism in reverse, a degree of hostility of coloured peoples against whites as whites, which has caused considerable worry to the responsible leaders of all the groups

concerned.

It remains true that in general, although with certain striking exceptions, the trend has been away from racialism. The rapid emergence of new nations, many of them former colonies, has meant that many more nations composed of "coloured peoples" have an independent voice in international affairs that commands a respectful hearing even from previous colonizers. The latter have, for their part, shown an evident willingness to grant such independence on an increasing scale. The recognition that the treatment of ethnic minorities within a country may have important implications for international relations has focused attention upon the need to improve intergroup relations in general. The work of scientists like Franz Boas in anthropology and Gunnar Myrdal and others in the social sciences has helped to destroy much of the mythological thinking associated with race. The trend has been reversed in the Republic of South Africa, where separation of ethnic groups has increased in recent years. In the United States, on the other hand, the movement has been gradually and progressively in the direction of providing greater equality of opportunity for all ethnic groups. The most dramatic expression of this tendency was furnished by the unanimous decision of the U.S. supreme court on May 17, 1954, based in part on social-science research, that the enforced segregation of Negro school children in certain states and localities was contrary to the principles of the U.S. constitution. (See NEGRO, AMERICAN.)

Studies **of Racial** Attitudes. — Although considerable progress has been made, a great deal of intergroup hostility remains, and much scientific effort has been expended in the attempt to understand its nature and its origin. One view has held that prejudice is inborn and inevitable; the philosopher Josiah Royce. for example, spoke of a "natural antipathy" against those who are different from ourselves. The fact that such antipathy is not found in young children, and the further fact that it does not occur in all individuals or even in all groups, throw considerable doubt upon this variety of explanation. There is, for example, much less prejudice against Negroes in Brazil than in South Africa or certain areas in the United States; there is more prejudice against Orientals in California and British Columbia than in Hawaii. Such variations are difficult if not impossible to reconcile with the theory that antipathy is natural and inevitable.

A variant of this theory is found in the writings of certain psychoanalysts who speak of a native aggressiveness or "death instinct" which may take the form of hostility against other ethnic groups. Others have suggested that aggressive tendencies can be explained as a consequence of the experiences of the individual, particularly the extent of his frustrations; the greater the frustration, other things being equal, the greater the tendency to aggressive action. Since, however, aggression may take many forms and may be directed against many different objects, this explanation does not carry us very far. The frustrated Brazilian does not look for a Negro scapegoat. There must be at least one additional factor; namely, that the individual learns what forms of aggression are permitted in his society, and against whom it may be expressed.

This learning process occurs in a variety of ways, and is facilitated from a number of different directions. In the home and in the school, the growing child learns, sometimes explicitly. sometimes indirectly, that others are "not like us," that they are not "our kind." The mass media often aid the process by developing or disseminating stereotypes of the pugnacious Irishman, the mercenary Jew, the lazy Negro, the dishonest Armenian — stereotypes that may frequently turn out to be untrue but which still affect our perceptions and our treatment of others. Institutions in the culture, sanctioned by law or by custom, which involve segregation, untouchability, occupational or recreational restrictions, may all contribute to feelings of ethnic or racial cleavage. A circular relation is established in which prejudice leads to discrimination, which in turn functions as an environmental support or stimulus for increased prejudice.

It is widely believed that our actual experience with members of other ethnic groups determines our attitudes toward them. This is undoubtedly true in many cases, but by no means always. Research has shown that there may be hostility or "social distance" among American students toward Turks, or among Guatemalans toward Jews, without any previous contact whatsoever. One investigator was able to demonstrate the existence of considerable rejection of even imaginary groups such as the Danerians, Pirenians and Wallonians. with whom there could hardly have been any unpleasant personal experience. This not only demonstrates the frequent irrationality of ethnic attitudes but also throws doubt on a theory described by the psychologist Gordon W. Allport as that of the "well deserved reputation"; namely, that if we dislike a particular group, they must certainly deserve our dislike. It seems more likely, as Eugene Hartley has suggested, that our attitudes toward other ethnic groups are not determined by contact with them but by contact with the attitudes that prevail in our community.

The question as to why such attitudes develop in the first place is not easy to answer, although at least a partial explanation can be found in the practical advantages that prejudice seems to confer on the dominant majority. The economic gain has been illustrated in the earlier reference to colonial expansion, in which a theory of racial superiority helped to rationalize and justify the expropriation of the property of others. This mechanism is easily discernible in the tendency to keep a minority "in its place," which essentially means to prevent it from competing with the dominant majority on equal terms. A second gain is represented by the practice of finding a scapegoat whom one can hold responsible for our ills, thus relieving ourselves of the obligation to blame ourselves for our shortcomings; the Jews served as such a scapegoat in Nazi Germany. A third gain, also illustrated by the Nazis, is in the feeling of superior status, of ego enhancement. A fourth may be described as a sex gain, which occurs when men of the dominant group have access to the women of the weaker but resist violently any effort by the men of the weaker group to obtain reciprocal privileges. The psychologist John Dollard believes that this was an important factor in maintaining the caste situation in the southern United States. This particular gain has evidently been renounced in South Africa, where all sexual contact between the races is strictly forbidden.

It should be added that prejudice and discrimination also involve significant losses. The sociologist Arnold Rose mentions, among others, the economic waste resulting from the failure to make adequate use of available manpower, the aggravation of social problems such as crime and delinquency, the harmful effect on international relations with the coloured peoples of the world. the creation of fears and anxieties and disrespect for the law. These are undoubtedly real losses, but they appear to be less obvious than the gains, which therefore are more likely to make themselves felt.

The gain in feelings of superior status and self-enhancement is related to a large amount of significant research on the part played by personality in the development of prejudice. Attention has been focused on the "authoritarian personality," characterized by generalized ethnocentrism but also by excessive conformity, rigidity, concern with status, a tendency to see the world as harsh and unfriendly and an inclination to favour strong punishment of deviants and offenders. This is only a partial list of traits found in prejudiced persons, who apparently "need" to feel superior to many out-groups and who dislike Jews and Negroes and Japanese and foreigners generally. The emphasis on the relation between prejudice and personality has added an important dimension to the understanding of intergroup relations, but it cannot be regarded as telling the whole story. Residents of South Carolina appear to be no more "authoritarian" than New Yorkers, but they usually have very different attitudes toward Negroes.

There is more than one dimension to prejudice. It may satisfy a number of different motives; it may be acquired in a variety of ways. An understanding of its many aspects, and of the manner in which they influence one another, has gradually replaced the attempts to explain the phenomena of race relations in terms of any one, single cause.

Similarly, programs designed to improve intergroup relations have become increasingly versatile instead of relying on any one method or technique. The debate as to whether one must first

reduce prejudice before embarking on legislation to combat discrimination, or whether the approach should be the other way round, has yielded to the conviction that both procedures should be followed simultaneously. As a result, many nations have developed a program of education and information, including the revision of their school textbooks, in order to improve attitudes toward other ethnic groups, at the same time strengthening the laws that make racial discrimination a punishable offense. At the international level. UNESCO has directed its efforts toward giving wide dissemination to scientific facts concerning race; and, on the other hand, the United Nations has sought to give human rights the sanction of a universal declaration leading to a universal covenant.

The fact that progress has been made cannot obscure the resistances that remain to be overcome. The birth of the new nation-states in Africa and Asia has frequently been accompanied by difficulties of racial adjustment. The international political situation has, on the other hand, paradoxically had a favourable effect on race relations because of the desire on the part of all the great powers to win the friendship of these new nations. There have been other favourable factors also, including a changed climate of public opinion. as well as a general desire to counteract the impressions and heal the wounds that resulted from colonialism and imperialism. There is still a long way to go before race is universally recognized for the myth it really is, but the movement is in that direction.

INTERREGNUM, strictly a period during which the normal constituted authority is in abeyance, and government is carried on by a temporary authority specially appointed (Lat, *inter,* "between!" and *regnum,* "reign"). Though originally and specifically confined to the sphere of sovereign authority, the term is commonly used by analogy in other connections.

The term originated in Rome during the regal period when an *interrex* was appointed (traditionally by the senate) to carry on the government between the death of one king and the election of his successor. The most noteworthy use of the term in post-classical times is that of the Great Interregnum between the death of Conrad IV (1254) and the election of Rudolf of Habsburg (1273). *See* GERMANY.

INTERSTATE COMMERCE, in U.S. usage, includes the movement of passengers and goods from one state to another, between a state and a territory of the United States and between points in territories or possessions. It includes the agencies and facilities by which the transfer is accomplished and comprises the mechanism and services of trade, transport and communication between citizens of different states' territories. Broadly defined, the term commerce applies to the wide range of economic services, including trade and the instrumentalities used in commerce, and to exchange or distribution in general. As here used, it is limited to the traffic and trade that crosses state boundaries or within or between territories in the internal or domestic commerce of the United States; foreign trade between the United States and other countries or their possessions is not included. Communication agencies and services, although closely related to interstate commerce. are excluded here.

Interstate commerce may be conducted by individuals or partnerships, but it is for the most part conducted by corporations, which, like those engaged in production, have tended to become larger as trade has increased. Their activities are increasingly subject to regulation by the states and particularly by the federal government. In the public interest the services and facilities employed by rail, highway, water, pipeline and air carriers must conform to standards fixed by state and national laws whose enforcement is furthered by government inspection of equipment of many kinds.

Corporations must compete in interstate commerce by methods that are "fair." and the accounts, finances, charges and services of carriers are comprehensively regulated by the federal government in the interests of the public, including the producers and users of their services.

The principal agencies by which interstate freight and passenger movements, or trade and travel. are effected are the railways; the vessels and barges operated in the intercoastal, coastwise, inland waterways trades, and on the Great Lakes; the carriers operating motor trucks and buses; the petroleum pipelines; express carriers; freight forwarders; and the air carriers. Carriers other than railroads subject to the Interstate Commerce act, as amended, include pipeline companies (other than water pipelines), sleeping car. express, motor carriers of freight and passengers, domestic common carrier water carriers and freight forwarders. A Federal Trade commission (*q.v.*) was created by congress in 1914 to prevent unfair competition in commerce. The Civil Aeronautics act of 1938 as amended, gave the Civil Aeronautics board and the Civil Aeronautics administration! which is subordinate to the secretary of commerce, jurisdiction over interstate air facilities and service. The Federal Maritime board and the Federal Maritime administrator. both under the jurisdiction of the United States department of commerce, were given jurisdiction over overseas water transportation.

Freedom of Interstate Commerce. — The commerce crossing state boundaries in the United States constitutes the world's largest interchange of commerce without customs duties. The United States is thus a vast free trade area. No state imposes customs duties upon imports from or exports to other states, and the United States throughout its continental territory and possessions is a single commercial unit with full freedom of internal trade. In this regard the United States is in marked contrast with Europe and countries on other continents where various historical causes brought about the existence of many nations, each concerned with safeguarding its own internal trade against the encroachment of the commerce of other countries.

Freedom of interstate commerce has been as great an aid to political success as to economic welfare in the United States. The commerce clause of the U.S. constitution made a united country possible. Despite sectional divergencies and a civil war. the nation has been held together, and the states have grown into a strong economic and political union because industry, trade. transport and communication have been kept relatively free of state taxes and restrictions. There are: however, some barriers to interstate cotnmerce.

Power of the United. States Government over Interstate Commerce. — The power of congress "To regulate Commerce with foreign Nations, and among the several States" is vested in congress by the commerce clause of the constitution so that no state can levy taxes on the export trade. The constitution provides that "No State shall. without the Consent of the Congress, lay any Imposts or Duties on Imports or Exports, except what may be absolutely necessary for executing its inspection Laws."

The constitution also provides that "No State shall, without the Consent of Congress, lay any Duty of tonnage," that the congress shall levy no tax or duty "on Articles exported from any State" and that "No Preference shall be given by any Regulation of Commerce or Revenue to the Ports of one State over those of another: nor shall vessels bound to, or from, one State be obliged to enter; clear, or pay Duties in another."

These prohibitions in the constitution prevent restrictive regulation of commerce by states, while the positive power granted to congress is comprehensive and has been so interpreted by that body and the U.S. supreme court as to make regulation positive and constructive. It has been held that the federal government's authority to regulate interstate commerce is "exclusive" and plenary." In regulating, congress can promote interstate commerce as well as regulate it, and that has been the policy of the federal government.

The interpretation of the commerce clause of the constitution, through a long series of supreme court decisions, tended to restrict the powers of the states and to broaden those of the federal government over interstate and indirectly over intrastate commerce. Chief Justice John Marshall laid a broad and firm foundation for federal authority in 1824, in the case of *Gibbons* v. *Ogden* (9 Wheaton 1). In this classic decision, denying to the state of New York the power to grant to a steamboat company a monopoly of steam navigation in the waters of the state to the exclusion of others owning vessels licensed by the United States, the supreme court enunciated the principle that guided the court in all subsequent interpretations of the commerce clause. It stated that "by virtue of the comprehensive terms of the grant, the authority of Congress is at all times adequate to meet the varying exigencies that arise, and to protect the national interests by securing the freedom of interstate commercial intercourse from local control."

The extension of the power of congress over interstate (and incidentally over some aspects of intrastate) commerce by legislation and court decisions has affected all categories of commerce and carriers.

Federal Regulation of Interstate Shipping.—Among the supreme court decisions defining the boundaries of state and federal power over shipping was *Sinnot* v. *Davenport* (22 Ho ard 227, 1860), which held unconstitutional a law enacted by Alabama in 1854 requiring special state registration of all vessels navigating waterways in the state.

The court ruled that a vessel enrolled by the United States cannot be required to obtain state registration. In 1871 the supreme court annulled a law enacted by Alabama in 1866 imposing a tax of $1.00 per ton on all vessels operating upon the navigable waters within the state. The supreme court held that states may tax ships as property, but they may not levy a tonnage tax *(Cox* v. *the Collector,* 12 Wall. 204, 1870). A state is also without power to impose port wardens' fees upon ships entering its ports *(Steamship Company* v. *Port Wardens,* 6 Wall. 31, 1867). It may not place an occupation tax on persons or corporations employing vessels in a manner authorized by a U.S. licence *(Moran* v. *New Orleans,* 112 U.S. 69, 1884).

These supreme court decisions negatived attempts of the states to burden unduly the facilities used in commerce. The legislative policy of federal regulation has been a positive one. Harbours have been improved, and inland waterways have been canalized and extended; the Shipping act of 1916 and the Merchant Marine acts of 1920, 1928 and 1936 provided for aiding and regulating shipping and water transportation.

Moreover, the Interstate Commerce act, particularly as amended by the Transportation act of 1920 and the Wheeler-Lea Transportation act of 1940, empowered the Interstate Commerce commission to establish through routes and rates by railroads and waterways and thus to promote the use of waterways by making them a part of a co-ordinated system of rail and water lines for the service of interstate commerce.

Regulation of Interstate Commerce by Rail.—The principal carriers of interstate commerce in volume of intercity traffic transported in the United States are the railroads. The federal regulation of railroads which began with the Act to Regulate Commerce of 1887 was extended in scope by subsequent laws until it applied comprehensively to all such carriers and many other types of carriers engaged in interstate commerce. Interstate and intrastate commerce and railroad services are so interrelated, moreover, that the federal government in exercising its plenary power over interstate commerce incidentally limited in large measure the regulation of intrastate trade and traffic by the states. The federal safety laws apply to all railroad equipment; railroad finances are regulated by the Interstate Commerce commission, which must approve of the location and construction of proposed railroads and of the issue of securities; and the states may not establish intrastate railroad rates that unreasonably discriminate against the interstate charges found reasonable and otherwise lawful by the Interstate Commerce commission.

When the states began to regulate railroad rates, shortly after 1870, some of the states, particularly the agricultural or Granger states of the midwest, fixed rates on all railroad traffic. including both that moving within and that crossing state boundaries. Some of these laws were upheld by decisions of the U.S. supreme court. In 1886 the supreme court in *Wabash* v. *Illinois* (118 U.S. 557) held that the states could not fix the rates on interstate traffic. To do so would be to regulate interstate commerce over which the United States has exclusive and plenary jurisdiction. For 25 years after that decision no question was raised as to the power of the states to fix rates on intrastate traffic that were per se reasonable.

In 1911, however, the railroad commission of Louisiana complained to the Interstate Commerce commission that the railroad rates fixed by the state authorities of Texas on traffic within that state were so much lower than the interstate rates, which had been found reasonable by the I.C.C., as to discriminate against traffic from Louisiana into Texas and to prevent Shreveport. La., from competing with Houston. Tex., and Dallas, Tex., for the trade of northeastern Texas. The commission decided in favour of the complainant and ordered the railroads to cease the discrimination, which they did by raising the rates that had been fixed by Texas. This order of the Interstate Commerce commission and this action of the carriers were sustained by the U.S. supreme court in the so-called Shreveport case, *Houston* E. *and W T. R. Co.* v. *United States* (234 U.S. 342, 1914). The principle established by this decision was extended and strengthened in the Transportation act of 1920, by which the Interstate Commerce commission was given authority to prescribe rates and fares in lieu of intrastate rates that the commission found to discriminate unjustly against interstate or foreign commerce.

To carry out the rate-making provisions of the Interstate Commerce act, as amended by the Transportation act of 1920, and to enable the carriers to obtain a reasonable return on their property, the Interstate Commerce commission raised rates and fares on all railroad traffic, intrastate as well as interstate. The state of Wisconsin had fixed passenger fares by statute at two cents a mile. The state commission did not change the statutory fare, but the carriers sought and obtained a federal court decree enjoining the state from fixing the intrastate fare on a level which would discriminate unjustly against the interstate fares. The U.S. supreme court in *Wisconsin* R. R. *Comm.* v. *C. B. and Q. R. Co.* (257 U.S. 563. 1922) upheld the federal statute and order of the Interstate Commerce commission.

On the same day that it handed down that decision, the court in *New York* v. *the United States* (257 U.S. 591, 1922) upheld the Interstate Commerce commission's order raising New Pork intrastate railroad rates and fares to the level of interstate rates and set aside as unconstitutional a contract provision in the charter of the New York Central railway in which the state had limited the fare on the main line of that road between Albany and Buffalo to two cents a mile, the court holding in effect that the state in requiring such a fare to be charged was unjustly discriminating against interstate passenger traffic subject, at that time, to a charge of 3.6 cents per mile.

Federal Authority Over Interstate Commerce by Highways.—The supreme court of the U.S., in a series of decisions,

defined the boundaries of state and federal authority over highway carriers engaged in interstate commerce, just as the powers of the states and the nation over commerce by railroads were determined by judicial interpretation. In 1923 the state of Michigan enacted a law requiring all motor carriers for hire upon the roads of the state to secure a certificate from the public utilities commission. The act also provided that such motor carriers for hire were common carriers subject to the laws applicable thereto and should be required to carry insurance or furnish an indemnity bond.

A motor carrier engaged solely in interstate transport on a contract basis contested the validity of the law, and the U.S. supreme court held that "It is a burden on interstate commerce to impose on plaintiff (a private interstate carrier) the . . . liability of a common carrier, and the obligation of furnishing such indemnity bond" and other regulations imposed on common carriers as conditions precedent to engaging in interstate commerce by highway. The court also held that a state could not by legislative fiat convert a private carrier into a common carrier, "for that would be taking private property for public use without just compensation" *(Public Utilities Commission, Michigan* v. *Duke,* 266 U.S. 570, 1923); *see* also *Frost* v. R. *R. Commission, California* (271 U.S. 583, 1926).

A person operating a common carrier bus line over a regular route between Seattle, Wash., and Portland, Ore., was granted an authorizing certificate by Oregon but was refused one by Washington. The director of public works in Washington ruled that there was no need for another carrier because the territory already was adequately served and denied the petition because "under the laws of the state, the certificate may not be granted for any territory which is already being adequately served." The U.S. supreme court, however. held that the law was a regulation of interstate commerce forbidden by the commerce clause of the federal constitution *(Buck* v. *Kuykendall,* 267 U.S. 307, 1925). But. in later decisions, particularly in such cases as *Stephenson* v. *Binford* (287 U.S. 251, 1932) and *Maurer* v. *Hamilton* (309 U.S. 598, 1940), the supreme court upheld the power of the states to regulate the use of their highways for gain by contract as well as common carriers. and the states were thus permitted to regulate motor carriers thoroughly subject to the limitation that the states may not prevent or unreasonably burden interstate commerce. The power of the states to regulate the use of the highways under the police power of the states is pervasive.

These and other decisions of the federal courts have given effect to a general definition of the powers of the states and of the United States respectively, which were clearly stated by the supreme court as early as 1915 in the case of *Hendrick* v. *State of Maryland* (235 U.S. 610). The court declared that "In the absence of national legislation covering the subject, a state may rightfully prescribe uniform regulations necessary for the public safety and order in respect to the operation upon its highways of all motor vehicles — those moving in interstate commerce as well as others. . . . The reasonableness of the state's action is always subject to inquiry in so far as it affects interstate commerce, and in that regard it is likewise subordinate to the will of Congress."

Federal **Aid** and Regulation of Air Transportation. — Congress encouraged the development of air transportation by liberal aid. The Air Commerce act of May 20, 1926. provided that all aircraft operated interstate or to foreign countries were to be registered and rated by the secretary of commerce, who was also empowered to establish airways and equip them with necessary lights, signals and landing fields, other than terminal landing fields or airports. The regulation of the services and charges of the air carriers began with the enactment of the Civil Aeronautics act of 1938. These economic regulations were made very comprehensive.

The government greatly aided the establishment and development of airline services by payments for the carriage of mail. Such payments initially were made large enough to enable the airlines to maintain and develop the services needed in the public interest. The Civil Aeronautics board was authorized to fix the compensation to be paid by the government for the transportation of airmail, part of the payments being considered subsidy and part compensation for service.

Terminal airports were provided by municipalities or other local government agencies and the facilities leased to the airline companies. Through the Work Projects administration and the Public Works administration, established to provide work for the unemployed, the federal government constructed a large number of airports for the municipalities. Federal funds were later granted to ensure the construction of airports of proper size, design and facilities under the National Airport plan.

The enforcement of the act of 1938 was vested in a Civil Aeronautics authority of five men and a three-man Air Safety board connected with the Civil Aeronautics authority. The act also provided for an administrator with the functions of establishing civil airways, surveying airports and developing a national system of airways. The Civil Aeronautics authority was reorganized in 1940 and renamed the Civil Aeronautics board. The board was associated with but was not made subordinate to the department of commerce, the board being independent of the secretary of commerce as regards its interpretation and enforcement of the Civil Aeronautics act. The functions exercised by the civil aeronautics administrator, an official of the department of commerce, include jurisdiction over the executive aspects of promotion and inspection. The functions of the Air Safety board were absorbed by the Civil Aeronautics board.

Thus, as a result of establishment and maintenance of landing fields and airports in large numbers by states and municipalities and the contributions of the federal government in adding to and extending the established air routes, equipping them with temporary landing fields, with navigation aids and communication facilities, the development of interstate and foreign air commerce proved to be spectacular.

Prohibition of Combinations in Restraint of Interstate Commerce. — The Sherman Antitrust act of 1890, as later amended and strengthened by the Clayton act of 1914 and other supplemental laws, made illegal contracts or combinations in the form of trusts, or in any other manner, in restraint of interstate or foreign commerce. In the case of *United States* v. *Trans-Missouri Freight Association* (166 U.S. 290, 1896). the U.S. supreme court held that the law applied to all combinations in restraint of interstate or foreign commerce, including those that had previously been considered reasonable under the common law. A similar decision was handed down in *United States* v. *Joint Traffic Association* (171 U.S. 505, 1898). This literal interpretation of the law hampered the development of large-scale organization in the conduct of commerce until 1911, when, in the Standard Oil company case *(United States* v. *Standard Oil Co.,* 221 U.S. 1), the supreme court enunciated and applied the "rule of reason," according to which the Sherman act prohibited only such combinations and restraints as were illegal at common law.

This decision was not satisfactory to those who favoured a stringent curb on combinations, and the Clayton act was passed to define more specifically what combinations or restraints were prohibited and to extend the law more definitely to agreements made to fix prices for the purpose of lessening competition or creating monopoly. The act, however, exempted labour and agricultural organizations from the provisions of the antitrust laws. The Clayton act did not, in fact, strengthen the Sherman act of 1890 in its general application, the terminology of the original law having proved more comprehensive than the more specific definitions and specifications of the later act.

Railroad rate agreements and associations, which by the decision of the supreme court in the Trans-Missouri Freight association case in 1896 and the Northern Securities case (*Northern Securities Co.* v. *United States,* 193 U.S. 197, 1904) had been brought under the prohibitions of the antitrust act, were, by the Reed-Bulwinkle act of June 17, 1948 (Interstate Commerce act, part i, section 5a), made legal when approved by the Interstate Commerce commission.

Fair Competition in Interstate Commerce. — In 1914 congress enacted a law "to create a Federal Trade Commission and to define its powers and duties." The purpose of the act was "to

prevent persons, partnerships. or corporations. except banks, and common carriers subject to the acts to regulate commerce. from using unfair methods in commerce." The commission of five members was given ample powers of investigation. If the commission found that methods of competition prohibited by law were being employed it might order the violator of the law to desist from such practices. If the order was not obeyed. the commission might apply to a C.S. circuit court of appeals to enforce the order. Since the court has the power to affirm, modify or set aside orders. the Federal Trade commission is essentially an investigating rather than a regulatory agency. It has. however, served a useful purpose, not only because it may proceed upon its own motion but also for the reason that it may be called upon by the United States attorney general to report upon the manner in which a corporation found by a court to be violating the antitrust laws is carrying out the court's decree. The FTC may also be directed by "the President or either house of Congress to investigate and report the facts relating to any alleged violation of the Antitrust Acts by any corporation."

The antitrust laws of 1890 and 1914 were enforced, broadened in scope and made increasingly effective by many decisions of the U.S. supreme court. The decision in the case of the *Cnited States* v. *Socony-Vacuum Oil Co.* (May 6, 1940) condemned as illegal an agreement of oil refining companies to pay independent refineries such a price for their excess or "distress" gasoline as to enable them to continue in business despite distress conditions resulting from a sudden excess in oil output caused by the opening of new wells. The court held that "Conspiracies under the Sherman Act (of 1890) are on the common law footing; they are not dependent on the doing of any act other than the act of conspiring." An agreement to raise the price of a commodity that enters into interstate commerce is a violation of the federal antitrust law irrespective of the reasonableness of the price agreed upon or of the purpose and intention of the members of the combination to pay a price that may be reasonable. The obvious purpose of the court proved to be to interpret the statutes so as to assure to consumers the full benefit of competition.

The fixing of prices through the use of "phantom freight" charges and by the use of the basing-point system of pricing were declared unlawful in several supreme court decisions, including *Corn Products Co.* v. *Federal Trade Commission* (324 U.S. 726, 1945); *Federal Trade Commission* v. *Cement Institute et al.* (331 U.S. 683. 1948).

The U.S. domestic commerce, most of which is interstate, changes constantly with the evolution of industry and industrial processes, with the shifting of the major centres of production of the leading products of manufacture and with improvements in transport agencies and in methods of transport. Moreover, while commerce was increasing in volume in the 1950s, large-scale organization of business was more and more taking the place of small enterprises. For these reasons! interstate commerce remained the subject of frequent legislation and of an increasing administrative regulation by the federal regulatory commissions. *(See* also FEDERAL TRADE COMMISSION.)

Volume of Interstate Commerce. — The volume of interstate as distinct from intrastate commerce is not stated in official records. A large percentage of goods shipped between points within the United States or sent to or received from foreign countries crosses state boundaries. A large share of the total traffic of railway. railway express, water, highway, pipeline, freight forwarder and airway carriers consists of goods carried from one state to another. Reference to the tonnage transported by these several carriers will indicate generally. therefore. the magnitude of interstate commerce in the United States.

During 1953, for example. the railroads in the United States originated about 33,000,000 carloads or about 1,876,000,000 tons of revenue freight. This was the tonnage originating on their several lines; many shipments of freight moved over more than one railroad in their routes between origin and destination. The total freight service was the equivalent of the movement of one ton over 605,000,000,000 ton-miles. The number of carloads and the ton-miles decreased after the peak traffic years during World War 1 More than 737,000,000,000 ton-miles of freight were moved by railroad in 1944. There were 8 tons and more than 3,750 ton-miles of railroad freight per inhabitant in 1953. Since the average distance a ton was hauled was nearly 420 mi., it is evident that most of the traffic must have been interstate.

The domestic water-borne commerce of the United States moving in the coastwise, intercoastal trades and on the Great Lakes and other inland waterways totals nearly 700,000,000 tons annually. The number of tons moved on rivers and canals is greater than the tonnage of the Great Lakes, but. as the average length of haul on the Great Lakes is much longer, the ton-mileage for the Great Lakes is about 20,000,000,000 annually as compared with 60,000,000,000 for the traffic on rivers and canals. The major portion of this large traffic on the Great Lakes consists of coal, iron ore, grain, stone and petroleum. Traffic on rivers and canals consists largely of bulk shipments of minerals, steel, petroleum products, sand and stone.

There is a large volume of traffic carried coastwise and via the Panama canal, although both the coastwise and intercoastal trades were adversely affected by World War II. during which vessels were placed in other services. and by railroad competition after the close of World War II.

In 1953 about 240,000 publicly and privately owned and operated motor buses were registered, but many of them were operated in private services, by contract carriers or by school authorities. At the same time the total mileage of highways and streets, state. county and local, was about 3,000,000, of which about one-half is surfaced. The number of motor trucks operated by contract, common and private carriers in intrastate and interstate operations was nearly 9,000,000. The total number of registered motor vehicles was about 45,000,000.

The bureau of public roads of the U.S. department of commerce conducted surveys in a number of states to determine the nature and volume of motor passenger and freight traffic. In small states with dense population and highly diversified industries there is usually a considerable use of the highways in interstate commerce. The same situation exists where several large cities are close together near state boundaries. In larger states a much smaller portion of the motor truck transportation is interstate. Interstate motor traffic constitutes a small share of the total because a large percentage of motor hauls are in local or short distance services.

Air transport routes are characteristically long, and most air services over regular routes are interstate. Air transportation has made rapid progress in the U.S. Its early development was relatively slow because. unlike the air transportation industries of several European countries, it did not receive direct government subsidies to establish and develop passenger, freight and mall air transport services. (See *Federal Aid and Regulation* of *Air Transportation,* above.) In 1953 airlines in domestic trunk line and local service operated over approximately 77,000 mi. of unduplicated routes. The number of passengers carried by the domestic scheduled airlines in 1953 was 3,475,065 and the lines provided more than 3,500,000,000 passenger miles of service. Air express matter carried totalled more than 42,000,000 ton-miles and 131,000,000 ton-miles of freight were transported. Scheduled airlines operated 1,122 planes in domestic services and 543 planes in international services.

Airmail transport in the United States was still rapidly increasing in the mid-1950s. In 1953 airmail carriers transported more than 72,000,000 ton-miles of airmail traffic in domestic services and more than 24,000,000 ton-miles in United States-foreign air services.

On Sept. 1. 1927, the American Railway Express company, later renamed the Railway Express agency, made an agreement with the airlines for an air express service. This service has been operated continuously since that time, and, in addition, airlines have their own freight service for freight of high value which requires fast transportation service. Frequent services are regularly operated between the principal cities in the United States and throughout the world carrying passengers, mail, express and freight in interstate and international commerce. Commercial air services

include domestic trunk lines, local service airlines, insular territorial airlines, international airlines, all-cargo airlines, helicopter airmail services, and nonscheduled and noncertificated air carriers.

BIBLIOGRAPHY.—The principal statutes concerning the regulation of interstate commerce by the U.S. may be found in convenient form in *The Interstate Commerce Act* (Washington). The U.S. supreme court decisions referred to in the article contain historical and economic information. These decisions are published in United States Supreme Court *Reports* (U.S. series). The annual reports oi the Interstate Commerce commission and of the chief of engineers, U.S. army (see volume on *Commercial Statistics),* may be consulted ior statistics of the volume of domestic traffic by rail and water. *See* also David Philip Locklin, *Economics and Transportation,* 4th ed. (1954); Truman Cicero Bigham and M. J. Roberts, *Transportation; Principles and Problems,* 2nd ed. (1952); George Lloyd Wilson, *Transportation and Communications* (1954) in which the services, basis of charges of railroad, highway, water, pipeline, and air carriers in the United States are discussed and the policy of regulation is summarized.

(E. R. J.; G. L. WN.)

INTERSTELLAR MATTER is material of exceedingly low density dispersed in the space between the stars in the form either of gas (detectable from its emission and absorption of light and radio waves, especially in certain spectral lines) or of "dust," which can be detected by its general absorption and reddening of starlight.

DARK MATTER IN THE MILKY WAY

Absorbing Clouds.—Inspection of the Milky Way with a small telescope (or in places with the naked eye) shows that the rich star fields of which it consists are interrupted by dark patches, such as the Coalsack near the Southern Cross. These dark clouds were examined around 1900 by Max Wolf and E. E. Barnard. who found them to be most abundant in Ophiuchus and Sagittarius, toward the centre of the Milky Way system. This fact. together with the appearance among them both of bright patches and of still darker globules. suggests that they are real dark clouds rather than starless "holes," which latter would have to be narrow tubes thousands of light-years in length converging on the solar system —an obvious absurdity. The absorptions. distances and thicknesses of these clouds have been determined by a method originally due to Wolf and improved by later workers: the apparent distances of stars (found from their spectral types and apparent brightnesses) are determined both through a cloud and in a neighbouring field outside the cloud.

The number of stars at a given distance is then plotted on a graph against this distance for the two cases; the tno curves coincide up to the distance of the near side of the cloud and then diverge until, on the far side, they run parallel with a constant horizontal displacement from which the amount of light absorbed by the cloud can be calculated. The results are greatly complicated by the frequent presence of several clouds in one direction, but a typical cloud seems to be about 100 parsecs across (1 parsec = 3.26 light-years) and to diminish the light passing through it by nearly 1 magnitude (equivalent to a factor of 2.512).

A further effect, known as interstellar reddening, arises in the clouds because blue light is absorbed more strongly than red light; hence a given star appears redder through a cloud than nhen seen through clear space, just as the sun appears red when near the horizon. The colours of stars are measured by their colour index; *i e ,* the difference between photographic or blue magnitude (measured in a wave length band centred near λ 4,250 Å) and visual magnitude (centred near λ 5,450 Å in the yellow-green region). The amount by which the colour index of a star exceeds the normal value for its spectral type is known as its colour excess In most clouds studied, the ratio of total absorption in photographic magnitude to colour excess has nearly the same value, about 3 j, suggesting the presence of the same absorbing material in these various cases. This fact has been applied by W. Becker and by H. L. Johnson and W. W. Morgan in order to obtain the degree of interstellar absorption and reddening for star clusters by comparing the normal colour index with an additional colour index obtained from photometry in the ultraviolet region of the spectrum (λ 3 600 -%).

General Absorption.— The possibility that the light of distant stars might be dimmed by absorption even where no dark clouds are actually visible was mentioned in 1720 by Edmund Halley, and discussed during the 19th century by H. W. M. Olbers, F. G. W. von Struve and others as a possible explanation of the fact that the number of stars per unit volume seems to diminish with distance in all directions. The alternative explanation is that we are near the galactic centre.

The 20th-century research on our galactic position has shown that we are close to the central plane of the galaxy, but a long way from the centre. so that the apparent distribution of stars in the Milky Way (though not at right angles to it) is indeed determined by absorption, although its amount varies greatly with direction and distance. Definite proofs of the presence of general absorption in the Milky Way have been provided by the invisibility of external galaxies in an irregular region roughly bounded by the circles of galactic latitude ± 20° ("zone of avoidance" studied in detail by E. P. Hubble and H. Shapley) and by R. J. Trumpler's extensive investigation in 1930 of galactic open clusters at distances between 600 and 2,200 parsecs.

By measuring the apparent brightnesses of cluster stars whose

RADCLIFFE OBSERVATORY (PRETORIA U OF S AF) PHOTOGRAPH, REPRODUCED BY COURTESY OF A D THACKERAY

M 16, A COMPLEX OF BRIGHT AND DARK INTERSTELLAR MATTER IN SERPENS, IN THE SOUTHERN MILKY WAY

real brightnesses could be estimated from their spectra. Trumpler estimated the actual diameters of the clusters and showed that these must increase systematically nith the distance of the clusters from us if the intervening space were assumed to be entirely transparent. This highly implausible effect is removed if one assumes an average absorption of about 1 photographic magnitude per 1,000 parsecs in the galactic plane.

A similar result was obtained by A. H. Joy (1939) and R. E. Wilson (1940) from a study of Cepheid variables whose absorptions and true distances were derived from the period–luminosity relation in conjunction with the theory of galactic rotation; but J. H. Oort, H C. van de Hulst and D. W. N. Stibbs later suggested twice this value. If the absorption is neglected, large distances are greatly overestimated; for example, the distance of the galactic centre—estimated at 16,000 parsecs by Shapley in 1930—turns out to be only 8.200 parsecs when the obscuration is allowed for. W. Baade's photographs of external galaxies suggest that the absorbing clouds are mainly confined to galactic spiral arms.

Scattering Nebulae.—When observed with a spectroscope, certain bright nebulae show a continuous spectrum with ddrk lines, identical with that of a nearby star, unlike the emission spectra of

gaseous nebulae near very hot stars. These nebulae are identical with the dark clouds mentioned above, which scatter incident starlight in all directions and thus appear bright when viewed sideways on. As in the case of the sunlit sky, but to a lesser degree, the scattered light is generally more blue than that of the illuminating star and shows a certain degree of polarization (see below). True absorption of starlight by obscuring clouds is probably absent, and the term "interstellar absorption" should strictly by interpreted as obscuration resulting from scattering by interstellar material.

Interstellar Polarization. — In 1949 W. A. Hiltner and J. S. Hall showed that the light of distant stars seen through obscuring matter often possesses an appreciable degree of polarization; *i.e.*, the electric vibration of the light is slightly (up to 8%) stronger in one plane than in the plane at right angles to it. The polarization is particularly strong toward Perseus, where we are probably looking along a spiral arm of the galaxy. In this direction, the strongest vibration is parallel to the galactic plane; this suggests the presence of elongated scattering particles with their long axes predominantly at right angles to the plane. According to L. Davis and J. L. Greenstein, this orientation may be caused by paramagnetic relaxation in a galactic magnetic field between 10^{-5} gauss and 10^{-4} gauss, if the particles have a small admixture of magnetic material.

Form of **Absorption-Colour** Curve and Nature **of** the Scattering Material. — The variation of the scattering coefficient from the violet to the red end of the spectrum has been studied by comparing the brightnesses ip various spectral regions of pairs of hot stars of identical spectral types seen through different degrees of obscuration. The most extensive measurements have been carried out photoelectrically (with colour filters) by J. Stebbins and A. E. Whitford (1943) and spectrographically by Greenstein (1938), C. Schalen (1952) and L. Divan (1951). The various results agree in showing that. in the limited range of wave lengths between λ 4,000 Å and λ 8,000 Å (roughly the visible range from violet to red) the scattering coefficient is nearly inversely proportional to wave length, but that the curve flattens off at both the ultraviolet and infrared ends. The absorption is thus neither neutral (as would be expected from large rocklike objects or from free electrons, neither of which could exist in sufficient quantities to explain the observations) nor is it in accordance with Lord Rayleigh's fourth-power law (which applies to atoms and molecules, *e.g.,* in the earth's atmosphere).

The absorption must arise from a fine dust or smoke with particles of dimensions comparable with the wave length of light (about $\frac{1}{20,000}$ cm). Van de Hulst has shown that the observed data, including the polarization of starlight observed through obscuring matter, are consistent with a distribution of dielectric grains (probably consisting of ice mith admixtures of solid hydrogen. methane, ammonia. metallic oxides and metals) having a typical diameter of 0.56μ (μ = micron. 1 micron = 10^{-4} cm.).

INTERSTELLAR GAS CLOUDS

Interstellar Absorption Lines.——Many distant, hot stars show in their spectra certain characteristic absorption lines with a red or violet shift differing from that shown by the remaining lines of the spectrum. This is particularly conspicuous in the case of certain spectroscopic double stars which show "stationary calcium lines," first discovered in the spectrum of δ Orionis by J. Hartmann (1904). Hartmann noted that the H and K lines of ionized calcium in the violet show a constant velocity shift, while that of the remaining lines goes through a cycle of variation every few days because of the orbital motion of the system. Hartmann recalled the behaviour of the exploding star Nova Persei 1901 in which the H and K absorption lines, and also the D lines of sodium in the yellow region, had remained sharp and fixed while the other lines underwent complex changes in position and structure; he concluded that these lines must, in the case of both stars. have been superimposed on the spectrum of the star proper by the passage of its light through a gaseous cloud in which calcium and sodium were present.

Afterward, M. L. Heger showed that the sodium D lines also remain stationary in δ Orionis, and high-dispersion spectra of this and other stars by T. H. Dunham and W. S. Adams revealed in addition stationary lines of potassium, titanium, neutral calcium and the diatomic molecules CH and CN. In cooler stars, these interstellar lines are hard to detect because of their blending with the corresponding lines in the star's own spectrum.

That the clouds mhich produce the interstellar lines are distributed throughout the galaxy and do not exist primarily in the neighbourhood of individual hot stars was first suggested by A. S. Eddington and confirmed from a study of numerous spectrograms in 1929 by Otto Struve, who showed that, on the whole, the intensity of the interstellar K line increases steadily with distance. In 1935, J. S. Plaskett and J. A. Pearce studied the velocities in the line of sight of numerous hot stars (which are distributed close to the galactic plane). They showed that, in a given direction, the velocities of individual stars increase in proportion to their distances, in accordance with Oort's theory of differential galactic rotation, and that the velocity shift of the interstellar K line generally corresponds to about one-half the velocity (and hence one-half the distance) of the star as though the gas were uniformly distributed in the intervening space.

Later work with spectrographs of higher dispersion by C. S. Beals (1936), R. F. Sanford, P. W. Merrill and **O.** C. Wilson (1938) and Adams (1943) showed that the interstellar lines are often split into numerous very narrow components, each being the effect of a separate cloud of gas with its own characteristic motion. According to estimates by A. Blaauw and B. Stromgren, a straight line 1,000 parsecs long in the galactic plane may traverse about 10 clouds with a mean diameter of about 5 parsecs. a mean density of 10 hydrogen atoms (or 2.7×10^{-23} g.) per cubic centimetre and a mean velocity relative to the average of the surrounding stars of about 7 km. per second. The chemical composition of the clouds seems to approximate closely to that of normal stars, but their temperatures are very low (of the order of 100° K., *i.e.*, 100° C. above absolute zero or −173° C.), so that the constituent atoms and molecules are practically all in their state of lowest energy. The absorption spectra therefore consist entirely of resonance lines, only a limited number of which occur in the observable spectral range. In 1953, Guido Munch showed that around Perseus the interstellar lines from hot stars at very great distances (up to 3.000 parsecs) split into two distinct groups of components, arising from gas clouds in the next spiral arm out from the centre of the galaxy as well as in the arm in which we are situated.

In addition to the lines mentioned above, certain highly diffuse absorption bands many ångströms wide are produced in interstellar space, the strongest being centred on λ 4,430 A. Their origin is unknown, but they appear to be associated with the clouds of obscuring dust rather than with the interstellar gas in general.

Radio Emission by Cosmic Gas. — In 1932, K. G. Jansky found that cosmic noise at radio frequencies was received by a directional antenna pointed at the sky; he and G. Reber afterward showed that the radio naves came from the Milky Way, the strongest radiation being received from the direction of the galactic centre in Sagittarius. After 1945, a number of point sources of radio emission were discovered both within and outside the galaxy. but only in certain cases was it possible to identify these visually. One such source within the galaxy is the Crab nebula in Taurus, which is the gaseous remnant of the supernova observed from China and Japan in 1054, a stellar outburst of unusual violence. An extragalactic source is Cygnus A, which was shown by Baade and R. Minkowski in 1952 to consist of two colliding galaxies. In this case the stars simply pass one another with little interference because of their enormous distances apart, but the clouds of interstellar gas and dust collide with relative velocities of 1,600 km. per second and are in violent turbulent motion.

Weak radio emission has been detected from the sun (enhanced by sudden bursts during solar flares), from the galactic plane, from the galactic corona (a large, spherical, extremely tenuous region roughly embracing the globular clusters and concentric with

the Milky Way) and from nearby extragalactic nebulae; but it is significant that the strongest sources always consist of ionized gas with violent internal motions. Furthermore. the Crab nebula shows a filamentary structure emitting polarized light which suggests the presence of a magnetic field. The evidence suggests that the chief cause of radio emission is the deceleration of electrons moving with velocities approaching that of light in a magnetic field (synchrotron radiation). These ionized, magnetized gas clouds also provide a likely mechanism for the production of some cosmic rays. In the case of the quiet sun and of ionized hydrogen clouds in the galactic plane. however, the radio emission is of thermal origin. as a result of the deceleration of electrons in the electric fields of nearby protons.

Interstellar Hydrogen and **21-cm.** Radiation.— Although hydrogen is by far the most abundant element in the interstellar gas, as in normal stars, its spectral lines are not detectable optically except as emissions from those clouds (known as H II regions) that are close enough to hot stars to be ionized by their ultraviolet radiation. In this case the capture of electrons by protons leads to the production of energetically excited hydrogen atoms which then lose their energy by emitting radiation, some of nhich appears in the visible region of the spectrum. At a certain distance from such a star (depending on its size and temperature and on the density of the nearby gas), the ultraviolet radiation is completely broken down into quanta of lower energies and longer wave lengths, so that hydrogen is no longer ionized (this is the H I region).

In accordance with the theory developed by H. Zanstra and Stromgren, the transition takes place quite suddenly, so that the typical H II region is a well-defined sphere surrounding a hot star or a group of hot stars. Such H II emission clouds are prominent in photographs of spiral galaxies, in which they were formerly often mistaken for bright stars. They occupy only about one-tenth the space taken up by the neutral H I clouds which produce the interstellar absorption lines; their physical state resembles that of the diffuse nebulae, such as the great emission nebula in Orion, but they are of a considerably lower density.

The development of radio astronomy has provided an extremely powerful method of detecting neutral hydrogen in interstellar clouds from the transition at 1,420 mc. per second (λ 21.1 cm.), a possibility which was suggested by van de Hulst in 1944. Radio waves of this frequency are respectively emitted or absorbed by a hydrogen atom in its lowest energy state, when the directions of spin of the proton and electron change from parallel to antiparallel or vice versa. This hyperfine structure transition takes place very rarely, the mean life of an atom in its upper state being about 11,000,000 years; but the clouds of interstellar gas are so vast that detectable amounts of radio noise are emitted at this frequency. The 21-cm. radiation from the Milky Way began to be observed in 1951, first by H. I. Ewen and E. M. Purcell (Harvard). then by C. A. Muller and Oort (Leiden, Neth.) and shortly afternard by W. N. Christiansen and J. V. Hindman (Sydney, Austr.). By observing the velocity shift of the 21-cm. line and applying Oort's theory of differential galactic rotation, van de Hulst, Muller and Oort plotted the spiral structure of the galaxy in the range of galactic longitude from 0° to 220°, while further spiral arms were detected in the southern Milky Way by Christiansen and Hindman.

In 1956, the 21-cm. line was detected in absorption from cool hydrogen clouds surrounding the intense radio source in Cygnus by A. E. Lilley and E. F. McClain, who showed that the recession velocity deduced from the Doppler shift of this line was in excellent agreement with the value of 16,700 km. per second measured in the optical spectrum by Minkowski. This result is strong confirmation of the view that the red shift observed in the spectral lines of distant galaxies is a true velocity shift.

Relationship Between Stars and Interstellar Material.— The distribution of interstellar gas and dust clouds is very heterogeneous, but roughly speaking they are confined within a distance of about 100 parsecs from the galactic plane (in the solar neighbourhood) and within the galactic spiral arms, which have a width of the order of 500 parsecs within the plane. While the dust appears to be confined to discrete clouds, which coincide with local concentrations of the gas with a density of about ten hydrogen atoms per cubic centimetre, there appears to be in addition a uniform distribution of gas with a density of about one hydrogen atom per cubic centimetre throughout the galactic disk. The temperature of the interstellar medium depends somewhat on the local intensity of stellar and cosmic radiation, but mainly on the absorbing properties of the medium; in H II regions it is about 10,000° K., in H I regions about 60° K. and the solid particles may be still cooler.

In the H I clouds there may be a statistical equilibrium between the gas and the dust grains, the latter being formed by combination and condensation and evaporated again by collisions between the clouds. The close association between bright, hot stars (which exhaust their nuclear energy sources so rapidly that they can be no more than 10,000,000 years old) and interstellar matter suggests that stars are being continuously formed by condensation from clouds of gas and dust. Possibly we are actually witnessing such a process in the T Tauri variables, stars which show emission spectra and are often accompanied by a visible nebulosity. The explosions of novae and supernovae and the slower ejection of matter from stars with expanding gaseous envelopes tend to replenish the interstellar medium, but only partially. since a certain fraction remains permanently locked up in white dwarfs. Thus the amount of interstellar material may be expected to diminish slowly with time.

At present the mean density of interstellar matter in the solar neighbourhood is about 3×10^{-24} g. per cubic centimetre, which is about equal to the density of material in the form of stars; but in the galaxy as a whole, most of which consists of relatively inconspicuous stars and of globular clusters distributed more or less spherically about the centre, the interstellar medium probably contributes only a small percentage of the total mass.

INTESTACY. If an individual dies without having made a valid will, the succession to his property is determined by the rules of intestacy. In England, until far into the 19th century, descent to real property was subject to rules diflerent from those applying to the distribution of personal property. For the former, the common law courts of the king developed the canons of descent, under which it descended undivided to a single heir, who among several relatives of equal nearness to the ancestor was determined by the rules of preference for males and of primogeniture.

Personal property was distributed in accordance with rules which the church took over from the Corpus Juris Civilis of the Roman emperor Justinian and which were ultimately codified in the Statute of Distribution of 1670. In the latter half of the 20th century, uniform systems of succession to both real and personal property prevailed in all common law jurisdictions of both the United States and the British Commonwealth, generally following the pattern of the Statute of Distribution but diverging in matters of detail. Differences exist particularly with respect to the position of the surviving spouse who, in England and in several states of the U.S., is entitled to a fixed minimum amount. In practically all U.S. jurisdictions the nidow, and in some the nidower and minor children, are entitled to an award to cover living expenses for the period during which the decedent's estate is wound up by the administrator. In numerous states the surviving spouse is also entitled to a priority over both other heirs and creditors of the decedent with respect to a minimum portion of the land used by the family as its homestead.

In the community property states, the community property is divided at the death of one spouse so that the surviving spouse has one half, while the other half. together uith the separate estate of the predeceasing spouse, passes under intestacy or under the will, as the case may be. In all U.S. jurisdictions the sur-

viving spouse is protected against complete disinheritance, but children are not usually protected.

While under older laws an illegitimate child has no rights of succession, modern acts generally provide for rights of intestacy between the illegitimate child and his mother and maternal relatives. A child who has been legitimated by the marriage of his mother and his reputed father or (as is possible in some U.S. jurisdictions) through acknowledgment by his reputed father, has the same position as a legitimate child. As to the intestacy rights between a person adopted, his adoptive parents, his natural parents and the relatives of the adoptive and the natural parents, the statutes of the several jurisdictions contain provisions which vary from each other in many respects.

If no relative of a decedent can be found, his estate escheats to the state.

See also ESTATE AND INHERITANCE TAXES; INHERITANCE; WILL.

(M. RN.; X.)

England. — Formerly devolution of property where its owner died intestate depended upon whether such property was realty or personalty. The Administration of Estates act (1925) for England abolished the whole law of inheritance. An heir now takes only where he is mentioned as such in the grant of an estate in land, and on the death of an owner of real and personal property intestate all his estate vests in the president of the probate, divorce and admiralty division of the high court of justice until the court appoints an administrator, whereupon such property vests in him or her. who holds his real estate on a trust for sale; this and the personalty form a joint fund for the payment of his debts and thereafter for distribution among the persons entitled. If there are no such persons, the fund goes to the crown as bona *vacantia.*

The scheme of distribution for which the Administration of Estates act, 1925, provided was as follows:

1. A surviving spouse was to take the personal chattels absolutely and a net sum of £1,000. Of the residue of the estate, the surviving spouse took a life interest in half if the intestate had children or in the whole if he had none.

2. Subject to the rights of a surviving spouse, the estate was taken by the children at 21 or on marriage, the issue of children who had died taking at 21 or marriage their share of what their parent would have taken if alive.

3. If there was no issue, and again subject to the rights of a surviving spouse, the parents of the intestate took equally, or if one parent survived he or she took the whole.

4. If there was neither issue nor parent, the following was the order: (a) brothers and sisters of the whole blood and their issue; (b) brothers and sisters of the half blood and their issue; (c) grandparents; (d) uncles and aunts of the whole blood and their issue; and (e) uncles and aunts of the half blood and their issue.

The Intestates Estates act, 1952, makes some important changes, mainly in the interests of a surviving spouse. If the intestate leaves no issue, no parents and no brother or sister, the whole of the residuary estate is held in trust for the surviving spouse absolutely. If he or she leaves issue, instead of £1.000 the surviving spouse receives £5,000 in addition, as before, to a life interest in half the residue; if the deceased leaves no issue but leaves a parent or brother or sister of the whole blood, or issue of such brother or sister, the surviving spouse is to receive £20,000 after payment of all liabilities, and one-half of the residue, while the other half of the residue is held in trust for the parent (or in equal shares for the two parents, if both survive) or, where there is no parent. on the statutory trusts for the brothers and sisters or their issue. Other important features of the 1952 act are that it gives the surviving spouse the right to call for the purchase or redemption of his or her life interest; that it modifies the law as to partial intestacies so that a surviving spouse obtains a statutory legacy diminished by the value of any bequest; that it enables a surviving spouse, on certain terms, to acquire the deceased's interest in the matrimonial home; and that it applies the provisions of the Inheritance (Family Provision) act, 1938, as amended to an intestacy, so that a spouse, an infant child, an unmarried or incapable daughter or an incapable son may apply to the court for further provision out of the estate of an intestate. (W. T. Ws.)

Scotland. — In the law of Scotland heritage descends to the heirs-at-law while the free moveable estate of the intestate is divided among the heirs in *mobilibus; i.e.,* next of kin and those entitled to share in the succession under the Intestate Moveable Succession acts. See also SCOTS LAW: Intestate Succession.

See for a digest of the intestacy laws of the U.S., Canada and other countries, Martindale-Hubbell, ***Law Directory,*** vol. 3 (annual).

(M. RN.)

INTESTINAL OBSTRUCTIONS. The alimentary tract digests and assimilates ingested food and disposes of the refuse. Any obstruction to the continuity of the bowel interrupts these three normal functions. Moreover, a blocked bowel often is accompanied by a chain of events which threatens life seriously. If the obstruction remains unrelieved, death follows.

Causes. — The bowel may become obstructed through a number of agencies, of which the following types are recognized:

1. Strictures of the bowel wall, congenital or acquired. Atresia and imperforation are types of congenital strictures which result from failure of the bowel to develop its lumen (canal) and are present at birth. The former (atresia) usually concerns segments of the small intestine — duodenum, jejunum or ileum — though the proximal reaches of the colon may occasionally be involved. Ordinarily, the atresic area is a short segment of an inch or less in length which looks like a fibrous cord. Imperforation concerns invariably the terminal end of the alimentary canal and involves only the anal canal and distal half of the rectum. Acquired types of stricture of the bowel which may give rise to obstruction are traumatic, inflammatory or neoplastic (cancerous) in origin. The first two are rare; strictures of the bowel, caused by malignant growths, are rather common, especially in persons past 45 years of age and not infrequently give rise to obstruction, particularly in the colon or large bowel.

2. Obstruction by obturation occasioned by the presence of a foreign body within the bowel lumen occurs occasionally. Faecal impaction is the most frequent variety of this type of obstruction. A large gallstone, ulcerating from the gall-bladder in the small intestine now and then gives rise to obstruction by obturation.

3. Occlusions of the bowel may occur through the agency of compression by tumours outside the bowel, especially in areas where the bowel is fixed (retroperitoneal duodenum or terminal ileum).

4. Adhesive bands are a frequent cause of intestinal obstruction. Adhesions are usually inflammatory in origin and follow in the wake of suppuration of the appendix, gall-bladder and female generative organs (Fallopian tubes). Adhesions giving rise to obstruction are often the accompaniment of an antecedent abdominal operation.

Ordinary talcum, with which surgeons formerly powdered their hands to facilitate pulling on of rubber gloves, is known to be a keen stimulus to adhesion formation, and undoubtedly a patient who has undergone previous elective abdominal surgery, followed by an uncomplicated convalescence, has occasionally developed intestinal obstruction from adhesions at a remote date from the adhesion-stimulating property of talcum powder.

5. Hernia or protrusion of a loop of bowel through a normal (inguinal, femoral, obturator, mesenteric or diaphragmatic) or abnormal orifice (defect in abdominal wound following operation) is a common cause of obstruction.

6. Volvulus or torsion of the bowel may occur in the small intestine, caecum or sigmoid — areas in which a segment of bowel is pedicled on a narrow strip of mesentery.

7. Intussusception or telescoping of one segment of the bowel into another occurs with predilection in infants from four months of age through the first year of life. The actual cause is unknown. After two years of age, intussusception is relatively uncommon and a tumour such as a polyp, lipoma or cancer of the bowel is frequently found at the apex of the telescoped segment.

8. A number of miscellaneous congenital factors resulting from errors in development of the intestine may give rise to obstruction, among which the following may be enumerated: (a) anomalies of intestinal rotation; (b) extrinsic duodenal compression by congenital bands; (c) a persistent vitellomesenteric duct (Meckel's

diverticulum) and umbilical eventration. In all of these, save the last, the obstruction may occur for the first time in childhood or even later.

9. Physiological imbalance in the nervous tone of the intestine may give rise to obstruction, which in this instance is often referred to as ileus. It may be paralytic (adynamic) in nature or spastic (dynamic). Symptomatically spastic ileus mimics mechanical obstruction. Peritonitis is the most common cause of adynamic ileus. Deficiencies in the electrolyte pattern of the blood occasioned by loss of digestive fluids, either by vomiting or from severe diarrhoea may give rise to paralytic ileus. Notably, loss of potassium, chloride or the sodium ion may be followed by a paretic state of the intestine, which can only be restored by replacing the lost electrolytes.

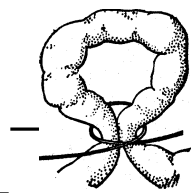

FIG. 1.—A LOOP OF SMALL INTESTINE STRANGULATED BY AN ADHESIVE BAND

10. Finally, thrombosis or embolism (plugging of the blood vessels of the mesenteric vessels, either arteries or veins) may give rise to intestinal obstruction.

Consequences.—Whereas a number of different causes may be responsible for the development of bowel obstruction, there are essentially only two pathological types: (1) simple obstruction to the continuity of the bowel, best exemplified by a stricture in the gut wall and (2) strangulating obstruction, in which in addition to mechanical occlusion there is actual or potential deprivation of blood supply to the bowel (hernia, volvulus and intussusception).

In obstructions high in the intestinal canal, the loss of intestinal fluids and electrolytes (salts) through the agency of vomiting is frequent and constitutes an important element in the disease. Obstructions in the lower reaches of the small intestine (ileum) and the large intestine (colon) are attended regularly by intestinal distension, because retrograde peristalsis and vomiting fail to evacuate the distended intestine.

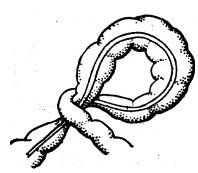

FIG. 2.—VOLVULUS OR TORSION OF THE SIGMOID LOOP OF COLON

In obstruction of the colon, moreover, the ileocaecal valve often delimits the distension to that segment of large intestine lying proximal to the obstruction, thus causing great hazard of rupture, particularly in the cecum which segment lies just beyond the ileocaecal valve and has the greatest diameter. It has been demonstrated by experiments on animals, in which the opportunity for the swallowing of air is excluded, that the chief source of gaseous distension in obstruction of the intestine is swallowed air.

Whereas students of intestinal obstruction prior to 1930 were likely to attribute the evil consequences of obstruction largely to abnormal permeability with absorption of noxious agents from the obstructed bowel, it later became more generally recognized that the ill effects of obstruction relate themselves essentially to the two items mentioned above: (1) loss of intestinal fluids and electrolytes by vomiting; and (2) the threatened loss of viability of the bowel wall occasioned by long-continued distension. With reference to the latter item, it is apparent that sustained intralumenal pressures maintained for some time above the mesenteric venous pressure (12 to 16 c.m. of water) will interfere with the normal nutrition of the bowel wall. Anoxia or poor oxygenation of the bowel wall ensues in consequence of the arrest of venous outflow as a result of which the bowel wall becomes devitalized. A bowel wall with impaired viability becomes abnormally permeable to noxious agents within its lumen, which now may migrate across the protective barrier of the damaged intestinal mucosa to the peritoneal cavity from which site absorption occurs readily.

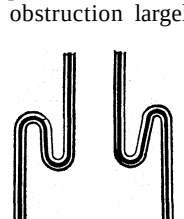

FIG. 3.—INVAGINATION OR TELESCOPING OF A SEGMENT OF BOWEL INTO THE PART BEYOND

Recognition.—All mechanical varieties of obstruction (by far the majority of all obstructions) are heralded by the presence of intestinal colic or "gas pains" occurring at the acme of an intestinal contraction or peristaltic wave. These contractions are accompanied by gurgling noises in the presence of a gut distended by both fluid and gas. The intestinal colic of gaseous distension (largely swallowed air) is accompanied by high-pitched sounds which have usually a metallic character. The noises (borborygmi) attending such contractions of the bowel are regularly attended by pain which is concurrent with the borborygmus, unlike the noise of the unobstructed gut which is painless. These noises may be audible to the unaided ear but are elicited readily on auscultation of the abdomen with a stethoscope. Recurrent crampy abdominal pain with concurrent intestinal noises is synonymous with intestinal colic. Food indiscretions and the taking of a cathartic may simulate the intestinal colic of intestinal obstruction; however, the history, observation and the absence of distension serve to distinguish them from mechanical obstruction of the bowel. Strangulating unlike simple obstructions regularly is attended by abdominal tenderness. Percussion reveals the presence of tympanitic areas caused by the distended intestine, and a scout X-ray film of the abdomen indicates the extent and the location of the distended intestinal coils. An experienced observer summarizing these various findings may therefore determine: (1) whether obstruction is present; (2) whether strangulating or mere interference with the continuity of the intestine is present; and (3) where the obstruction is. He cannot in many instances, without recourse to exploratory operation, determine the exact variety of obstruction present.

Treatment of Intestinal Obstruction.—The object of treatment is to relieve distension and to restore the continuity of the intestinal canal. In obstructions in which vomiting has been an important factor, restoration of fluid and electrolyte loss by the intravenous administration of physiological saline solution (0.6% to 0.85% sodium chloride) is important. Sir Frederick Treves of London who wrote an important monograph upon the subject of intestinal obstructions in 1899 stated: "Those who are enamoured of statistics could, I have little doubt, show that it is less dangerous to leap from the Clifton suspension bridge than to suffer from acute intestinal obstruction and decline operation." Operation is still the mainstay of therapy. Every strangulating obstruction must be operated upon, freeing the strangulated loop from the agent which threatens its viability. All simple obstructions, in which the block to intestinal continuity is persistent such as a stricture, must of necessity be subjected to operation. However, in a fairly large number of instances suction applied to an indwelling duodenal or long intestinal tube may succeed in decompressing the distended segment. Obstructions which owe their origin to inflammatory causes, nervous imbalance (paralytic or spastic ileus) or intestinal adhesions not uncommonly may relent with the decompression of the bowel achieved by an indwelling intestinal tube. The hazard of attempting to relieve obstruction by such a tube lies in the circumstance that, the obstruction may be strangulating in type or that the obstructive mechanism may continue unrelieved. When satisfactory decompression of the distended bowel has not occurred within 12 hours following the employment of suction attached to a long intestinal tube, recourse should be had to operation.

The necessity of transfusing blood into the veins of patients having strangulating obstructions is apparent; for under the motive force of systolic blood pressure, blood is pumped into the vessels of the bowel wall and becomes imprisoned in the strangulated intestinal loop, thereby causing loss of blood from the circulation with consequent shock.

The inhalation of high concentrations of oxygen has been advised on the assumption that, despite the low coefficient of diffusion of nitrogen, inasmuch as the gas in the distended intestine is largely swallowed air (80% nitrogen), the breathing of pure oxygen by the patient will succeed nevertheless in removing by exhalation small but definite increments of gas from the distended

bowel. Whereas this therapeutic procedure is sound in theory, it operates so slowly that it has little merit in practice.

Prognosis.—Recognition of the presence of intestinal obstruction earlier in its course, a better understanding of the ill consequences of obstruction, improvement in surgical technique, the employment of suction applied to indwelling long intestinal tubes and better schemes of intubating the duodenum quickly—all of these agencies have combined to reduce materially the hazards of intestinal obstruction. The mortality of the presuction era (1931) was in the neighbourhood of 40% to 60% in the best surgical clinics of the world. By the mid-1950s, however, mortality reduced to the range of 10% to 12% represented the accomplishment in surgical clinics with a special interest in the problem of intestinal obstruction. Despite this obvious progress, surgeons had yet to learn how to wrestle with conditions which may obstruct the intestine and give rise to distension with the same effectiveness as they can treat these same agencies in the absence of intestinal distension.

INTROIT: *see* **PLAINSONG.**

INTROSPECTION, in psychology, is the process of observing the operations of one's own mind with a view to discovering the laws that govern the mind (Lat. *introspicere,* to look within). In a dualistic philosophy which divides the stuff of the natural world (matter, including the human body) from the contents of consciousness, introspection is the chief method of psychology. Thus it was the method of primary importance to the English school of philosophy—to Thomas Hobbes, John Locke. George Berkeley, David Hume, James Mill, John Stuart Mill. Alexander Bain and most of their contemporaries—as it was to the pioneers of the new experimental psychology, especially to Wilhelm Wundt, Oswald Kulpe and E. B. Titchener.

To all these men the contents of consciousness appeared to be immediate experience: to have an experience was for them also to know that you have it, and in this sense introspection appeared to be self-validating; it could not lie.

Wundt and Titchener, as well as Kulpe in his early years (1893), believed that introspection finds in consciousness only sensory materials—sensations proper, images which are centrally excited sensations, and feelings which closely resemble sensations. This view is known as classical introspection. Many other psychologists, however, found other kinds of content in consciousness. Franz Brentano and Kulpe in his later years were the most influential act psychologists who reported consciousness as constituted of both sensory contents and more impalpable acts.

Perpetual controversy about the results of introspection made it quite clear by 1920 that introspection is not infallible and. later, that its fallibility is due to the fact that it is not immediate but is an observational inferential process that takes time and is subject to errors of observation. This discovery came in with the rise of objective psychology and behaviouristics in America.

By 1940 both the concept of dualism and the word "introspection" had largely disappeared from scientific psychology, especially in the U.S. where behaviouristics ruled. It is true that Gestalt psychology retained a dualistic philosophy, but its leaders rejected introspection because the word was so closely identified with the classical form.

Actually the repudiation of dualism by modern experimental psychology led only to the surrender of the word "introspection," not to the abandonment of the method. The general method (not classical introspection) is used without the name (1) in phenomenological description as the Gestalt psychologists use it and as it is employed in the description of experience in perception; (2) in psychophysics where are determined the relations of conscious events, usually of a sensory nature, to magnitudes of the stimulus, especially in the determination of the sensory thresholds and sensory scales; and (3) in the protocols of patients as they describe their consciousnesses to psychiatrists and psychoanalysts, sometimes in free association on the psychoanalytic couch, sometimes in projective tests, like the Rorschach ink blots, where the subject. for diagnostic purposes, reports the train of thought aroused in him by an equivocal stimulus or situation.

See E G. Boring, "A History of Introspection," *Psychological Bulletin,* vol. 50 (1953). (E. G. BOR)

INTUITION is the power of obtaining knowledge directly, without recourse to inference or to reasoning. Two senses of the word must be distinguished, one of them ordinary and one technical, the technical differing from the ordinary in the respect that it refers to supposedly primary or self-substantiating and not alternative sources of knowledge. These senses are: (1) the acquisition of knowledge of matters of fact without reliance on the ordinary procedures of inquiry; (2) the acquisition of knowledge of a kind which cannot be obtained by inference (e g., the knowledge of the axioms and rules of inference employed in logic and mathematics and of the principles of morals). There are in addition two further technical senses (3 and 4), as mentioned below.

1. In its colloquial sense, as in the phrase, "feminine intuition," the word is used to refer to the capacity for making rapid and accurate assertions about matters of fact in circumstances where reliance on the standard procedure of inquiry is ruled out. It is often, perhaps usually, exercised predictively, on such matters as the outcome of horse races, impending disasters or the behaviour of someone in a yet unrealized state of affairs. For final justification of a claim to knowledge about the future we have to wait for the actual outcome. But before the event one may be quite confident of the truth of one's prediction. This confidence may arise from the strength of the inference leading to the prediction. But it may be that one "just knows," that one is not aware of any inference supporting one's prediction; and in such cases one is making a claim to intuition of the event predicted. This claim is not substantiated by the correctness of the prediction; it may have been a lucky guess. It is only if a man's claims to knowledge in advance about a certain subject matter are regularly correct that a power of intuition can be ascribed to him. For there is then inductive ground for taking his conviction as a reliable index of the truth of what he is convinced about. The existence and unequal distribution of such powers are not difficult to explain. One may be sensitive to significant features of what is currently observable without being aware of the fact (*e.g.*, facial expression as an index of character). This sensitivity will depend in part on natural endowment (*e.g.,* acute hearing) and in part on thorough familiarity with the subject matter in question. In this sense, then, claims to intuition arise either from implicit inference or from lucky guessing. We can only tell which, and thus on which to rely, by waiting to see if the claims are borne out significantly often.

So intuition here is not an independent source of knowledge. It is either inferential knowledge in a disguised form or not knowledge at all but guesswork.

2. In its most familiar philosophical interpretation intuition is the power of obtaining knowledge which cannot be acquired by either inference or observation, reason or experience. As such it is thought of as an original, independent source of knowledge, since it is designed to account for just those kinds of knowledge which other sources of knowledge do not provide. Our knowledge of necessary truths and of moral principles has been explained in this way.

In the first place, some necessary truths, statements of logic and mathematics, can be inferred, logically derived, from others. But not all can: there must be some uninferred statements (*i.e.,* axioms). Furthermore, the interconnected character of the system, the derivability of statements from axioms, presupposes rules of inference. Now the truth of axioms and the validity of basic rules of inference cannot be established by inference, since inference presupposes them, or by observation, which can never establish necessary truths. So they are held to be objects of intuition. Axioms are ordinarily truisms, consequently self-evidence is taken as a mark of intuition. To "see" that one statement follows from

another, that a particular inference is valid, enables one, it is said, to make an "intuitive induction" of the validity of all inferences of that kind. Other nonformal necessary truths (e g., "nothing can be red and green all over') are also explained as intuitive inductions: we are held to "see" a universal and necessary connection through a particular instance of it.

Secondly, moral philosophers, from Bishop Butler and the Moral Sense school to G. E. Moore and the Oxford moralists, have held that moral assertions record knowledge of a special kind. The rightness of actions (or, in Moore's case, the goodness of states of affairs) is discovered by a special moral faculty, seen as analogous to the power of observation (Moral Sense school, Moore) or the power of intuiting logical principles (Oxford moralists). This theory, like that which holds logical principles to be the outcome of intuition, bases its case on the self-evident and unarguable character of the assertions with which it is concerned.

Against both theories much the same argument can be brought forward. The "axioms" of logic and morality do not require for their interpretation a special source of knowledge. since neither record discoveries: rather they record resolutions or conventions, attitudes that we adopt toward discourse and conduct, not facts about the nature of the world or man. A further argument against the theory of moral intuition depends on the markedly discordant character of the deliverances of the supposed source of knowledge.

3 and 4. Two further technical senses of the word may be briefly mentioned. One, deriving from Kant, is that in which it is understood as referring to the source of all knowledge of matters of fact not based on, or capable of being supported by, observation; that is to say, of matters of fact which observation directly or immediately reveals. The other is the sense attached to the word by Spinoza and by Henri Bergson, in which it refers to supposedly concrete knowledge of the world as an interconnected whole as contrasted with the piecemeal. "abstract" knowledge obtained by science and by common observation.

(A. M Q.)

INULIN, a polysaccharide which bears to levulose (D-fructose) a relationship similar to that of starch to glucose. Inulin occurs in many plants of the large family Compositae (*q.v.*) to which the elecampane (*Inula* helenzum) belongs and it is especially abundant in tuberous roots such as those of dahlia (*Dahlia variabilis*) and Jerusalem artichoke (*Helianthus tuberosus*) Inulinlike substances from various sources have been given distinctive names such as graminin (from Festuca, *Trisetum* and other grasses), irisin (from Iris *pseudacorus*), etc

Fine inulin forms a white tasteless powder, sparingly soluble in cold water, very soluble in hot water and insoluble in alcohol. Dilute mineral acids or the enzyme inulase convert inulin into levulose (D-fructose). In many plants the presence of inulin is detected by the spherocrystals which form on steeping tissue slices in strong alcohol. See CARBOHYDRATES. (F. C. SD.)

INVAR, an alloy of 36% nickel, small amounts of manganese, silicon. and carbon (less than 1% total) and balance iron characterized by an extremely small thermal expansion. The average coefficient is 0.70×10^{-6} per 1° F. for invar compared with $6 8 \times 10^{-6}$ per 1° F. for steel (0"–zoo" F.). In applying these alloys it is important to recognize that their expansivity is dependent upon the temperature involved. The range for lowest coefficient is —6o° F. to 175° F. Invar is used where it is advantageous to avoid temperature compensation; *i.e.,* for absolute standards of length, thermostatic strip, rods and tapes for surveying, and horological instruments. The name invar was selected to express the invariability of its dimensions with heat. (R. A. LR.)

INVARIABLE PLANE, in celestial mechanics (*q.v.*), that plane on which the sum of the moments of momentum of all the bodies which make up a system is a maximum. It derives its celebrity from the demonstration by Laplace that to whatever mutual actions all the bodies of a system may be subjected, the position of this plane remains invariable.

INVENTIONS AND DISCOVERIES. It is impossible to define "invention" with the breadth demanded by literary, scientific and legal usage. A poem, a musical composition, a theory which explains how light is transmitted from a source to the eye is as much of an invention as an electronic computer that solves in minutes problems that would ordinarily engage a mathematician for weeks. The atom is an invention. So is the universe of any cosmologist, ancient or modem. In this article technological inventions are the principal subject of discussion.

No sharp distinction can be drawn between invention and discovery. Gunpowder, a mixture of potassium nitrate, carbon and sulphur, certainly had to be discovered; yet it was also an invention. There are hundreds of such examples not only in chemistry but in engineering.

Discoveries often lead to invention. Thus the discovery that liquids expand and contract with variations in temperature led to the invention of the thermometer. Michael Faraday's discovery of electromagnetic induction was the basis of the telegraph, the telephone, the electric generator and motor, in fact of electric engineering. Conversely inventions often lead to discovery. Out of the steam engine came important theories that led to the development of thermodynamics and thus to more efficient steam engines. Out of Edison's electric lamp came the discovery that a feeble current could pass from the hot filament through empty space to a metal plate sealed in the bulb—the basis of the vacuum tube.

If the term "invention" is to be broadly defined as an act of the creative imagination, it is easy to understand why the French patent act of 1791, based on the Declaration of the Rights of Man (1789), placed economic or social inventions on the same footing as mechanical and scientific inventions. Patents were therefore granted for tontine life annuities, tariff systems, credit plans, types of mortgages, banking systems, exchange controls and methods for guaranteeing the value of assignats. When it became apparent that there would be an avalanche of such schemes the national assembly on Sept. 20, 1792 decreed that the executive power should not only cease to grant patents for financial inventions but also counteract the effect of those already granted.

Given a technical heritage and the right social environment, invention is inevitable. The phenomenon of simultaneous invention and discovery proves it Alexander Graham Bell and Elisha Gray filed applications for telephones on the same day. Charles Martin Hall (1863–1914) and Paul L. T. Héroult (1863–1914) discovered or invented the process of making aluminum independently and almost simultaneously. Tessie du Rlotay (French) and Thaddeus Lowe (American) independently devised the process for making street gas by passing steam over red-hot coal; William Kelly and Sir Henry Bessemer, the one in the Cnited States. the other in England, made steel by blowing air through molten iron to burn out the carbon. Every year there are "interferences" in the United States patent office—judicial processes to settle rights of inventors who apply for patents on identical machines or processes. The history of invention and of the patent law is full of such examples. Since so many important inventions are conceived simultaneously and independently it is evident that inventive genius is not unique. In any community of 100 000 there are bound to be a certain number of ingenious mechanics, exceptional painters and fine musicians.

From this it almost follows that there are very few "first" inventions, in the sense that they owe nothing to earlier technical knowledge. Most of these must be credited to primitive man Among them are the wheel. the bow and arrow, the fire drill. the boat. pottery, agriculture. domestication of animals. basket-making. The melting of metals (gold, copper), the use of the lever, saw, nedge, pulley and rope are very old. Modern inventions as a whole are combinations of well-known elements that produce new results and serve new and useful purposes. Without a heritage technology could not advance. It was largely lack of a technical heritage that made it impossible for Leonardo da Vinci to invent a practical flying machine. For lack of a technical

heritage Edison as a caveman would not have invented the phonograph. electric lamp and the hundreds of other devices with which his name is coupled.

How difficult it is to credit any inventor with having been the first in his field is shown by the history of the steamboat. About 30 steamers, more or less successful, had been built before Robert Fulton went up the Hudson river in his "Clermont" (1807). There was John Fitch who had a steamboat that ran on the Delaware river in 1787; Oliver Evans who built for Philadelphia in 1803 a combined scow and dredge nhich ran as a steam automobile on land and as a steamboat on the Schuylkill river; James Rumsey who began his experiments in the presence of George Washington; John Stevens who built a screw-propelled steamer in 1802; and William Spmington. an Englishman whose "Charlotte Dundas" was a notable success (1802). The histories of the telegraph, the reaper, the motion picture, the filament electric lamp, the sewing machine and the elevator also shatter the pretensions of "first" inventors as a class.

Much, though not all industrial progress, followed discoveries made in the laboratory. Thus the discovery of the benzene ring by Friedrich August Kekulé (1829–96) emphasized the importance of molecular structure in organic chemistry and made it possible literally to design organic molecules with valuable properties. Similarly the mathematical development of the theory of the electromagnetic field by James Clerk Maxwell (1831–79) left it to be inferred that there is a broad spectrum of electromagnetic waves at one end of which lie light Raves and at the other what were first called Hertzian waves and later radio waves. Inventors of mechanical and electrical machinery apply such broad generalizations and theories, but the original discoveries or theories are not patentable.

The Statute of Monopolies of James I of England, enacted in 1624. was designed to abolish privileges and monopolies which had become a public scandal. An exception was made of letters patent for the invention of new products. This dislike of monopolies as a whole and the exception made in the case of patents granted to inventions are part and parcel of the legal policy of the United States. Great Britain and some other countries.

Patent legislation in the modern sense made its appearance toward the end of the 18th century. The constitution of the United States provided for the granting of patents somewhat after the British system but with the important stipulation that an application for a patent could be filed only by the inventor. In France, as noted above, patent legislation goes back to 1791. Before that the granting of patents was a royal prerogative. Some of the German states passed patent laws as early as 1815, but an over-all German patent law was not enacted until 1842. Most European countries followed the example set by the United States. Britain and Germany, some applying the British system, some the German.

Though Anglo-Saxon countries encouraged invention by the granting of patents it became apparent in the first half of the 20th century that there mere as many objections to patent monopolies as to those that led to the promulgation of King James's Statute of Monopolies In the United States large corporations acquire literally several thousand patents to dominate an entire industry. This domination of a whole "art," as it is called in legal parlance, is opposed to Anglo-Saxon thinking on monopolies of any kind. Even in countries such as the United States, which are not socialistically inclined, the government is undermining the patent monopoly sometimes in direct violation of the patent law. The interests of the inventor are subordinated to those of society, with the result that in both Britain and the United States great corporations have been compelled to grant licences to those who want them. sometimes without the payment of royalties Thus the United Shoe Machinery company was forced to grant licences under its hundreds of patents to all its competitors Similarly the Aluminum Company of America had to relinquish monopolistic control of its many patents. Imperial Chemical Industries and du Pont de Nemours had to dissolve an agreement that was regarded as a cartel and to throw about 2,000 patents into the public

By the second half of the 20th century, about 2.000.000 inventions had been patented in the United States. Prior to 1900 about 600 000 patents covering the first 110 years of the United States patent system had been granted. Most of these patents described inventions which lacked novelty or which were commercially impractical. Adjudication is not the sole test of novelty of subject matter nor of industrial importance, but unless a patent has been adjudicated its commercial value is problematical for the simple reason that the government of the United States does not guarantee the validity of the patents that it grants. In defense of the U.S. patent system it is often argued that only two or three patents out of every thousand are invalidated by the courts. The argument loses force because so many patents cover unimportant and valueless inventions. The higher courts of the United States had invalidated considerably more than half the patents that had come up for consideration by the 1950s.

Patent laws in general and those of the United States in particular were formulated on the theory that inventors should be encouraged, that inventive genius was rare, that society must await the coming of a Morse, Bell, Marconi or Edison before it could receive a new technological impetus, and that privileges in the form of limited monopolies should be granted to such men to make, sell and use their inventions as they saw fit in return for complete disclosure. The principle seems sound, yet the hundreds of thousands of patents granted in advanced countries leave no doubt that inventive ability is commoner than is generally supposed. Moreover, physicians, surgeons, engineers and university professors of science invent many ingenious instruments and procedures that are never patented.

Leaders of industry attribute the remarkable rise of industry in the United States to the patent laws. There is no doubt that the patent laws have had a beneficent economic effect in exploiting rich natural resources, but after the earlier years of the 20th century sociologists and economists as a class discounted the encouragement-of-invention theory. Creative art stands on the same footing as creative mechanical invention. It can hardly be maintained that painters and poets need the spur of copyright laws to create, and copyrights, like patents, are intended to protect intellectual property rights. Frank William Taussig (1859–1940) in his lectures on *Inventors and Money-Makers* showed that inventors are much like artists and that the urge to create is so strong within them that they fly off at half a dozen tangents and too often fail to finish what they have begun.

No doubt professional inventors are encouraged to invent by rewards in the form of profits. Yet a study of the lives of such inventors as James Watt, Samuel F. B. Morse and Alexander Graham Bell fails to reveal any convincing evidence that they derived the slightest encouragement from the patent system, though all patented their inventions. The profit motive is as strong as it ever was; yet ior some undetermined reason the rate at which applications for patents had been filed in the United States up to the 1950s did not keep pace with the rate of population growth. From 1840 to 1921 the number of applications filed with the U.S. patent office rose steadily. Patents granted by the United States patent office in 1950 numbered 43,072, but in 1955 only 30,480. This decline was international. The trend was the same in Britain, France, Germany, Canada and Japan; it indicated that something was happening to invention itself. That something could have been the increasing complexity of technology. An electronic computer which can solve a dozen simultaneous equations in a minute or two is hardly the type of invention that can be evolved by an ordinary mechanic who can design a reaping machine. The release of atomic energy by fission and the application of that release to the making of an atomic bomb could be expected only of highly trained theoretical physicists.

Whether or not a country is distinguished ior its contribution to scientific discovery and invention depends on the social environment. Oriental countries played no important part in the development of modern technology, and yet the Arabs at one time were the most cultured and scientific people. In the Renaissance Italy led the world in science. In the early 18th century industrial supremacy passed to the northern countries, with Great Britain, Germany and the United States in the lead. It can hardly be maintained that one nation is naturally more inventive than another. The British, Germans, Swiss and Scandinavians have made quite as good a record in invention as citizens of the United States so far as quality is concerned, and in some branches of science they excel. The social environment is all important because it determines what will be discovered and invented. This does not mean that we can dispense with men of exceptional ability or so-called geniuses, but it does mean that only when the social environment is

favourable has ability the opportunity to express itself, whether or not there is a patent system. The progress of medicine was assuredly as remarkable as all the progress in technology. Though pharmaceutical companies patent drugs, it can be hardly maintained that patent laws encouraged medical discovery or improved health and raised the mean expectancy of life at birth. If anything, the spirit of medical research is opposed to patents.

That social pressure accounts for many important inventions and discoveries is proved by the events that brought about the industrial revolution. After the introduction of the earliest steam engines and the substitution of coke ior charcoal in the smelting of iron ore, coal was regarded as potential energy as well as a fuel. This brought about a profound change in outlook Coal ceased to be merely a fuel; it symbolized industrial might. With the invention of the gin by Eli Whitney (1765–1825), cotton became the most important of all textile fibres. Because of its leadership in metallurgy and in spinning and weaving, England was overwhelmed by the demand for yarns and cloths. The consequence was a further development of coke production and metallurgy to meet the demand for more and better textile machinery (chiefly power looms) and more steam engines to work mines and drive factory wheels. In the United States the introduction of Whitney's gin made it necessary to revivify the moribund institution of slavery because of the increasing demand ior cotton pickers. Slavery became one of the issues of the Civil War. The need of cloth woven in England irom cotton exported by the southern states inspired the high-tariff policy of the Republican party as a protection for the spinners and weavers of New England.

In the later stages oi the industrial revolution steam engines become more and more efficient, and the energy in coal was thereiore more rationally applied. An invention that gave industry an impetus second only to that of the steam engine of Watt was Eli Whitney's unpatentable system of interchangeable parts. As a government contractor Whitney had obligated himself to produce 10,000 muskets for the army. The parts of the muskets were interchangeable, so that out of a beterogenous mass it was possible to assemble hundreds of muskets. The principle was old, but it remained ior Whitney to apply it on a new scale. The innovation was of incalculable social and economic importance. Whitney was the forefather of standardization and hence of mass production by machine of countless articles ranging from automobiles to tins of vegetables, from bathtubs to electric lamps.

With the discovery in 1856 by William Henry Perkin (1838–1907) of mauve, the first aniline dye, the rise oi the coal tar chemical industry began. It was the Germans who realized that Perkin's achievement meant as much for synthetic chemistry as did Watt's condensing steam engine for mining and manufacturing. Germany rapidly assumed leadership in synthetic chemistry and maintained it up to the outbreak of World War I. Out of German laboratories came thousands of chemicals derived from coal tar—dyes, photographic developers, explosives, drugs.

The history of the industrial revolution is an illustration of the effect of social and economic pressure on the inventor. Moreover, the industrial revolution also changed the character of invention. By 1900 the professional inventor appeared in the person of the scientist hired by an industrial corporation to improve old processes and machines and to invent new ones. For this innovation the Germans deserve a large measure oi credit; the laboratories of their chemical industries demonstrated what could be accomplished by trained scientists and engineers, many of them former university proiessors, in transforming invention and discovery from a haphazard activity to an enterprise as systematic as manuiacturing and selling. Germany's example was ultimately followed by the industrial nations of the west.

Revolutionary inventions have been usually conceived not within but outside an industry. Here and there are found a iew spinners and weavers such as James Hargreaves (d. 1778) and Samuel Crompton (1753–1827) who patented daringly new types of labour-saving spinning machines, but, as a rule the inventors whose devices made it possible to spin and weave on a wholesale scale and to transfer yarn and clothmaking from the home to the factory were "outsiders," who neither made nor traded in textiles. Richard Xrkwright (1732–92), an illiterate barber and hairdresser, invented the spinning frame; Edmund Cartwright (1743–1823) was a clergyman and poet when chance turned his mind to the invention of the power loom; James Watt (1736–1819) never concerned himself with steam engines until a model of a Newcomen pump was given him to repair; Eli Whitney was not a cotton grower when he invented the gin but a young teacher who thought of becoming a lawyer; both Robert Fulton (1765–1815) and Samuel F. B. Morse (1791–1872) were artists; neither Ottmar Mergenthaler (1854–yg) nor Tolbert Lanston (1844–1913) were proiessional compositors when they patented the Linotype and Monotype.

Usually about 20 years elapse before an epoch-making invention is successfully introduced commercially, partly because time and money must be spent in its perfection, partly because of the inertia of businessmen. Until the outbreak of World War I it was the practice of inventors to offer their patents to businessmen at a price. It is always difficult to challenge vested interests in this way. Hence the many tales, most of them untrue, oi inventors who have all but starved to death before they succeed in selling their inventions or finding financial backers and disciplinarians, as James Watt did in Matthew Boulton or Alexander Graham Bell in Gardner Hubbard. The average businessman regarded an invention much as he did some new raw material that might be useiul. Too often he rejected the offered invention, partly because he did not see its potentialities, partly because he lacked the energy and the money to found a new industry. So patents in related fields accumulated until a venturesome promoter saw that they represented enormous wealth. Such is the history of inventing and patenting in the older industries.

No matter how it is conducted invention implies experimentation, hence research. The "heroic" theory of invention, the notion that an idea flashes from a brain and gives the world a sudden, fresh impulse must be dismissed. Watt's engine did not leap from his brain to the drafting board. New machine tools had to be devised by others to bore cylinders with the requisite accuracy; studies had to be made oi heat losses; model after model had to be built in order to proportion moving parts and to determine the precise point at which steam might be cut off and used expansively. So it was with the Linotype, the typewriter, the phonograph, the incandescent lamp and many other devices and processes. Crude as was the experimentation that culminated in commercial periection, it nevertheless deserved the name of research.

The laissez-iaire policy of letting invention take care of itself gave way to organized industrial research. An important invention is an assemblage of known elements that produces a new result. Organized research hastens the process of accumulation, aggregation and combination; the salaried engineers, chemists or physicists oi industry work contemporaneously in single establishments rather than separately decades or generations apart; correlation occurs simply, speedily and directly; time is telescoped. The "outside" inventor finds it more and more difficult to upset established manuiacturing methods because he is likely to have been anticipated by industrial research scientists who know the technical literature oi the field that they are exploring and who have at their disposal ample facilities for experimentation. By the 1950s about half the applications for patents in the United States were being filed by individual inventors; the other half were filed by research scientists and engineers in corporation laboratories or connected with such corporations.

From 1930 to 1940 private and public expenditures of the united' States for research increased from $166,000,000 to $345,000,000. Between 1941 and 1945 the total expenditure (excluding that for the development of atomic energy) was $600,000,000. The federal government's contribution steadily increased until in the war period of 1941–45 it reached 83% of the total. Peak annual expenditures during World War II for all research and development amounted in the United States to more than $800,000,000 in each of the years 1944 and 1945. By the mid-1950s total expenditures for research in the United States, predominantly industrial, rose to about $4,000,000,000. The acceleration in research was accompanied by an acceleration in the introduction oi new inventions and discoveries. It took more than a century for the steam engine to establish itseli, fewer than 50 years for electric energy, fewer than 30 years for the internal-combustion engine and fewer than 1: years for the vacuum tube.

INVENTORY: see STOCKTAKING.

INVENTORY CONTROL. An inventory is a stock of goods purchased or manufactured for use or for resale. Inventory control is the term applied to procedures designed to limit the investment in these goods to a minimum without interrupting their flow to production or to the customer. These control procedures are also designed to protect the investment from the moment an order for purchase is issued until the goods are used or sold to the customer.

The value of the investment in inventory is determined by the quantity and cost of the goods purchased and by the time elapsing between acquisition and disposal. Quantity control may be obtained by establishing maximum and minimum limits. The minimum number of units of each item to be carried in inventory should be determined by considering both the quantity used or sold in a given period and the time required to place and receive an order.

The maximum quantity should be determined by considering the most economical order size and the available storage space. The nature of the item will also affect these limits. Perishable goods and goods subject to style changes, for example, must be given special analysis.

The cost of the inventory items is determined to a large degree by the external factors of supply and demand. Yet inventory control procedures can aid immeasurably in limiting the investment in goods to a minimum. Centralized purchasing procedures may result in savings from quantity buying and reduce the cost of placing orders. Verification of the price to be paid for goods purchased, including freight, should be made by comparison of receiving reports, purchase orders and invoices. Invoices subject to cash discounts should be paid within the discount period.

The time required to dispose of an article, or turnover time, is quite frequently beyond the control of the business, but measures designed to speed up the turnover cycle cannot be ignored. A retailer may resort to markdowns, increased advertising and loss-leader sales (selling items at a loss to attract trade) to obtain a more rapid turnover. A manufacturer should institute procedures to follow the product through its stages of manufacture to ensure that costly work-in-process inventories do not accumulate. Overtime charges or additional machinery costs may be a small price to pay to avoid bottlenecks which build up work-in-process inventories.

One of the most effective inventory control procedures is the perpetual inventory system. An account is kept for each inventory item. Purchases are added to the existing balance, and items sold or issued upon proper authorization are deducted from the balance. The exact quantity on hand at any time may be determined by reference to the account. Frequent physical counts should be made to confirm the accuracy of the inventory card. (J. H. McM.)

INVERARAY, royal and small burgh and county town of Argyllshire, Scotland. Pop. (1961) 501. It lies on a small bay where Glen Aray comes down to Loch Fyne near its northern end, 40 mi. N.W. of Glasgow but 58 mi. by road. There is a pier at which steamers call and formerly the herring fishery was prosperous (the town arms represent herrings in a net). On the quay is a finely sculptured Iona cross. The town originally stood on the north side of the bay, clustered round the old castle, but was removed to its present site in 1742. Its history is that of the Campbells, earls and dukes of Argyll, whose ancestral seat is Inveraray castle. The present castle was built in Scottish baronial style by Robert Adam. The earls and dukes of Argyll were great planters of trees—mainly larch, spruce, silver fir and New England pines—and their estates are still among the most finely wooded in the highlands, despite drastic clearances during recent years. A celebrated beech avenue leads from the quay to the modern Episcopalian church, which has a fine peal of bells. Inveraray became a burgh of barony in 1472. Charles I while a prisoner in Carisbrooke castle raised it to a royal burgh in 1648.

INVERBERVIE, royal and small burgh, Kincardineshire, Scotland, at the mouth of the Bervie Water about 13 mi. N.E. of Montrose by road. Pop. (1961) 921. It is contained in the civil parish of Bervie (pop., 1951, 1,908). The leading industry is flax spinning. At the mouth of the Bervie is a salmon fishery. In 1341 David II, under stress of weather, landed there with his queen, Joanna, and out of gratitude for hospitality granted a charter which James VI confirmed. John Coutts (1699–1751), whose son Thomas founded the banking house of Coutts and Co., was born in Inverbervie. At Arbuthnot, on the banks of the Bervie 2½ mi. northwest of Inverbervie, is the Romanesque church (1242) of St. Teman. It comprises an aisleless nave and chancel to which the Arbuthnot aisle was added in 1508. John Arbuthnot, friend of Pope and Swift, was born in the village. Beneath the floor of Kinneff church (2 mi. N.E. on the coast) the Scottish regalia were concealed during the siege of Dunnottar castle in 1652, being removed to Edinburgh castle at the Restoration. A monument in the church recalls Mrs. Grainger, the minister's wife, who daringly smuggled the regalia out of the castle.

INVERCARGILL, chief town of Southland county, South Island, New Zealand, 139 mi. by rail S.W. by W. from Dunedin. Pop. (including Maoris) (1961) 35,604. It lies on an estuary of the south coast named New River harbour, which receives several streams famous for trout fishing. It is the centre of the grazing and farming district of Southland. which is an important cheese producing area, and has a number of factories, including breweries, foundries, woollen mills and timber works. The plan of the town is rectangular, with wide streets, and there is a fine open reserve. The harbour is deep and well sheltered, but the greater part of the trade passes through Bluff harbour, a few miles distant, with which Invercargill is connected by rail and road. Bluff harbour, the southernmost town of New Zealand, is a port of call and departure for vessels for Melbourne and Hobart. Southland was a separate province between 1860 and 1870, but subsequently it rejoined the parent province of Otago.

INVERCLYDE, BARON: see BURNS, SIR GEORGE.

INVERELL, a town of Gough county, New South Wales, Austr., on the Macintyre river, 415 mi. N. of Sydney by road and 509 mi. by rail. Pop. (1954) 7,514. It lies at an elevation of 1,912 ft. on the western margin of the New England plateau. The district produces chiefly wheat and wool and there is cattle raising, sheep breeding and fattening. There are silver, tin and diamond mines near the town. Inverell became a municipality in 1872.

INVERNESS, royal and large burgh, seaport and county town. Inverness-shire, Scotland. Pop. (1961) 29,773. Known as the "capital of the highlands," it lies at the north end of the Great Glen (Glen More), on either side of the River Ness about 1 mi. south of its entry into Beauly firth. Though the town is relatively low lying the beauty of its environment draws many tourists to it in the summer. Loch Ness lies about 5 mi. southwest. Commanding the main (and almost the only) routes between the central highlands and northern Scotland, Invemess is an important distributing centre, with a well-known annual market for sheep and wool. Industries are small and petroleum is the largest import. There is a little shipbuilding and a coastal trade with Aberdeen, Leith and east coast ports down to London. The harbour, formed by the mouth of the Ness, covers about three acres. There are piers, a breakwater, good anchorage and a slipway. The Caledonian canal passes through the western outskirts of the town shortly before entering Beauly firth. The river at Inverness is crossed by four bridges and a railway viaduct. The modern airport is at Dalcross, 8 mi. southeast of the town.

The modern castle (1835) crowns a low cliff on the east bank of the river and occupies part of the site of the ancient fortress blown up by the Jacobites in 1746. It houses the county offices and law courts. In the tower of the high or parish church (1769–72) is one of the bells which Cromwell removed from Fortrose cathedral. The town clock and bells are in the town steeple (1791) which was once the jail. St. Andrew's Episcopal cathedral for the see of Moray, Ross and Caithness, west of the river, dates from 1866. Public buildings include a library and museum with a collection of Jacobite relics. Inverness academy was founded as a school in 1792. Opposite the town hall (1882) is the old town cross (1685), in the foot of which (and protected since the fire of 1411) is an ancient stone known as Clach-na-Cudainn (stone of the tubs) from its having been the resting place of women carrying water from the river. West of the river rises the wooded hill of Tomnahurich (hill of the fairies) on which is the cemetery. Attractive islands in the river are connected by footbridges with the mainland and with each other and are laid out as a public park.

Inverness was one of the chief strongholds of the Picts and *c.* 565 was visited by St. Columba with the intention of converting the Pictish king Brude, who is supposed to have resided in the vitrified fort of Craig Phadrick (Patrick's rock), 1½ mi. west of the town. The castle is thought to have been built by Malcolm III (Canmore), after he had razed the one in which Macbeth is said to have murdered Malcolm's father, Duncan It was a royal residence and fortress for centuries and saw a great deal of fighting. William the Lion (d. 1214) granted the town four charters by one of which it was created a royal burgh. Hardly a trace remains of the Dominican abbey founded by Alexander III in 1233. On his way to the battle of Harlaw in 1411 Donald of the Isles burned the town, and 16 years later James I held a parliament in the castle to which the northern chiefs were summoned. Three of these chiefs were to be executed for asserting an independent sovereignty. The house occupied in 1562 by Mary, queen

of Scots, when denied admission to the castle, stands in Bridge street. At the north end oi the town Cromwell built a large fort, known as the Sconce, but it was practically demolished at the Restoration.

INVERNESS-SHIRE, highland county, Scotland, bounded north by Ross and Cromarty, and the Beauly and Moray firths, northeast by the shires of Nairn and Moray, east by Banff and Aberdeen shires, southeast by Perthshire, south by Argyllshire, west by the Atlantic. It includes the isles of Skye, the St. Kilda group and all the Outer Hebrides except Lewis, as well as several of the Inner Hebrides and is the largest shire in Scotland. Its land area is 2,695,094 ac., or 4,211.1 sq.mi., of which more than one-third belongs to the islands. The county comprises the districts of Moidart, Arisaig and Morar in the southwest, Knoydart in the west, Lochaber in the south, Badenoch in the southeast and the Aird in the north. Excepting comparatively small and fertile tracts in the north on both sides of the river Ness, in several of the glens and on the shores of some of the sea lochs, the county is wild and mountainous and the scenery is very beautiful. There are more than 50 mountains exceeding 3,000 ft., among them Ben Nevis (4,406), the highest mountain in the British Isles, the extraordinary assemblage of peaks forming the Monadhliadh mountains in the southeast, Ben Alder (3,757) in the south and the group of the Cairngorms on the confines of the shires of Aberdeen and Banff. Almost the whole mainland part of the county is occupied by the younger highland schists and metamorphic rocks, with many isolated patches of granite, of which the largest is on the eastern boundary, including Cairngorm. Across the county from southwest to northeast strikes Glen More (the Great Glen or Glen More-nan-Albin), an old fault or line of earth-fracture along which displacements have occurred during more than one geological period. It contains Loch Lochy and Loch Ness, and through it was constructed the Caledonian canal (*q.v.*). Striking similarities between rock formations at Foyers and at Strontian, about 56 mi. southwest, are thought to indicate that the fault was accompanied by a very considerable lateral movement. (On the islands, see HEBRIDES. SKYE and ST. KILDA.)

Rivers and Lakes.—In the northwest the Beauly river (10 mi.) is formed by the confluence of the Farrar and the Glass rivers. The Enrick (18 mi.), rising in Loch-nan-Eun, falls into Loch Ness, just beyond Drumnadrochit. The Ness (7 mi.) forms the natural outlet of Loch Ness to the sea north of Inverness. The Moriston (19 mi.) flows out of Loch Cluanie and falls into Loch Ness 4 mi. southwest of Mealfourvounie (2,284 ft.). The Lochy (8 mi.), issuing from the loch of that name, runs southward, parallel with the Caledonian canal, and enters Loch Linnhe at Fort William. The Spean (20 mi.), flowing westward from Loch Laggan, joins the Lochy as it leaves Loch Lochy. The Nevis (12 mi.), rising at the back of Ben Nevis, enters Loch Linnhe at Fort William. The headwaters of the Leven (16 mi.), which enters Loch Leven at its eastern end, was much affected by the construction of the Blackwater reservoir serving Kinlochleven aluminum works. The Dulnain (28 mi.), rising in the Monadhliadh mountains, enters the Spey near Grantown, falling in its course nearly 2,000 ft. The Truim (16 mi.), rising close to the Perthshire frontier, flows into the Spey near Newtonmore.

Three of the larger rivers of Inverness-shire finish their course in other counties. These are the Spey, which for the first 60 mi. of its course belongs to the shire; the Findhorn (72 mi.), rising in the Monadhliadh mountains a few miles northwest of the source of the Dulnain; and the Nairn (38 mi.), rising within a few miles of Loch Farraline.

There are many hill tarns and little lakes, considerably more than zoo being named. Loch Ness, the most beautiful and best known, is 223 mi. long, 1¾ mi. broad at its widest point and 754 ft. deep. It is the largest body of fresh water in Great Britain, and forms part of the scheme of the Caledonian canal. Loch Oich (3¾ mi. long) and Loch Lochy (10 mi.) also form portions of the canal. Loch Arkaig (12 mi.) lies in the country of the Camerons, Achnacarry house, the seat of Lochiel, the chief of the clan, being situated on the river Arkaig near the point where it issues from the lake. Near Spean bridge a monument commemorates Commando troops, trained around Achnacarry, who fell in World War II. The old castle was burned down by the duke of Cumberland in 1746, but a few ruins remain. Loch Quoich (5¼ mi.) lies north by west of Loch Arkaig, and Loch Garry (4½ mi.) a few miles to the northeast; Loch Morar (12 mi. long by 2 mi. broad) is only about 600 yd. from the sea, to which it drains by the river Morar, which falls over a rocky barrier. The loch is 1,017 ft. deep and is thus the deepest in Great Britain. Loch Ericht, partly in Perthshire, is 14½ mi. long and lies at a height of 1,153 ft., being thus the highest lake of such large size in Great Britain. In the south are Loch Laggan (7 mi.) and Loch Treig (5 mi.). The principal salt-water lochs on the Atlantic seaboard are Loch Hourn ("Hell's lake," so named from the wild precipices rising sheer from the water), running inland for 14 mi. from the Sound of Sleat and separating Glenelg from Knoydart; and Loch Nevis (14 mi.), a few miles farther south.

The "parallel roads of Glen Roy," a glen with a northeasterly to southwesterly trend, a few miles east of Loch Lochy, presented a problem that long interested geologists. At heights of 1.148 ft., 1.067 ft. and 835 ft., there run uninterruptedly along each side of the glen terraces of a width varying from 3 to 30 ft. They are now generally taken to be the gently sloping banks of lakes dammed up at different levels successively by glacier ice. Further evidences of glacial action are abundant in many places, in the form of *roches moutonnées,* striations, moraines, etc. At several points on the coasts remains of marine terraces are seen at 100 and 25 ft. above present sea level.

Among the finer glens are Glen Urquhart and Glen Moriston to the west of Loch Ness, Glen Feshie in the east, and Glen Nevis at the southern base of Ben Nevis. Glen Garry, to the west of Loch Oich, gave its name to the well-known cap or bonnet worn both in the Highlands and Lowlands. In Glen Finnan, at the head of Loch Shiel, Prince Charles Edward raised his standard in 1745. The great straths or valleys are in the north and east, the chief among them being Strathfarrar, Strathglass and Strathnairn, and the heads of Strathearn and Strathspey.

History.—In Roman times. Picts occupied the country to the north of the boundary hills of the present counties of Argyll and Perth (beyond which the Romans attemgted no occupation). The territory was afterward called the province of Moray, and extended from the Spey and Loch Lochy to Caithness. These limits it retained until the 17th century, when Caithness (in 1617), Sutherland (in 1633) and Ross-shire (in 1661) were successively detached. Toward the end of the 6th century Columba undertook the conversion of the Picts, himself baptizing their king. Brude, at Inverness; but paganism died hard and tribal wars prevented progress. In the 11th century, after the death of Duncan I (1040), Scotland was divided between Macbeth and the Norwegian leader Thorfinn, who took for his share the land peopled by the northern Picts.

Macbeth was defeated by Earl Siward in 1054 and was finally overthrown in 1057 when Malcolm III (Canmore), the son of Duncan I, became king of the Scots. Insurrections continued until the reign of David I, when colonists of noble birth were settled in various parts of the shire. After the battle of Largs (1263) the Norse yoke was thrown off. In 1300 Edward I's expedition to Scotland passed through the northern districts, his army laying siege to Urquhart and Beaufort castles. As a result of the colonization the clan system gradually developed and attained in the shire its fullest power. the chief being the Frassers, Chisholms, Grants. Camerons. Chattan, Macdonalds of the Isles, Clanranald Macdonalds, Macleods, Mackintoshes and Macphersons. The clans were constantly fighting each other. or their sovereigns.

In many quarters the Protestant movement made no headway, the clansmen remaining steadfast to the older creed. At the era of the Covenant. Montrose conducted a campaign in the interests of the royalists, gaining a brilliant victory at Inverlochy (1645), but the effects of his crusade were speedily neutralized by the equally masterly strategy of Cromwell. Next Episcopacy appeared to be securing a foothold. until Viscount Dundee fell at Killiecrankie, that battle being followed by a defeat of the Highlanders at Cromdale in 1690. Maj. Gen. Hugh Mackay suppressed an attempted rising and a combined effort was made to hold the clans in check.

Forts were constructed at Inverness, Kilchumin (Fort Augustus: a Benedictine abbey now occupies the site) and Kilmallie (Fort William); Marshal George Wade's famous roads constructed between 1726 and 1737—exhibiting at many points notable examples of engineering—enabled the king's soldiers rapidly to scour the country. and general disarming was required.

Prince Charles Edward's attempt in 1745 had the effect of bringing most of the clans together for a while; but the clan system was broken up after his defeat at Culloden in 1746 and subsequent escape. Heritable jurisdictions were abolished. Even the nearing of the highland dress was proscribed. The effects of this policy were soon evident. Many of the chieftains became financially embarrassed, their estates were sold, and the glensfolk, impoverished but high-spirited, sought homes in Canada and the United States. As time passed and passion abated, a proposal to raise several Highland regiments for the British army was entertained with surprising favour, among the regiments then enrolled being the 79th Cameron Highlanders. Fort George, afterward the depot of the Seaforth Highlanders. 124 mi. northeast of Inverness, mas begun in 1748.

Stone axes and other neapons or tools have been dug up in the peat, and prehistoric jewelry has also been found. Crannogs (*q.v.*) occur in some of the lochs and stone circles are numerous, as at Clava and in the valley of the Ness. Pictish towers or brochs are met with in and near Glenbeg, and duns (forts) in the Aird and to the west and southwest of Beauly and elsewhere. Among vitrified forts the principal are those on Craig Phadrick (Inverness), Dundbhairdghal in Glen Nevis, Dun Fionn or Fingal's fort on the Beauly near Kilmorack, Achterawe in Glen Garry and in Arisaig.

Agriculture and Forests.—Only a very small percentage of the total area is arable land, and apart from a narroa coastal fringe on the northeast it is of only poor to medium quality. The lowlying land bordering the Moray and Beauly firths is devoted to cropping and the rearing and fattening of stock. On the poorer arable land, at higher elevations, cattle rearing is important. Speyside has long been famous for the quality of its store cattle. which are sold to be fattened on lower and more fertile farms. The principal stock on the hills is sheep, the Blackface breed predominating. Stock are also raised on the islands off the coast, though on these the problem of winter fodder is acute because of poor soil and moist climate. Beginning in 1947 important experiments (near Fort William and in the northwest) in large-scale cattle raising combined with the reclamation of unproductive land demonstrated the possibility of providing ample winter feed in the form of silage.

Many of the rivers and several of the lochs abound with salmon and trout, the salmon fisheries of the Beauly, Ness and Lochy yielding a substantial return. Deer forests occupy an enormous area, particularly in the nest, in the centre. in the south and southeast and in Skye. From the number of trees found in peat bogs, the county must once have been thickly covered with mood. The famous forests of Strathspey were largely cut down in World War II Natural woods on Loch Arkaig, in Glen Garry, Glen Moriston, Strathglass and Strathfarrar, and at the head of Loch Sheil, are extensive and considerable reafforestation has taken place. Part of the ancient Caledonian forest extends for several miles near the Perthshire boundary. In 1952 reindeer from Sweden were introduced into Rothiemurchus forest. There are also large tracts of grouse moor.

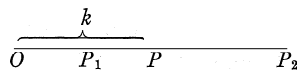
Communications.—The main railway between Inverness and the south (via Edinburgh and Perth) enters the county through the pass of Drumochter (1,484 ft. above sea level and the highest main line summit in Great Britain). It is joined near Inverness by the line from Aberdeen. Another line from the south (via Glasgow) enters 2 mi. N.W. of Rannoch station and runs via Fort William to Mallaig. For a short distance the Inverness-Kyle of Lochalsh (for Skye) line is in the county. Mallaig has important connections with the outer islands. There are good public motor services, an airport at Dalcross, 8 mi. S E. of Inverness and a landing ground at Barra. an island of the Outer Hebrides.

Industries.—Mallaig and Fort William are the main centres of the herring and lobster fisheries, but fishing is also carried on among the various outer islands. There is a whaling station at Tarbert in Harris and a deep-freeze food preserving plant at Bunchrew, $3\frac{1}{2}$ mi. W. of Inverness. Harris, Skye and other islands produce tweeds. There are distilleries at Tomatin, Dalwhinnie. Fort William, Inverlochy and Carbost in Skye. Seaweed is processed at Lochboisdale in South Uist and diatomite is exported from Staffin in Skye. Inverness has some small industries.

Hydroelectric stations for the aluminum works at Foyers. Kinlochleven and Fort William have been followed since 1947 by several great schemes of the Korth of Scotland Hydro-Electric board. Some, such as those at Morar, provide local supplies, while others, Glen Affric, Glen Garry and Glen Moriston, provide power for industrial areas further afield. 'lhe schemes include several large dams and many miles of tunnel. The power stations at Morar and Invergarry are mainly underground and efforts were made in all the schemes to spoil the scenery as little as possible.

Population and Government.—The population in 1951 was 84,930 In 1951 Gaelic only was spoken by 1,008 persons and Gaelic and English by 23,664. Inverness (1951 pop. 28,107) is a royal burgh and large burgh. Fort William (2,674) and Kingussie (1,075) are the small burghs. There are nine county districts. The county returns three members to parliament nith Ross and Cromarty: for Inverness. Ross and Cromarty. and the Western Isles. Inverness with Moray, Nairn, and Ross and Cromarty forms a sheriffdom, with resident sheriffs-substitute at Inverness, Fort William, Portree and Lochmaddy.

INVERSION, a term used in the study of geometric figures. To take a simple case, suppose in this figure



that $OP = 1$, $OP_1 = \frac{1}{2}$, and $OP_2 = 2$. Then $OP_1.OP_2 = OP$. Let us say that $OP = k$. Then it is evident that there is an infinite number of points P_1, P_2 on the line such that $OP_1.OP_2 = k$. A geometric transformation which replaces each point P_1 by a point P_2 such that $OP_1.OP_2 = k$ is called an inversion. In such case O is the centre of inversion and k is the radius of inversion. As P_1 moves nearer to O, P_2 moves farther away. As P_1 approaches P, P_2 also approaches P. In general we say that, when $xy = k$, x and y are inversely proportional, one decreasing as the other increases. We may also say that if $y = f(x)$, we may inversely consider x as a function (implicit) of y.

INVERSION OF TEMPERATURE. Over much of the earth most of the time the air temperature decreases with increasing elevation up to a height of 10 to 15 km. (6 to 10 mi.) above the surface. Frequently, however. layers of air are present through which the temperature increases with height instead of decreasing. Such layers are called inversions of temperature or. briefly, inversions. The rate of decrease of temperature with height is called the lapse rate. When the temperature increases with height, as in an inversion, the lapse rate is negative. Occasionally in meteorological articles the term inversion is applied loosely to any layer in which the lapse rate, though positive, is smaller than the lapse rates below and above it. In the following it will be used only in its strict sense.

Inversions are measured by (1) the thickness of the layer, (2) the rate at which the temperature increases and (3) the total rise in temperature through the layer. The last is called the magnitude of the inversion. Inversions with rapid rates of temperature increase are termed sharp, those which have large total temperature increase are called large, and those which are sharp and large are called strong.

The lower 10 to 15 km. of the atmosphere, where the lapse rate is usually positive, is called the troposphere. As has been stated, however, even in the troposphere inversions are frequent, and in some regions they are invariably present at small or moderate heights. An examination of all the aerological soundings made in Sweden in 1924 and 1925, for example, showed that inversions occurred in 44% of them and in 69% of those made in winter. The following table, resulting from another study, shows the number of soundings having inversions present at various heights up

to 6 km. out of 1,000 observations made over Europe:

Height (mean sea level)	0.j km.	1 km.	2 km.	4 km.	6 km.
Number of inversions	212	124	56	196	77

The stratosphere is the portion of the atmosphere above the troposphere. There the temperature normally is constant or increases slowly with height, and at higher levels it increases at a greater rate. Between 16 and 50 km. the evidence indicates that a permanent inversion of varying sharpness is present; *i.e.*, the "inverted" state is normal. The stratosphere is sometimes called the upper inversion.

An inversion starting at the earth's surface is called a ground inversion, while one uith normal temperature decrease in the layer of air below it is sometimes called a high inversion. In fig. 1, curve I shows the variation of temperature with height in a case of normal lapse rate at all levels, curve II shows a ground inversion, surmounted by a layer with normal lapse rate, and curve III shows a high inversion with normal lapse below and above.

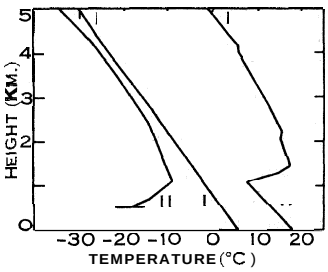


FIG 1.—CURVE I: SOUNDING IN SPRING AT HAMBURG, GER., SHOWING NORMAL DECREASE OF TEMPERATURE WITH HEIGHT CURVE II: SOUNDING IN LATE FALL AT BISMARCK, N.D., U.S.. SHOWING GROUND INVERSION. CURVE III: SOUNDING IN SUMMER OVER PACIFIC OCEAN AT 30° N., 125° W.. SHOWING TRADE-WIND INVERSION

Relation of Inversions to Weather.— Inversions play an important role in determining cloud forms, precipitation and visibility. The ease with which vertical motions of air parcels, and in particular vertical mixing, take place depends on the lapse rate. This can be understood readily when it is remembered that an ascending air parcel cools by expansion at the adiabatic rate of 1° C. der 102 m rise if it is unsaturated, or a somewhat smaller rate if saturated. (See ADIABATIC PROCESSES IN ATMOSPHERE.) If the air through which it rises has a lapse rate less than the rate of adiabatic cooling, the ascending air parcel becomes cooler and heavier than the surrounding air, and is subjected to a force which tends to return it to its original level. Even a parcel which is heated at the ground to a temperature higher than the surrounding air will in rising cool more rapidly than the temperature of its surroundings decreases with height. Thus it will reach a height where its temperature is the same as the air around it, and in rising higher under its momentum it will set up a force which will tend to return it to that level. The height to which a heated parcel will rise is smaller, and the force arising from a given vertical displacement of a parcel originally in equilibrium is larger, the smaller the lapse rate. In case of inversions vertical motions are resisted by large forces, and effectively suppressed. An inversion acts as a lid on vertical motions in layers below. The consequence is that convection produced by heating the air from below is limited to levels below the inversion. and diffusion of dust and smoke is likewise limited. In regions where a pronounced inversion is present at a low level, convective clouds cannot grow high enough to result in showers. and at the same time the visibility may be greatly reduced below the inversion. even in the absence of cloud, by the accumulation of dust and smoke particles. Because the air near the base of the inversion is cool, cloud or fog is frequently present there (see FOG).

The suppression of vertical turbulence allons inversions to act as slip surfaces across which the upper layers slide freely, unimpeded by the exchange of momentum aith the lower layers. The resulting wind shear, together with the abrupt density change, may produce bumpiness in an airplane flight through the inversion, even though the actual atmospheric motion is smooth. This is caused by the sudden change in dynamic lift on a plane passing from air moving slonly to less dense air moving rapidly or from a different direction. Furthermore. if the inversion slopes (frontal inversion), the air above it may be carried upward along the slope because of its motion relative to the air below, and layer clouds and precipitation may result from the adiabatic cooling of the ascending air.

Except in the last-named case, of air being carried upward above a sloping inversion, the base of the inversion forms a quite sharp boundary between air with low visibility below and extremely clear air above. Because the inversion likewise limits water vapour diffusion it also usually represents a boundary between humid air below and very low humidity above.

Another important influence of inversions on the weather is the effect upon the diurnal range in temperature. The principal heating of the air during the day is produced by contact with the ground. the temperature of which is raised by solar radiation to which the air is transparent. The sun's radiation is absorbed by the ground. and the heat is communicated to the air by conduction and convection. Since the inversion base represents the upper limit to which heat is carried by convection, only a shallow layer of air will be heated if the inversion is low and large, and the temperature rise mill be great. On the other hand, if the inversion is high or no inversion is present a deeper layer of air must be heated, and the temperature will rise less.

Ground Inversions.— These inversions are produced by cooling of the air by contact with a colder surface. The most general cause is cooling of the ground by radiation on clear nights, and for this reason they are also called nocturnal or radiation inversions. The radiation downward from the atmosphere is much less than that upward from the ground. resulting in a net loss of heat by the latter when the sun is not shining. The air in contact with the ground is cooled by conduction. and if the air is in motion, the cooling effect is transmitted upward by mixing of the air at the ground with that a little higher, as well as by radiation.

The effect of this turbulent mixing and radiational exchange is to increase the thickness and decrease the magnitude of the inversion. If the air is cooled below its dew point by this process, fog may result. When the wind is sufficiently strong, the turbulent mixing may wipe out the inversion at the ground, establishing an adiabatic lapse rate there and sharpening the upper part of the inversion. In this case if condensation occurs the fog is also raised from the surface to form "high fog" or stratus cloud in the coldest air just below the inversion.

Curve II in fig. 1 shows a large ground inversion, as observed at Bismarck, N.D., in the late fall, when the long nights provide a long period of radiational cooling of the ground. The temperature increase of 11° C. in 600 m. is not at all unusual in these circumstances.

Topography greatly affects the magnitude of ground inversions.. If the land is rolling or hilly, the cold air formed on the higher land surfaces tends to drain into the hollows, producing a larger and thicker inversion above low ground, and little or none above the higher points.

Ground inversions are usually removed during the day by heating from belon. The ground is warmed by solar radiation, and the air above it by conduction and convection. In middle latitudes in winter, however, the insolation during the day is often insufficient to offset the cooling which has occurred the previous night, and ground inversions are augmented day after day during periods of light winds. In these cases fog may persist both day and night. The great valleys of California and the valleys of central Europe are characterized by persistent fog of this type in winter.

Farther poleward, where little or no sunlight is received in winter, stagnating air is subjected to long periods of cooling at the ground. An inversion of great magnitude, considerable thickness and tremendous areal extent develops, blanketing the entire interior of high latitude continental areas, and also (in the northern hemisphere) the Arctic ocean. This inversion is known as the arctic (or. over the antarctic continent the antarctic) inversion. It is strongest and most persistent in the central portion of continents at high latitudes Thus, at Jakutsk, Sib., the arctic inversion occurs in 98% of the soundings during December. January and February, with average thickness 1,720 m. and average magnitude 18° C. Corresponding figures for Fairbanks. Alaska, are 91%, 1,355 m. and 14° C. Fig. 2 shows the average topography of the

FIG. 2.— AVERAGE HEIGHT IN METRES OF THE TOP OF THE ARCTIC INVERSION OVER SIBERIA IN WINTER

top of the arctic inversion over Siberia. as evaluated by Hermann Flohn.

Inversions beginning at the earth's surface are also formed when warm air flows over a colder surface. In this case also the air undergoes contact cooling which is carried upward by mixing, and if the mixing is intense the inversion may be dissolved at the ground and sharpened higher up. Among the places where inversions produced in this fashion are dominant, the Grand Banks of Newfoundland are outstanding. In one case, for example, the air temperature increased from 4° C. immediately above the sea surface to 21.5° C. at an elevation of 1,150 m. The persistent sea fogs of this region are caused by the cooling of the warmer air flowing over the cold sea surface. Similar inversions are produced over continents by the flow of warm air from subtropical regions over snow-covered areas in middle latitudes, particularly in spring when the latent heat of melting or evaporation of the snow is withdrawn from the air, increasing the cooling effect.

Turbulence Inversions. — Turbulent mixing in strong winds would establish an inversion even in the absence of a pre-existing one. The effect of vertical mixing in case of a normal lapse rate is to carry heat downward, cooling the upper part of the mixed layer, and heating the lower, until an adiabatic lapse rate is established. If the mixed layer had an abrupt top, the cooling would be a maximum there. and there would be an abrupt increase in temperature at that level. Instead, the mixing tapers off gradually, and above the thoroughly mixed adiabatic layer there is a finite layer of transition to the unmixed and therefore uncooled air above; *i.e.*, a turbulence inversion is established above the thoroughly mixed layer.

If an inversion is already present, stronger winds than otherwise are required to mix the surface air and establish an adiabatic layer, but if they occur, the inversion is raised to a higher level and sharpened. The cooling in the upper part of the mixed layer may produce stratus or stratocumulus cloud there. while the heating in the lower part may dissolve fog at the ground.

The formation of stratus or stratocumulus clouds by turbulence is very general. The stratiform sky is typical of anticyclonic weather over the British Isles and western Europe in winter. The cloudiness may persist for several days, but no rain. or at most a slight drizzle, falls from it. While turbulence is the principal cause of the cloud in this type of anticyclonic weather, another factor contributes considerably to the formation or strengthening of the inversion. This factor is called subsidence.

Subsidence Inversions. — By subsidence is meant the sinking and vertical shrinking of a layer of air. When a layer of air descends bodily, the increase in pressure compresses it, so that the upper portion descends farther than the lower. The heat of compression will be greater for the upper part than the lower, consequently, and the lapse rate of temperature will thus be reduced. If at the same time as it sinks the air layer spreads out horizontally, the upper portion will descend still more. and the compression may be sufficient to heat it to a higher temperatuie than the lower part, producing an inversion.

Near the ground the air, because of the influence of friction, tends to flow outward from anticyclones (areas of high atmospheric pressure), and the air above must sink to take its place. In addition. because of the dynamics of atmospheric motion. the air moving around anticyclones and in equatorward currents must spread horizontally and shrink vertically (see WINDS, GENERAL CIRCULATION OF). Subsidence thus occurs in anticyclones at all levels, and especially in their eastern portions, where the air flows toward the equator.

The areas which are dominated by anticyclones are: (1) the northern portions of continents in winter; and (2) the subtropical oceans throughout the year. These regions, then, are the ones where subsidence inversions prevail.

The inversions associated with continental anticyclones frequently are dome shaped. The base of the inversion layer may be from three to five kilometres high somewhat to the east of the centre of highest pressure and slope gently downward in all directions to a level of one kilometre or lower. Where the subsidence

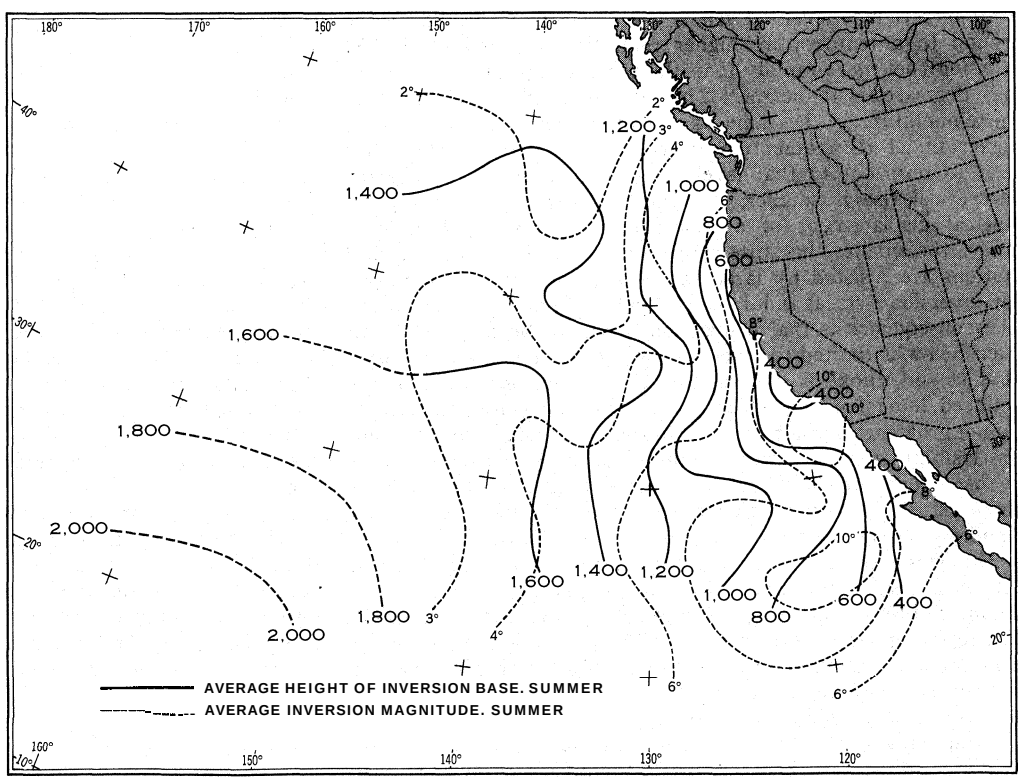

FIG. 3.— AVERAGE HEIGHT OF INVERSION BASE. IN METRES. AND AVERAGE MAGNITUDE OF INVERSION, IN ° C., OVER EASTERN NORTH PACIFIC OCEAN IN SUMMER

inversion is low, it may merge with the ground inversion to produce an extremely large and thick inversion. Whether or not they merge with ground inversions, low subsidence inversions in winter are usually associated with persistent fog or stratus cloudiness, with the valleys covered with cloud and the mountains which penetrate into the inversion enjoying clear mild weather.

Associated with anticyclones over the subtropical oceans there occur strong inversions with bases from 300 to 2,000 m. above sea level. Curve III in fig. 1 shows a typical sounding taken through such an inversion. These inversions persist throughout the year in tropical regions, and follow the seasonal migration of the subtropical high-pressure belt, extending into middle latitudes in summer. The extent and distribution of the inversion over the Atlantic ocean was investigated during an expedition of the German research ship "Meteor" during 1925–27. Numerous soundings made by kite over this area showed that the inversion is present everywhere over the Atlantic from 30° S. to 30° N., but is weaker and higher near the equator and over the western portion of the ocean than in the region where the trade winds are strongest.

Over the Pacific the inversion appears to extend from the North American coast westward about halfway across the ocean, with greatest strength and persistence in the trade-uind areas. Few data are available for the Pacific inversion in the southern hemisphere. Fig. 3 shows the average topography of the base of the inversion and its average magnitude over the eastern North Pacific ocean in summer. It will be noted that the inversion base slopes upward and its magnitude decreases as one proceeds westward from the North American coast. The inversion top slopes upward in fashion similar to the base, and the thickness varies only slightly, ranging between zoo and 400 m. The thickness is least just off the coast, where the large magnitude and small thickness combine to give increase of temperature with height greater than 5° C. per 100 m., and over the Hawaiian Islands, where the small magnitude and thickness and considerable height of base combine to permit convection to break through the inversion at times, producing showers.

When the inversions over subtropical oceans were first observed they were called trade-wind inversions and were attributed to the difference in source of air between the trade winds, originating on the poleward side of the subtropical anticyclones at low levels. and the antitrades flowing over them from equatorial regions at greater heights. This name was retained, although it was established as additional data became available that the change in wind direction does not coincide in position with the inversion layer.

Another theory suggested for the formation of the trade-wind inversion was that it is produced by vertical turbulence. This theory, too, was belied by the "Meteor" observations, which showed that the inversion is too large to be formed that way, with temperatures aloft frequently higher than at sea level, and that it is highest in the region of equatorial calms and lowest in the regions of strongest trade winds. Turbulence would produce the highest inversion where the winds are strongest. Study of the increased number of observations available enabled the demonstration, in 1945, that the explanation of the trade-wind inversion lay in the subsidence associated with the subtropical anticyclones. Analysis of the winds in these regions showed that there is sufficient divergence in them to produce the extremely large sinking motion needed to create the pronounced inversion. Over most of the tropical regions the lapse rate below the inversion is kept nearly adiabatic by heating from below by warmer water, by radiation from cloud tops and by turbulence. Along the west coasts of North America and Africa, however, the air passes over a belt of cold water which rises from considerable depths. In these regions the air is cooled by the surface and the inversion sometimes starts at sea level. On the California coast an inversion at the surface may be produced also at times by winds from the continent subsiding down the high coastal mountain ranges.

The Weather Associated With Trade-Wind Inversions.— The air structure resulting from the processes described above consists of a cool humid layer next to the sea surface and a much warmer dry layer above it. Stratus or stratocumulus clouds are usually present from a few hundred feet above the sea to the base of the inversion. If the inversion starts at sea level, fog will occur if the air is cool enough, or the air may be cloudless. The slope of the inversion upward to the west and equatorward permits more active convection to take place and the clouds to grow higher in those directions. Where convective activity takes place the clouds tend to be broken, but their greater thickness makes showers possible.

While the stratus associated with the trade-wind inversion is characteristic of the eastern portions of subtropical and equatorial oceans, it is commonly referred to as west coast stratus because it is at the shore that it affects aviation and other human activities.

Since a large proportion of the earth's surface is covered by the trade-wind circulation, the trade-wind inversion is one of the major features in the structure of the atmosphere. The principal ueather changes in low latitudes have been attributed to long waves in the inversion, convective showers occurring when the wave motion raises the inversion sufficiently high. The relationship of these waves to the genesis of tropical cyclones was studied, but no conclusive results were obtained. It appears to be definite that the formation of hurricanes or typhoons is associated with convergence which would lift the inversion and, offsetting the effect of earlier divergence and subsidence, wipe it out.

Frontal Inversions.— When a cold mass of air and a warm mass of air are side by side the cold one extends like a wedge below the warm one. The sloping boundary between the two air masses is called a front (*q.v.*). Because of mixing at the boundary, the front is not an abrupt discontinuity, but a transition zone. The warm air overlies the cold, and the transition zone represents a region where, in passing upward, the temperature increases from that characteristic of the cold air to the temperature of the warm air. Thus the frontal zone is an inversion.

The frontal inversion differs from the other inversions discussed in two respects: (1) it has considerable slope, while the others are nearly horizontal; (2) the humidity may be high and clouds may be present immediately above it. Frequently fronts, instead of being real inversions, have smaller positive lapse rates than the air masses below and above. In these cases the air above the front would be warmer than that below if brought to the same pressure. Because it is at a lower pressure, it actually has a lower temperature than the (potentially) colder air mass below. Because the warm air frequently is ascending over the cold-air wedge, and being cooled by expansion, actual inversions at fronts are rarely found at heights greater than two kilometres; at greater heights a slower rate of decrease of temperature almost always characterizes the transition zone, rather than an increase. On the other hand, there is frequently an inversion at the top of the cloud produced by the ascent of the warm air. Fronts and frontal inversions play a principal role in the modern theory of extratropical cyclones or depressions (*see* CYCLONE). Most of the precipitation in middle and polar latitudes in winter is associated with fronts.

Discussions of inversions in meteorological literature are spread through the treatments of the various associated phenomena: fog, clouds, haze, radiation, turbulence, and maximum and minimum temperature forecasting. The reader wishing further information on this topic cannot be directed to any single article or small number of articles. By looking at the index of any standard meteorological textbook he will be provided with additional material and with references to journal articles which enlarge upon the treatment given here. (Ms. N.; X.)

INVERTEBRATE, any animal not possessing a backbone or vertebral column (*e.g.*, worms, snails, insects, sea stars). Invertebrates are distinguished from vertebrates (*q.v.*), all of which possess some kind of cartilaginous or bony axial skeleton. In modern systematic zoology, some invertebrate forms (amphioxus, tunicates, etc.) are included with the vertebrates in the phylum Chordata (*see* CHORDATE); thus the invertebrates do not constitute a homogeneous or natural taxonomic grouping, but the distinction between vertebrates and invertebrates remains a convenient one. It is estimated that more than 90% of all known

species of animals are invertebrates. See INVERTEBRATE EMBRYOLOGY; ZOOLOGICAL NOMENCLATURE; ZOOLOGY. (J. M. A.)

INVERTEBRATE EMBRYOLOGY. Organisms reproduce themselves sexually, asexually, or by a combination of both methods. Asexual reproduction occurs by fission, on simple division into two, by budding, and by formation of spores, and is usually not included in discussions on embryology. Sexual reproduction implies the union of two germ cells, egg and sperm, to create a new individual. The history of an organism, from the first formation of germ cells whose union produced it until its death, is the life cycle of that animal, or its ontogeny. This cycle is made up of different stages, as follows: the development of the germ cells or gametogenesis, fertilization of the egg by the sperm, the embryological period during which the organs that are characteristic of the animal are laid down structurally and grow into a fully formed but small animal, infancy, youth, adolescence, maturity and old age, ending in death. This article deals only with that restricted portion known as embryology (*q.v.*). For other phases of ontogeny the reader is referred to appropriate accounts elsewhere.

Embryology in the broad sense includes the origin and development of germ cells and their union in fertilization to form a new zygote, or fertilized egg, which consists of one cell. Since all Metazoa are multicellular, the first step is the multiplication of that fertilized egg to form a multicellular individual. This multiplication is accomplished through cleavage, or segmentation, by which the materials within the egg are distributed to different cells, thus making further development possible. Cleavage is followed by germ-layer formation, that is, the formation of ectoderm and endoderm and then mesoderm. From the germ layers, the organs characteristic of the animal develop (organogeny). Finally these organs undergo histological and physiological differentiation by which the various tissues become structurally and functionally organized. This step is known as histogenesis, and when it is completed only growth remains in the transformation into the fully developed animal. In the narrower sense embryology is limited to the development of the fertilized egg through the stages up to the final histogenesis of tissues.

Many facts of embryology were accumulated by the ancients, but there was no organizing concept through which the scattered observations could be united into a science until 1828, when Karl Von Baer published his theory of the germ layers. He conceived that the goal of early development is the formation of the three layers — ectoderm, endoderm and mesoderm — out of which all later organs are formed. This view harmonized many apparently unrelated previous findings and offered a basis for new and scientific interpretations. The establishment of the cell theory by M. J. Schleiden and Theodor Schwann (*q.v.*) in 1838–39 made it possible to understand more details of the developing embryo. Charles Darwin's publication of his theory of evolution in 1859 offered further unification and gave a better foundation for the work of later years. When the method of cell division was worked out in the '70s and '80s, embryology was ready to enter into its modern period and the history of development could be carried back to the one-cell or fertilized-egg stage. At this same time F. M. Balfour founded comparative embryology, by gathering together what was known of the development of the different animals and showing that there were general principles of development, common to all of them, based on the broad generalizations just mentioned.

All of the observations up to about 1889 had to do with the structural or morphological aspects of embryology and are accordingly spoken of as descriptive embryology, as distinguished from functional embryology, which depends upon experimentation. While many descriptive studies must still be made, the dominant note in embryological study of the 20th century has been the experimental. The invertebrates have furnished much material for these studies, which have given insight into the causal aspects of development.

Since the emphasis in research has shifted from descriptive to experimental and causal embryology. the old distinctions between vertebrate and invertebrate embryology have lost much of their force. The animal kingdom is divided into great divisions called phyla, there being some 1 j to 18 according to different specialists. One of these, the Chordata. includes all vertebrate animals, and more embryological facts are known about them than about all other animals (see VERTEBRATE EMBRYOLOGY). The remaining phyla are, for convenience, called invertebrates, although technical systematists find little use for this term which of itself lacks essential unity. Embryological principles that clarify the development of both vertebrate and invertebrate animals have now been established. The principles are found to apply to many different forms or groups and to emphasize the fundamental biological unity among animals rather than their dissimilarities.

Although embryos come from eggs, not all eggs are alike. Balfour (*q.v.*), in 1880, distinguished three types: alecithal,[1] which lacks or nearly lacks yolk; telolecithal, in which the yolk is predominately at one pole of the egg; and centrolecithal, in which the yolk is at the centre surrounded by the developing cells. The name centrolecithal does not apply in a strict sense to the egg itself or to its very early stages, for in them the nucleus and the surrounding layer of protoplasm is in the centre of the egg. As cleavage progresses, however, the nucleated masses of protoplasm move to the periphery where they form the cells of the blastoderm (the cellular layer from which the embryo develops). leaving the yolk at the centre, as the name implies. The eggs of sponges, coelenterates and echinoderms are isolecithal. Centrolecithal eggs are characteristic of the arthropods. Most other animals produce eggs that are to a greater or less degree telolecithal in character. The amount and distribution of yolk in the egg cell is a factor of the greatest importance for subsequent development.

As do other cells, eggs contain nucleoplasm and cytoplasm, in the latter of which may be deposited various inert bodies such as yolk globules and oil spherules. While the nucleus is concerned chiefly with cell division, the cytoplasm contains the materials that are to undergo differentiation. Cleavage, or segmentation, by dividing the egg into numerous cells, the blastomeres, sorts the organ-forming contents of the egg into them. At the time of fertilization differentiation has progressed much farther in some eggs than in others. The former are said to be determinative and their cleavage pattern is that of a mosaic. The latter are indeterminate or regulatory eggs. Determinative eggs permit a sequence of cleavages, "cell lineage," to be worked out with great precision, and therefore in these eggs the history of a particular organ in the embryo can be traced back to the early cleavage. Indeterminative eggs do not display this sharp succession of stages; their differentiation into organs is slower and of later appearance.

Developmental processes are accomplished through the activity of the embryonic cells, and this activity in turn depends upon the operation of various factors and relationships involving cellular dynamics. Among these are the following: quantitative ratios be- t een nuclear and cytoplasmic materials; the ratio of nucleus to ectoplasm (which is the specialized surface layer of the cells and which, as cleavage progresses, increases relatively in amount when compared with both nucleus and endoplasm); the ratio between the amount of cytoplasm and deutoplasm, especially yolk (the amount and distribution of which is a major factor influencing the pattern of subsequent development); the direction of the axis of the mitotic spindle (which determines the plane of cell division, but for changes in which no adequate explanation can now be given); and the rhythm of development. It is not possible in the space at hand to discuss the significance of these factors nor of the application of the physical and chemical principles that are also involved.

Of the types of cleavage, the simplest is radial, which occurs in sponges, coelenterates and echinoderms. The only early evidence of differentiation in these eggs is polarity, the materials at the animal pole, where the polar bodies appear, being destined to form the sensory and covering tissues of the animal, and those at the vegetative pole being concerned with nutrition. In radial cleavage, any plane which passes through the two poles will divide the egg into like halves, since its symmetry is radial (fig. 1). In

[1] Actually, all eggs have sqme yolk, and it is, therefore, better to use the terms isolecithal or homolecithal, meaning the yolk uniformly distributed.

the group of coelenterates known as Ctenophores, radial symmetry is displaced by biradial or disymmetrical cleavage, in which there are two centres of symmetry. Ctenophore eggs differ from all others in that the polar bodies are given off at the vegetative pole, and cleavage begins to cut in there first. The third type of cleavage is bilateral and applies to eggs which are telolecithal in character. Only one plane passing through the axis can cut these eggs into two like halves. The anterior end of the embryo develops later in the animal hemisphere of these eggs

Fig. 1.—Blastula of the Starfish. 16-cell stage and radial cleavage. Animal pole at top. Fig. 2.—8-cell stage showing spiral cleavage of the snail, *Planorbis*. Fig. 3.— Discordial cleavage in the cephalopod, *Loligo*. A blastodere disc is formed separate from the yolk mass

and the posterior in the vegetative. Bilateral cleavage occurs in nematodes and rotifers and is the primary type in the Chordata. The fourth type is spiral cleavage, which occurs in the polyclads (flatworms), nemertians, annelids and molluscs (fig. 2). It is the most highly differentiated type and, therefore, the most strictly determinative of all. In eggs of these four types the entire egg participates in the act of division, and cleavage is said to be total or holoblastic.

In the remaining two types the cleavage planes do not cut the eggs completely, cleavage being partial, or meroblastic. Eggs in which the yolk is concentrated at the vegetative pole, and the cytoplasm is restricted to form a disc at the animal pole, are said to have discoidal cleavage. Scorpions, cephalopods and all of the vertebrate animals not of the bilateral type have eggs which cleave discoidally (fig. 3). There remain the centrolecithal eggs of the arthropods (fig. 4). These have superficial cleavage in which a blastoderm is formed on the outside, the yolk remaining in the interior, as explained above.

The end result of cleavage is the blastula, the simplest form of which is a hollow sphere of cells arranged in one layer. Blastulae of this type, called coeloblastulae, occur in eggs having radial cleavage and in those bilateral eggs in which there is not much yolk. Coeloblastulae are equal or unequal, depending upon the amount of yolk in their vegetative cells. If these cells which are to form endoderm contain much yolk, they are larger than those in the animal half, and the cleavage cavity is thus crowded out of centre into the animal hemisphere to make the coeloblastula "unequal." If a coeloblastula is much flattened, it becomes a placula (fig. 5). Blastulae without cavities, because their cells are large, are stereoblastulae, equal or unequal as the case may be (fig. 6). A special type of stereoblastula is the morula, in which some internal cells are not in contact with the surface of the blastula. This usage is in distinction to the former practice of calling the 16-cell stage of radial and bilateral eggs a morula because it resembles temporarily a mulberry. Technically a morula is produced by shifting the axis of the cleavage spindles

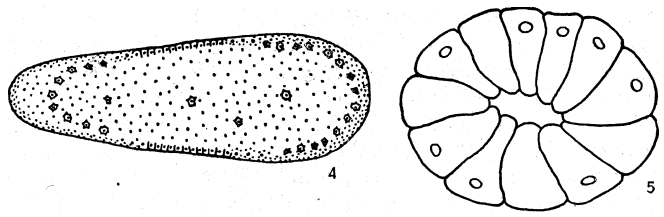

Fig. 4.—A superficial cleavage in the embryo of the blow fly. The cleaving nucleated cytoplasmic masses have reached the surface to form the blastoderm in some parts but not in others. Yolk is at the centre of the embryo. Fig. 5.—Placula of *Cynthia*, an Ascidian

so that some cells are cut off in the interior and do not lie in contact with the surface. The other types of the blastulae are the discoblastula and the superficial blastula, which occur in forms having the corresponding types of cleavage, and, finally, the stomoblastula of a sponge (fig. 7), described by O. Duboscq and O. Tuzet in 1937 as a stage preceding the amphiblastula which is really a larva.

Blastulae next undergo germ-layer formation, the first step being gastrulation, or the separation of the blastula into primary ectoderm and endoderm (fig. 8). In the simplest case (equal coeloblastula) gastrulation is comparable with the pushing in of one side of a hollow rubber ball and the subsequent closure of the opening thus formed (fig. 9). This converts the hollow one-layered ball into a two-layered or double one. An embryo of two

layers of cells is a gastrula, and this simple process is invagination, or embolic gastrulation. In blastulae in which the cavity is very small or absent the cells of the animal hemisphere begin to grow over the vegetative cells and thus form a two-layered embryo by the method of epiboly (fig. 10). A third method of gastrulation known as ingression occurs in eggs whose cells do not retain their layerlike formation but crowd into the interior en *masse*, usually from one point, the vegetative pole (fig. 11). The fourth type of gastrulation is delamination, or the formation of an inner layer of cells by division of the cells of the blastula in which the spindle axes are perpendicular to the surface of the egg (fig. 12).

Gastrulation by invagination is found to occur in a great many different phyla of animals. Among them the Coelenterata. Chaetognatha, Molluscoidea, Nemertinea, Echinodermata, Arthropoda, Annelida, Mollusca and the Protochordata—in short: wherever coeloblastulae are found. Epiboly occurs in Ctenophores, Rotifera, Turbellaria, some molluscs, some annelids and many crustaceans. Ingression is found in many coelenterates, some nematodes, some molluscs and some arthropods. The various types of endoderm formation by delamination are known mostly from the embryos of the Hydrozoa.

From the primary ectoderm and endoderm come the three definitive germ layers—ectoderm, endoderm, and mesoderm—primary ectoderm producing definitive ectoderm and ectomesoderm, and primary endoderm producing definitive endoderm and endomesoderm. All triploblastic animals (those with three germ layers) possess endomesoderm. Some possess in addition ectomesoderm, sometimes called secondary mesoderm. The group in

which only endomesoderm occurs is called by some the Deuterostomia, and includes Chaetognatha, Echinodermata and Chordata. Current phylogenetic assumptions derive the echinoderms and the

Enteropneusta from a hypothetical ancestor, the dipleurula, and from the enteropneustan stock come the higher chordates. The animals of the other portion of the phylogenetic scheme, those possessing ectomesoderm, are of three main groups, first, the Platyhelminthes and nemertines; second, the Rotifera, the Nematoda, the Acanthocephala and the Nematomorpha; and third, those which are derived from a trochophorelike ancestor, these being the Echiuroidea, the Annelida, the Arthropoda and the Mollusca. Those who hold to this interpretation of phylogeny see the main line of development progressing from the flagellate protozoa through the planula of the coelenterates to the triploblastic forms represented by a primitive ancestral flatworm having no coelom, to the two main branches just mentioned, the Deuterostomia, and the Protostomia. The possession of the ectomesoderm by the Protostomia and of an endoskeleton by echinoderms and chordates are embryological points in favour of this diphyletic treatment.

Ectomesoderm is best known from the study of annelids and molluscs, in nhich it produces connective tissues and the larval musculature. There is some doubt as to whether other organs developed from it. At least in the annelids and molluscs it degenerates upon the metamorphosis of the trochophores.

There are said to be five methods by which the endomesoderm arises. One of them, the aggregation of scattered mesenchyme cells, has been described chiefly for Phoronis, one of the Molluscoidea, and is not generally significant. In the Deuterostomia the formation of mesoderm is either as enterocoeles which arise as out-pocketings of the gut wall (echinoderms, amphioxus, etc.) (fig. 15) or as solid masses of cells which grow out from the gut.[1] The distinction between enterocoeles and solid outgronths arises largely because the cells retain their layerlike arrangement in the enterocoeles and hence form the cavity as the evagination develops, while in solid outgrowth they proliferate outward as a mass, the cavity of which appears later as they split apart. In the Protostomia, endomesoderm arises either as teloblastic bands or as secondary bands on either side of the gut which presently segment and form the somites that hollow out to produce coeloms (where these occur). Teloblastic bands of the annelids (fig. 14) and molluscs come from the mesentoblast cell *4d* of the spiral cleavage (fig. 13), which after further divisions gives rise to the teloblast cells, M^1 and M^2, and by continued proliferation produces the bands. These grow posteriorly and are converted into the mesodermal organs. Secondary bands occur in the arthropods, and form somites, in a manner much like the teloblastic bands But they do not originate from teloblast cells. They form as solid bands from

[1]The trunk coelorns of the New England tornaria of *Balanoglossus*, that of the tunicates, of some brittle stars, and of the mesoderm of vertebrates usually arise as solid outgrowths also.

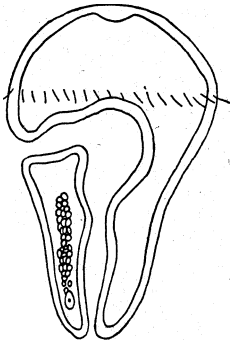

Fig. 14.—Diagram of an annelid trochophore larva showing the left teloblastic band which elongates and segments to form mesodermal somites. The right one is similar

an area which is multicellular from its first recognized appearance. The primitive endoderm separates into an endodermal mass and into the paired mesoderm bands.

The production of mesoderm completes the formation of germ layers, from which the organs of the embryo arise. Primordia which are to become the various organs appear by changes of a few types, such as rapid and differential multiplication of cells resulting in localized thickenings of any one of the layers, and, conversely, the retention of embryonic thinness of some areas; invagination to form sacs and pockets, or evagination to form rods or tubes or pouches of tissue; unequal growth, folding, and bending. These devices occur in many combinations at varying times and speeds, thus accounting for the different processes of organ formation as they are observed in the embryology of the many invertebrates. Organogeny is a series of formative events during which the organs take on their structural characters but are not yet able to function. When the organs, at least the essential ones, have reached sufficient differentiation to begin functioning, the embryonic stages (strictly speaking) have passed, the little animals hatching either as larvae or as immature young. If they hatch as larvae. development is said to be indirect, involving partial or complete metamorphosis. Thereupon the larvae transform into small, complete. but immature animals morphologically like the adults. If there is no metamorphosis, development is direct, proceeding to the characteristic form of the adults without the intervention of any unlike intermediate conditions. In this event the further histological differentiation of tissues and the growth (increase in size) of the entire organism are the major processes of later development.

There is an ecological background to the embryological pattern of all embryos. Ecology (see ECOLOGY, ANIMAL), which concerns the relation of organisms to their surroundings, is not a matter of adults only, but embryos and larvae must also be so adapted as to exist where they find themselves. If an embryo undergoes development in a habitat where both it and the adults may find sustenance suitable to both, development is direct. But if the egg is laid in a place where it can develop but the adult cannot live, then embryonic development leads toward a larva which is adapted to that type of environment and its metamorphosis is necessary before the adult can become established in its final habitat. Sometimes several larval stages are needed for the transition from the early habitat to that of the adult, but all find their explanation in the succession of different adaptive relationships.

There are many kinds of larvae in the various groups of invertebrates, but their diversity is more apparent than real and the principles of their growth and metamorphosis are less numerous than one might think. Most animals develop either while submerged in sea or fresh water, or while in a watery medium within the egg membranes. This relation is necessary to promote the interchange of solutes of gases and salts which are needed for nutrition, for osmotic processes can take place only through moist membranes. The typical form of a primitive larva. therefore is that of a ciliated swimming larva nhich is easily derived from the common invaginate and epibolic gastrulae. Assuming this type as the starting point for the diverging types of invertebrate larvae, a few principles of larval growth may be listed.

Larval metamorphosis (see METAMORPHOSIS) involves principles and processes that recur frequently throughout the animal kingdom. They operate at different stages of development in different larvae, the duration of their effectiveness varies, and they are present in all different combinations, a single one rarely being responsible for any major changes in metamorphosis. The variation in the times of onset of the dynamic principles. the duration and speed of their effectiveness, and the co-operation of each with the others, are responsible for the diversity f developmental results. These phenomena in their turn depend upon causes that are

up to the present outside the scope of observation and experiment. Some of the processes involved in the dynamics of metamorphosis may be listed under the following heads: differential growth, loss of parts. continuous and uniform growth and cellular and histological differentiation.

Differential growth manifests itself through the acceleration of the rate of cell division in the regions which become the primordia of organs to appear later. The increase may be detected by a study of the comparative number of cells during rest and in division. Acceleration may also involve migration of cells into the primordia from neighbouring regions, for embryonic cells which are still undergoing differentiation have not lost their powers of independent movement. Acceleration of growth may also be accomplished by the imbibition of water and of nutrient materials in solution. Opposed to the acceleration of growth is partial or complete arrest of development in localized regions. These tno factors have to do with the rhythm of growth. and not a few embryological processes are largely explicable on this basis. Their timing, related in part to the genic mechanism, is an important factor in determining their significance. It has been discovered that there are "critical moments" at which developmental changes are effective and upon which the sequence of later events depends. The processes of differential growth are by no means limited to indirect development. They play their part also in the establishment of organs nhere animals develop without metamorphosis.

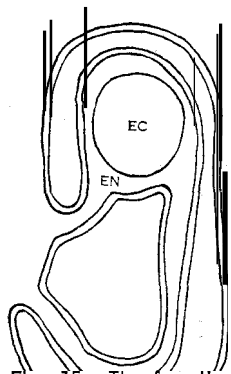

Fig. 15.—The formation of mesoderm in *Patiria* as an enterocoele (ec), an outgrowth from the enteron (en)

It is common to speak of the "loss of parts" in the metamorphosis of some larva, but this process may be relative rather than actual. Where temporary larval organs occur, whose functioning is needed for a limited period of development only, these organs sometimes become constricted off and are actually discarded. In other cases loss of parts occurs by resorption, which may be brought about by disintegration of tissue through phagocytosis (destruction by phagocytes), or by enzymolysis (induced by enzymes), and it may follow liquifaction of cells in some larva. The loss of parts may also result from dedifferentiation of cells (that is, their return to a more primitive embryological condition), whereupon morphogenetic reconstitution causes them to migrate elsewhere and to be incorporated in other tissues. In still other instances the loss of parts may be apparent only, for the extensive growth of adjacent parts may be sufficient simply to include them as the animal grows.

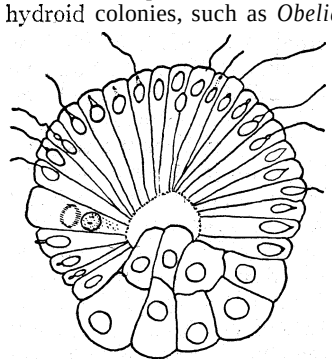
An innate property of cell protoplasm is that of continuous and uniform rhythmic growth, nhich is as much a factor in larval metamorphosis as it is in direct development. Where new primordia are being established, both cellular and histological differentiations are undergone. Differentiation of cells involves their organization into layers, with changes in their shapes in line nith the assumption of the histological characteristics of the different tissues; the deposition in the cytoplasm of specialized structures such as granules. fibrils and others; and the production of noncellular material, largely for support and protection. One thinks of these embryological devices as comparable with the notes of the musical scale which, when employed in different combinations, durations and frequencies make possible the endless varieties of musical forms.

The embryological stages of sponges (the Porifera) are simple, as they must be, in view of the low degree of integration of the cells of these animals. Cleavage results in the formation of a blastula (fig. 7) for which in *Sycon* and *Grantia* the term "stomoblastula" has been suggested by Doboscq and Tuzet. There are two kinds of cells in it. dermal and flagellated, the flagella developing on the inner ends of the cells of the stomoblastula. By a curious phenomenon the entire inner, flagellated surface arches itself to form a dome, then inverts through the mouth to form the amphiblastula, which is the typical larva of a sponge (fig. 16). It consists of large posterior granular and anterior flagellate6 cells, and swims at the surface of the water for some hours. then sinks and presently attaches. Fixation is at the anterior end, the flagellated cells being overgrown by the granular, and thus again taking up an internal position. Since the adult sponge is a body of organized tissues rather than of specialized organs, subsequent changes are only in the nature of histological differentiations. A dermal layer and a gastral layer of cells results. In the dermal layer there are two kinds of cells, the superficial which secretes monaxone spicules and the deeper which produces triradiate ones. The gastral cells take on a radial arrangement, develop collars and flagella (as choanocytes). The canals and pores develop gradually and the gelatinous middle layer, the mesoglea, with its feltwork of spicules, is formed as the gastral cells are rearranged and the flagellated chambers appear.

Animals which belong to the phylum Coelenterata are diploblastic with quite definite cell layers, and there is a mouth opening into a gastric cavity that is not homologous to the cavity of the sponges. In addition to the organs concerned uith digestion, coelenterates exhibit sensory, prehensile, protective and reproductive organs. Individual animals, the zooids, are of two general forms, the hydranths (polyps) and medusae. Sometimes both of these types occur in the life cycle of a single species, as in the colonial Hydrozoa, and in other cases all the animals of a class are developed from one or the other of them. The Anthozoa, the sea anemones and corals, are elaborations of the hydranth, while the Scyphozoa, the jellyfishes, are medusae. Although these two morphological types are very different in appearance, they have much in common and are both derived from a simpler larval form, the planula. Some authorities regard the hydranth as an immature form, a sort of persistent larva, and the medusae as the adult which through a series of changes came to be produced by budding rather than by the direct transformation of the larva.

Although the methods of cleavage and gastrulation are varied, as indicated earlier, the typical larva of coelenterates is almost always a ciliated planula (fig. 17). It is elongated and has an outer ectodermal layer of cells and an inner mass of endoderm, usually solid at first, the cells of which rearrange themselves and form a gastric cavity with an oral opening. The planula settles down, develops tentacles at the oral end, and in the simplest cases grows to form a primitive type of polyp or hydranth. This primitive polypoid larva may develop: (1) into an animal like the familiar *Hydra;* (2) into the first zooid of a hydroid colony as in *Obelia;* or (3) into the actinula (fig. 18) nhich is an interposed larva in some hydroids and in the trachyline forms as *Gonionemus* and *Craspedacusta.* The larva of Scyphozoa is the hydra-tuba or scyphistoma, which undergoes an interesting and complicated series of metamorphoses to develop into adult jellyfishes (fig. 19. 20). Only further differentiation and direct growth are necessary to convert the polypoid larva of the Anthozoa into typical coral polyps or into sea anemones.

According to some, the actinula most closely resembles the primitive larva, and, therefore, it suggests the ancestral type. From it five possibilities of development are presented: (1) the hydroid colonies, such as *Obelia,* in which the hydranth and medusae generations are of equal importance; (2) the gradual reduction of the medusae. leading to a form like *Hydra,* in which no medusa stage is present; (3) the reduction of the hydranth. leading to a form like *Cunina,* in which no hydranth stage occurs; (4) the line leading to the Anthozoa; and (j) that leading to the Scyphozoa.



FROM DUBOSCO AND TUZET IN "ARCH DE ZOOL EXP ET GEN (1937)
FIG. 16 —THE AMPHIBLASTULA OF A SPONGE, SYCON RAPHANUS

In the typical hydroid colony such as *Obelia,* the hydranths developing from the sexually produced egg become differentiated into nutritive and reproductive

polyps. The reproductive ones give rise by budding to medusae which form the free-swimming stage, develop sex organs, and produce eggs and sperm. Thus the alternation of generations characteristic of coelenterates comes about. Asexual budding is a common phenomenon in the group, as is further illustrated by the metamorphosis of the scyphistoma. After this larva has settled down and grown for a time, a process of successive terminal budding begins in which the first bud is not completely cut off before a second one appears. In well nourished individuals there may be formed perhaps a dozen and a half ephyrae (the larvae resulting from the budding process) before the outer one is cut off. The ephyrae grow rapidly and become transformed from their immature condition to that of a fully differentiated sexual adult.

Above the Coelenterates the progress of phylogeny follows two lines. the Protostomia and the Deuterostomia, as already described. The coelenterate type of organization could hardly have given rise directly to this divergence and it may be presumed that an intermediate form not now alive (the so-called Bilateria) may have been interposed. In any event in both lines the animals are bilaterally symmetrical, have anterioposterior and dorsoventral axes, and a digestive cavity; and a third germ layer, the mesoderm, in the first line ectomesoderm as well as endomesoderm, is present.

The first group of the Protostomia is represented by the flatworms. Of them only the first class, the Turbellaria, is regarded as on the direct line of evolution, for both trematodes and cestodes have undergone such extensive parasitism that they are quite anomalous. In the Turbellaria spiral cleavage leads to an unequal coelablastula which gastrulates by epiboly. The resulting oval, ciliated larva known as Miiller's larva (fig. 21) swims about for a while, gradually elongates and acquires bilateral symmetry. Meanwhile the mouth shifts to the prospective ventral side and the eight ciliated lobes which distinguish this larval type appear. The continuous band of cilia which edges the lobes is the locomotor organ. Eye spots develop in the region where the apical cells of the blastula were. As the larva elongates, the lobes become proportionately smaller and they disappear with its conversion into a creeping polyclad worm. The eight lobes have been

thought to show relation to the eight comb plates of the ctenophores.

All nemerteans except the Heteronemertini develop directly, but in one family of that group the pilidium larva is found, and in another there is the "larva of Desor," which is a pilidium modified for creeping. The nemerteans are the first forms showing a posterior opening to the digestive tract, in which feature they are advanced over the flatworms, but they also have some primitive developmental traits that suggest the ctenophores. The pilidium has likewise been thought to foretell the trochophore larva of the annelids (fig. 22). It has the shape of a child's helmet and has an apical sense organ, atop of which is a long spike of cilia. Except for this tuft and the marginal locomotor cilia called the prototroch, the cilia are uniform in size and distribution. The two lobes which hang from the sides suggest the corresponding ones of Müller's larva. The gut cavity opens by a wide blastopore and curves posteriorly to form a stomach. Four ectodermal invaginations from the base of the caplike portion of the helmet grow inward between the gut and the apical organ, coalesce and form the amnion. Its innermost layer surrounds the intestinal tract, the rudiment of the proboscis sheath, the excretory organ, and the brain primordium, which are parts of the definitive animal. The outer layer of the amnion, the larval ectoderm, the prototroch, lobes, apical sense organ, and the larval musculature are all left behind like a discarded cap when the little worm has become sufficientlydifferentiated to constrict itself free from its coverings. The discarded portion presently dies, but the worm takes up its life at the bottom.

Above the flatworms the course of evolution evidently led through a stock resembling the trochophores (Trochozoon?) which is represented among living creatures only by these larva. As is true of both the pilidium and Miiller's larva, the trochophore has features resembling the ctenophore type of organization, and it may be presumed that the ctenophores are near the base of this evolutionary line, the Protostomia. From the trochophore stock is derived a group of invertebrate phyla which are clearly related to this branch of the phylogenetic tree but whose development and metamorphosis as well as adult structures have been clouded by some uncertainties of details and of interpretation. These are the Rotatoria, Podaxonia, Polyzoa and Brachiopoda, whose larvae are all modified trochophores, and the Nematoda, Gordiacea and Acanthocephala, which develop directly or are parasitic. The embryology of these forms must be left for more detailed accounts. The trochophore stock then gives rise to the segmented Annelida and the nonmetameric Mollusca.

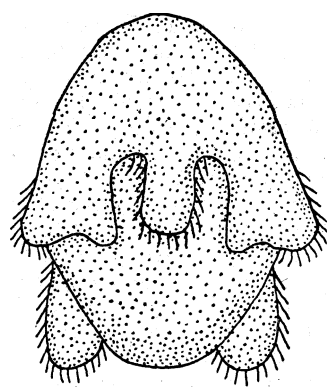

Fig. 21.—Müller's larva, ventral view

The trochophore larva as it occurs in these two phyla is important not only for its own embryological story but for the light it casts on evolutionary processes (figs. 23, 24, 25). The adults of these phyla are exceedingly diverse and, if their life histories were unknown, would not be thought to be closely related. But their early embryological development is almost identical until the fully formed trochophore is reached, after which the divergence begins. The metamorphosis of the annelid and molluscan trochophores are practical demonstrations of the meaning of evolution, for by the further development of different regions of the larvae completely different types of organization are produced.

The trochophore is at first a simple ovoid larva the most conspicuous features of which are the equatorial band of powerful cilia, called the prototroch, and the apical sense organ with its tuft of cilia. In the primitive annelid, *Polygordius,* and in the limpet, Patella, it has been shown that the prototroch first appears from cells in the four quadrants of the embryo on which the cilia are arranged in transverse rows like the "combs" of the ctenophores, and E. B. Wilson called this stage in Patella the "ctenophore" stage. In Polygordius there is also an additional band of cilia, the metatroch, a row of weaker cilia posterior to the prototroch, and the telotroch which is only a posterior tuft of cilia. In other annelids the arrangement of the bands varies from the atrochal conditions (having only the apical tuft and a uniformly ciliated covering) through monotrochal (having only the prototroch), telotrochal (having also the telotroch), mesotrochal (having only the metatroch), to the polytrochal state which comes later as additional locomotor organs are developed as circlets of cilia to assist the worm in movement. The trochophores of other phyla exhibit somewhat similar variability.

Trochophores have a complete digestive tract, with a wide mouth derived from part of the blastopore, a bulblike stomach, and a short intestine leading to a posterior anus. There is a pair of archinephridia, which are basically flame cells and tubules. Mesodermal structures in these larvae are of special interest. The ectomesoderm produces mostly larvae musculature, while the

1. Apical sense organ: 2. Mesenchyme cells; 3. Mouth; 4. Stomach

endomesoderm, also called adult mesoderm, is largely concerned with the coelomic walls and related structures. It is derived from the mesentoblast cell, *4d*, whose division products are the two teloblasts or mother cells of the mesoderm bands. From the continued multiplication of the teloblasts, a band of cells forms on each side of the gut. The coelomic spaces and their walls come from the hollowing out and swelling of these bands.

The transformation of a trochophore into an annelid worm is accomplished primarily by the lengthening of the region behind the prototroch (fig. 24), the intestine becoming a long tube and the mesoderm long bands. Segmentation of the bands and later of the body of the worm then sets in. The bands are cut into a series of blocks, each of which becomes hollow by the separation of the cells and perhaps by absorption of some of them. The spaces thus formed are the coelomic cavities, and the mesodermal layers between them form the septa. The external appearance of a segmented worm is produced by the superficial annulations which arise through a series of indentations of the skin and body musculature. The prototrochal cells, and those anterior to them, are either absorbed or cast off while the body of the worm is being completed through the growth of the post-trochal region.

This procedure is quite in contrast with the metamorphosis of the molluscan trochophore, the early development of which is almost the exact counterpart of that of the annelid trochophore. The distinguishing characters of molluscs include the presence of shell, the mantle which secretes it, and the foot, the absence of segmentation and the reduction of the coelom. Therefore, the differentiation of the trochophore is not by the elongation of the posterior post-trochal portion but by the differentiation of dorsal and ventral post-trochal regions (fig. 25). A dorsal region just behind the prototroch arches into a visceral hump at the apex of which the shell gland, a mere groove of thickened cells, appears. This gland secretes the first semblance of a shell as a horny cap. At the middle of the ventral side the foot is formed as a median projection just back of the prototroch. Thus the metamorphosis of the mollusc proceeds on different lines because of a changed regional differentiation. The annelids find their food by burrowing, the molluscs by creeping or gliding over surfaces. Adaptive structures to correspond to these needs are the result of very different evolutionary steps.

The final metamorphosis of some molluscs involves some other larval stages such as the veliger and the glochidium. When the trochophore of a gastropod has developed its visceral hump and caplike shell. its girdle of prototrochal cells becomes much enlarged to form a velum and the entire larva is now called a veliger. Further changes occur producing torsion of the visceral mass and rearrangement and modifications of the forming organs. These may be looked upon as secondary larval characteristics having to do with special modes of life of the particular animals. The glochidium is similarly a secondary adaptation of the Unionidae to the last part of their immature life as parasites on the gills or fins of fresh-water fish. This larva lacks mouth, velum and foot. but possesses a shell of two valves each of which is equipped with a sharp inturned hook. These hooks seize upon the soft projecting gill or fin of a passing fish, injure it sufficiently to stimulate the swelling and growth of its tissue until it encloses the glochidium in a cyst. In this chamber the larva lives until ready to emerge as a tiny clam. In contrast with these secondary types of larvae, the trochophore is regarded as primary since its characters are related to many different great groups of the animal kingdom. These primary forms show what has been the evolutionary history of these groups and are the basis for present view on the racial history or phylogeny.

The remaining phylum of the Protostomia is that of the Arthropoda, of which the three major classes are the Crustacea, the Insects and the Arachnida. There are also other forms—the Myriapoda, Onychophora, the Trilobita, Pycnogonida, Pentastomida. and Tardigrada—whose relationships to the three main groups are of varying degrees. It is generally held that the entire phylum descended from the Annelida, but beyond this fact there is much uncertainty and little agreement. This division is by far the Largest of the animal kingdom and by far the most studied excepting possibly the vertebrates, but its diversity is so great and its problems so difficult that its phylogeny is still too little understood. Our embryological knowledge often does not warrant assurance. The characters of special interest embryologically are the reduction of the coelom so that the body cavity is morphologically a haemocoele developed in relation to the circulatory system, the increased importance of metamerism so that each typical segment bears a pair of appendages, the greater thickness of the cuticle over that of the annelids, and the general absence of cilia.

There is wide variation in the extent to which the larval phase is shown. In most Arachnida development within the eggsnell sees the formation of all the organs nearly completed before hatching. In the Crustacea there are many kinds of larva, and

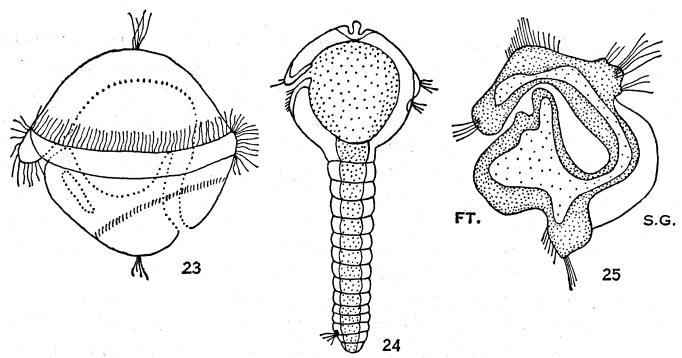

Fig. 23.—Trochophore of *Polygordius*, an annelid. Redrawn from Woltereck. Heavy band of cilia is the prototroch; secondary band is the metatroch. Apical tuft of long cilia, the telotroch at opposite pole, alimentary tract and position of protoneptridium are also shown. Fig. 24.—Older trochophore of *Polygordius*, showing posterior growth which is to transform the larva into a worm. Also redrawn from Woltereck. Fig. 25.—A diagram of a transforming larva of the limpet, *Patella*, showing the dorsal enlargement of the shell gland, the ventral differentiation of the foot. The posterior portion does not elongate. Diagram based on Patten's figures

they hatch in different stages of similarity to the adult. In the Insecta some animals show no metamorphosis while others undergo a series of changes that are the most complete in the animal kingdom.

The primitive crustacean larva is the nauplius (fig. 26) which in the lower members of the class is free swimming with three pair of appendages, the first and second antenna1 and the mandibular, and a single median egg. In the higher classes the nauplius may occur merely as an embryonic stage in which the appendages are represented as cellular aggregations or thickenings. Following the nauplius, there is a series of larvae among Crustacea which show increasing degrees of progress at the time of hatching. The metanauplius adds the next two pair of appendages in order, the first and second maxillae, and shows the first signs of segmentation. The protozoea has the first and second maxillipeds and shows the first compound eyes. The zoea[1] has third maxillipeds, some thoracic appendages, stalked compound eyes, the abdomen completely segmented, and that process begun in the thorax. The mysis is completely segmented in both thorax and abdomen, has all the eight pair of thoracic appendages characteristic of the higher Crustacea. and six pair of abdominal appendages. The walking legs of the mysis larva are equipped with well developed exopods or outer branches for it is a swimming

[1]The common English spelling, zoaea, is incorrect, for this larva is named for the genus Zoea (Bosc, 1801).

animal as contrasted with the heavy bottom living lobsters whose walking legs have only strong endopods. There are about 14 different kinds of crustacean larvae, but those listed are the most important. In addition, the fresh-water shrimp. *Crangon,* hatches in what is practically the adult condition; that is, it has direct development. The nauplius larva is found in the primitive Phyllopoda (leaf-footed), the Copepoda, Ostracoda, Cirripedia (barnacles), and in some shrimps (*Penaeus*) and crabs. In most higher orders. however. it is recognizable only in the embryo. The metanauplius is found in *Eubranchipus,* the fairy shrimp, and in *Lucifer,* a prawn. The young of *Squilla* hatches as a protozoean. The crabs commonly hatch as zoeae and the lobster as a mysis larva (fig. 27).

The chitinous exoskeleton of all arthropods is a hard resistant protective cuticle secreted by the cells of the skin. The animal, therefore, is confined in its own exoskeleton and can grow only by moulting. At intervals the animal breaks out of its skeleton and moults. It then expands rapidly while the new chitin is being secreted and is hardening. The periods between moults are called instars, during each of which the external appearance does not change but the soft internal parts continue development in preparation for the next moult. In the larval series just mentioned, as they pass from one larval stage to another, the higher forms undergo successive moults. Of course the lower crustacea complete the progress only through the stages appropriate for each order.

The embryological record is especially useful in determining the relationships of some of the Crustacea. The outstanding example is that of *Sacculina,* parasitic on the abdomen of crabs, a creature which looks more like a tumour than a separate animal. Parasitism has brought about extreme modification and the animal is unrecognizable except for its embryological history. The egg develops into a nauplius which transforms into a larva resembling the ostracod, *Cypris.* Further development shows the degenerate adult, with the rootlike branches penetrating into the tissues of the crab, to be a close relative of the barnacles.

This case, as well as other larval relationships of this class and the numerous others that could be cited, has been used to illustrate the biogenetic law, especially as it was propounded by Ernst Haeckel (*q.v.*), or, as it is usually referred to, the recapitulation theory. This doctrine concerns the parallel which in general exists between the embryological story and the development of the race. "Ontogeny recapitulates phylogeny." This theory was very important in the history of embryology, for much of the research of the 19th century was stimulated by it. But later studies first cast doubt in it, then showed many instances in which it was a misinterpretation, and now it is looked upon merely as a tendency and not a law in any proper sense of that term.

The embryology of insects (see EMBRYOLOGY) differs from that of other animals in that all eggs are centrolecithal and are well filled with yolk. This limits the embryonic cells to a peripheral position where they form a wall, the blastoderm, about the central yolk mass. Along the midventral, longitudinal line an aggregation of cells arises that forms the germ band from which the body proper of the insect is to come. This ventral position is in contrast with the formative regions of other eggs. The germ bands grow in length and also laterally and dorsally until their edges meet to form the dorsal wall, under the flattened dorsal cells of the original blastoderm which have been converted into the serosa. Mesoderm is formed as an invaginating groove along the midline, by the proliferation of a flat middle plate of cells that is overgrown at the edges by the lateral folds, or by the proliferation and invagination of median ventral cells of the blastoderm. This last method is responsible for the formation of amnion and serosa, embryonic membranes inside the shell which protect the embryo during development. The amnion is formed either as an invagination by the posterior end of the germ band forming a cavity inside the yolk, or by "overgrowth" of the amniotic folds (and the tail fold) until the edges meet closing over the germ band (fig. 28). The outer thin flattened cells are the serosa, and the inner the amnion. These later become membranous and enclose the cavity in which the embryo develops.

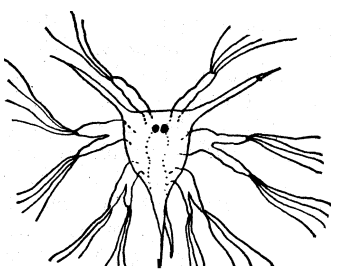

FIG. 26. — NAUPLIUS LARVA OF LEPAS, A BARNACLE

Life histories of insects are markedly adaptive, and the variety of environmental conditions to ahich they are exposed is very wide. Therefore larval forms are of many types. The significance of these larvae is a matter of dispute, some thinking them to be secondary modifications of life histories and others that they are recapitulations of primitive ancestral insects. In either case, it is a matter of interest that some very simple insects hatch in a condition very like their parents, the development being well completed in the embryo, while on the contrary many of the most specialized insects hatch at an early stage in their development and have larvae (often a series of them) that are wormlike in appearance.

There are three kinds of development in the insects, so far as larval conditions go, and the orders may be grouped correspondingly. First, the Ametabola hatch as small fully-formed insects. They are the Thysanura and Collembola. Second, the Heterometabola have incomplete metamorphosis, that is, they hatch as nymphs which are quite similar to the adults but have only rudimentary wings. This group includes the orders Orthoptera, Dermoptera, Hornoptera, Hemiptera and Anoplura. Third, the most highly specialized insects undergo complete metamorphosis, often involving several larval moults and several larval phases. These are the Holometabola and comprise the orders Coleoptera, Strepsiptera, Neuroptera, Mecoptera, Trichoptera, Lepidoptera, Diptera, Siphonaptera and Hymenoptera.

The Protostomia reach their climax in the arthropods, which are very unlike the primitive flatworms from which this great branch of the animal kingdom originated, or the more primitive ctenophore, whose relationships are suggested in many of the embryological stages of the phyla included in it. Among these animals is the greatest diversity in form, size, habits, habitats, and numbers of species and individuals.

Some are very well suited to their environment, while others have not reached much stability in regard to their surroundings, and hence are actively undergoing evolutionary changes even now.

The branch of the animal kingdom opposed to the Protostomia is the Deuterostomia, which doubtless was derived from the same primitive bilateral ancestors as the flatworms. Presumably these two main branches represent divergent developments from about the same low ancestral types. The Deuterostomia include the peculiar, aberrant animal, *Sagitta,* belonging to the phylum Chaetognatha, and also the echinoderms and the chordates. Animals belonging to this stock are characterized by the development of an anus which is one of blastoporal origin; by the absence of ectomesoderm; the formation of the coelom primarily as enterocoeles, or out-pocketings from the primitive alimentary tract; by skeletal structures which are derived from mesoderm and hence are endoskeletal; and by numerous features which are probably less important phylogenetically.

The position of the chaetognaths in classification has been the subject of much debate. Their embryology is known chiefly from the work of Leonard Doncaster on *Sagitta,* published in 1902. This work shed light upon the general problem, but left many points far from clear. It showed no larval form that could be closely compared with any other invertebrate larva, although it recorded the general scheme of embryology fairly well. The blastopore closes and a new mouth develops; a head coelom is

formed as an evagination from the primitive gut; it is not clear that there is any ectomesoderm. For these reasons it seems hardly possible that the animals can be included among the Protostomia. However, they are much more primitive than other Deuterostomia, and many of the characters of the latter are lacking. About all that one can safely say is that this phylum is one of the earliest representatives of the Deuterostomia, but that it shows little affinity for other animals of this general stock that are higher in the scale of development.

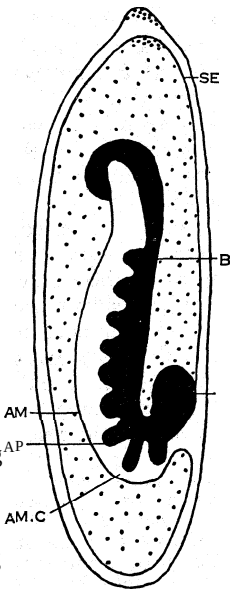

Fig. 2s.— Diagram of embryo of grasshopper, after Brandt. am, amnion; am.c, amniotic cavity; ap, appendage; b, body, h, head lobe; ser, serosa

The development of the embryos of the Echinodermata has been much studied and is of great importance because of the light that it throws upon fundamental living processes. Experimental embryology especially has profited from the study of the echinoderm eggs. The echinoderms represent an ancient group of which the living classes go back to Cambrian times. They are of wide-spread distribution and well adjusted to their present environments, but the range of variation in their individual habitats is not very wide, nor is there much variation in the habitat within a species. Where a species is well adjusted to its environment, little evolutionary change takes place at any given time and, therefore, this phylum displays little of the diversity that is found in those comprising the Protostomia. Evolution at the present time is not progressing rapidly in this great group.

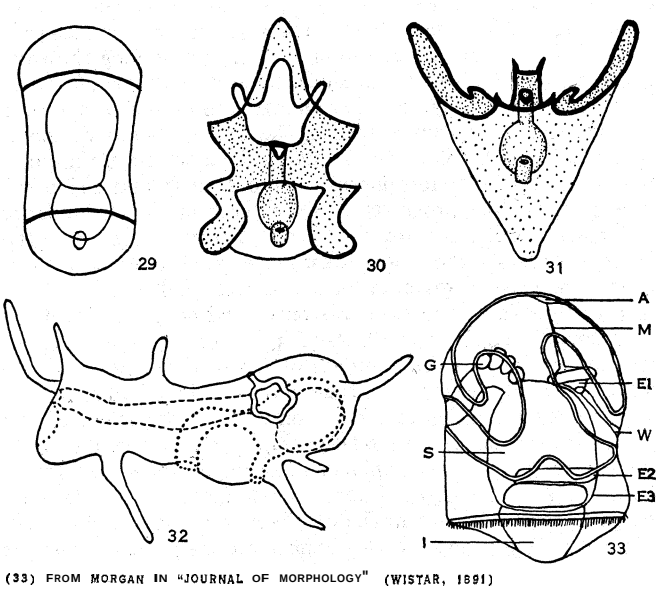
There are five living classes of echinoderms, one of which attaches itself to the substratum and the others of which move very slowly over the bottom and in very limited range. Sessile animals or slow moving ones can be distributed widely only because they have active larvae, a principle which is amply illustrated in the echinoderms. There are four general larval types, of which all were thought by their discoverers to represent separate genera, and their present names are those originally given them as genera. These types include the larva of the Asteroidea, or starfishes, which is the bipinnaria; that of the Ophiuroidea, or brittle stars, the ophiopluteus; that of the Echinoidea, or sea cucumbers, the auricularia. There is also the pentacrinus larva of the Crinoidea, but the development of only one crinoid has been well studied and its eggs are heavily yolk laden so that its entire history is quite unlike other echinoderms. Hence the larvae of the other classes are much more important. They show characteristically different structural features, as well as different habits. But there are many common features in their development which indicate that they must have come from a common ancestor. The larval phases are of long duration and the types of metamorphosis are very involved, implying distinctive differences in the mode of life before and after metamorphosis. Since the individual larvae present characteristic features, each for its own class, it may be assumed that the modifications which each has undergone are departures from a common stock that existed long ago in simpler and more primitive form than any living echinoderm now displays. From the characters that are common to the various types of development, it has been possible to reconstruct a hypothetical ancestor which has been called "dipleurula." From it, or some similar form, it may be presumed that the modern larval types were derived.

The distinctive characters of the echinoderms are the adult radial type of symmetry (secondarily bilateral) following the embryological bilateral arrangement, and the unique water vascular (ambulacral) system which arises from the differentiation of the coelom. It is to be noted also that the muscle cells, connective tissue and skeletal plates are all of mesodermal origin. These characteristics of the adults, in addition to the active phases of larval life, are the bases both for the interpretations of the larvae and for the reconstruction of the hypothetical dipleurula.

The dipleurula is conceived to have had the following features: the symmetry was bilateral; the locomotor organ took the form of a longitudinal ciliated band with preoral and anal loops; the alimentary canal, with mouth, narrow oesophagus, globular stomach and narrow intestine was derived as an invaginate archenteron from a coeloblastula. The widely open blastopore was posterior in position and later became the anus, while the mouth appeared at the opposite end as a new structure (hence the name, deuterostomia). As the embryo bent upon itself, the mouth was carried to a new position which became ventral. The coeloms arose as two pockets evaginating outward from the primitive gut. They opened to the exterior through a dorsally directed ciliated tube (sometimes there were two) called the stone canal. From the coeloms the water-vascular system was differentiated.

The living form which is most nearly like the dipleurula is the ophiopluteus. (The name pluteus was given to larvae of the ophiuroids by Johannes Muller because he inverted his specimens uhich he had not seen alive and thought they resembled painters' easels. The term pluteus was also applied to the larvae of the echinoids because they are of quite similar appearance) (fig. 31). Long arms with skeletal rods give these larvae their shape and distinguish them from the other types found in echinoderms. But if the arms are disregarded, all of the types look surprisingly alike and are easily comparable with the dipleurula. As the larvae grow toward maturity, the arms are gradually absorbed.

The most important transformations which the bipinnaria of the starfish display are clearly those concerned with the coeloms (figs. 29, 30). In bipinnaria the right and left coelomic cavities fuse anteriorly around the oesophagus while partially constricting into two, sometimes three, parts posteriorly. Then the hinder part of the left anterior coelom grows to form a five-lobed swelling, the first trace of the hydrocoele. It is the beginning of the water-vascular system. Meanwhile the eight arms of the bipinnaria have formed, a median ventral and a median dorsal, a pair each of anterior dorsals, posterior dorsals and postoral arms. The bipinnaria swims about for perhaps two months, after which it settles



(33) FROM MORGAN IN "JOURNAL OF MORPHOLOGY" (WISTAR, 1891)

Fig. 29.— Young bipinnaria of *Patiria* in a condition comparable with a young dipleurula. Ciliated bands and three-part alimentary tract are shown. Fig. 30.— Older bipinnaria redrawn from Leuckart's chart. Pre- and postoral ciliated bands, the arms and the three part alimentary tract are shown. Fig 31.— An echinopluteus redrawn from Leuckart's chart. Its parts are comparable with those of a bipinnaria. Fig. 32.— Brachiolaria of *Patiria* from left side. Semidiagrammatic. The hydrocoele is shown in solid lines with the beginning of the radial buds that are to develop into arms and show radial symmetry. Alimentary canal drawn in dotted lines and anterior and posterior coeloms with short dashes. Position of fixation disc is at left end. Fig. 33.— A tornaria larva of *Balanoglossus* from the left side The anterior ciliated band is folded both in front of and behind the oesophagus. The posterior band is a simple circlet. Gill slits (g) are shown in the wail of the oesophagus. Of special importance are the anterior enterocoeles (e1), and the paired second (e2), and third (e3) enterocoeles. A, apical organ; m, muscle band leading to enterocoele; s, stomach; I, intestine; w, water pore

to the bottom to become an attached brachiolaria (fig. 32). The brachiolar arms appear, there being of these a median dorsal and two laterals. This partly-transformed larva fastens itself by the fixation disc near the anterior end, and that portion is thus converted into a stalk for the growing left, posterior swelling that is to become the disc of the starfish. Into the latter the lobes of hydrocoele project. In the disc also the other coelomic structures, the mouth, oesophagus, stomach and intestine develop. But the relations of the mouth, oesophagus and anterior coeloms are altered, for the anterior parts that formed the stalk are resorbed into the growing disc. The new mouth appears in such a way as to make the left side of the larva become the oral side of the adult. The hydrocoele separates entirely from the other parts of the coelom, puts out processes that grow to form the radial canals, the tube feet, and other ambulaceral parts. Thus the distinctive water vascular system arises in these larvae, and the peculiar symmetry of the starfish is explained.

The egg of the sea urchin corresponds in its development to that of the starfish through the stages preceding the formation of the echinopluteus. After gastrulation, right and left vesicles appear as outgrowths from the gut and from them the coeloms develop. The sides of the larva flatten in such a manner that it becomes wedge-shaped and is sometimes known as the prism larva. A stomodeum breaks through from the outside and connects up with the primitive gut whose blastoporal opening forms the anus. Lobes, or arms, develop, supported by calcareous skeletal rods. The first arms are postoral, the second are the anterolateral, then follow the preoral and finally the posterodorsal.

After some weeks of increase in size, the larva goes to the bottom and transforms into a young sea urchin. The hydrocoele develops from the anterior section of the left side. It grows, curves on itself, its ends join to make a ring, which is the ring canal of the water vascular system. From the ectoderm opposite it a depression forms and deepens. Its sides fold upward, and close together, thus making a sac the outer part, or roof, of which is the amnion. On the floor of this sac the spines and tube feet are formed and into them the hydrocoele then branches. The adult mouth, unrelated to the larval mouth, appears at the centre of the floor of the amniotic sac. This portion of the larva is spoken of as the echinus rudiment. It grows, presently becoming the entire side of the larva. Then the amniotic covering is absorbed and the tube feet project freely. Further changes are passed through rapidly, the larval arms are absorbed, the ciliated bands disappear, and there is left a small flat disclike animal which is the young sea urchin. The metamorphoses of the starfish and sea urchin larvae illustrate the processes as they occur in the echinoderms. For further details, and for the special embryology of the other echinoderm classes, the reader must be referred to more extensive accounts than can be given in the space here available.

The final larva of the Deuterostomia, and of the entire list, is the tornaria of *Balanoglossus* (fig. 33). Strictly speaking, this animal is regarded as the chordate of lowest development, but it bridges the gap between that group and the echinoderms, and this fact justifies its mention in connection with invertebrate embryology. It also emphasizes the relationship of the vertebrates to the invertebrate groups. Some animals belonging to the genus *Balanoglossus* develop directly without the formation of a tornaria. Others display variations in the details of the larval morphology. But the correspondence to the basic structure of the dipleurula is sufficient to establish the relationship to the satisfaction of most authorities of our day. The tornaria resembles the larva of the echinoderm so closely that it could easily be mistaken for one of them. (The name was originally proposed by Johannes Müller in 1848 as a generic name.) But in contrast to the radial symmetry of the adult echinoderm, it transforms into an animal that is wormlike and bilateral. Some workers feel that the Enteropneusta, to which this genus belongs, should be separated from the other chordates and given a separate status; but in any case, the relationship is clear enough to warrant the inclusion of them and the other chordates into the Deuterostomia.

Modern embryological research has thrown light on the structural development of animals, upon the varied functions which animals perform, upon taxonomic relationships, upon the phylogenetic and evolutionary tendencies both of individuals and of the different larger groups including phyla, and upon the nature of living processes. The transformations of a one-celled egg into a complex multicellular organism are expressions of the activities of the living stuff itself, and their study offers one of the best approaches to the understanding of the nature of that stuff, protoplasm.

During the period from Von Baer to Balfour, embryos, including invertebrates, were studied morphologically. The structure of organs in their different stages and their bases of organization were gradually worked out with the aid of the cell theory and the evolution doctrine. Then Balfour, by comparing the development of the systems of different groups of animals, made embryology comparative and derived many of the principles now familiar. After that time (1881), experimental embryology, cytology, general physiology and genetics clarified many of the problems raised by the older embryologists. Therefore the embryology of our day has only a basis in morphological discoveries (many of which still demand further research); present day students pass on from morphology to functional studies, evolutionary, genetic and now chemical.

Much that is known of genetics is based upon invertebrates, especially insects, and the same is true of cytology. At the present time there is probably no question more puzzling than that of the manner in which the genetically determined characters of the fertilized egg become translated into the functioning structures of embryos and adults. Invertebrate embryology has its part in answering questions of this kind. Differentiation of embryos is an obvious process hut a very intangible one both as to its exact nature and the factors which bring it about.

Much research is now being directed to the solution of the influences that govern embryological development. Both invertebrates and vertebrates are used for these studies, and much of the work is experimental in method. The presence of "organizers" has been demonstrated by Hans Spemann and his school; these are chemical substances produced in early stages which condition the future development of a given region. There is a special division of the general subject which has been called "chemical embryology" (Joseph Needham); it indicates something of the direction further studies may take. Organic chemists are now finding it possible to correlate some of the features of protoplasm with peculiarities of the complex structural formulae they are now able to derive. Much more may be expected of this phase of study. Some somatic characters may now be related to definite genes in the chromosomes by the methods of both genetics and cytology. Already embryological studies have been made on some of these characters, and it may be assumed that many more will follow in the not distant future.

Thus invertebrate embryology is much more than an immense subject filled with detailed observations. It ramifies into the most significant phases of biology, unifying and integrating them and suggesting new directions for research.

See also EMBRYOLOGY; REPRODUCTION; METAMORPHOSIS and the articles on the various groups of invertebrates.

INVERURIE, a royal and small burgh of Aberdeenshire, Scot., situated at the confluence of the rivers Don and Urie, 16 mi. N.W. of Aberdeen by road. Pop. (1951) 5,057. Papermaking and the making of mineral waters and gloves are the chief manufactures; and it is the centre of a large agricultural district with a big bulb farm. It also contains railway workshops and is a summer resort.

To the N.N.E. near Old Meldrum is Barra hill where Robert Bruce is held to have defeated Comyn, earl of Buchan, in 1308. At Harlaw. about 3 mi. to the N.W., was fought in 1411 the great battle between Donald, lord of the Isles, and the victorious royal forces under the earl of Mar. Not far from the scene of this conflict stands Balquhain castle, a seat of the Leslies, now a mere shell, which was occupied by Queen Mary in Sept. 1562 before the fight at Corrichie.

INVESTIGATION, CRIMINAL. Criminal investigation is that branch of criminal jurisprudence which applies the principles and practices of philosophical analyses, science, art and

technical skill in judicial proceedings, subject to legal rules and forms in which there must be elucidation of questions relating to crime. This covers the questions: who the victim mas; the exact place at which the offence occurred; how the crime was committed, with what weapon it was committed, or what were the means employed in its commission; what was the time of attack, what was the motive or object of attack, and the identity of the offender or offenders. Criminal investigation is employed also in the search for and interrogation of material witnesses who are able and willing to give competent and relevant testimony against the suspect or offender, and in the reconstruction of all facts connected with the crime in order that, at the trial of a defendant, a true picture of what occurred may be presented in such manner as to leave no doubt in the minds of the jurors or judge regarding the guilt or innocence of the accused.

History. — Although the beginning of criminal investigation is unknown, there is reason to believe that in a very rudimentary form it came into existence with the origin of legal trials. It is clearly laid down in the Code of Hammurabi that suspicion does not give ground for condemnation; receiving of testimony and even elaborate examination of sites or circumstances by the court itself were established rules of procedure.

In Athens, by about 500 B.C., the examination of facts had become meticulous; a defendant, having lost his case, might bring suit against a witness for bearing false testimony and, if successful in his new suit, would go free of his earlier condemnation. In the Fuotinian legislation (6th century A.D.) evidence was so construed as to imply the co-operation of experts in certain cases. In the middle ages, whether in civil or in ecclesiastical courts, and generally in the commercial and customary tribunals, the weighing of evidence was as careful as it has ever been. The introduction, in that period, of courts of inquest whose object was avowedly to procure condemnations, such as those of heretics, and the survival of certain ancient uses of the ordeal have obscured the prevalence of careful taking of evidence in the middle ages.

In 1507 a penal code containing exact instructions as to evidence was issued by a bishop of Bamberg, and in 1532 the Caroline code of the German states contained provisions for the examination of criminals. In 1575 a French physician described the form in which judicial reports should be made in medico-legal cases, and at the close of the 16th century outlines of the method of testifying in such cases were numerous, especially in Italy. Toward the end of the 18th century legal medicine was recognized as a science. Mathieu Orfila, who occupied the chair of chemistry and medical jurisprudence in the University of Paris, was employed as an expert in judicial proceedings; in 1814 he published a *Traité* des Poisons. In 1689 Johannes Bohn, of Leipzig, published a work on the examination of wounds. the distinction between ante-mortem and post-mortem wounds. the different effects of death by injury, strangulation and drowning. In another of his works, published in 1704, he gives rules for the conduct of physicians during court testimony. During the latter part of the 18th century German scientists published numerous books on the subject. Lectures in medical jurisprudence were given at the University of Edinburgh in 1792, and in 1806 the university gave the title of "Professor of Medical Jurisprudence" to A. Duncan, Jr. Thomas Percival, with his *Medical Ethics* (1803), made himself one of the first noteworthy English contributors to medical jurisprudence. and was followed by John Gordon Smith. In 1823, Paris and Fonblanque published the first English work which associated the medical and legal professions. In 1836, Alfred Swaine Taylor published his Elements of *Medical* Jurisprudence, an authoritative work. The first Spanish treatise on legal medicine (1796–97) was written by Juan Fernández de Valles. In 1844, Pedro Mata of Madrid published the first edition of a work on legal medicine and toxicology, which, in the development of its subsequent editions, became the most important Spanish treatise on the subject. The fathers of the modern school of scientific investigation were Hans Gross, a professor of criminology; R. A. Reiss, of the University of Lausanne and Alfred Niceforo. Most procedure came to follow their principles.

The old trial-and-error method in criminal investigation was rapidly displaced in the 19th and 20th centuries by scientific methods, including the use of very highly specialized instruments. Philip Valois had initiated the modern police system of criminal investigation. In Paris, as early as 1327, he appointed *commissaires,* or royal officers, who were not part of the judicial system and who conducted preliminary examinations in the enforcement of police regulations. The *Maréchaussée,* a military police, was organized in 1356, becoming the Gendarmerie in 1720. The first modern police organization, however, was founded in London in 1829. Twenty-five years later the Paris civil police were reorganized on the London model. In 1830 all ungarrisoned Prussian cities were authorized to establish a police force.

Large police departments make two major divisions of their detective force. First, there are groups of detectives assigned to definite geographical areas and responsible for the investigation of crimes committed therein. Second are the specialized "squads" or "details," formed for the purpose of dealing with specific types of crime such as homicide, safe burglary, forgery, and confidence games. These investigators are expected to possess special sources of information and an intimate knonledge of the special types of crime together with an acquaintanceship with the physical appearance, haunts and practices of known criminals.

With the development of rapid means of transportation the scope of an individual criminal's activity became greatly enlarged, and jurisdictional boundaries of police forces often hindered the success of an investigation. To combat this trend local police forces maintain close liaison with their neighbours by means of such methods of communication as teletype, telephone, radio and television. In this manner the pursuit of a fugitive can be pressed by broadcasting his description together with information concerning his haunts and personal habits.

The complex organization of the modern state led to the establishment of large investigative forces within the various departments of the government. Thus, the military, post office, state and other departments maintain their own, independent investigative units to conduct inquiries into crimes affecting these departments. Since these investigations are often nation-wide in scope, an elaborate system of report writing, mutual co-operation and centralized control has been developed. These agencies are also better equipped to cope with such crimes as espionage and sedition, which are directed against the nation as a whole and which, consequently, assume the form of a widespread conspiracy. In addition, the character of modern organized crime has tended toward increasingly complex structure. A key group of criminals, centrally located, may have representatives in every large city. Local police forces can deal with the problem only in a fragmentary way. A national investigative agency can form a coherent and unified picture of the crime situation and take the necessary remedial measures with the co-operation of the local police departments. (A. Vo.; C. E. O'H.)

METHODS OF INVESTIGATION

General Principles. — The threefold aim of the criminal investigator is to identify and find the guilty person and to provide evidence of his guilt. He must proceed objectively to gather data and uncover facts which may be presented in court to establish the guilt of the defendant. The final test of the efficiency of an investigation is the presentation of the evidence in court. Does the evidence establish the fact that a crime has been committed? Are all the elements of the offense present? Can the defendant be identified? Can he be associated with the scene of the crime? Has the probative value of the evidence been fully realized? Have competent, credible witnesses been obtained? Can all these elements of the investigation be integrated to provide an orderly, coherent presentation of the case so that the guilt of the defendant is established beyond a reasonable doubt under the appropriate rules of evidence?

To accomplish this objective the investigation must be intelligently managed at its inception. At the scene of the crime the evidence must be regarded from two points of view. First, will

it enable the investigator to reconstruct the manner in which the crime was committed? Second, mill it provide clues to the identity of the culprit? Thus, the examination and collection of the evidence should be made with a view to preserving its validity and integrity for ultimate presentation in court. The following procedures are useful: examine localities with minute care; make measurements of places and things, and take photographs; never alter the position of, pick up, or even touch an object before it has been described in the report; note all points where traces of the crime or important details are to be found, *e.g.*, clothing, fingerprints, footprints, hair, stains, and marks caused by firearms or tools; record and check statements of witnesses; interview persons living or employed in the district; obtain preliminary information regarding the crime from the victim, relative, or interested person.

Identification. — The major concern of criminal investigation is the professional criminal — the recidivist, whose name will appear periodically on the arrest record. If his identity can be conclusively established, his later efforts at concealment can usually be thwarted. A system whereby the identity of the criminal can be positively determined at each arrest is an invaluable aid to the investigator. The qualities of an effective identification medium are the following: (1) it should be fixed and unalterable by deformation or replacement; (2) it should be found on every person; (3) it should be unique for each person; (4) it should be susceptible of being recorded in a simple manner; (5) the records should be classifiable so that each person has a unique position in the files.

The search for a valid identification medium has been a constantly recurring quest in the history of investigation. Tattooing, branding, physical description, measuring and photography have had their successive vogues. The latter three methods, still in common use at mid-20th century, were established as techniques of identification by Alphonse Bertillon, chief of the identification bureau of Paris. He is best known for his development of the science of anthropometry in which an individual is identified by means of his bodily measurements. In the Bertillon system of identification, which he introduced in 1882, identification is completely accomplished by a series of refined bodily measurements, peculiar markings such as scars, and personality characteristics. Bertillon's system was later discarded by most police departments in favour of fingerprint systems, but his descriptive methods are used by investigators as an excellent means of furnishing a minutely descriptive verbal portrait of an individual.

Large police departments possess an identification division where experts compile information which will assist the investigator in his work. The duties of an identification expert are as follows:

1. To ascertain identification of the perpetrator of the crime prior to his apprehension (a) by the use of the alphabetical index when the name of the offender is known; (b) by photograph when the criminal has been seen by his victim or by witnesses; (c) by the *modus* operandi of the criminal; (d) by the handwriting of the criminal; (e) by finger impressions left at the scene of the crime.

2. To ascertain identification of offenders after arrest (a) by the alphabetical index; (b) by a photograph, where no fingerprints have been taken; (c) by the *modus* operandi system connecting the arrested criminal with numerous other crimes; (d) by comparison of the criminal's handwriting with documents connected with criminal offences; (e) by finger impressions of the criminal found at scenes of crimes committed by him, of which he was not suspected by the investigator; (f) by the ten-digit fingerprint system when the offender has been previously recorded in the bureau.

Fingerprints. — Identification by means of fingerprints (*q.v.*) was removed from the realm of theory and made practical by Juan Vucetich of Buenos Aires in July 1891. A fingerprint registry was established by him at La Platte on Sept. 1 of the same year to supplement the Bertillon system, which at that time was found to be wanting in many respects. Later the Bertillon system was eliminated.

Vucetich divided all fingerprints into four primary groups. The first group (arches) consists of all those designs formed by curved ridges without angles or deltas, the ridges extending from one side of the finger to the other without recurving. The second group (internal loops) has the angle or delta situated at the right of the person observing it and the directive lines have their exit toward the left. The third group (external loops) has the delta situated at the left of the person observing it and the direction of the lines runs to the right. The fourth group (whorls) has two deltas and the directive lines circumscribe circular figures.

In 1900 E. R. Henry published the system of fingerprint classification which was later adopted by English speaking countries, Henry divided all impressions into four types, namely: arches, loops, whorls, and composites; (1) in arches the ridges run from one side to the other without backward turn or twist and, ordinarily, have no delta; (2) loops have at least one recurving ridge and at least one ridge between the delta and the core. In ulnar loops the ridges recurve toward the little finger; in radial loops the ridges recurve toward the thumb; (3) whorls have at least one ridge making a complete circuit; (4) composites are patterns having characteristics of two or more of the foregoing patterns.

By means of these primary groups or types and by using a method of ridge counting between conventional points of reference, a set of fingerprints can be represented by a formula and filed accordingly. In each system it is a relatively simple matter to search for a given set of ten fingerprints. It is difficult, however, to discover the identity of a person from a single finger impression left at the scene of the crime, even though the criminal's fingerprints are filed in the identification bureau.

At the scene of the crime the investigator endeavours to discover the criminal's latent fingerprints, which he can "develop" or make visible for photography. The latent print is a thin layer of perspiration or grease deposited in the pattern of the friction ridges. Hard, glossy objects such as glass and enamel paint present ideal surfaces for the development of latent fingerprints. Dirty objects and absorbent materials do not readily bear prints. On smooth surfaces the print is made visible by carefully applying a fine powder of suitable colour with a brush. The powder adheres to the small amount of fat present in the perspiration or to the grease which frequently lies on the fingers. Chemical treatment such as iodine fuming or a 5% silver nitrate bath is used to develop fingerprints of paper. The silver nitrate reacts with the sodium chloride present in the perspiration to give silver chloride, a light-sensitive substance that darkens on exposure to a bright light source to reveal the fingerprint outline. The developed print is photographed and retained in the files for subsequent comparison with the prints of suspects.

Modus Operan&. — Criminals have a tendency to use the same techniques in their operations. Often the procedure is highly characteristic and will serve to identify the criminal and enable the police to attribute a series of crimes to one offender. Classification of criminals by their methods of operation thus became a permanent and invaluable feature of investigation. Some departments use the Atcherley *modus* operandi system for this purpose. L. W. Atcherley, originator of this system of classifying criminals according to their *modus* operandi, utilizes the following classes:

(1) Classword — Kind of property attacked, whether dwelling house, lodging house, hotel, etc.
(2) Entry — The actual point of entry, front window, back window, etc.
(3) Means — Whether implements or tools used, such as a ladder, jimmy, etc.
(4) Object — Kind of property taken.
(5) Time — Not only time of day or night, but whether church time, market day, during meal hours, etc.
(6) Style — Whether criminal describes himself as mechanic, canvasser, agent, etc., to obtain entrance.
(7) Tale — Any disclosure as to his alleged business or errand which the crlminal may make.
(8) *Pals* — Whether crime was committed with confederates, etc.
(9) Transport — Whether bicycle or other vehicle was used in connection with crime.
(10) Trademark — Whether criminal committed any unusual act in connection with crime, such as poisoning a dog, changing his clothes, leaving a note for the owner, etc.

Police Files. — Informational files are maintained by police departments to assist the investigator in his efforts to trace the fugi-

tive from justice. The primary purpose of these records is to indicate the source of evidence material discovered in connection with a crime. For example, a file of automobile tire patterns will assist in identifying a tire impression found at the scene of a crime. Automobile registrations and records of firearms will assist in establishing ownership. In addition to their own files the police have recourse to the records of the many governmental agencies that record titles, contracts, significant events, and official acts in general. Among other files maintained by the police the following prove exceptionally useful:

Missing Persons.—Each year thousands of persons are reported missing to the police. In addition, the police must investigate cases of unidentified persons, living and dead, since a suspicion of foul play is often present. Ordinarily the police are not concerned with adult missing persons unless they are wanted for the commission of a crime. Descriptive files are maintained of missing persons under the age of twenty-one, unidentified dead, and unidentified persons who are physically and mentally afflicted.

Laundry and Dry Cleaners Marks.—One of the best clues to the identity of an unknown person is the mark in his clothing placed there by the laundry, dry cleaner, or tailor. The dry cleaner, for example, identifies each article of clothing received by means of a set of numbers and letters. These marks are kept in a systematic file by larger police departments for the purpose of tracing a lost, dead. or wanted person by means of clothing, whether found on his person or at the scene of a crime. Each mark is associated with an individual laundry, dry cleaner's or tailor's establishment, which can often give the investigator the address of the wanted person. In many cities more crimes are solved by means of this file than through the medium of latent fingerprints.

Lost or Stolen Property.—Many burglaries are solved merely by tracing stolen property to the possession of the criminal. For this purpose police maintain a central cross-indexed file of property lost and articles of value pledged at pawnbrokers or sold to secondhand dealers. The common objects of larceny—automobiles, watches, jewelry, furs and cameras—usually bear identifying serial numbers or marks.

If the criminal disposes of the stolen article through a pawnbroker or a secondhand dealer, the police may trace him through the record of sale whicn is fonvarded to them by the dealer, as required by law.

Informants and Surveillance.—In combatting crime the police require an effective system of positive intelligence. Owners of licensed premises, cab drivers, bartenders, and others whose business involves contact with the public at late hours are excellent sources of information. Their co-operation can be enlisted without any difficulty because of the nature of their occupations. In some countries criminals, prostitutes, gamblers and other underworld characters are employed as undercover agents and report regularly to one or more contact officials. A safe burglar lavishly spending money; a bandit suffering from gunshot wounds; an automobile thief with stolen licence plates; a pawnbroker buying "hot stuff"—all these are types of instances reported to contact officials by undercover agents. Apart from the regularly employed undercover agents, individual investigators obtain information from criminals and other persons whom they have befriended.

It is customary in some courts for the judge to instruct the jury to weigh with extreme care the testimony of informers and accomplices, since their credibility is particularly vulnerable to attack on the grounds of character as well as motivation. In general, a conviction cannot be had upon the testimony of an accomplice unless corroborated by other evidence. A coniession of the accomplice cannot be used against another offender unless it is made in court or unless the confession was made in the presence of the accused and he made no reply or otherwise failed to deny it.

Where the services of an informant cannot be obtained, the investigator can initiate a surveillance of criminal activities. This may be done by covert observation or by arranging to have a police agent work within the criminal group, ostensibly as one of them, When this method is successfully employed, it is extraordinarily effective since it provides the direct testimony of a reliable witness. Past crimes can be solved and projected illegal ventures anticipated. Another form of surveillance is the "planting" of microphones and "tapping" of telephone lines. Radio communication can also be employed.

Legal difficultiesare encountered with evidence obtained through tapping telephones or planting microphones. The United States code prohibits the use of information acquired by tapping a telephone as evidence against an accused. if he is being tried in a United States district court. State courts are less rigorous in the limitations they place on evidence of this nature, some permitting the interception of telephone messages if a court warrant is first obtained. In regard to information acquired by means of concealed microphones, federal courts have ruled that such evidence is permitted if the microphone is installed without committing a trespass. For example, placing a contact microphone on the opposite side of the wall of the hotel room of a subject would not constitute a trespass.

Interrogation.— Since the purpose of a criminal investigation is to discover the truth of the facts surrounding a crime, obviously the shortest road to this goal is to obtain a confession from the guilty person and to elicit significant information from witnesses and informants. The skilful interrogation of a suspect is often the key to a successful investigation. Experience, shrewdness, patience, and imagination are required for effective questioning. Guile, forcefulness of character and practical psychology must be employed without resorting to duress or other violation of the suspect's rights. The interrogation is, therefore a delicate proceeding, since a confession obtained in violation of the suspect's rights can be repudiated in court.

The skilful interrogator briefly analyses the character of the subject and estimates his weaknesses. Experimentally he assumes different attitudes and employs various procedures to determine the most effective technique of questioning the subject. If he can enlist the subject's co-operation, a confession will be readily forthcoming. In the case of a reluctant or obstinate subject, he will endeavour to lead him into contradictions, inconsistencies and improbable statements, thus showing him the futility of continued deception.

The most difficult of all subjects is one who flatly refuses to talk about the case. In these situations, the investigator, who must respect the rights of the subject, is usually forced to abandon the interrogation and rely on other types of evidence.

Detection **of** Deception.—The act of lying is ordinarily accompanied by a bodily reaction such as flushing, increased heart beat, swallowing, or other evidence of emotional reaction. Some understanding of the practical psychology of lie detection has always been part of man's knowledge. The 20th century saw the introduction of a number of efforts to apply instrumentation to the art of detecting deception. These instruments are called "deception indicators" or "lie-detectors." Their function is to produce a record of physiological phenomena which may be used as the basis of applying a technique for diagnosing deception. The success of a deception indicator depends on the sensitivity of the mechanism, the phenomena chosen for record, and the ability of the operator.

It cannot be stressed too greatly that the greatest single factor in the success of a lie detection technique is the professional capacity of the operator.

The phenomena which should be chosen for recording are those that are not subject in any great degree to voluntary control and which, moreover, are such that the subject is not usually aware of them. Experts in the field consider blood pressure, pulse and respiration as the most dependable criteria. The electrodermal response or current flow between two different areas of the body is also considered useful. To these was added the unobserved muscular activity which has been found to affect the blood pressure. None of these phenomena is a sufficient indicator in itself, but taken together, their recording offers an effective means of determining deception. The blood pressure-pulse-respiration recorder employs pens to record impulses on moving graph paper driven by a small synchronous electric motor. A pneumograph tube is adjusted around the subject's chest and a blood pressure-

pulse cuff is strapped around the arm. The examiner first acquaints himself with the details of the case. He establishes norms of reaction by asking preliminary questions of an irrelevant nature and then injecting questions pertaining to the investigation. Three or four lie-detector records are ordinarily required for a diagnosis. A study of the graphical records and an evaluation of the deviations caused by certain responses will reveal unusual emotional activity. To attach significance to a given reaction the response must appear on at least two different test records.

Although the lie-detector test proved a great boon to the investigator, information obtained by this means is not generally accepted as direct evidence in the United States courts of law. Many of the court decisions denying recognition to this evidence have been based on the contention that the technique has not won general scientific acceptance. Confessions obtained consequent to but not as part of a voluntary lie-detector test have been admitted. In the event that these tests are accepted as competent legal evidence, it is anticipated that the question of compulsory tests will give rise to legal disputes as to whether they affect the subject's privilege against self-incrimination.

SCIENTIFIC AIDS

Police Laboratory.——With the rapid advance of scientific methods of analysis physical evidence such as paint, dirt, and fibres assumed increasing importance as sources of clues. After 1920 the larger police departments endeavoured to employ experts for the purpose of examining evidence at the scene of the crime and at the laboratory. These police scientists are distinguished from medical examiners in that the latter are ordinarily concerned with homicides and then only with regard to the cause of death and the nature of the fatal weapon. The police laboratory expert, however, must deal with a wide variety of crimes and with all the possible clue materials that can be used to provide evidence. The application of the physical sciences to the detection of crime is sometimes called scientific criminology or, more specifically, criminalistics. Chemistry, biology. and physics are the major branches of knowledge employed in examining evidence.

The physical evidence found in connection with a crime may be divided into two classes. In the first the evidence constitutes part of the corpus *delicti;* it is one of the essential facts of the crime. Thus the white powder found on the person of an alleged narcotics seller constitutes an essential part of the crime. It must be identified as being a particular narcotic such as heroin or morphine. Poisons and other substances used illegally fall into this category. The second class consists of associative evidence, clue materials which link a suspect to the scene of the crime and thereby establish a higher probability of his guilt. A suspect, for example, apprehended near the scene of a burglary may have glass fragments in the lining of his trouser cuffs. A spectrogrdphic analysis of the glass fragments may show that the chemical composition is the same as that of a broken glass window at the scene of the crime, thus connecting the suspect with the crime. Similarly a foot impression at the scene of a murder can be traced to the owner of a particular shoe; a flake of paint at the scene of a motor vehicle accident can be connected with a definite automobile; a tool mark can be matched with the defects in the blade of a burglar's jimmy. In all these comparisons the aim of the investigator is the same as that of the fingerprint expert: to discover a sufficient number of characteristics in the evidence to connect it uniquely with a known source by the laws of probability.

Chemical Analysis.— The forensic chemist ordinarily performs the relatively few biological examinations as well as the chemical analyses associated with criminal investigation. In cases of homicide the medical examiner makes the examinations connected with the autopsy and the cause of death. In the field of biology the chemist is primarily concerned with blood and semen stains. Semen stains occur in connection with rape cases, and their analysis is a simple microscopic examination to discover spermatozoa. Blood stains are found quite commonly in assault cases. A preliminary field test such as the benzidine or the phenolphthalein test is used to establish the probability that the stain is blood. These tests require only a minute stain area. The precipitin test, employing a larger area, may then be used to determine whether the blood is human. Depending on the amount, age, and preservation of the stain, the blood may be grouped into one of the four major divisions and in some cases into the subdivisions.

Micro-analysis is employed by the forensic chemist to study structures by means of the compound microscope. Minute quantities of trace materials can be identified and their source determined. Plants and animal tissues, vegetable, animal, and synthetic fibres, sand. soil, and minerals are recognized and their connection with the case under investigation is established.

Deposits found under fingernails and dust or stains found in or attached to clothing or weapons have furnished the investigator with significant clues. Hair can be identified as human and the race of the person determined from it. It is not, however, possible to identify hair as belonging to a single individual. At best a similarity can be established.

The most challenging problem of the police chemist is the analysis of a minute sample of evidence material such as paint or glass to determine the source of the substance. If sufficient trace elements and impurities are present. the evidence sample can be connected uniquely with the source material. A stain on a suspect's shoe can be shown to have been acquired at the crime scene. The spectrograph serves well in this work.

Instrumentation has provided other techniques of rapid chemical analysis such as X-ray diffraction, spectrophotometry, and electron microscopy. These instruments can deal with minute samples. which are often the only clue present, and can reveal physical or chemical characteristics so great in number, so diverse in nature or so rare in occurrence as to preclude all but a negligible probability of duplication by coincidence. They permit analysis nithout disturbing the sample, thus making it possible to keep the evidence intact for presentation in court and for tests by the defense.

Moreover, a police scientist does not have to be an expert in every branch of chemical analysis to use these instruments effectively. A reasonable familiarity with the techniques, the basic materials, the fillers, and the accidental trace elements of the industries from which his samples come is usually sufficient.

Photography.— Of the technical aids available to the investigator the camera is by far the most important and the most widely used. The full resources of photographic science are employed: photography through the spectral range from the infra-red region to gamma rays; photomicrography; microphotography; cinematography; orthostereoscopy; radiography in the hard and soft X-ray regions; and electron photomicrography. Six major functions are served by investigative photography: (1) for identification records, it provides a picture of the criminal or missing person; (2) in conducting a surveillance the, camera can be used to obtain a visual record of the illegal activities; (3) the original appearance of the scene of the crime can be preserved for the court's consideration; similarly, a re-enactment of the crime can be recorded in motion pictures for court demonstration; (4) the initial appearance of evidence can be photographed before it is submitted to necessary changes by the police laboratory; (5) the camera can be used to reveal hidden aspects of the evidence; by the employment of filters or magnification certain details and relationships of the evidence can be revealed and emphasized to prove a point in question; (6) to demonstrate investigative findings to the court the photograph serves as an invaluable visual aid. Court exhibits in the form of photographic enlargements vividly supplement the testimony of investigators and laboratory experts and provide a meeting ground for the contentions of opposing counsels.

Firearms.— In crimes of violence, the bullet or cartridge case found at the scene of a homicide is often the most valuable clue available to the investigator. From an examination of these articles of evidence the firearms expert is usually able to determine the type of ammunition and weapon employed. From his knowledge of ballistics (*q.v.*) and the characteristics of various types of firearms he endeavours to determine the distance and direction of discharge by examining the size and relative positions of bullet holes. The owner of a firearm left at the crime scene may often be determined by tracing the serial number from records of

Dear Marie,

I have your last letter. Sorry to hear about Al and his troubles, but thats the way Al is. When hes over it things will be different.

Marie, you can sell that piano if you think its in the way. Its getting old, anyway. Hold on to the accordion. I think I can use it when I get out.

I have a clerical job now, Marie, so youll be hearing from me more often.

Yours.

FINGERPRINT RECORDING AT THE FEDERAL BUREAU OF INVESTIGATION

1. Section of the fingerprint files department, where finger impressions are classified and compared
2. Electrical sorting machine which obviates the necessity of searching among large groups of fingerprints. punch cards bearing coded classifications are seoarated by electrical contacts
3. A child being fingerprinted in the identification division of the Federal Bureau of Investigation. The bureau maintains separate noncriminal files for civil identification

In the various fingerprint patterns illustrated, whorl types are shown in the left column; other types in the right column

But investment in a wider sense includes hoarding, since that too is an addition to the individual's capital, though in money form. His investment cannot therefore be different from his saving. Saving and investment are only different aspects of the same phenomenon. If we look at it as the part of his income which he does not consume we call it saving. If we look at it as the addition to his capital (which is what any unconsumed income must be) we call it investment. Every individual's investment is equal to his saving.

The Social Point of View.—Investment by an individual does not necessarily mean social investment. If an individual invests by buying a security there is no investment from the point of view of society because there is no addition to society's capital. The individual's private investment is offset by the equal private disinvestment of the man who sells the securities which he buys. Nor does hoarding by an individual constitute social investment. Any increase in the amount of money held by one individual must diminish the amount of money held by the others, the hoarding being offset by the dishoarding, unless the total amount of money in the economy is increased. And even in that case there would be no addition to the social capital, the issuing of new money being itself a kind of dishoarding by the monetary authorities.

On the other hand if an individual builds a new factory with borrowed money this is not private investment by him because his own wealth or capital is not increased by the value of the factory, but it is social investment because it is an addition to social capital. Although there is no reason why any individual's social investment should be equal to his private investment, the sum of all the social investment by the individuals (the total social investment) is equal to the sum of all the private investment by individuals, and so also equal to the sum of all the private saving (which is the total social saving). Total social investment is equal to total social saving just as any individual's private investment is equal to his private saving. This is because every divergence between an individual's private investment and his social investment is due to an equal and opposite divergence for somebody else. Only when an individual's private investment is offset by another's private disinvestment or when his hoarding is offset by another's dishoarding can there arise any divergence between an individual's private investment and his social investment.

Individual incomes can be considered either from the point of view of where they come from or from the point of view of where they go—either as income created in one way or another or as income available to be used in one way or another.

The first point of view shows that all individual incomes originate from the sale of goods and services and are created by the outlay of the purchasers. The goods and services are either consumed or not consumed. If any goods are not consumed they are additions to the social capital and constitute social investment.

The second point of view enables us to see that all incomes available to be used can be divided into the part that is spent on consumption and the part that is not consumed but saved—that is, into consumption and saving. The part of total income that is created by consumption must be equal to the part of total income that is spent on consumption, since these are merely two different aspects of the same transactions. It follows that the remaining part of the total income created—the total social investment—must be equal to the remaining part of the total income available to be used—the total social saving—and so also to the sum of individual private investment. Since total social investment and total private investment can never differ from each other, it is possible to speak simply and yet unambiguously, of total investment which is both social and private. It does not matter whether total investment is considered as the sum of individual private investment or of individual social investment.

But in the case of individual investment it is necessary to be very clear whether private or social investment is meant. Most of a prolonged discussion in the 1930s about differences between saving and investment was due to the use of mixed definitions, individual saving being defined as private saving while individual investment was defined as social investment.

Investment and Income—The decisions to undertake (private) saving and the decisions to undertake social investment are freely made by different people and in response to apparently quite different stimuli. But the fact that their sums are inevitably equal shows that there must be some connection which compels this equality and belies the apparent freedom. To some degree the compulsion takes the form of unintended social investment in swollen inventories forced on sellers by the saving of customers who restrict their purchases. But this can last only as long as the sellers acquiesce in increasing inventories. Much more important is the effect of social investment in making individuals save.

There is first of all the direct effect. An increase in social investment creates additional income and so there is inevitably an equal increase in saving. This direct saving can last only until the recipients of the additional income consume some of it. But as quickly as they consume it, so that their additional saving disappears, they create other income by this consumption expenditure so that the total rate of saving is not diminished at all and stays equal to the increased rate of investment.

The degree to which a change in investment will indirectly affect the level of income depends on the marginal propensity to consume. This is the fraction of any increment of income that the society will consume out of the increment of income, saving the rest of it. The marginal propensity to save is the complementary fraction. The ratio of the increase in income to the increment of investment is the inverse of the marginal propensity to save and is called the "multiplier." Thus if the marginal propensity to consume is four-fifths, the marginal propensity to save is one-fifth and the multiplier is five. An increase in the rate of investment of $roo (per week or per month) results in an increase in income of $500. Only when income has increased by this amount will the population feel that the additional $100 which it cannot help saving corresponds to what it freely and voluntarily wants to save.

The increase in income, which makes the public feel they are perfectly free agents in deciding to save just as much as is being invested, must be an increase in real income and not merely in the money value of the same real income through a rise in prices. Such a real increase is possible only if there are unemployed resources which can be put to work to produce additional real income. The multiplier measures the effectiveness of investment in increasing the national income in times of depression. The $100 of investment not only directly increases the accumulated capital wealth of society by this amount but indirectly results in an increase in output of consumption goods by another $400 which would otherwise have been wasted in unemployment.

The indirect benefit stems from the income-creating effect of the investment and will be just as effective even if the products produced directly by the investment should turn out to be completely useless—even if it consists of paying people for "digging holes in the ground and filling them up again." It is of course better for more useful things to be done, but because of the indirect benefits in increasing consumption and income it is better, in times of depression, to invest in completely useless activities than to permit resources to remain unemployed. There is however no need for such wasteful investment, even if no useful investments are possible, because additional expenditure on consumption is just as income-creating as investment. The multiplier works just as much on an increase in consumption as on an increase in investment. An investment of $100 by the government in subsidizing additional consumption by some deserving part of the population will also increase income by $500. Of this, $400 will be spent in buying additional consumption goods that would otherwise not have been produced while $100 will be saved parallel with the increased investment.

Special Definitions of Saving **and** Investment.—The inevitable equality of saving and investment has oppressed many economists who sought to discover a source of economic instability in differences between the two. The more careful of these have seen that it is necessary to give a special definition to at least one of the terms if reference to differences between them is to be meaningful.

Since saving is defined by all economists as the excess of in-

come over consumption, it is possible to redefine saving by redefining income. In *A Treatise on Money* (1931), John Maynard Keynes defined "normal" income as actual income exclusive of windfall profits. The resultant saving is therefore less than saving in the usual sense by the amount of these windfall profits and is less than investment by exactly the same amount. An excess of investment over such saving is equal to the windfall profits and an excess of saving over investment is equal to windfall losses. Such differences reflect important causal forces operating on the economy which cannot be expressed as differences between the usual saving and investment. But these forces can be discussed just as effectively without the special definitions by simply speaking of the effects of windfall profits and of windfall losses. When this was made clear Keynes abandoned his special definitions.

Professor D. H. Robertson found many followers in defining income as the income earned in a preceding period and consequently disposable for consumption or saving in the current period. His saving is consequently obtained by subtracting consumption from the income earned yesterday instead of from today's income, and differs from saving in the usual sense by the difference between yesterday's income and today's income.

This procedure is useful insofar as it draws attention to the income earned yesterday as one of many influences on today's consumption. But it tends to give excessive emphasis to this influence and encounters very great difficulties in trying to fit many different time lags into a single series of periods of days. It has led many to say that an excess of saving over investment causes income to fall when it does nothing but repeat in other terms the amount by which today's income is less than yesterday's. There seems to be nothing which this difference between saving and investment enables us to say that cannot be said more clearly in explicit statements about changes in income from period to period.

Professor Gunnar Myrdal and the Swedish economists distinguish between *ex ante* and *ex post* concepts of both saving and investment. *Ex post* saving and *ex post* investment are the actual saving and investment that take place as they would appear to anyone *ex post* or *after the event,* and are inevitably equal to each other. *Ex ante* saving and *ex ante* investment are the amounts that the public expects to save or invest — in each case *ex ante* or *before the event.* Since expectations may be in error there is no need for these to be equal to their *ex post* counterparts or to each other. It is therefore possible to speak without self-contradiction about differences between saving and investment if these are defined as *ex ante.*

In an economy where all expectations are fulfilled there is no difference between *ex ante* and *ex post* and there cannot be any difference between saving and investment even *ex ante.* A difference between them, therefore, indicates that we are not in such a society because it means that the expectations are inconsistent with each other and therefore cannot both be fulfilled. But it does not tell us how the expectations mill be falsified or in what direction. Furthermore, the absence of any difference might merely mean that equal errors are made in both sets of expectations or that correct expectations about saving and investment are accompanied by serious instabilities in the level of income because of inconsistent expectations about other important elements such as the level of consumption.

All the advantages of *ex ante* analysis are obtained more simply and more thoroughly by R. G. Hautrey *(Capital and Employment,* 1937), who speaks of planned or active investment and saving. Unintended or passive investment can take place when sellers find they have unwittingly invested in stocks that they had expected to sell, and unintended saving can take place when there is an unexpected increase in one's income or a failure to spend because of the temporary unavailability of goods to buy. This procedure enables one to consider separately all the unexpected elements, positive and negative, which are merged in their algebraic sum called the difference between *ex ante* saving and investment.

Net and Gross Investment. — The definition of income as the amount that can be consumed without eating into capital is not quite free from arbitrariness. Capital is a variable collection of many different kinds of things, some of which are worn out and replaced by others and even by entirely new elements. There is always some arbitrariness in deciding just how much of the total output must be considered as replacing the disappearing old elements. Saving and investment suffer from the same arbitrariness because the definition of saving is derived from that of income, and because the definition of investment as additions to capital means additions over and above the replacements necessary to keep the capital intact.

This arbitrariness is not of practical significance since the same conclusions always follow, no matter where the line is fixed from which income, saving and investment are to be measured, as long as the same line is applied to all three concepts and is not moved in the middle of the argument. The arbitrariness can be avoided altogether by considering *gross investment* which includes all expenditure on output which is not consumed, whether it is needed for replacement or not; *gross income* which includes the expenditure on all output whether consumed or not (*i.e.,* it is equal to the sum of gross investment and consumption); and *gross saving* which is the excess of gross income over consumption, and which is always equal to gross investment.

The Determinants of Investment. — The volume of investment, together with the volume of consumption, make up the income of society and determine the volume of output and employment. Investment comes to much less than consumption but it is of special importance for problems of employment because investment is much more variable than consumption and the changes in consumption are themselves due to changes in income brought about primarily by the multiplier operating on changes in the volume of investment.

The volume of investment in society is determined by the decisions of the entrepreneurs who undertake social investment. These decisions themselves depend on the entrepreneurs feeling that the chances of gain outweigh the risks of loss. While subtle psychological influences are very important in colouring the entrepreneurs' judgments, there are several general objective elements that are also important in determining the volume of investment.

The volume of investment will be greater if the level of income is greater because this means better prospects for the success of any venture as well as a more optimistic entrepreneur. It will also be greater if the rate of interest is lower because among the costs must be reckoned the interest on the capital invested. Even if the investor invests his own capital, so that he does not have to borrow it and actually pay interest, he must count among the costs of the investment the interest that he could have earned by lending out his capital instead of applying it to social investment. This element is not as important as it used to be because with the modern rate of technical advance in many fields an investment must often pay for itself in three or four years or less. For such short periods the interest becomes unimportant in relation to the capital amortization that must be earned, especially at the low rates of interest that monetary authorities are likely to maintain to facilitate the management of the enormous public debts incurred during World War II.

The Marginal Efficiency of Investment. — The relationship between the volume of investment and the rate of interest can be illustrated by a curve or schedule showing a greater rate of investment for lower and lower rates of interest. Relative unimportance of the rate of interest would mean that changes in it would result in relatively small changes in the rate of investment. At any rate of interest the rate of investment would adjust itself to the volume where the yield on an increment of investment which is the *marginal efficiency of investment* is just equal to the rate of interest.

The marginal efficiency of investment is frequently called the "marginal efficiency of capital," following Keynes who first clarified the concept but gave it this unfortunate title which suggests that it is a function of capital rather than of investment.

The actual connection between capital and investment is that as investment takes place the capital of society is being added to uhile the opportunities of profitable investment are being used up. This has the effect of lowering the whole schedule of the marginal

efficiency investment, diminishing the rate of investment corresponding to each rate of interest on the schedule.

The Mature **Economy.**—Other forces tending to diminish the opportunities of profitable investment are the declining increase in population and the end of the frontier of free land. This means that the investment opportunities used up as the capital grows are no longer being recreated to the same extent by an increase of the other factors, labour and available land. A recognition of this has given rise to the notion of the mature economy. in which consumption can be increased because resources need no longer be used up so much in investment (and in which consumption must be increased if the decline in investment is not to cause extremes of unemployment).

Many economists have tried to belittle the argument by pointing to the investment opportunities to be provided by the increasing rate of new inventions. This overlooks an important change in the nature of inventions. In the 19th century most inventions resulted in the substitution of production with complicated machinery for production by hand and so created vast opportunities for investment in providing the machinery. In the 20th century, inventions result more and more in the substitution of one kind of machine production for another. Whether an invention increases investment opportunities or decreases them depends on whether the new machine absorbs more capital than the old one. It is .impossible to say beforehand which kind of invention is likely to predominate.

Investment Policy.—Investment policy consists of governmental measures for encouraging or discouraging either particular investments or the rate of investment in general. Discouragement of investment is easily accomplished by taxes, by credit restrictions, by curtailing supplies, or even by direct prohibition. It is important only when demand threatens to outstrip supply as in times of wartime shortages. Investment policy is nearly always concerned with the encouragement of private investment or the direct undertaking of public investment.

Some people believe that only private investment can safely be expanded while others believe that only public investment can work in the general interest. The experience of public investment in the depression of the 1930s and in World War II has tended to make the partisans less extreme so that more and more would allow the kind of investment they disapprove of to be undertaken in cases where it can clearly be shown to work much better than the other kind. This is only a step from the rational view that both kinds of investment are periectly legitimate and that each should be able to supplant the other wherever it is more efficient in serving society.

In capitalist societies it is still felt that public investment needs special justification, such as that without public investment some useiul investment would not be undertaken at all.

In time of depression this special justification is satisfied not only by highways and flood control and the like, hut by any kind of investment that provides employment for workers who would otherwise be unemployed. The public investment is of great social useiulness, even if the immediate product is not counted at all, because of the multiplier effect in increasing employment in the production of additional consumption goods.

Such benefits are not limited to investment but flow from any kind of additional expenditure. They derive not irom the direct addition to social capital but irom the income created by the additional expenditure. The recognition oi this has led to an extension of the word investment to cover additional expenditures even if they do not directly add to social capital. When men were employed by the government in the depression to rake leaves, the expenditure was called government investment because the effects of providing employment and increasing the demand for and output of consumption goods were just the same as if real investment had been taking place and these effects were much more important than whether or not real investment—additions to social capital—was taking place.

This extension oi the meaning oi investment can be reconciled with its relationships to income and saving by redefining investment as expenditure (in this case by the government) other than on goods currently being consumed. Normally this will mean expenditure on goods that are produced but not consumed so that they are additions to the capital stock, but the definition also covers the case where the expenditures are made without bringing about any addition to social capital. This is not so serious a perversion of language because whether any investment will in fact bring about an addition to the social capital is always a matter for the iuture. There may in the end turn out to be no real useful increase in social capital, even if the investor's intentions are of the best. The future useiulness of any investment may be destroyed by fire or flood, by new inventions or by competing investments, or may simply have been misguided in the first place.

As it becomes clearer that investment is important for employment policy only as one of several forms of income-creating expenditure, it becomes more and more possible for governments to maintain a satisfactory level of employment without having to disguise their operations on total expenditure as investment. Thus in March 1945, the Swedish Postwar Planning commission, headed by Gunnar Myrdal, proposed to combat unemployment in depression by subsidizing the sale of clothes and household equipment, on the theory that these are more useiul than investment in digging holes in the ground and filling them up again. The completion of this process of clarification will enahle the kind of expenditure to be supported which is socially most useiul even if it means increasing the output of even less durable goods than clothes and waffle irons.

INVESTMENT BANKING. Business enterprises attempt to make a profit by rendering a product or service more want-satisfying than its competitors and by selling it at a price higher than its cost of production. This process requires an extensive variety and large amounts of physical goods. Enterprises assign to each physical object in use a value, stated in the currency of the country in question, combine these objects into groups and list the value of these groups of objects on the asset side of their balance sheets. These assets represent purchases made with cash obtained from various sources. Assets are spoken of as uses of funds. The sources from which funds are acquired are listed on the opposite side of the balance sheet and are designated as liabilities and capital. . The part which investment banking plays in the acquisition of business funds can be described in two ways. (1) In a broad sense, investment banking includes all the institutions and processes by which capital formation takes place, including: (a) the transfer of ownership of existing wealth through brokerage houses; (b) security substitution, such as is involved in the issuance of securities by investment companies; and (c) security management, or the decision as to where investors' funds are to be placed. (2) In a narrower sense, investment banks are firms which originate, underwrite and distribute new security issues of corporations and government agencies.

Investment banking requires an understanding of the place of the corporation in modern economic society and of the organization of the market for funds within which investment banking makes funds available.

It is often said that modern production is "capitalistic," that it requires large amounts of physical capital, of assets, of funds used. This need for funds explains to a significant degree the shift from the sole proprietorship and the partnership to the corporation as the dominant legal form of business organization. Individual proprietorships and partnerships can for the most part look only to their owners, one or a few, as sources of funds. Corporations can obtain funds from thousands and hundreds of thousands of owners (shareholders) and can obtain these funds by varying the terms of successive stock issues in such a manner as to make the most effective appeal to prospective stock purchasers. In addition, corporations can borrow funds and can tailor their debt contracts to the requirements of lenders. The corporation has access to larger amounts of funds because it can offer a greater variety of security contracts and thus can adapt itself to the willingness or unwillingness of investors to take risks. Bonds (debt contracts) can be offered when investors demand safety; stocks (equity contracts) can be sold when investors are willing to take greater risks for the opportunity of greater gains.

The market for funds, the commodity with which investment deals, is made up of the demand for funds and the supply of funds. Three important component parts of the demand for funds may be distinguished. The business demand for funds has already been mentioned. Similarly. governments and public authorities demand funds for the construction of public buildings, highways and governmentally owned utility plants. Third, consumers enter the market to borrow funds to finance the purchase of homes and other durable consumer goods. The supply side of the funds market is made up of four constituent parts. Individuals save portions of their disposable income and make them available in the funds market through the purchase of bonds, stocks and mortgages. Financial institutions (insurance companies, savings and loan associations. investment companies) and nonfinancial institutions (churches, hospitals, universities) receive funds from individuals and make them available to fund users by buying securities. Business corporations provide funds by retaining portions of income earned and using this income to purchase operating assets, thus supplying some of their own demand for funds And governments may provide funds by collecting taxes in excess of current revenues and investing the funds in outstanding government security issues.

Institutions in the Funds Market. — It has been pointed out that individuals, financial institutions and government; operate in the market for funds. The financial institutions referred to in this sense are sometimes called fund-aggregative institutions. They obtain funds through some form of arrangement with those whose investments they manage. For example, insurance companies obtain funds through the receipt of premiums on policies; commercial banks and savings banks receive deposits; and savings and loan associations and investment companies sell shares. These institutions then purchase the bonds and stocks of governments and corporations which are in the market for funds on the demand side. Institutions operating in this manner gather together the small funds of many individual investors and attempt to provide such investors with a better diversification and a more skilful management of funds than the individual could have achieved through his own efforts. Individual savers, rather than buying bonds or stocks of operating companies directly. also place their funds with financial institutions oi the fund-accumulative type. which in turn offer them in the funds market.

This means that corporations and governments seeking funds must take note of this trend and adapt their security offerings to the requirements of these institutions.

A second class of financial institutions in the field of investment banking engages in the marketing of securities rather than holding them for investment. Such institutions are not on the supply side of the market, as are the fund-aggregative institutions. Rather, they are in between those who demand the funds and those who supply them; they endeavour to bring the two sides of the market together with as little friction and as low a cost as possible. Securities marketing institutions are divided into two groups: institutions which facilitate the original distribution of securities from corporations to investors; and those which assist investors to trade among themselves in securities which corporations have issued some time in the past. Marketing institutions which purchase security issues from corporations and sell them to investors are often spoken of as investment banking firms, but it should be noted that investment banking in the proper sense encompasses all the institutions, processes and procedures by which funds are transferred from savers to users. Marketing institutions having to do with "old" or already-issued securities are in turn subdivided into two classes: the securities exchanges, together with the members and member firms which buy and sell securities on the floors of these exchanges; and the over-the-counter market, made up of security brokers and dealers who buy and sell through contacts provided by the telephone, the telegraph and the teletypewriter.

Financial houses dealing in securities which have been outstanding for some time aid in the transfer of funds in several ways. Corporations desire to have their outstanding securities sell at as high prices as possible since the prices of these securities determine the prices at which new securities can be issued and thus determine the cost of new funds. For example, if a corporation's stock is selling at 40, the firm cannot sell a new issue of stock having the same contractual features at 60, for no one would buy it. Often a corporation will find it to its advantage to list its securities on a securities exchange. (*See* LISTED SECURITIES.) Trading on the floor of an exchange takes place among individuals who are members of the exchange. Those who are not members can use the facilities of the exchange by employing a member, through a member firm of which the exchange member is a partner, to trade on the floor for a commission paid to the member firm. (See STOCK EXCHANGE.)

The securities of most corporations are not listed on an exchange, but are bought and sold among investors through purchases irom and sales to dealers. This is the over-the-counter market. A dealer may buy a security from an investor and sell it to another investor. or may sell it to another dealer who in turn sells it to one of his investor clients. Most small and medium-sized corporations find that theinterest in and sponsorship of their securities provided by a dealer serves to maintain prices at higher levels than if the securities were listed. Practically all trading in government bonds and most trading in corporate bonds takes place in the'over-the-counter market. Since the stock issues of the largest corporations are listed on exchanges and since the stocks of these companies are traded in more frequently. it is probable that the volume of trading in stocks on the exchange exceeds that on the over-the-counter market, but many classes of stocks are traded predominantly in the over-the-counter market) particularly the stocks of insurance companies, banks and mutual investment companies.

Acquisition of New Funds. — The next consideration is that of investment banking in the narrower sense, the origination, underwriting and distribution of new security issues. Corporations obtain funds from two major sources on the basis of the term of the contract with the supplier of the funds. Short-term funds which must be repaid within one year are obtained from commercial banks, from trade creditors and from the government in the form of accrued tax liabilities. Long-term funds are obtained from individual and institutional investors through the sale of securities to these investors. These funds may be acquired from investors as creditors through the sale of bonds and mortgages, or from equity investors through the sale to owners of shares of stock or through the retention in the business of earnings which might have been paid to the owners as dividends. It is the function of investment banking firms operating in the new-issue market to assist corporations to acquire new long-term funds. Corporations use these iunds to enlarge their operating assets or to pay off maturing security issues.

The investment banking house operates by purchasing all of the new security issue from a corporation and selling the issue in smaller units to the investing public. It buys from the corporation at one price and attempts to sell to investors at a higher price, a price sufficiently high to cover expenses of sale and leave a profit. Since the expenses of undertaking the sale may be relatively large for small issues, small and new corporations often find it uneconomical to pay the required "spread" of the investment bankers. Such corporations may obtain funds privately by sale of stock and bond issues to friends and relatives of the management and to employees without the intermediation of an investment banking firm. In other cases investment banking houses decline to assist new and small companies because they believe that the risks of investment in these companies are too great, and they are unwilling to recommend to their clients that the securities be purchased. As a result, investment banking firms are used to a much greater extent by companies which have lived through the first few difficult years, are now able to present a good earnings record and show promise of being able to make profitable use of additional funds.

Often a corporation seeks funds from its common stockholders by offering them the opportunity to buy more shares of the common stock issue presently outstanding. These shares may be offered to present shareholders at a price of, say. 40 even though the price of shares currently outstanding is 50. If the price falls be-

low 40 before the new shares have been sold, the corporation will be unable to sell any more at the offering price, the stock offering will be a failure and the corporation will not have all the funds it planned to acquire from the issuance of the shares. To meet such a contingency the corporation will make a contract with an investment banking firm whereby the latter agrees to buy from the corporation at a price of 40 all shares which, by a certain date, have not been taken by the stockholders. In this way the corporation is assured of getting the funds it needs. The investment bank is paid a few cents a share for assuming the risk that it will have to take the shares, and a larger compensation per share for those shares which it has to take at the end of the period and sell to the general public. This arrangement is often called a pure underwriting contract or a stand-by underwriting.

'The Mechanics of Underwriting and Distribution.— The typical underwriting arrangement involves the purchase of a security issue from a corporation by an investment banking firm or a group of such firms! and the sale of the issue to the general investing public, institutional investors as well as individuals. This procedure is followed in the case of bond issues of corporations as well as for stock issues which are not required by law or by decision of the board of directors to be offered first to old shareholders. The first step in the origination of a new security issue is a conference between officials of the corporation and the investment banker to determine whether the issue is feasible. The buying department of the investment bank conducts a preliminary investigation and decides whether the assets and earning power of the corporation are such that it can recommend the securities of this company to its clients. This action is followed by conferences in which it is decided what amount and type of security is best suited to the corporation's needs. When this has been accomplished the formal documents in connection with the issue are prepared. In the United States the issue must in most cases be registered with the federal Securities and Exchange commission. Also a prospectus describing the security must be prepared and sufficient copies printed so that a copy may be given to each investor considering purchase. The arrangements between corporation and underwriters are set forth in a purchase agreement.

The underwriting and distribution of most security issues involves the organization of two groups or syndicates of investment banking firms. The first is called the purchase or underwriting group. When a corporation puts out a $100,000,000 bond issue no one investment banking firm nishes to take the risk of purchasing the entire issue. Therefore the investment bank which initiates the issue with the corporation organizes a group of investment bankers to divide the liability for the purchase, with the originator acting as manager of the group. Each member of the purchase group agrees to take a specific part of the entire issue. This arrangement is formalized in a contract called a purchase group agreement, or agreement among underwriters.

In addition to the underwriting group, the originator forms a selling group whose function is wholly one of distribution. Distribution is effected both by the purchase group and by the selling group. The members of the purchase group reserve portions of the issue for themselves and distribute these amounts through their own merchandising facilities. The remainder of the issue is "given up" to members of the selling group. The selling group members buy from the purchase or underwriting group the amounts given up by this group and sell them to investors. Generally the selling group has more members than the purchase group. Members of the selling group are widely distributed geographically and are selected on the basis of their ability to sell the issue rapidly. The members of the purchase group may be thought of as wholesalers who purchase from the "manufacturer" (the issuing corporation), who sell some of the issue themselves to large "consumers," particularly institutional investors, and who sell the remainder to retailers nho in turn sell to small investors.

Determining the Price.—One of the most important problems in security distribution is the pricing of the issue. There must be a decision first on the public offering price, the price which investors are to be asked to pay. If this price is too high. the issue will not be sold and the purchase group will bear a heavy loss. If the offering price is too low, the issue will be sold quickly but it will be traded in above the offering price immediately after issuance and the corporation will be dissatisfied with the price received. The major responsibility for setting the offering price rests on the investment bank, since it is in close contact with the market and is best able to judge the probable demand for the issue in question.

The underwriters pay to the corporation a price which is lower than the public offering price by the amount of the spread. The spread is affected by the costs which the investment bankers anticipate in marketing the issue, by the difficulties foreseen in selling the issue at the offering price and by competition among investment bankers to obtain the issue for sale. The spread is divided into three parts, a fee to the originator of the issue, compensation to the members of the purchase group for undertaking the risk and a commission to the members of the selling group for selling the securities to investors. When new securities are to be issued the investment firm having close contact with the corporation is likely to be asked to originate the issue. This process is often called private negotiation. An alternative arrangement is competitive bidding. The corporation may itself settle upon the terms of the issue to be offered, and then invite all banking firms to submit bids. The issue will be sold to that firm which bids the highest. Competitive bidding has increased in importance in the United States, partially because it is favoured by the federal Securities and Exchange commission.

The investment banking system plays a significant role in the process of capital formation by transferring funds from savers to users. It is an extremely dynamic system, and adjustments to adapt it to changing conditions take place continually.

See Investment Bankers Association of America, *Fundamentals* of *Investment Banking* (1949). (M. D. KM.)

INVESTMENT PAPER. The term investment paper, or, commonly, corporate or investment securities, applies to bonds, debentures, share certificates, collateral notes. equipment trust certificates and the like. Though called securities, not all such paper is issued upon mortgage or other security; and, though usually issued by a corporation, this too is not a requisite. The financial community divides investment paper—by issuer—into four main categories. governments, rails, utilities, and industrials.

Bonds and Debentures.— It is not clear what were the antecedents of the bond. The East India bond before the court in *Glyn* v. ***Baker,*** 1811, commenced as a receipt. "The United Company etc, do acknowledge to have received of W. G. Sibley 100 *l*," (£100) and ended with an indemnity clause "in the penal sum of 200 l." But midway it contained a promise to repay 100 *l* "to the said W. G. S. his executors, Etc. (by indorsement hereon)," and it was urged that this made for negotiability. The court, however, was clear that instruments of the sort were not negotiable "like bills of exchange." Parliament provided soon afterward that East India bonds were negotiable.

In the U.S., during the early part of the 19th century, great numbers of bonds were issued by states and counties in a frenzy to build canals and railroads. Like the modern bond these were elegantly engraved instruments, thrice the size of a merchant's note, and with the seal of the issuer "conspicuously put"; all with an eye to inspire confidence. But there were almost as many frauds as bond issues, and accordingly many were defaulted. By 1868, however, it was established that such bonds. as a simple promise to pay a sum certain in money to bearer, must be held fully negotiable. It made no difference that they were issued under seal while the merchant's note was not; the same law should apply.

Instruments called debentures, or debenture bonds, are usually issued for short terms, say, 10 or 15 years. In the U.S., the word debenture signifies that there is no mortgage security, as is usual with the corporate bond. But, to add a speculative element (and, ultimately, to bring about a better capital structure), many debentures—like some bonds—are issued with a conversion privilege. That is, the holder is given an option, on stated terms, to turn his debentures into stock. To add further spice to the transaction, the issuer may establish a sinking fund, and agree to call a given number of debentures by lot, at stated times, for

payment. The lottery provisions were all spelled out on the back of the debenture in the *Crouch* case, 1873, which inclined the court to say that such an instrument could not be negotiable; later English cases reached a contrary result. These regulations, and many others lodging powers with a trustee, are now put in the indenture.

Bonds and debentures are almost as precarious to hold as money. That is, if they should be lost or stolen, a subsequent purchaser in good faith would get good title, since they are payable to bearer. Why a practice did not develop to issue such paper payable to "so-and-so or order," thus requiring an indorsement upon transfer, is a matter of surmise. But, for one thing, the long maturities, often 30 years or more in the case of bonds, would make the usual indorsement machinery very cumbersome. For another, there never was any thought that the transferor of a bond should engage to pay the instrument, upon default of the issuer, as the indorser of a negotiable note engages to do. Bonds are not negotiable in that sense; at most the transferor makes certain warranties, of title and so on, as upon the sale of a chattel.

One consequence was the invention of the coupon. It would be highly unsafe, as well as inconvenient, if holders had to bring their bonds and debentures to the issuer each time when collecting interest. But, by writing one coupon for each interest payment, and printing these with the bond, this was made unnecessary. Thus a 30-year bond, for example, is issued with 60 coupons attached, one for each semiannual interest payment, and the holder may clip his coupons as they mature and put them through his bank for collection with relative safety. Coupons are themselves small promissory notes, payable to bearer, and may be negotiated apart from the bond. The following is a typical wording: The company "will pay to bearer twenty five dollars . . . on the first day of July, A.D. 1900 . . . being six months interest on its first mortgage bond number 4028."

Registration provides a further safeguard. That is, most bonds and debentures are issued payable "to bearer, or, if registered, to the registered holder hereof." This means that a holder of such a bond may send it to the issuer to have it recorded in his name. If fully registered, the issuer will return the bond, minus all coupons, with the name of the sender entered on the back of the bond as owner. It is more usual to register only as to principal, in which case the coupons are not detached. In the U.S., registration renders the bond not negotiable, since it is no longer payable to order or to bearer, though of course it may be sold by being transferred on the issuer's books. Only a small percentage of an issue is ever registered; bonds are quoted at a slight discount when registered.

Share Certificates. — It was not until late in the 19th century that share certificates became a medium for the investment of vast sums of money. At one time, in fact, no certificate at all was issued; the shares were simply inscribed in the owner's name on the books of the company. Transfer was effected, as it still is, by giving a power of attorney (usually with an assignment) to someone to appear before the company or its transfer agent and have the shares entered in the name of the transferee. One reason for this was that the corporation's share obligation was looked on as a chose in action (shares are called *actions* in France), of a different tenor than that of a bond or promissory note, but still a chose in action, to be set up on the liabilities side of the ledger, as is done in modern practice. Thus, while the common law said that a chose in action could not be assigned, it was nevertheless possible to achieve the same result by other means.

However, the shareholder wanted some evidence of his claim. The few specially created corporations of the 17th and 18th centuries, therefore, commenced to issue certificates. When the many privately organized joint-stock companies also started to do so, abuses crept in, and the British parliament passed the Bubble act, forbidding them to issue certificates. Thus, for more than a century, or until 1825 when the act was repealed, there were relatively few share certificates in the market. By the middle of the 19th century, though, the dam had burst; general incorporation statutes were being passed everywhere, and these enabled anyone — on complying with certain simple requirements — to form a corporation and to issue share certificates for sale to the public.

The wording of the certificate has not changed materially. It is a bare recital: "This is to certify that (so-and-so) is the owner of 100 full paid and non-assessable shares of the Common Stock of the General Popcorn Corporation. par value $100, transferable on the books of the company by the holder hereof in person or by duly authorized attorney. . . ." It became the practice for the corporation, as in the case of bonds, to issue elegantly engraved certificates, over the seal of the corporation, "conspicuously put." It may be doubted, though, that this inspired much confidence in the investor, for he has long since come to look first to such things as the company's dividend record, the quality of its management, the price-earnings ratio and the like.

Share certificates are spoken of in financial circles as "equities," bonds and debentures as "debt." This is a useful, but loose, way of speaking. For, as was pointed out in the Rhode Island Trust Co. case (1926), the shareholder "does not own the corporate property"; it is owned, in legal theory, by the corporation. Upon liquidation the shareholder, like the bond or debenture holder, merely has a claim upon the corporate assets, with mortgage bond holders generally being paid first (if the security is adequate), debenture and other unsecured claims next, and common shareholders last. Many corporations also issue preferred stock, which may be given precedence over the common upon liquidation, and usually has priority in the payment of dividends. But common shareholders, unlike other security holders, do have voting rights, though these are coming to have less significance in the large corporation, where shares are widely held.

Negotiability. — The share certificate, in the U.S., never attained negotiability before the courts. The McNeil case (1871), held that they would be treated as quasi-negotiable, where an owner had entrusted his certificates to another, indorsed in blank, but that was on estoppel principles. When equipment trust certificates and security receipts were introduced early in the 20th century, they, too, were denied negotiability: the latter because the promise is to deliver securities, not to pay money, the former because the trustee promises to pay only if and when money is received from the equipment buyer, usually a railroad. When bonds and debentures came to be issued with clauses making the holder's rights subject to the provisions of the indenture, these too were held to be not negotiable; the promise of the issuer, not being an unconditional one, did not fit the pattern of the merchant's note.

The share certificate presented special difficulties. Instead of being regarded as a mere chose in action, shares had come to be looked on fictitiously as tangible property, having a situs at the corporation's office; the certificate was called a muniment of title, like a deed to real estate. The recital on the face of the certificate, providing for transfer on the books of the company, gave some support for the view; but in 1909 the Commissioners on Uniform State Laws proposed the Stock Transfer act to give controlling importance to the market sale of the certificate. The act, with few modifications, was soon adopted throughout the U.S. Under it the good-faith purchaser of a stolen certificate, properly indorsed, obtains full title, and may have the shares transferred into his own name on the company books; nor may a creditor of the registered holder defeat transfer, as once was possible, by serving a writ of attachment upon the issuer. The book transfer recital is recognized only to the extent necessary to protect the issuer; that is, the issuer may still treat the registered holder as share owner: to vote, to receive notices, and as the person to whom dividends may be paid.

Until mid-20th century no comparable legislation was proposed for bonds and similar instruments. In Great Britain, none was necessary, for the court in *Goodwin* v. *Robarts* (1875), assumed jurisdiction to declare new instruments negotiable upon proof of custom. However, in the U.S., a few states amended the Negotiable Instruments Law to include bonds. New York in 1926 passed a more ambitious act, bringing "security receipts," "equipment trust certificates," and "corporate bonds" into the fold. Government issues, such as income or toll-road bonds and special assessment bonds, which also were being held not negotiable, were

sometimes covered by the statute authorizing the issue, that is. by a clause providing specially for negotiability. Finally, in 1952. the Commissioners proposed a Uniform Commercial Code which deals comprehensively with investment securities.

The code defined investment securities in broad terms to include any instrument that is commonly dealt in as a medium for investment, is issued in series, and evidences either a share interest or an obligation, provided only, it is "issued in bearer or registered form" Thus, notes and bills payable to "so-and-so or order," which must be transferred by indorsement, are excluded; these are dealt with in a section of the code concerning commercial paper. The line is a somewhat arbitrary one, but it is an important one to draw, for those instruments defined in the code as investment securities may take such form as the issuer may choose to give them and still be negotiable, while commercial paper is held closely to the traditional pattern. Moreover, there are several places where different law applies; defaulted or overdue securities, for example, are given a limited negotiability, contrary to the rule concerning commercial paper.

Liquidity. — During the first half of the 20th century corporate wealth reached vast proportions. Mines, ships, factories, skyscrapers, whole industries in fact, came to be represented by paper instruments, negotiable in form. Thus the buyer may readily put his savings into a bond or debenture of a Delaaare corporation, which in turn may own gypsum mines in Canada or a banana plantation in Guatemala. So, too, a person in San Francisco, by simply indorsing his name on the back of a share certificate, may transfer control of the company to a buyer in New York or London. Many things have contributed to this, but the existence of a securities market is essential; it provides liquidity. Savings would never have been put into paper securities on this scale were it not readily possible to sell them again, at a price.

A market for shares in common stocks (stocks are called shares in England) existed in London throughout the 18th century; it was provided by the brokers of the time who met in coffee houses, in Change alley and elsewhere. The first regular list of prices, for the dozen or more stocks then being traded, appeared in 1714. The present London stock exchange was organized in 1802; the New York stock exchange was organized in 1792, though it did not assume its present name until 1863. Essentially a stock exchange (*q.v.*) is a place where members meet to execute customers' buy and sell orders for listed stocks; sales "at the market" are made to the highest bidder. Thus it is possible in a very few minutes for stocks worth millions of dollars to be sold. The ticker, which has been in use since 1871, reports current sales and prices by wire to all parts of the country.

The exchanges list only those securities which meet their standards. Many issues are not listed, either because the issue is too small, because it is not sufficiently seasoned, because the company does not wish to make the required reports, or for other reasons. These securities, which in the aggregate greatly exceed the value of the listed securities, are traded in by brokers in what is called the over-the-counter market. Aiso, new issues, which customarily are sold to syndicates of investment bankers on a negotiated basis for later distribution to investors, are traded over-the-counter prior to listing. Since 1926, when the Interstate Commerce commission ordered that equipment trust certificates be sold at competitive bidding, many rail and utility issues have been sold in that way to investment bankers.

Following the stock market crash of 1929, Congress passed the Securities act of 1933 and the Securities Exchange act of 1934 to regulate the securities business; these acts do not apply to securities issued and sold intrastate. Many states have blue-sky laws, so-called because their purpose is to prevent promoters from selling blue sky to the unwary investor. The Securities act, on the other hand, follows the British model, and is designed to safeguard investors, both new and existing, by giving publicity to the important facts concerning each issue before it comes on the market. Bonds and shares today may be purchased with far more information than was the case prior to 1929. See also BOND (IN FINANCE); COMMERCIAL PAPER; FINANCE; STOCK. (R. T. S.)

INVESTMENTS: INDIVIDUAL. In the economic sense investment is the productive employment of capital — the direction of savings into uses that fill an economic need. From the point of view of the suppliers of capital, investment is the commitment of present funds for the purpose of deriving a future return in the form of income or capital appreciation. Inherent in the concept of investment (as against speculation) is the emphasis on income and/or growth in value over a period of time (as against short-term trading profits), and the assumption of only that degree of risk that the investor can afford. This requires the selection of investment mediums that are appropriate to the investor's objectives.

Investment Mediums. — Investors have a wide range of general mediums from which to choose. These include: (1) savings types: social security benefits. pensions: annuities, the reserve element in life insurance contracts. savings deposits in commercial and savings banks and United States savings bonds; (2) securities: federal! state and municipal obligations and corporate securities including bonds (debentures), preferred stocks (preference shares) and common stocks (ordinary or deferred shares) in a variety of industries; (3) real estate held for occupancy and for income, and real estate mortgages; (4) direct investment in a business.

Other classifications of investments are: (1) by investor status: either that of creditor (as through the holding of bonds and annuities) or owner (as through common stocks and real estate); (2) by security: whether the investment (if debt) is a secured (viz., mortgage) or general (viz.. bank account) claim; (3) by maturity: whether the principal will mature at a future date (bond or life insurance) or will never mature except through market resale (viz., stocks); (4) by degree of marketability: whether the principal can be recovered through resale (as in a listed stock) or may suffer from a poor market (viz., specialized real estate); (5) by tax status: whether the investment has advantages to investors concerned with high income (tax-free municipal bonds) or seeking capital gains (stocks for appreciation) as against investments producing current taxable income (viz., dividend-paying stocks); (6) by degree of management required: whether constant care and attention is required of the investor (as in a portfolio of corporate securities) as against delegation of investment management to others (viz., life insurance, pensions, trust funds, investment company securities); (7) by degree of risk to income and principal: no risk (United States savings bonds) versus high risk (speculative stocks); (8) by degree of protection against inflation: no protection (bonds. pensions, bank accounts) versus possible protection (stocks, real estate).

Types of Investment Risk. — Investors must take into account various types of risks associated with different investment mediums and develop an investment program that is appropriate to their resources and particular investment objectives.

Quality Risk. — Investments differ with respect to assurance of income and safety of principal. At the one extreme are federal obligations and the savings types; at the other extreme, low-grade common stocks. Corporate securities and real estate include a wide range of quality. The task of selection to minimize risk or to assume only that degree the investor can afford may be undertaken by the investor, or the analysis and selection can be delegated to others. In the investment market the quality of an investment is evidenced by the yield or return that is produced in relation to market price — the higher the quality, the lower the yield. (An exception is iound in those "growth" common stocks that pay low dividends in relation to market price and whose appeal is mainly one of possible price appreciation.)

Risk of Price Change. — Cyclical variations occur in interest rates and in corporate profits and dividends that affect the price and income of marketable fixed-income investments as well as equities. The value of high-grade (marketable) bonds rises and falls moderately as interest rates fall and rise. Equity-type securities (common stocks) rise and fall with investors' and traders' estimates of expected earnings and dividends. They reap the benefit of high corporate profits and suffer the most in periods of recession. Purchase of bonds with varying maturities and diversification of stockholdings over various industries will reduce the price risk somewhat; complete avoidance of price risk would re-

quire concentration on the savings types of investments. A long-range program of "dollar-cost averaging" whereby the same dollar amount is regularly invested in a diversified selection of stocks, through high and low prices, will minimize the problem of timing their purchase and sale.

Various formula plans that involve an automatic switching to and from defensive securities — high-grade bonds — into more volatile common stocks, depending on the course of stock prices, have been developed to obviate the need for judgment with respect to the course of security prices. Or the task of timing the changes in the investment portfolio may be turned over to others such as trustees, investment counsel or investment companies, which provide investment management (at a fee).

Money-Rate Risk. — As indicated previously, the prices of marketable securities that return a fixed dollar income (bonds and preferred stocks) rise and fall inversely with interest rates, without necessarily any change in quality. If the investor wishes to avoid such price changes he must concentrate his investments in the savings types whose return is not influenced by any but long-run changes in interest rates, or attempt to select equities whose value is determined mainly by prospective profits.

Purchasing-Power Risk. — The purchasing power of the income and principal of fixed-income investments rises and falls with changes in the general price level or cost of living. Placement of a substantial proportion of the fund in equities — common stocks and real estate — in the hope of obtaining a higher dollar income and an appreciation of dollar value offers the best possibility of an inflation hedge. But such a hedge works only over a considerable period of time. The equities must be purchased at depressed levels (a problem of timing); and all equities are not equally good for inflation protection because industries and companies do not behave alike during any phase of the general business cycle

Investment Goals and Objectives. — The steps in an investment program are: (1) to determine the investor's goals or objectives in order of their relative priority or importance and to select the general types of mediums that are appropriate; (2) to select the specific investments after careful analysis and with due consideration of the problem of timing.

Individual investors and their needs differ in so many respects that it is impossible to generalize concerning investment objectives or the means by which these may be attained. There are variations in the amount of income available for investment. size of the investor's total resources, age, health, number of dependents, standard of living desired, time and skill available for investment management. And these and other factors change through the years, so that the objectives themselves change. In budgets allowing for modest savings, only the most urgent goals can be attained. As savings accumulate or responsibilities diminish. the objectives can be widened and more risk can be assumed. The following is a suggested list of objectives offered as an illustration of the approach.

Emergency Funds. — The first goal is to provide for unexpected expenditures or interruptions to income. Absolute safety is required, at a sacrifice of investment income. Savings accounts and savings bonds are the mediums used. These provide assurance of principal with very modest income, require no management and have satisfactory denominations (savings bonds may be purchased in units of face value as low as $25). They have no tax advantages and offer no protection against inflation.

Protection *Against* Death *of* the Income Producer. — Until a living estate is created, this goal is accomplished for the majority of investors through adequate life insurance. Policies should be selected that provide the greatest protection during the earlier years at the lowest cost; additiondl and later policies can provide substantial reserves and retirement income. The amount of insurance needed depends on number and age of dependents, income desired for dependents and the size of the estate exclusive of the insurance element. Insurance provides assurance of some income or principal for dependents, freedom from care and management, satisfactory denomination and diversification. It does not provide against inflation save through an increase in the dollar amount of coverage.

Over and above insurance sufficient to provide a minimum income for dependents, funds accumulated for their support can be invested in a variety of mediums. For small investors, savings types and high-grade bonds are indicated. For wealthier investors, who can assume more risk, common stocks and real estate offer opportunities for appreciation and the tax advantages of capital gains, while tax-free municipal bonds are useful in protecting current income against high tax-bracket rates.

Home Ownership. — This is probably the most substantial single investment goal of most investors. The modern method of amortizing the purchase of a home through a long-term mortgage forces savings into this use and relieves the investor of the problem of accumulating and managing funds for this objective. Once invested in real estate for occupancy, savings are concentrated and are subject to special risks pertaining to such property. An offsetting advantage is the possible increase in value as a protection against inflation.

Education and Other Family Needs. — A variety of objectives fall within this category. In most instances safety, of principal and assurance of modest income are important. Accumulations toward this goal should be so planned as to provide definite sums at definite times of need. A program of regular investment in savings bonds is appropriate in many cases. Special insurance protection should be arranged to assure the fulfilment of these goals in the event of the death of the income producer.

Retirement Income. — This is the next investment objective in many cases. Its importance will vary with the age and standards of the investor and his dependents. Annuities, pensions and social security benefits should be combined to provide a minimum risk-free income. In addition, an investment portfolio consisting first of high-grade bonds such as savings bonds, then of carefully selected equities chosen for appreciation as well as soundness may be added as the investor's income and savings increase. The additional sums invested in equities will depend not only on the size of the fund but also on the investment skill of the investor. as well as on his tax requirements and his need for offsetting possible inflation. New York Stock exchange houses make possible the purchase of stocks through constant monthly payments. For many investors equities can best be acquired indirectly through regular purchase of investment company shares (see below).

Supplementary Income Before Retirement. — When the above primary goals have been fulfilled, or while the later ones are being concurrently fulfilled, the remainder of the program may involve more risk taking. Safety of principal and future assured income may be given less attention, and current income to supplement salary or business earnings may be stressed. If the investor does not wish to undertake the tasks of selection. timing and management of a fund he may seek the advice of brokers, investment bankers or investment counsel; or he may set up a trust fund or buy investment company shares. The wealthy investor may take advantage of the tax-exempt feature of municipal securities, and much of his fund can be invested in higher-risk equities.

Creation of an Estate. — The final goal of some investors, after providing for the above requirements, is the creation of an estate (over and above minimum requirements) for dependents, charities and other beneficiaries. The complex aspects of estate planning may deserve the employment of firms that make a specialty of advice on such problems. The general investment requirements in planning for an eventual estate are: (1) tax relief on current income; (2) substantial liquidity (and insurance) to provide for estate taxes; (3) growth of some of the fund through capital appreciation; and (4) provision against inflation. Practically all of the general mediums of investment listed previously might be involved in such a program.

Selection of Specific Investments. — Selection of the savings types of investments presents few difficulties. Questions of form and convenience predominate. The same is almost true of high-grade bonds, although these must be watched for possible deterioration in quality; also the timing of their purchase (and possible resale) requires some forecast of the trend of interest rates.

The chief difficulties arise in connection with the selection and timing of investment in equity-type investments in those programs

in which such investments are appropriate. Investment in real estate for income involves so many special problems that most investors would be advised to avoid it; also, they may already have a substantial commitment in real estate held for occupancy. Common stocks show the greatest cyclical changes in value, the greatest range in quality and may involve considerable risk. Their exact value is always indefinite. The investor faces the task of appraising general business conditions, the course of stock prices as a whole, the relative outlook for different industries and the earnings, dividends and price performance of individual companies. If he undertakes the task himself he may study business and financial sources, subscribe to investment and statistical services and seek the advice of his broker or bank. Having selected the industries that appear to have the most promise or are most suited to the type of diversification he needs, he will then give attention to the analysis of the individual enterprise. emphasizing its characteristics and peculiar risks, quality of management, financial strength and earning power as revealed by financial statements, prospects for earnings, dividends and price appreciation and the degree of seasoning and marketability of the issue. He must also make a valuation to compare with current market price and be prepared to reappraise his holdings for changes in quality and appropriateness for his particular purposes.

These problems of timing, selection, diversification and continuous management of a portfolio of common stocks are too formidable or too time-consuming for many investors. Consequently, they may turn to one or more of several methods of transferring the responsibility to others. Professional investment counsel may be retained, at a fee. For those who can afford his advice, the registered investment adviser can fit the program to his client's individual needs, balancing the several factors of income, preservation of capital, appreciation. tax matters and diversification in one co-ordinated program. Other methods of transferring managerial responsibility on a fee basis include the use of investment departments of larger banks, the supervisory services of the larger stock exchange firms and the common trust funds operated by some banks and trust companies. These funds are conservatively invested but, through diversification, superior stability and emphasis on regular income and protection of principal and purchasing power value, have a strong appeal to many investors seeking these requirements.

Two types of institutions provide means for buying into a large portfolio of common stocks by way of the purchase of their shares —fire insurance companies and investment companies. While established to underwrite risks, the insurance company invests its reserves in a diversified portfolio of securities from which it derives a substantial investment income. Depending on the nature of the portfolio, its shares may offer opportunity for substantial capital appreciation as well as regular income.

Stocks of fire insurance companies are, however, highly specialized and difficult for the layman to analyze and evaluate. He is likely to turn to the investment company (investment trust) for a more understandable medium for indirect purchase of equities. So important has this institution become that it merits special consideration at this point.

Investment Companies (Investment Trusts.)— Investment companies are financial corporations that pool the funds of their shareholders in a substantial portfolio of securities. so that the investor has a part interest in a variety of individual concerns. Each share of the company's stock represents a fractional interest in the portfolio. The general advantages held out to the investor are: (1) diversification and spreading of risk through holding securities in a cross-section of industries and companies; (2) selection and management of the portfolio by professional experts who through research and constant study adjust the fund continually to changes in market and business conditions; (3) timing of purchases and sales within the portfolio, presumably on the basis of seasoned judgment; (4) convenience through handling for shareholders the details connected with the ownership of corporate securities. These advantages would be especially valuable to the investor who cannot afford investment counsel, cannot obtain diversification with his limited capital and lacks the time and skill to select and manage his own portfolio with successful results.

Most modern investment companies are of the management type, that is, their management has complete discretion over the portfolio held, subject to any charter provisions concerning the general nature of the portfolio, in contrast with the older fixed trusts that could only invest in a given list of securities. The two main classes of investment companies are closed-end companies having a fixed capitalization and whose shares are bought and sold by the investor in the market, and open-end or mutual funds which make a continuous offering of new shares (through distributors) and redeem them on demand; the shares of open-end funds are offered at their net asset value plus. in most cases, a loading fee of 2% to 9% and are redeemed at net asset value, calculated daily. Investment companies may also be classified by type of portfolio securities held as assets. Those owning both bonds and stocks are called balanced funds. Others are common-stock funds holding common stock only. plus a varying amount of cash. Some of the latter are diversified funds; others hold securities in one or more special industries.

Investment companies also differ with respect to their investment purpose. Some are designed primarily to produce income, others for capital appreciation, still others for a combination of both. They differ also in the degree of risk undertaken, ranging from very conservative to frankly speculative funds.

The problem of the investor is to select the fund or funds whose objectives and degree of risk taking most closely match his own situation — the ones that will accomplish for him what he would wish to do for himself if he could diversify and manage his own holdings.

Investment companies in the United States are closely regulated by the Securities and Exchange commission, under the federal Investment Company act of 1940, vith respect to promotion and sales practices, standards of operation and dissemination of information concerning financial condition and investment policies.

Investment companies (including a few that still operate as trusts rather than as corporations) had their origin in the English and Scottish trusts that were formed as early as 1860 to provide an investment service to individuals either unable or unwilling to select and manage their own security holdings. The early British trusts were mostly of the closed-end type and were conservatively managed. Wide diversification was practised and operating expenses were modest. The early American trusts copied the basic idea of diversification but were less soundly managed. They often indulged in short-term trading; inferior securities were acquired for the portfolio; affiliations with sponsoring banking firms led to abuses.

The collapse of the stock market in 1929–32 brought enormous losses and many failures. After a period of confusion in the 1930s, the stronger survivors and new companies enjoyed the renewal of general interest in equities and, by improved performance under federal regulation, grew rapidly and became widely accepted. This is not to say, however, that they have all been well managed and have all produced satisfactory results for their shareholders.

As indicated previously, investment companies do not follow uniform investment policies. They differ with respect to the general types of portfolio securities held, the degree of risk undertaken, the extent of diversification of investment holdings, the extent to which they keep their funds fully invested in various stages of the securities cycle, the relative emphasis placed on income as against capital appreciation and the results obtained for their owners. Most investment companies pay out at least 90% of their net investment income (after expenses) in dividends, and thus avoid taxation on income. Capital gains taxes are paid on any realized but undistributed gains from buying and selling portfolio securities.

In the selection of an investment company, the investor should first eliminate those whose purposes and record do not coincide with his own aims and objectives, and whose general policies indicate more risk taking than he is prepared to assume. The reputation of the management, the size and growth of the company and its performance during periods of market weakness should all be

examined. Performance is best measured by the cumulative results over a considerable period of time (preferably covering all phases of the business cycle) with respect to dividends and change in net asset value per share as compared with other companies, individual securities and general stock market averages. Other factors to be studied include the expense ratio (per cent of income or of asset value consumed by operating expenses of research and administration), the dividend yield on purchase price and the proportion of dividends representing investment income and capital gains, respectively.

Many open-end investment companies make it possible for the shareholders to reinvest any dividends in new shares without a loading fee and to accumulate new shares by deposit of a regular sum at stated intervals: and thus to obtain the advantages of dollar-cost averaging as the value of the shares rises and falls.

Regulation in the Investor's Interest.— In addition to state blue-sky laws, U.S. federal laws provide protection to investors in a number of respects. The Securities act of 1933 requires corporations that offer new securities in interstate commerce or through the mails to present prospectuses containing a description of the securities and the issuer. Civil and criminal penalties are imposed for fraud and for omission or misstatement of material facts in the prospectus.

The Securities Exchange act of 1934 provides for regulation of securities exchanges and trading to prevent manipulation of prices and abuses of credit in securities transactions. The Trust Indenture act of 1939 requires compliance with standards concerning the indentures that support corporate bond issues and regulates the activities of corporate trustees. The Investment Company act of 1940 (above) and the Investment Advisers act of 1940 regulate investment companies and registered investment counsel firms.

The Securities and Exchange commission is the regulatory body under all of these federal statutes.

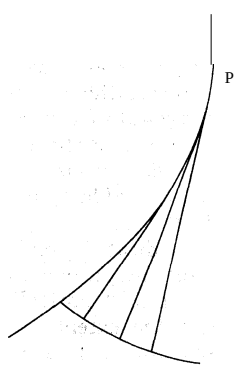
INVOLUTE, of a curve C, is a curve which intersects all the tangents of the curve C at right angles. Each curve has infinitely many involutes.

To construct an involute of a curve C, use may be made of the so-called "string property." Let one end of a piece of string of fixed length be attached to a point P on the curve C and let the string be wrapped along C. Then, as the string is unwrapped, being held taut so that the portion of the string that has been unwrapped is always tangent to C, the locus of the free end of the string is an involute of C. With the same point of attachment P, different involutes of C are obtained by using pieces of string of different lengths. (E. P. L.)



INVOLUTE OF A CURVE C (*see* TEXT)

INVOLUTION, in arithmetic, is the operation of raising a number to any power; rolling it up, as it were, by continued multiplication. Before the invention of a satisfactory symbol like a^2 or a^3, the Greeks spoke of the second power as a tetragon number (*tetragonos arithmos,* "four-angled number") or a "power" (dynamis, from which also "dynamo" and "dynamite").

Diophantus (c. 275) called the third power a cube (*cubos,* see CUBE); the fourth power, a "power-power" (*dynamodynamis*); the fifth power, a "power-cube"; and so on, using the additive principle.

Involution is the converse of evolution (*q.v.*), which is the operation of finding a root. (See ARITHMETIC.) In projective geometry (*q.v.*), involution is a special kind of one-to-one correspondence between the points of a line, the lines of a flat pencil, or the planes of an axial pencil. etc. For example, consider all the points on a straight line and select two distinct points I_1, I_2 on the line. Then. given any other point P_1 on the line, there is a unique point P_2 on the line such that P_1 and P_2 separate I_1 and I_2 harmonically, and this relation between P_1 and P_2 is reciprocal. When the point P_1 is allowed to vary, the point P_2 also varies. This pairing of the points of the line into pairs P_1, P_2 separating the fixed pair I_1, I_2 harmonically is an involution on the line. It may be said that an involution is a projective transformation of period two. and also that an involution is a symmetric projective transformation.

IO, in Greek mythology, daughter of Inachus. the river-god of Argos and its first king. Under the name of Callithyia, Io was regarded as the first priestess of Hera. Zeus fell in love with her, and, to protect her from the wrath of Hera, changed her into a white heifer; according to Xeschylus in his *Supplices,* the metamorphosis was the work of Hera herself. Hera, having persuaded Zeus to give her the heifer, set Argus Panoptes to watch her. Zeus thereupon sent Hermes. who lulled Argus to sleep and cut off his head or killed him with a stone. But the wrath of Hera still pursued Io. Maddened by a gadfly sent by the goddess, she wandered all over the earth, crossed the Ionian sea (traditionally called after her). swam the strait known on this account as the Bosporus ("ox-ford") and at last reached Egypt. where she was restored to her original form and became the mother of Epaphus. She was thus identified with Isis, and Epaphus with Xpis. He was said to have been carried off by order of Hera to Byblus in Syria. where he was found again by Io. This fable connects Io with the Syrian Astarte (*q.v.*). Both legends reflect intercourse with the east and identification of foreign with Greek gods. She was a favourite subject among Greek painters, and many representations are preserved on vases and wall paintings.

IODINE, a chemical element belonging to the halogen group, was discovered in 1811 by B. Courtois, a manufacturer of saltpetre. He noticed a substance that corroded the copper vats in which he was using a water extract from burned seaweed. He treated the extract with suliuric acid, and the impurity was isolated as a black powder. When heated, this yielded a violet vapour and condensed in crystalline flakes. In corresponding with chemists to whom he sent samples of the unknown substance, he referred to it as "X". It was identified as an element by J. L. Gay-Lussac in 1815. Iodine at room temperature is a nearly black crystalline solid, vaporizing easily to the deep-violet vapour from the colour of which its name is derived (iodes, Greek for "violet").

The bactericidal property of iodine was first described by C. J. Davaine in 1873 However, tincture of iodine was being used widely to counteract infections, on an empirical basis. half a century earlier.

Potassium iodide is used in analytical chemistry, photography and medicine. In medicine, soluble iodides such as potassium and ammonium iodides have an important place in the treatment of many diseases, among which are syphilis, rheumatism and goitre. Arsenic iodide is employed in treating diseases of the skin. Many pharmaceutical preparations consist of iodides, either pure or mixed with other materials. Among the iodides employed in medicines are paraiodophenol, tetraiodopyrrole and thyroxin. As many as 200 diseases have been treated with compounds of iodine. Iodoform. CHI_3, made by electrolysis of a solution containing potassium iodide, sodium carbonate and ethyl alcohol, is employed as an antiseptic. Iodine as thyroxin is produced in the thyroid gland. and a small amount of iodine is essential in the diet. In most places the drinking water contains sufficient iodine, but in some localities goitre is prevalent because of the absence of iodine in the water supply. To insure against iodine deficiency a small quantity of iodide is frequently added to table salt.

Sources.—Iodine is never found uncombined. It is present in sea water as iodide, 1 part of iodide to 8,000 parts of chloride; it occurs in much animal and vegetable matter. generally in very small amounts, but most abundantly in seaweeds. Appreciable quantities are also found in many natural brines. The largest

source of iodine for commercial preparation is the nitrate deposits of Chile, from which saltpetre is prepared. iodine being present as sodium iodate. Iodine is estimated to account for 10^{-5}% of the earth's crust, and to be in 28th place in order of abundance.

For a long time in France and Great Britain and. more recently, in Japan, iodine has been recovered on a commercial scale from seaweed. The stages in the preparation are: drying and burning of the seaweed, leaching of the ash, release of the iodine by chemical reaction, and purification. The burning is done in large ovens at as low a temperature as possible to avoid volatilizing sodium iodide On extracting the ash with water a liquid containing 7–9 g. of combined iodine per litre is obtained. When cooled, considerable sodium sulfate and chloride crystallize, and the remaining liquid is concentrated by evaporation to a content of 30–100 g. of iodine per litre. The addition of sulfuric acid decomposes any sulfite and sulfide. Manganese dioxide added to the acidified liquor releases iodine, which is vaporized and purified by sublimation. In the modern French process, cuprous iodide, obtained by the reaction of cupric sulfate with the concentrated liquors, is the product instead of iodine.

Iodine from Chile nitrate deposits is a by-product of the preparation of Chile saltpetre. The mineral, containing 0.05% to 0.3% of iodine, is treated with hot water. filtered and cooled, precipitating most of the nitrate and leaving a liquor containing 6–12 g. of iodine per litre as sodium iodate. On the addition of a second liquid containing sodium sulfite and bisulfite, the iodate is reduced to iodine:

$$2NaIO_3 + 5NaHSO_3 = I_2 + 3NaHSO_4 + 2Na_2SO_4 + H_2O$$

The amount of bisulfite liquor must be carefully controlled since excess will reduce the iodine to iodide. The free iodine is purified by sublimation in retorts.

A more recently developed source of commercial iodine is the brine extracted from oil wells. In California some brines contain 30–60 parts per 1,000,000 of sodium iodide. Two methods have been employed to obtain the iodine. In one process, silver nitrate in 2%–3% solution is added, precipitating the iodine as silver iodide, accompanied by considerable ferric hydroxide. On acidifying with hydrochloric acid, the ferric hydroxide is dissolved, and the addition of scrap iron yields a solution of ferrous iodide and metallic silver which is recovered. The ferrous iodide is decomposed by chlorine, or by sodium dichromate and sulfuric acid, the iodine precipitating in granular form. The precipitated iodine is melted under concentrated sulfuric acid and drawn off in liquid state at as high as 99.8% purity. In a second method, sodium nitrite and sulfuric acid are added to the brine, setting free the iodine in dilute solution. The iodine is concentrated by adsorption on activated charcoal which, after it has become nearly saturated with iodine, is treated with sodium hydroxide to give a solution containing sodium iodide. The iodide solution is oxidized to iodine by acidified sodium nitrite, chlorine or chromic-sulfuric acid. The production of iodine from oil-well brines, while not amounting to more than a small fraction of the total world production. about 1930, caused a decline in the price of iodine, previously fixed at $4.65 per pound. By 1950 the price was about $2 per pound.

Physical Properties. — The atomic weight of iodine is 126.91, the atomic number 53 and the molecular weight 2j3.82. By mid-20th century, isotopes of masses 119–139 had been detected. Except for the natural iodine 127, these isotopes are radioactive and mainly short-lived. The radioactive isotopes are formed in the bombardment of tellurium and iodine with high-velocity particles and in the slow neutron fission of U^{235}. The electron configuration for the unfilled outer orbits (N and O) is: $4s^2$, $4p^6$, $4d^{10}$, $5s^2$, $5p^5$. The electron affinity of the gaseous atom is 3.22 ev. The molecules are normally diatomic but somewhat dissociated at high temperatures. Iodine has a density of 4.93 g. per millilitre at 20° C. The solid melts at 114° C., but has a sufficiently high vapour pressure to sublime readily at lower temperatures. The boiling point of liquid iodine is 183° C. The heat of fusion is 3,6jo cal. per mole, the heat of vaporization 9,970 cal. per mole at the boiling point, and the heat of sublimation 14,460 cal. per mole at the melting point. The specific heat of the solid is 0.0513, the liquid 0.0631, the vapour 0.0355 cal. per gram. The entropy of the solid at 25° C. is 27.9 cal. per mole per degree. Iodine dissolves but little in water; at 20° C. the saturated solution contains 0.00133 mole per litre of solution. In most non-aqueous solvents the solubility of iodine is greater; in carbon tetrachloride it is 85 times the solubility in water The solutions in water and alcohol are brown, in most other liquids. violet.

Chemical Properties. — In compounds the common oxidation states are minus one. plus five and plus seven. Iodine combines readily with most metals and some nonmetals to form iodides. With hydrogen, combination is incomplete since hydrogen iodide is unstable at temperatures sufficiently high for iodine and hydrogen to react. Iodine is reduced to iodide ion by reaction in solutions of hydrogen sulfide, sulfur dioxide and thiosulfate. In all these reactions iodine acts as an oxidizing agent but is the least active of the halogens in this respect. The formation of an iodide is accompanied by the evolution of less heat than is evolved in the formation of the corresponding bromides, chlorides and fluorides. The molal potential of the iodine-iodide electrode in aqueous solution at 25° C. is 0.535 v.

Iodine is the most readily oxidized of the halogens to an oxygen-containing compound. Potassium iodate is more stable than potassium chlorate. and iodine will react with the latter to go to the iodate. Iodine is oxidized to iodic acid by concentrated nitric acid and in basic solution to iodate by such oxidizing agents as chlorine.

Iodine reacts with aqueous ammonia to form nitrogen tri-iodide, $NI_3.NH_3$, which is highly explosive.

Iodine combines with iodides to form polyiodides. With aqueous iodide. the reaction, $I_2 + I^- = I_3^-$, accounts for the large solubility of iodine in solutions containing soluble iodides. A solution containing 100 g. KI in 100 g. of water dissolves 153 g. of iodine. Iodine at high concentration is poisonous and may cause serious burns; in dilute alcoholic solution (tincture of iodine) it is used as an antiseptic.

Hydrogen Iodide and Iodide Ion. — Hydrogen iodide is a colourless fuming gas with a sharp odour It is commonly prepared by the hydrolysis of phosphorus iodide. $PI_3 + 3H_2O = 3HI + H_3PO_3$. A solution may be prepared by the reaction of iodine with hydrogen sulfide in solution, $I_2 + H_2S = S + 2H^+ + 2I^-$. Hydrogen iodide liquefies at −36° C. and freezes at −51° C. The heat of formation at 18° C. is −5.91 kg. cal. per mole. The compound is not stable thermally, being 22% dissociated to the elements at 450° C. Iodine is liberated from hydrogen iodide by any of the other halogens. by oxygen or by concentrated sulfuric acid. Like the other hydrogen halides, the gas is very soluble in water, 250 vol. dissolving in 1 vol. of water at 20° C. The aqueous solution. known as hydriodic acid is a strong acid containing hydrogen and iodide ion. A constant boiling mixture containing 57% HI by weight. boiling at 127° C., of density 1.70, is formed.

Hydriodic acid may be used to prepare iodides by reaction with metals or their oxides, hydroxides or carbonates. and as a reducing agent in organic chemistry. The iodide ion is a strong reducing agent. the strongest of the halide ions. It is oxidized to iodine by chlorine. bromine, ferric ion, cupric ion and many other oxidizing agents. Because of the reducing ability of the iodide ion, certain metallic iodides cannot be prepared; *e.g.,* cuprous iodide rather than cupric iodide results on the addition of an iodide to a cupric solution. While the iodide ion is colourless. solutions of soluble iodides tend to acquire a brownish tint as a result of oxidation of the iodide to free iodine by atmospheric oxygen. Iodides are generally soluble in water. common exceptions being those of silver, cuprous. mercurous, and lead. Although silver iodide is less soluble in water than silver bromide or chloride. in nonaqueous solvents the iodides are generally the most soluble of the halides. The iodides of metals in general form ionic-type crystals in which the iodide ion has a radius of 2.16 A.

Potassium iodide, a white crystalline solid, melting at 682° C., of 3.12 specific gravity. is produced commercially to a greater extent than other iodides It is made by the reaction of ferrous iodide, prepared from iron and iodine, with potassium carbonate. $2FeI_2 + 2K_2CO_3 + \frac{1}{2}O_2 = 4KI + Fe_2O_3 + 2CO_2$, or by the reaction of

cuprous iodide with potassium carbonate, $2CuI + K_2CO_3 = 2KI + CO_2 + Cu_2O$.

Many organic iodides are useful in organic syntheses. Iodine enters organic molecules by direct addition at double bonds and by displacement of hydrogen. The latter reaction occurs less readily than with chlorine or bromine, and the iodine in organic compounds is in general more reactive than the other halogens. When used as a reducing agent in organic chemistry, hydrogen iodide is more effective in the presence of phosphorus, since the liberated iodine forms the more reactive phosphorus iodide.

Oxy Compounds.— Iodine is readily absorbed in alkaline solutions in which some hypoiodite is presumably formed, but since the hypoiodite is unstable, the product is a mixture of iodide and iodate, $3I_2 + 6OH^- = 5I^- + IO_3^- + 3H_2O$. This reaction is reversed in acid solution, with iodide and iodate forming iodine. With the addition of an oxidizing agent such as chlorine in alkaline solution. all of the iodine may be oxidized to iodate and solid iodates crystallized from solution. Iodate may also be formed by anodic oxidation of iodide solution and by the reaction of iodine on a chlorate. The iodates are the most stable of the series chlorate. bromate and iodate, and usually the least soluble. Potassium iodate melts at 560° C., and at higher temperatures decomposes to potassium iodide and oxygen. Acid iodates such as $KIO_3.HIO_3$ exist, although no bromate or chlorate of this type is known.

Iodic acid is a moderately strong acid. It may be formed in solution by acidifying solutions of iodates or by the oxidation of iodine by nitric acid. $I_2 + 10HNO_3 = 2HIO_3 + 10NO_2 + 4H_2O$. Iodic acid is much more stable than chloric and bromic acids. It is readily dehydrated at 110° C. to give the anhydride, iodine pentoxide, I_2O_5, a white solid which decomposes at about 300° C. without melting. The oxide readily recombines with water to give iodic acid. Treatment of iodic acid with concentrated sulfuric acid yields a different oxide, I_2O_4. The tetroxide is not an acid anhydride; with water it forms iodic acid and hydriodic acid.

The action of excess chlorine in alkaline solution will change iodide or iodate to periodate. A solution of periodic acid may be formed by acidifying a solution of barium periodate with sulfuric acid. Periodic acid is a stronger oxidizing agent in solution than perchloric acid although iodic acid is a weaker oxidizing agent than chloric acid. Periodic acid differs from perchloric acid also in that it is not always monobasic. Thus, not only such metaperiodates as KIO_4 and $AgIO_3$ but also mesoperiodates of which Ag_3IO_5 is an example, and paraperiodates such as Ag_5IO_6, are known. The existence of these salts may be attributed to the large size of the central iodine atom about which a larger number of oxygen atoms may be co-ordinated. Most periodates are but sparingly soluble; this property as well as the proportion of acid and base are factors in determining which of the possible periodates forms in the reaction of periodic acid with a given base or metal ion. In commercial preparation, the reaction of sodium iodate with chlorine in alkaline solution yields the disodium meso salt, $2Na^+ + IO_3^- + 3OH^- + Cl_2 = Na_2HIO_5 + 2Cl^- + H_2O$. Periodic acid, itself, crystallizes from solution as H_5IO_6, which may be dehydrated to HIO_4 by heating to 100° C. in a vacuum. Attempts to prepare the anhydride of periodic acid, I_2O_7, have not succeeded as oxygen is lost in further dehydration of the acid.

Analytical Chemistry.— Iodine is detected by the violet colour of its vapour or of its solution in carbon disulfide or carbon tetrachloride. In aqueous solution minute amounts of iodine in the presence of starch give a bright blue colour. None of the other halogens gives these colours. If present as iodide, the iodine is first set free by the action of an oxidizing agent such as chlorine water; or if present as iodate or periodate, by reduction with sulfurous acid. Iodine is determined gravimetrically by precipitation as yellow silver iodide. which is insoluble in nitric acid and ammonia. Volumetrically, iodine is titrated with a standardized solution of sodium thiosulfate, usually in the presence of starch as indicator. The iodine is consumed by reaction, $I_2 + 2S_2O_3^{-2} = 2I^- + S_4O_6^{-2}$, and at the end point the blue colour disappears, leaving a colourless solution.

The reaction of iodine with thiosulfate is of great importance in analytical chemistry. It is employed in the determination of many substances which have oxidizing properties. For example, dichromate may be determined quantitatively by first allowing the dichromate solution to react with excess potassium-iodide solution, $Cr_2O_7^{-2} + 6I^- + 14H^+ = 3I_2 + 2Cr^{+3} + 7H_2O$, and then titrating the liberated iodine with standard thiosulfate solution. Even substances with weak oxidizing powers may be determined in this way; *e.g.*, copper, by the reaction $2Cu^{+2} + 4I^- = 2CuI + I_2$. Some other determinations that may be made in this way are of chlorine, bromine, iodate, persulfate, hydrogen peroxide, nitrite, arsenate, ferricyanide, permanganate, manganese dioxide and ferric iron.

Many reducing agents may be titrated directly with a standard solution of iodine in potassium iodide using the starch indicator. In these titrations the iodine is reduced to colourless iodide; *e.g.*, with arsenite, $HAsO_3^{-2} + I_3^- + H_2O = AsO_4^{-3} + 3I^- + 3H^+$. Titrations of sulfite, sulfide, thiosulfate, ferrocyanide, stannous and antimonous ion may be made in this way. Determination of reducing and oxidizing agents in which iodine or iodide is employed are known respectively as iodimetric and iodometric determinations.

Iodine compounds are employed in other analytical procedures. A solution of mercuric iodide in excess potassium iodide, containing the complex ion HgI_4^{-2}, known as Nessler's reagent, is used in the determination of ammonia. with which it forms a yellow precipitate, $Hg_2NI.H_2O$. Small amounts of water in organic liquids are determined by titration with a pyridine solution containing iodine, sulfur dioxide and methyl alcohol. This solution is known as the Karl Fischer reagent. Potassium iodate and biiodate, $KIO_3.HIO_3$, are of importance as oxidizing agents in analytical chemistry. Potassium periodate is a valuable oxidizing agent in the determination of manganese. It will oxidize manganous ion to permanganate ion quantitatively in acid solution, the permanganate being determined colorimetrically.

The content of unsaturated compounds in oils is determined by measurement of the quantity of iodide absorbed. The per cent of its own weight of iodine which a sample of oil will absorb under certain specified conditions is known as the iodine number. Concentrated hydriodic acid is used in the Zeisel method for determination of methoxy groups.

Soluble iodides are employed in detection and estimation of alkaloids with which they form precipitates.

IODINE BUSH or PICKLEWEED (Allenrolfen *occidentalis*), a North American plant of the goosefoot family (Chenopodiaceae), native to moist alkaline clay soil from western Texas to central California. It is an erect, diffusely branched shrub, 2 ft. to 5 ft. high, with alternate. fleshy, green, apparently leafless, jointed branches, the leaves being reduced to minute pointed scales or wanting. The numerous small flowers are arranged spirally by threes in crowded cylindrical spikes, $\frac{1}{4}$ in. to $\frac{3}{4}$ in. long, borne in the axils of fleshy bracts near the ends of the branches. In appearance the plant is suggestive of a tall, much-branched form of the glasswort (*q.v.*) or samphire, to which it is closely allied.

IODOFBRM, formerly valued as an antiseptic, although now no longer widely used in medicine, was discovered by G. S. Sérullas in 1822. It can be prepared by the action of iodine and an aqueous base on ethyl alcohol, acetaldehyde, acetone, isopropyl alcohol or almost any other compound containing either the CH_3-CO-C or the CH_3-CHOH-C groups. For this reason, the "iodoform test." which consists in the formation of iodoform by the procedure described, is commonly employed in the chemical laboratory for establishing the presence of the stated groups.

Iodoform, CHI_3, crystallizes in yellow hexagonal plates melting at 119°–120° C., and is readily soluble in alcohol or ether, but insoluble in water. It has a characteristic odour and is volatile in steam.

IOLITE: see CORDIERITE.

ION OF CHIOS (*c.* 490–*c.* 422 B.C.), Greek poet and prose writer, competed perhaps ten times with tetralogies in Athenian dramatic contests, and one year was victorious in both tragedy and dithyramb. Athenaeus relates that in his delight. Ion gave every Athenian citizen a jar of Chian wine. Alone of Greek tragedians Ion also tried his hand at comedy (if the scholiast on Aristophanes' Peace 83j is to be trusted); elegy, epigrams, hymns, encomiums, prose memoirs and monographs on historical and perhaps philosophical subjects showed his remarkable versatility. The Alexandrian critics admitted him to their canon of the five best tragedians; the author of the treatise On *the Sublime,* however, pronounced his poetic style smoothly finished without genius. His most original achievement was his prose memoirs. *Epidemiai,* an anecdotal work which started a new literary genre.

IONA, an island of the Inner Hebrides, Argyllshire. Scot., 6½ mi. S. by W. of Staffa and 1¼ mi. W. of the Ross of Mull, from which it is separated by the shallow Sound of Iona. Pop. (1951) 173.

Iona is low-lying. The highest eminence is Dun I, which rises to a height of only 332 ft. above sea level. It is 3 mi. long and 1½ mi. wide, and at no time has it given accommodation to more than a handful of permanent residents. The island is 3.3 sq.mi.

The name of Iona, although originally a mistake for Ioua, has long established itself as the accepted representative of the ancient "I" found in the Gaelic name "I-Chaluim-Chille" or in the Anglicized form oi "Icolmkill," meaning "Island-of-Columba-of-the-Church" or "Cell." It was admirably suited to be the home of a small community of celibate clerics. Columba, in 563, when 42 years old, was glad to leave his native Ireland, then known as Scotia, because of certain church and state troubles in which he had been involved. Iona, readily accessible from Ireland by sea, formed an integral part cf the dominions of the Gaelic-speaking kings of Scottish Dalriada (*q.v.*). These rulers were near kinsmen of Columba, and one of them, King Conall, granted Iona to him. His career in Scotland till his death in 597 was very successful. He evangelized the Picts living in east and northeast Scotland, and by his religious propaganda prepared the way for the absorption oi the Picts into the evolving Scottish kingdom. He sent his missionaries through many districts of insular and mainland Scotland, achieving a wonderful degree of religious success. He was followed by an unbroken line of abbots until, with the increase of papal influence, the abbey was subordinated to the bishopric of the isles and ultimately amalgamated u-ith it.

Iona's fame led to its selection as the royal burial ground of Scotland for several centuries. Donald Monro, who visited Iona in 1549, stated that the *tumuli regum* or "graves of the kings" contained the remains of no fewer than 48 Scottish, 8 Norse and 4 Irish kings. In 795, pagan Norsemen first visited the islands in quest of plunder; they returned in 802 and again in 806. In 82; Blathmac and several fellow monks mere murdered by marauding Norsemen. Iona's growing insecurity led to the temporary transfer in 849 of the relics of Columba partly to Dunkeld in Perthshire and partly to Ireland. Ultimately in 878 all the relics were taken to Ireland and never restored to the Scots.

These Norsemen were gradually won over to Christianity and became firm supporters of Iona abbey, but insisted that it should acknowledge the supremacy of the archbishop of Trondheim. This supremacy terminated with the end of the Norse control over western Scotland about 1266. While the Norse power was declining, semi-independent Hebridean chiefs, such as Somerled, took an active interest in Iona. Somerled's son Reginald is believed to have founded in 1203 the Benedictine nunnery of St. Mary, of which his sister Beatricc was the first prioress. Somerled's descendants, the MacDonald lords of the Isles. were most generous to the abbey, granting various estates for its upkeep. With the forfeiture oi the last MacDonald lord in 1493, the former vassal clans became independent and lawless, and during periods of unrest diverted some of the abbey's revenues to their own private purposes. Although the impact of the Reformation was harmful to Iona at first, it is untrue that 300 Icna crosses were cast into the sea by Protestant vandals. Iona's subsequent ecclesiastical life coniormed to the prevailing pattern of Scottish church government, whether episcopalian or presbyterian, until presbyterianism finally prevailed. In 1899 George Campbell, 8th duke of Argyll, transferred to the Church of Scotland all the ecclesiastical buildings in Iona.

A religious brotherhood for the training of students, called the Iona community, was founded by George F. MacLeod in 1938. This organization undertook as a corporate task the restoration of the abbey of Iona, and the dormitory block was the first part to be rebuilt. (C. M. M.)

ION EXCHANGE, a process in which ions (see SOLUTIONS) attached to or incorporated within the molecular structure of insoluble substances, called ion exchangers, exchange with ions present in a surrounding solution. The process has also been called base exchange and exchange adsorption. Ion exchangers are essentially insoluble acids or bases, the salts of which are also insoluble. Ion exchangers may undergo exchange either with positively charged ions (cations) or negatively charged ions (anions). In the former case the process is referred to as cation exchange and in the latter as anion exchange.

Numerous substances, of both natural and synthetic origin, possess ion exchanging properties. These include proteins: synthetic resins, cellulose. bone, living cells, silicate minerals and soils. For commercial and laboratory uses the commonest types of inorganic ion exchangers include the natural zeolites, glauconite and greensand; but the most widely used inorganic exchangers are synthetic sodium aluminosilicates. The organic ion exchangers include the sulfonated coals and. most important of all, synthetic resins. The synthetic resins are plastics which may be chemically modified to impart or enhance their ion exchanging properties.

Since the discovery in 1935 of synthetic ion exchange resins, technical application has increased to the point where it is regarded as a unit operation along with processes such as distillation, adsorption: filtration and solvent extraction. Ever since it was proposed, in 1905, the major use of ion exchange has been in water softening. in nhich calcium and magnesium ions, largely responsible for the hardness of water because they form insoluble compounds (see WATER), are removed by a granular bed of cation exchanger and replaced by sodium ions from the cation exchanger. When the cation exchanger becomes exhausted, by no longer having sufficient amounts of exchangeable sodium left, it is regenerated by passage of an excess of a strong solution of sodium chloride through the bed thus removing the calcium and magnesium, which are usually discarded. Technical applications of ion exchange include the recovery of valuable metals from waste solutions, purification of antibiotics and antibodies, separation of mixtures of closely related substances and in acid-base catalysis. Medical applications include treatment of ulcers. diarrhea and removal of excess sodium ions from the body For further information on the uses of ion exchange, see below, *Applications.*

Historical Development.— In 1850, in separate publications by the English agriculturist Harry Stephen Meysey Thompson (1809–74) and the English chemist John Thomas Way (1821–84), the phenomenon of ion exchange occurring in soils uas recognized and systemically investigated. In 1935 two English chemists, I. B. A. Adams and E. L. Holmes, discovered the ion exchanging properties of synthetic resins.

In the early 19th century it was known that plants require nitrogen for growth and, further, that the ammonia given off by manure heaps nas taken up by the soil. Sulfuric acid or sulfate salts were often used to fix the ammonia by the formation of ammonium sulfate In 1845 Thompson, in collaboration with Joseph Spence. a chemist and druggist, conducted a series of experiments in order to test the extent to which soils could fix ammonia and "to ascertain whether it also extended to the sulfate, as if not, the use of sulfuric acid as a fixer, though preventing the escape of ammonia in a volatile form. would have been objectionable from its forming a highly soluble salt that would readily be washed down into the subsoil or carried off in drains." In one experiment a sample of soil forming a six-inch-high column was placed in a glass percolator The soil had been mixed previously with a known quantity of ammonium sulfate. When nater was passed through the column it was found to the experimenters' "complete surprise" that most of the ammonia nas retained by the soil, that it could not be removed by leaching nith water and that "this process was in some way connected with the presence of lime in the soil, as the sulfuric acid was mashed out in combination with lime." In other words, though Thompson was actually unaware of the correct explanation, the ammonium ion had exchanged with the calcium ion present in the soil. while the negatively charged sulfate ion was unabsorbed. The process can be written as:

$$Ca \cdot Soil + (NH_4)_2SO_4 \rightleftarrows 2NH_4 \cdot Soil + CaSO_4$$

In 1848 Thompson communicated a brief outline of his results to Way, nho had recently been appointed consulting chemist to the Royal Agricultural society of England. Way conducted a carefully designed series of experiments to elucidate the reaction of soils with metal ions. One of the most important conclusions Way drew from his investigations was that the cation exchange reaction was chemical in nature. He also pointed out that the displacing ability of individual cations from inorganic cation exchanging silicates was different but followed a reproducible order.

Way also demonstrated that the inorganic minerals in soil possessed marked exchanging properties. In fact he prepared the first synthetic cation exchangers of the aluminosilicate type having the approximate formula for the sodium form of $Na^+ AlSi_3O_8$ in which the Na^+ is exchangeable. The first successful commercial applications of ion exchange were initiated in 1905 with publications and subsequent patents by Robert Gans a German chemist. Gans obtained several patents for the preparation of synthetic hydrated aluminosilicates capable of softening water

One of the important disadvantages of the inorganic or siliceous type of cation exchangers is that their use is restricted to a narrow pH range near neutrality, because they eventually disintegrate in acid or highly basic solutions. Consequently their use is confined principally to aater softening. In 1930 it was found that the sulfonation of various types of coal converted them to cation exchangers which could function even in highly acid mediums; this made it practicable to exchange metal ions for hydrogen ions. The predominating exchanging group in the sulfonated coals was a sulfonic acid group ($-SO_3H$) in which the hydrogen is exchangeable.

An outstanding milestone was Adams and Holmes's discovery of the ion exchanging properties of synthetic resins. Both men were employed as chemists in the British government research laboratory at Teddington. Eng.; Adams was a specialist in the treatment of water, and Holmes had done considerable work on the synthesis of resins. Their joint efforts led to the synthesis of phenolic resins, resembling Bakelite. capable of undergoing cation exchange; and resins capable of anion exchange. The latter resins mere prepared from condensation of polyamines nith formaldehyde. Although these first resins were not very useful in themselves, their synthesis meant that chemists could now synthesize ion exchange resins with properties nearly as desired. For the first time practically all the ions could be removed from water by simple filtration without the application of heat as in distillation. Adams and Holmes were well aware of numerous other applications for utilizing ion exchange. The commercial production and improvement of synthetic resin exchangers soon followed. particularly by Holmes and I. G. Farbenindustrie. A major advance in resin development took place in 1942 when G. F. D'Alelio showed that remarkably efficient resins could be made by incorporating individual chemical groups possessing exchanging properties into preformed synthetic plastics which in themselves had no exchanging properties but were exceedingly stable.

Concomitantly with the development of greatly improved ion exchange resins went the discovery of new applications and techniques which greatly accelerated the introduction of ion exchange processes into numerous technological and laboratory operations. Three of the more important developments were: (1) Chemists of the Manhattan project (atomic bomb research program) demonstrated that by simple and rapid ion exchange processes, individual members of the chemical group known as the rare earths could be isolated (see RARE EARTHS). This finding led to the remarkably successful use of ion exchange to resolve highly complex mixtures. The purified materials included nucleic acids, amino acids. isotopes and several new elements. (2) In 1949 ion exchange resins mere first prepared in the form of sheets or membranes. While the use of membranes which permitted only ions of one sign to pass through had been known for many years, the commercial availability of more stable and effective membranes from the physically and chemically tough ion exchange resins greatly expanded the potential applications of a membrane system. In use, these membrane systems employ an electrical current to induce selective transport of ions, as explained below. (3) In 1953 chemists of the Dow Chemical company introduced a process utilizing ion exchangers to separate ionized substances from nonionized or slightly ionized substances in water solution. This process. called ion exclusion, made use of the fact that nonionized substances such as alcohols and sugars are free to diffuse unhindered into the water phase of the ion exchange resin, while ions are excluded because of their electrical charges. Inasmuch as the nonionized materials retained by the resin can be removed by additional water washes. the technique of ion exclusion made possible the deionization and separation of many products without the use of heat, electricity or chemical regenerants.

Ion Exchange Resins.—An ion exchanging resin consists of a polymeric organic network or backbone and ionized or functional groups which undergo exchange. A very effective organic network is formed by the polymerization of styrene in the presence of varying amounts of divinylbenzene, which serves to crosslink the long chains of styrene into a three-dimensional fish-net type of structure. Functional groups are introduced subsequently into the polystyrene or, in the case of other ion exchangers. may be part of the monomer. Common functional groups in the case of cation exchangers consist of acid groups such as carboxylic groups (R—COOH), sulfonic groups (R—SO_3H) and phenolic groups (R—OH); while anion exchangers contain basic amine groups such as quaternary ammonium groups (R—R'_3N—OH^-) and primary, secondary and tertiary amines (R—NH_2, R—R'SH, R—R'_2N), where R represents the organic network and R' represents organic radicals such as the methyl group (—CH_3). In a given resin the R' groups may be the same or different. Resins in which all the functional groups are identical are called monofunctional. Schematic diagrams of a crosslinked polystyrene strong acid and strong base ion exchanger are shown in fig. 1. These ion exchangers are prepared in the form of spheres or beads varying, from less than 0.04 mm. to 1 mm. in diameter. Larger-size beads tend to crack during the manufacturing process. The

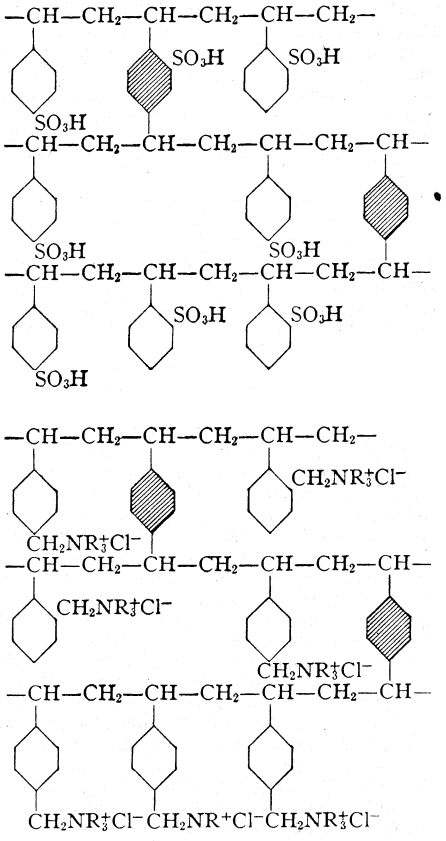

FIG. 1.— HYPOTHETICAL SCHEMATIC DIAGRAM OF A SULFONATED POLYSTYRENE CATION EXCHANGE RESIN CROSSLINKED BY DIVINYLBENZENE (TOP DIAGRAM) AND A STRONGLY BASIC QUATERNARY AMMONIUM ANION EXCHANGE RESIN (BOTTOM). THE CROSSHATCHED BENZENE RINGS SHOW THE DIVINYLBENZENE CROSSLINKAGE POINTS

commonest particle diameters used for water treatment are the range from 0.84 to 0.297 mm., but for certain difficult separations smaller sizes are used.

The type of ion exchange resins shown in fig. 1 are markedly resistant to chemical and physical attrition and are insoluble in all the common organic and inorganic solvents, including mineral acids and bases. High concentrations of oxidizing agents such as nitric acid can have deleterious effects by attacking the resins at a vulnerable point—the crosslinks. The salt forms of the cation exchange resins in contact with solutions can withstand temperatures up to about 140° C ; those of the anion exchange resins are stable up to about 90° C.

When immersed in water the ion exchange resins take up water and swell. The extent of swelling depends on the degree of crosslinkage—a quantity expressed by the percentage of divinylbenzene (DVB) used to prepare the resin. Thus a 10% DVB resin—the most commonly used—is made up of beads synthesized by the use of 90% by weight of styrene and 10% by weight of divinylbenzene. The extent to which a resin swells or shrinks depends on the salt concentration of the surrounding solution—the higher the concentration the less the suelling.

Ion exchange resins must have a crosslinked structure because the ionizable groups enhance the solubility and thus promote swelling. Too few crosslinks result in excessive swelling and reduced selectivity toward ions; while too many crosslinks so tighten the structure that the rate of the ion exchange reaction is too slow, since it depends on ionic diffusion. In practice a compromise must be effected in order to obtain a useful exchange resin. However, in special applications the ability to utilize resins of different crosslinkage is highly useful and sometimes indispensable. For example, when very large ions are to be taken up it is often desirable to use a low crosslinked resin so as to facilitate the entrance of the large ions into the "pores" of the resin.

Special resins are synthesized so as to contain functional groupings which have a specific or marked affinity for certain ions. Other special resins include types which undergo oxidation-reduction reactions. Instead of exchanging ions, these electron exchange polymers exchange electrons.

In the table a summary is given of some of the major types of available ion exchange resins, together with other pertinent information.

Principal Types of Ion Exchange Resins Available Commercially

Resin	Total capacity (Milliequivalents 1 g.)	Total capacity (Milliequivalents 1 c.c.)
Cation exchangers		
Strong acid (sulfonated polystyrene)	4.2	2.2
Carboxylic	4–10	1–4
Phenolic methylene sulfonic	1.3–2.5	0.5–1
Sulfonated coil	1.6	0.6
Aluminum silicate	1	—
Anion exchangers		
Strong base	2.3–2.5	1.0
Weak base	6–10	2–2.5

When the acid or hydrogen form of a cation exchanger is neutralized with sodium hydroxide, a plot of the cubic centimetres of base added against the pH yields a titration curve. Such curves are an important and convenient method of characterizing ion exchange resins. because they give information on the number of kinds of functional groups present, their acid or base strength and the capacity of the resin. The behaviour of a carboxylic acid resin of the type (R—COOH) closely parallels that of moderately weak acetic acid (CH_3—COOH), while the behaviour of monofunctional sulfonic acid resins resembles that of the strongly acid hydrochloric acid. On the other hand, the quaternary-ammonium-type anion exchange resins are nearly as basic as sodium hydroxide.

Techniques. — Contact between a solution and an ion exchanger involves either a batch or column process. In the batch process the resin is simply mixed with solution and agitated continuously or intermittently until equilibrium is reached—a period of a few minutes or several days depending on the resin and type of ions being exchanged. After equilibration the resin is removed by filtration. Batch techniques are infrequently employed for industrial purposes, but are often used in the laboratory for fundamental studies of the mechanism of ion exchange reactions.

Column methods generally involve fixed-bed operation, which refers to the use of a packed column of resin through which is passed the feed or regenerant solution. The resin is supported on a porous support while solution flows through by gravity or under pressure. The solutions are usually passed donn through the resin, though up-flow operation is not uncommonly employed, especially when it is desired to remove suspended particles from the resin bed during regeneration.

A fixed-bed cycle generally consists of the following steps: (1) saturation of the bed with solution until the desired or undesired ions break through to a predetermined level; (2) removal or elution of the retained ions by regenerant solutions; (3) rinsing of the bed free of regenerant so that the cycle can be repeated. Between cycles the bed may be backwashed by up-flow passage of water.

A less used but potentially important variation of column operation is the so-called moving bed or continuous countercurrent system. Here both the resin and solution are made to flow through the system.

An effective method for separating difficultly resolvable mixtures on the laboratory scale is by the technique of chromatographic elution. The ions to be separated are placed on the top of the resin bed and subsequently eluted stepwise with a solution containing ions capable of displacing the absorbed ions. The displaced ions move down the column as bands or zones at different velocities. If the column is long enough the bands may completely separate from one another. and the substance confined to each band is recovered in the outgoing solution, called the effluent.

Most applications of ion exchange involve column operation, because of the completeness of separation which can be obtained and the ease with which automatic instrumentation can be employed. Column techniques correspond to the use of a large number of batch operations in series, an analogy closely akin to fractional distillation processes.

Mechanism of Ion Exchange Reactions. — The equilibrium between monovalent exchanging ions. A^+ and B^+, for a cation exchanger can be written as a simple chemical reaction:

$$A^+ + BR \rightleftarrows B^+ + AR$$

where R represents the immobile resin anion with an assumed charge of −1. Ion exchange reactions show two important characteristics: (1) exchange of equivalent amounts of ions; and (2) preferential uptake by the exchanger of one ion over another. These properties are defined by the selectivity quotient, Q:

$$Q = \frac{[AR][B^+]}{[BR][A^+]}$$

where [AR/BR] is the molar ratio of the ions A^+ and B^+ in the resin phase in equilibrium with concentrations $[A^+]$ and $[B^+]$ in the solution phase. When $Q=1$ the resin shows no preference for A^+ over B^+. For easy separation it is important that Q be as far as possible from unity. When $Q>1$ then the resin shows preference for A^+ over B^+ and vice versa.

The selectivity quotient is not constant under varying conditions; it depends, for example, on the nature of the resin, the total concentration of the solution and the ratio of ions in the resin phase, and the nature of the ions. Inasmuch as the efficiency and hence the design of a column operation depend on the values of Q, it is apparent that the determination of Q is important. The greater Q differs from unity, then the shorter can be the column, the faster the flow rate and the sharper the separations.

In general terms and for dilute solutions, the affinity of an ion for an ion exchanger is governed largely by electrostatic forces and depends mainly on two factors—ionic charge and ionic size. Ions of higher charge are generally held more tightly, as in the series $Th^{+4} > La^{+3} > Sr^{+2} > Na^+$. For ions of the same charge the ion with the smallest radius in solution is held the

strongest. Thus for the alkali metals the order is: $Cs^+ > Rb^+ > K^+ > Na^+$; which reflects the fact that while Cs^+ has the largest crystal radius its hydrated radius is the smallest. That the hydrated radius is the important parameter is shown by the fact that in alcoholic solution where the ions become dehydrated, the affinity of the alkali metal ions for the ion exchanger is in the reverse order. The affinity of a cation exchanger for H^+ depends on the acid strength of the functional group.

A related and much-used quantity for evaluating separability is the distribution coefficient K_d, defined for a given ion in any ion exchange system, as for A^+, for example:

$$K_d^A = \frac{[AR]}{[A]} = \frac{\text{concentration } A^+ \text{ per unit weight resin}}{\text{concentration of } A^+ \text{ per c.c. of solution}}$$

The ratio $K_d^A/K_d^B = Q$ is called a separation factor.

Inasmuch as the functional groups of a resin are fixed. it is possible to formulate ion exchange reactions as a Donnan equilibrium. Consequently, for a reaction involving H^+ and Na^+:

$$Na^+ + HR \rightleftarrows NaR + H^+$$

and omitting activity coefficients (see SOLUTIONS), the equilibrium quotient, K, is

$$K = \frac{[NaR][H^+]}{[HR][Na^+]}$$

This equation is identical in form with one based on the law of mass action.

When the resin phase is treated as an ordinary aqueous solution, and the standard state is taken to be the same in both phases, then the value of K becomes unity when both phases are dilute. However, in the ordinary 10% DVB resin the internal concentration is about 6 molal; hence it is necessary to insert activity coefficients into the equation to take into account the marked effects of concentration changes on equilibrium. When resins of very low crosslink are used. the internal resin phase becomes more dilute; *i.e.*, the resin takes up more water. This serves to reduce the selectivity of the resin for one ion over another because the differences in activity become less.

When ions of unequal valences are exchanging, such as Ca^{++} and Na^+, the ion exchange reaction is

$$Ca^{++} + 2NaR \rightleftarrows CaR_2 + 2Na^+$$

and

$$K = \frac{[CaR_2][Na^+]^2}{[Ca^{++}][NaR]^2} = Q\left[\frac{Na^+}{NaR}\right]$$

From the definition of Q it is found that the selectivity of the resin for Ca^{++} relative to Na^+ is given by the expression

$$Q(Ca/Na) = \frac{K[NaR]}{[Na^+]}$$

When the concentration of Ca^{++} is very small relative to Na^+, then [NaR] remains nearly constant; and it is seen that the selectivity of the resin for the divalent cation is inversely proportional to the sodium concentration in solution. Thus in water softening, where a dilute solution of Ca^{++} and Na^+ salts is dealt with, the resin is very efficient in removing the Ca^{++}. However, in regeneration the use of a strong solution of sodium chloride is effective in eluting calcium. The use of greater concentrations of the ion of lower valence tends to reduce its relative affinity for the resin.

In very concentrated solutions, usually above 3 M (molar), the resins may have a greater affinity for ions of lower charge. This polyvalent ion effect also holds for anion exchange.

The resin phase must maintain electrical neutrality at all times. Because of the presence of a preponderance of nondiffusible "resinate" ions (R^- in the case of a cation exchange, and R^+ in the case of anion exchange) the penetration of ions of the same charge into the resin phase is hindered—a manifestation of the Donnan effect. Consider the case of the hydrogen form of a cation exchanger immersed in a solution of hydrochloric acid. In dilute solutions the concentration of Cl^- in the resin phases is nearly nil. However, as the external concentration of HCl increases, the concentration of Cl^- in the resin phase in the form of HCl increases and approaches that of the outside solution. Neglecting activity coefficients. the expression for the diffusion of HCl into the resin phase is:

$$\frac{[Cl^-]\text{resin}}{[Cl^-]\text{solution}} = \sqrt{\frac{1}{1+\frac{[R^-]}{[Cl^-]\text{resin}}}}$$

One gram of a 10% DVB resin, HR, contains about 5 millimoles of H^+ and R^- in roughly 1 c.c. volume; *i.e.*, it is roughly 5 M in H^+ and R^-. When immersed in a 0.1 M solution of HCI, the equation illustrates the fact that the ratio $[R^-]/[Cl^-]$ resin $= \frac{5}{0.1} = 50$, so that the concentration of Cl^- in the resin is very small; namely. about 0.014 M. When the concentration of HCl in solution is 10 M, the concentration of Cl^- in the resin is calculated to be about 8.1 Ill. This example shows that while the total exchange capacity of the resin nas only 5 millimoles. the actual concentration of H^+ in the resin was 8.1 M, 3.1 millimoles greater than the total exchange capacity.

Those ions which enter the resin as a result of Donnan effects can be leached out mith water, while those ions needed to neutralize the functional groups remain. In the case of uncharged substances, their concentration in the resin phase may actually exceed the external solution concentration because there exist no charge factors to exclude them and. in addition, the resin phase often acts to hold them selectively. This is the basis for the ion exclusion process described in the section *Historical* Development.

The rate nith which an ion exchange reaction reaches equilibrium does not depend on the chemical exchange reaction but rather on the rates of diffusion of the exchanging ions into and away from the ion exchanger. In a well-stirred solution. ion exchange kinetics is governed by one of two diffusion mechanisms: (1) diffusion of the ions through a hypothetical film of solution surrounding each ion exchange particle (F mechanism); or (2) diffusion of the ions through the exchanger particle itself (P mechanism). When both mechanisms are significant in an ion exchange reaction, one has the condition termed "intermediate" (I mechanism). It is helpful to know which diffusion mechanism is operativc because it gives both qualitative and quantitative information on how the rate varies mith changes in the particle size of the exchanger. concentration of the solutions, charge of the ions and manv other warameters, including the internal structure of the resin. Since column methods are usually operated under nonequilibrium conditions, kinetic information helps to predict the performance of a given column process and hence the design

The differences between ion exchange reactions governed by F or P rate mechanisms may be summarized in general as follows: (1) a P mechanism is independent of stirring or flow rates while the reaction rate of an F-mechanism-controlled reaction increases with increasing stirring or flow rates; (2) in the early stages a plot of the amount of exchange which has taken place against the square root of time gives a linear plot for a P mechanism: while an F mechanism gives a linear plot when the log of the amount of exchange is plotted against the first power of time; (3) at high concentrations in the surrounding solutions the rates tend to be governed by a P mechanism, and at low concentrations by an F mechanism; and (4) the rate constant varies inversely as the first power of the radius of the exchanger particle for an F mechanism, and as the square of the particle radius for a P mechanism.

Applications.— As noted previously, the softening of water is the most widely used ion exchange process. Water-softening units in individual homes find widespread use in the U.S.; home uses are being developed in Great Britain and in Europe. Some communities soften water before it reaches the home. Los Angeles, Calif.. softened about 80,000,000 gal. of river water a day in the 1950s and could. at full capacity, provide 200,000,000 gal. of softened water a day. Numerous industries soften water or provide deionized water in order to improve the quality of various products,

such as television tubes, storage batteries, drugs, sugar and paper.

One interesting technique increasingly used in water conditioning includes the use of mixed-bed units. In this technique, the cation and anion exchange resins are mixed so that complete

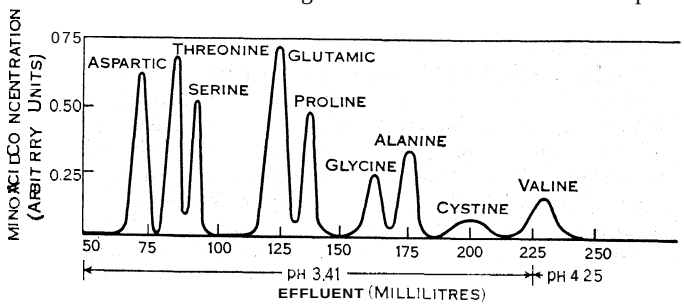

FIG. 2.—ION EXCHANGE SEPARATION OF AMINO ACIDS BY ELUTION WITH BUFFERS OF INCREASING pH FROM A STRONGLY ACID CATION EXCHANGE RESIN

The shapes of the curves, as those of other systems, vary depending on flow rate, concentrations of substances being separated, temperature, length of column and other factors

demineralization occurs in the passage of water directly, instead of the usual technique in which water runs through a series of alternate anion-resin-containing tanks. In a mixed bed the resins are regenerated separately by separation of the lighter anion resin by hydraulic classification. After regeneration the resins are mixed, compressed air being used for agitation.

The recovery of metals from industrial wastes and the purification of solutions for re-use are important applications of fixed-bed exchange. However, for such processes to be worthwhile, the recovered metal must have a relatively high economic value, or the savings resulting from the re-use of the solution must be high. The first large-scale use of ion exchange for metal recovery (copper from rayon spinning wastes) took place in Germany beginning about 1940. Deionization. of many organic chemicals such as gelatin. sorbitol and glycerine is achieved by ion exchange. Anion exchange resins are used successfully to remove formic acid from formaldehyde.

The isolation of materials present in small amounts is another successful ion exchange technique. Streptomycin is a large organic molecule which behaves as a cation. It is concentrated from fermentation broths by absorption on a cation exchange resin, and is recovered in high concentration by displacement with dilute acid.

The separation of complex mixtures of ions has found especially useful applications in scientific studies. Examples of two such processes are given because they illustrate important principles which are of great utility.

Rare earths are trivalent cations so similar in properties that ordinary ion exchange separation methods do not work with them. However, it is possible to convert the rare-earth cations into complexes by the use of complexing agents such as citric, lactic and other organic acids. These complexes are usually anions and as such are not absorbed by a cation exchange resin. The rare-earth cations are placed on the top of a bed of a cation exchanger, and elution is facilitated by the use of complexing solutions of suitable pH and concentration. Since the stability of the complex ions varies, the over-all differences in affinity of the individual rare earths for the resin are enhanced. Of further interest is the fact that under given conditions the rare earths are eluted in an orderly sequence based on atomic number. This behaviour led to the first positive identification and subsequent solution of element 61, named promethium. Similarly, the same complex or chromatographic elution technique led directly to the discovery of the elements curium, berkelium, californium, einsteinium and fermium.

Amino acids possess both acidic and basic groups so that they can be absorbed on either cation or anion exchange resins. By suitable variations in pH of an eluting solution, it is possible to obtain separations of individual amino acids, as is shown in fig. 2.

In medicine, weak base anion resins are useful in the treatment of ulcers. When taken orally in the form of a powder or in a capsule, they act to neutralize excess hydrochloric acid in the stomach. Cation exchange resins in the form of mixed potassium-ammonium forms are capable of removing excess sodium from the body, and thus reducing water retention believed to result from the water held by sodium ions.

It is possible only to mention the myriad of other uses of ion exchangers. These include the separations of peptides, nucleic acids, sugars, aldehydes and ketones, and the removal of calcium from blood to prevent coagulation. Since ion exchange resins are essentially acids or bases, they find considerable uses as catalysts in hydrolysis and esterification reactions. They have the advantage that as catalysts they can be removed from the reaction mixture by simple filtration and re-used after regeneration.

Many studies of a fundamental nature are carried out with ion exchange resins, since they serve as tools for measuring the stability of complex ions, determination of the state of an element in solution and measurement of activity coefficients. Ion exchangers are widely used in analytical chemistry and other branches of chemistry for the purification of reagents and the preparation of different salt forms of compounds. Salts of acids, when passed through the hydrogen form of a cation exchanger, liberate H^+ which can be titrated, thus yielding the concentration of the original salt. Electrochemical methods of utilizing ion exchange resins, particularly in the form of membranes, are used for demineralization of water and chemicals. In a simple three-compartment cell a cation and an anion exchange membrane divide a container into three regions. Upon application of a current, the cations present in the middle compartment move through the cation membrane, while the anions move into the anion compartment. Thus the middle compartment is demineralized. A series of such cells can be used in which water or other liquids passing continuously through the middle compartment are demineralized. Electrochemical operations become less economical as the salt concentration in solution increases; *i.e.*, current consumption becomes higher. It was found impractical, therefore, to demineralize salt water, but it did appear practical for reducing the salt concentration of brackish waters to render them fit for drinking or irrigation.

In summary, the most widely used industrial application of ion exchange is in water treatment (softening. demineralization, silica removal and reduction of alkalinity). Next in importance industrially is metal recovery, followed by removal of ash from organic chemicals, ion separation, recovery of acids and bases, and catalysis.

(J. ST.)

IONIA, in ancient geography, the name given to a portion of the west coast of Asia Minor, adjoining the Aegean sea and bounded on the east by Lydia. It consisted of a narrow strip of land near the coast which, together with the adjacent islands, was occupied by immigrant Greeks (Ionians), and thus distinguished from the interior district, inhabited by the Lydians. According to the universal Greek tradition, the cities of Ionia were founded by emigrants from the other side of the Aegean (*see* IONIANS), and their settlement was connected with the legendary history of the Ionians in Attica, for the colonists were led by Neleus and Androclus, sons of Codrus. the last king of Athens. Modern thought tends to support the popular Greek idea that Ionia received its main Greek element rather late—after the descent of the Dorians and, therefore, after the Aegean period. Herodotus says (i, 146) that the colonists comprised settlers from many different tribes and cities of Greece (a fact indicated also by the local traditions of the cities) and that they intermarried with the native people.

The cities called Ionian in historical times were 12 in number—an arrangement copied, as it was supposed, from the constitution of the Ionian cities in Greece which had originally occupied

the territory in the north of the Peloponnesus subsequently held by the Achaeans. These were (from south to north)—Miletus, Myus, Priene, Ephesus, Colophon, Lebedus, Teos, Erythrae, Clazomenae and Phocaea, together with Samos and Chios. Smyrna (*q.v.*), originally an Aeolic colony, was afterward occupied by Ionians from Colophon and became an Ionian city—an event which had taken place before the time of Herodotus. But at what period it was admitted as a member of the league is not known. Like the Amphictyonic league in Greece, the Ionic was rather of a sacred than a political character; every city enjoyed absolute autonomy. and, though common interests often united them for a common political object, they never formed a real confederacy like that of the Achaeans or Boeotians.

Ionia was a mountainous country, 90 mi. long from north to south, with a breadth varying from 20 to 30 mi.; to this area must be added that of the peninsula of Mimas, together with that of two large islands. Among the outstanding peaks were Mimas and Corycus, situated on the peninsula which stands out to the west. facing the island of Chios; Sipylus, to the north of Smyrna; Corax, extending to the southwest from the Gulf of Smyrna, and descending to the sea between Lebedus and Teos. The strongly marked range of Mycale. a continuation of Messogis in the interior, forms the bold headland of Trogilium or Mycale, opposite Samos. None of these mountains attains a height of more than 4,000 ft. The district comprised three extremely fertile valleys: the Hermus in the north, flowing into the Gulf of Smyrna; the Cayster. which flowed under the walls of Ephesus; and the Maeander, which in ancient times discharged its waters into the deep gulf that once came up to the walls of Miletus, but which has been gradually silted up by deposits brought down by the river. In ancient times Ionia was considered the most fertile of all the provinces of Asia Minor.

The colonies naturally became prosperous. Miletus especially was at an early period one of the most important commercial cities of Greece; the mariners of Phocaea extended their influence to the shores of the western Mediterranean; Ephesus from an early period became a flourishing city.

History.—About the middle of the 7th century B.C., the Cimmerii (see SCYTHIA) ravaged a great part of Asia Minor, including Lydia, and sacked Magnesia on the Maeander, but failed to take Ephesus. About 700 B.C. Gyges, first Mermnad king of Lydia. invaded the territories of Smyrna and Miletus; and is said to have taken Colophon as his son Ardys did Priene. But it was not till the reign of Croesus (560–545 B.C.) that the cities of Ionia successively fell, under Lydian rule. The defeat of Croesus by Cyrus was followed by the conquest of all the Ionian cities. They became subject to the Persian monarchy with the other Greek cities of Asia. They continued to enjoy a considerable amount of autonomy, but were subject to local despots. It was at the instigation of one of these, Histiaeus (q v.) of Miletus, that in about 500 B.C. the principal cities broke out into insurrection against Persia. They were at first assisted by the Athenians, with whose aid they penetrated into the interior and burned Sardis, an event which ultimately led to the Persian invasion of Greece. But the Ionian fleet was defeated off the island of Lade. and the destruction of Miletus after a protracted siege was followed by the reconquest of all the Asiatic Greeks.

The Greek victories during the Persian war had the effect of enfranchising their kinsmen on the other side of the Aegean; and the battle of Mycale (479 B.C.), in which the defeat of the Persians was in great measure due to the Ionians, secured their emancipation. They henceforth became the dependent allies of Athens (see DELIAN LEAGUE), though still retaining their autonomy, which they preserved until the peace of Antalcidas in 387 B.C. once more placed them, as well as the other Greek cities in Asia, under the nominal dominion of Persia. They appear. however, to have retained a considerable amount of freedom until the invasion of Asia Minor by Alexander the Great. After the battle of the Granicus most of the Ionian cities submitted to the conqueror. Miletus, which alone held out, was reduced after a long siege (334 B.C.). From this time they passed under the dominion of the Macedonian rulers of Asia, but continued, with the exception of Miletus (*q.v.*), to prosper both under these Greek dynasties and as part of the Roman province of Asia.

Ionia was the home of the Ionian school of philosophy (*q.v.*); it led the way also for the brilliant artistic development of Athens in the jth century. Ionian art flourished in the 8th, 7th and 6th centuries, distinguished by fineness of workmanship and minuteness of detail. See GREEK ART.

IONIAN ISLANDS, the collective name for the Greek islands of Corfu (Kérkyra), Cephalonia (Kephallēnia), Zante (Zakynthosj, Santa Maura (Levkas), Ithaca (Ithakē), Cythera (Kýthēra) and Paxo (Paxoi) (*qq.v.*), with their minor dependencies. These islands, though often described as the *Heptanesus* ("Seven Islands"), have no geographical unity. The name Ionian is obscure, but is probably due to ancient Ionian colonies, for example in Corfu from Eretria. The political unity of the islands is comparatively modern; their independence lasted only seven years (1800–07). Pop. (1951) 228,597.

The Ionian islands consist almost entirely of Cretaceous and Tertiary beds, but in Corfu Jurassic deposits have been found. The oldest beds which have yet been recognized are shales and hornstones with Liassic fossils. These are overlaid conformably by a thick series of platy Viglas limestone, representing the rest of the Jurassic and the lower Cretaceous. Then follow dolomites and unbedded *Hippurites* limestones evidently Upper Cretaceous age. The Eocene beds are folded with the Cretaceous. Both occasionally assume the form of Flysch. Miocene beds are found in Corfu and Zante, and Pliocene deposits cover much of the low ground. (X.)

HISTORY

Mediaeval and Venetian **Periods.**—The beginning of Heptanesian history dates from the 9th century. Leo the Philosopher (*c.* A.D. 890) formed all or most of the islands into a distinct province of the Eastern empire under the title of the Thema of Cephallenia. Robert Guiscard captured Corfu (1081) and Cephalonia, but his early death prevented the establishment of a Norman dynasty. When the Latin empire was established at Constantinople in 1204 the Venetians received Corfu. After defeating the Genoese corsair Leon Vetrano, the senate granted fiefs in Corfu to ten noble families in order that they might colonise it (1206). The Greek "Despot" of Epeiros, however, captured the first Venetian colony in 1214, and a long period of Epeirote, Sicilian and Neapolitan-Angevin rule followed till in 1386 the people of Corfu made voluntary submission to the Venetian republic.

Paxo, created a barony, was treated as part of Corfu. The County Palatine of Cephalonia (with Zante), seized by Matteo Orsini in 1194, owned the suzerainty first of Venice, then of Achaia, to which it was annexed in 1324. In 1357 it was bestowed upon the Tocco family of Benevento, and was united with Santa Maura and Ithaca (called Val di Conspare) in the Duchy of Leucadia. In 1479 the Turks annexed these four islands. But they gradually became Venetian; Cephalonia and Ithaca 1483–85, and from 1500 onwards; Zante 1482 and from 1485, and Santa Maura 1502–03 and from 1684. Cerigo, a Venetian Marquisate of the Venier family from 1207, became a Venetian colony in 1363, but was parcelled out between Venice and the Venier in 1393.

The Venetians, who exacted heavy contributions from the islands, won the adherence of the principal native families by the bestowal of titles and appointments; the Roman Catholic Church was established, and the Italian and Greek races were largely assimilated by intermarriage; Greek ceased to be spoken except by the lower classes, which remained faithful to the orthodox communion. On the fall of the Venetian republic in 1797 the Treaty of Campo Formio annexed the Ionian islands to France; but a Russo-Turkish force drove out the French at the close of 1798; and in the spring of 1799 Corfu capitulated. By treaty with the Porte in 1800, the Emperor Paul erected the "Septinsular Republic," but the Treaty of Tilsit (1807) declared the islands an integral part of the French empire. They were incorporated with the province of Illyria (*q.v.*); but British forces under General Oswald took Zante, Cephalonia and Cerigo in 1809, and Santa Maura in 1810; Colonel (afterwards Sir Richard) Church

(*q.v.*), reduced Paxo in 1814; and after the abdication of Napoleon, Corfu, which had been defended by General Donzelot, was, by order of Louis XVIII. surrendered to Sir James Campbell. By the Treaty of Paris (Nov. 9, 1815) the contracting powers (Great Britain, Russia, Austria and Prussia) agreed to place the "United States of the Ionian Islands" under the exclusive protection of Great Britain.

British Protectorate. — The constitutions, voted by a constituent assembly in 1817 and applied in the following year, placed the administration in the hands of a senate of six members and a legislative assembly of 40 members; but the real authority was vested in the high commissioner, Sir Thomas Maitland ("King Tom") (1815). The successive British commissioners, General Sir Frederick Adam (1823), Lord Nugent (1832) and Sir Howard Douglas (1835–41) did much for the administration, justice, education and communications of the islands, but their firm, often despotic rule was resented by the natives, the principal exponent of the opposition being the historian Andreas Mustoxidi (d. 1861). A complete change of policy was inaugurated by Mr. Mackenzie (1841–43), and Lord Seaton (1843–49) was induced by the European disturbances of 1848 to initiate a number of important reforms. But the party in favour of union with Greece was rapidly growing. Serious insurrections of the peasantry, especially in Cephalonia, had to be put down by military force, and the parliament passed a resolution in favour of immediate union with Greece.

Cession to Greece. — Contrary to the expectations of the Greeks, Mr. Gladstone, who toured the islands as high commissioner extraordinary, did not propose the abolition of the protectorate, and his successor, Sir Henry Storks, seemed indifferent or blind to the popular feeling, but on the abdication of King Otho of Greece in 1862 the British Government declared to the provisional government of Greece that the selection of Prince William George of Gliicksberg would be followed by the cession of the Ionian islands. After the prince's election by the national assembly in 1863 the high commissioner laid before the Ionian Parliament the conditions of the cession. The rejection of one condition (the demolition of the fortifications of Corfu) led to a new prorogation, but on March 29, 1864, the plenipotentiaries of the five great Powers signed the treaty by which the protectorate was ended. Neutrality was confined to Corfu and Paxo. On May 3, 1864 Sir Henry Storks left Corfu with the British troops and men-of-war. King George made his entry into Corfu on June 6.

After their annexation to Greece the history of the Ionian islands was uneventful; their prosperity somewhat declined. Corfu with Paxo; Cephalonia; Santa Maura (Levkas) with Ithaca and Zante (Zacynthos) each formed separate monarchies or departments; Cerigo (Cýthera) formed part of the monarchy of Laconia. The islands retained the exemption from direct taxation which they enjoyed under the British protectorate; in lieu of this there was an ad *valorem* tax of 20½% on exported oil and a tax of 6% on wine exported to Greek ports; these commodities were further liable to an export duty of 1½% levied on all agricultural produce and articles of local manufacture. Axis troops occupied the islands in 1941.

IONIAN MODE: *see* PLAINSONG.

IONIANS. This name was used in classical times for one of the four divisions of the Greek world, the remaining three being Aeolic, Doric and Arcado-Cypriote or Achaean. This is strictly a linguistic division, and the Greeks did not recognize it in an exact sense. Aeolian, Dorian and Ionian were well-marked divisions socially as well as linguistically. There was also a strong race antipathy between Dorian and Ionian, manifested particularly in the Peloponnesian War, in which Athens and Sparta were the protagonists. Each was inclined to regard the other as not fully Hellenic. The Ionians claimed that the Dorians were the descendants of non-Greek northern invaders commingled with an earlier Greek population of the Peloponnese. The Dorians asserted that the Ionians were pre-Greek or Pelasgian, standing much in the same relationship to true Greeks as do the Welsh and other Britons to the Anglo-Saxons.

Attica was the centre of Ionic culture on the mainland. Euboea and the Cyclades were also regarded as Ionic with the exception of the Dorian islands of Melos and Thera, but the name Ionia itself in classical times was confined to the tract of land on the coast of Asia Minor that contained the Ionic cities. This lay between Aeolis on the north and Doris on the south, and extended from Smyrna to Miletus. The twelve cities, while retaining their independence in true Greek fashion, formed a league for social and religious purposes, their central cult being that of Poseidon carried on upon Mt. Mycale. The Ionians claimed that this worship derived from Achaia in the Peloponnese, but it at least contained elements that were Anatolian in origin. The Ionian cities were energetic, thriving and opulent. Their wealth made them luxurious and they had a name for effeminacy. They were subdued by Croesus, king of Lydia, in the middle of the sixth century and passed at his subjugation under the Persian empire. In 500 they revolted but were conquered by King Darius and a higher tribute was imposed upon them. After the successful termination of the Persian wars they were set free by the Greeks of the mainland under the leadership of Athens, but later fell again under Persia when that empire recovered its strength. They remained nominally subject to Persia till its overthrow by Alexander the Great. There were various Ionic colonies on the coast of the Euxine and in Sicily and Magna Graecia.

The chief characteristics of the Ionic dialect to which Attic was closely akin were: (i.) the representation of an original long *ā* by *ē*, for example in the word *μήτηρ* for Doric, etc., *μᾶτηρ*, Lat. *mater;* (ii.) the lengthening of the vowel before a nasal or liquid that preceded a lost digamma, *e.g.*, *ξεῖνος*, *κούρη* for Attic *ξένος*, *κόρη*; (iii.) the nom. plur. of the personal pronouns in *-εις* instead of *-ες*, *e.g.*, *ἡμεῖς* for Doric *ἀμές*; (iv.) the termination *-ου* for pronominal adverbs of place (*ποῦ*, etc.) for West Greek *-ει*; the third person plural of certain aorist forms in *-σαν* (*ἔθεσαν*, *ἔδοσαν*) by analogy from an s-aorist; (v.) the very early loss of digamma, etc. Ionic-Attic with Aeolic formed loosely an eastern group of dialects as opposed to Doric and North-West Greek. The turning of the original dialect of the Homeric poems, Aeolic or otherwise, into Ionic where possible, *i.e.*, where the exigencies of the metre, vocabulary, and other considerations permit, produced the artificial Epic dialect.

The name Ionians had probably a more extensive use in early times than in historical. In the Pentateuch, in the 15th or 16th century B.C. (Gen. x. 2), Javan appears as a son of Japheth. To the Hebrews the name represented the whole Greek race. To the Persians the Greeks were known as Yauna. It does not follow from this fact that the Greeks knew themselves by this name, for the case may be parallel to the Italians and Illyrians later applying to them'the name of Graeci, that of the small Epirote trihe with whom they first came in contact. In view of the name of the

Ionian sea, which was ancient, it is possible that the mainland of Greece was once known as Ionia or its inhabitants as Ionians. No Ionian Greeks lived in historical times on the shores of the Ionian sea.

The Homeric Ionians were inhabitants of Attica (*Il.* xiii. 685). In the Hesiodic genealogies Ion was son of Xuthus and brother of Achaeus. According to Herodotus the original home of the Ionians was in north-east Peloponnese in the region around Troezen. Hence they were expelled by the Achaeans and occupied Attica, from which they later spread to the Cyclades and to Asia Minor. This traditional history of the Ionians is feasible and need not be dogmatically contradicted. We may perhaps regard the Ionians as pre-Achaean inhabitants of the Peloponnese disturbed by Achaean invaders from the eastern Aegean. This is the view of Kretschmer and of N. P. Nilsson, except that they bring the Achaeans as a second wave of Greek-speaking peoples from the north. Nilsson regards the Ionians as the foremost wave of Greek-speaking peoples to reach Greece and as the originators of the Mycenaean culture. Later came the Dorian invasion of the Peloponnese, consisting perhaps of two coincident elements, an irruption of Illyrian and Epirote tribes from the north-west and an invasion by sea from Crete. The Ionians when they emerge into history are a recognized integral part of the Greek world, distinguished like the Dorians by a well-marked dialect and a common cult. (See DORIANS; ACHAEANS: GREECE: *History.*)

C. A.)

IONIAN SCHOOL OF PHILOSOPHY. Under this name are included a number of philosophers of the 6th and 5th centuries B.C. Mainly Ionians by birth, they are united by a local tie and represent all that was best in the early Ionian intellect. It is a most interesting fact in the history of Greek thought that its birth took place not in Greece but in the colonies on the west coast of Asia hlinor. But not only geographically do these philosophers form a school; they are one in method and aim. They all sought to explain the material universe as given in sensible perception; their explanation was in terms of matter, movement, force. In this they differed from the Eleatics and the Pythagoreans who thought in the abstract, and explained knowledge and existence in metaphysical terminology. In tracing the development of their ideas, two periods may be distinguished. The earliest thinkers down to Heraclitus endeavoured to find a material substance of which all things consist; Heraclitus, by his principle of universal flux, took a new line and explained everything in terms of force, movement, dynamic energy. The former asked the question, "What is the substratum of the things we see?"; the latter, "How did the sensible world become what it is; of what nature was the motive force?"

The first name in the list of the Ionian philosophers—and, indeed, in the history of European thought—is that of Thales (*q.v.*). He first, so far as we know, sought to go behind the infinite multiplicity of phenomena in the hope of finding an infinite unity from which all difference has been evolved. This unity he decided is Water. It is impossible to discover precisely what he conceived to be the relation of this unity to the plurality of phenomena. Later writers from whom we derive our knowledge of Thales attributed to him ideas which seem to have been conceived by subsequent thinkers. Thus the suggestion preserved by Stobaeus that he conceived water to be endowed with mind is discredited by the specific statement of Aristotle that the earlier physicists (*physiologi*) did not distinguish the material from the moving cause, and that before Anaxagoras no one postulated creative intelligence. Again in the De *anima* (i. 5) Aristotle quotes the statement that Thales attributed to water a divine intelligence, and criticizes it as an inference from later speculations. It is probably safest to credit Thales with the bare mechanical conception of a universal material cause, leaving pantheistic ideas to a later period of thought.

The successors of Thales mere Anaximander and Anaximenes, who also sought for a primal substance of things. Anaximander postulated a corporeal substance unlike any of the known substances. This substance he called "the Indeterminate" (τὸ ἄπειρον). He felt that all determinate things have emerged from primal unity (first called ἄρχη by him) into which they must ultimately return. Change, growth and decay he explained on the principle of mechanical compensation.

Anaximenes, pupil of Xnaximander, seems to have rebelled against the extreme materialism of his master. Perceiving that air is necessary to life, that the universe is surrounded by air, he was convinced that out of air all things have resulted. The process by which things grow is twofold, condensation (πύκνωσις) and rarefaction (ἀραίωσις), or, in other words, *heat* and *cold.* From the former process result cloud, water and stone; from the latter, fire and aether. This theory is closely allied to that of Thales, but it is superior in that it specifies the processes of change. Further, it is difficult not to accept Cicero's statement that Anaximenes made air a conscious deity; we are, at all events, justified in regarding Anaximenes as a link (perhaps an unconscious link) between crude Hylozoism (*q.v.*) and definitely metaphysical theories of existence.

We have seen that Thales recognized change, but attempted no explanation; that Xnaximander spoke of change in two directions; that Anaximenes called these two directions by specific names. From this last, the transition to the doctrine of Heraclitus is easy. He felt that change is the essential fact of experience and pointed out that any merely physical explanation of plurality is inherently impossible. The Many is of Sense; Unity is of Thought. Being is intelligible only in terms of Becoming. That which is, is what it is in virtue of its perpetually changing relations (πάντα ῥεῖ καὶ οὐδὲν μένει). By this recognition of the necessary correlation of Being and Not-being, Heraclitus is in a very real sense the father of metaphysical and scientific speculation, and in him the Ionian school of philosophy reached its highest point. Yet there is renson to doubt the view of Hegel and Lassalle that Heraclitus recognized the fundamental distinction of subject and object and the relations of mind and matter. Like the early Ionians he postulated a primary substance, fire, out of which all things have emerged and into which all must return. This elemental fire is in itself a divine rational process, the harmony of which constitutes the law of the universe. Human knowledge consists in the comprehension of this all-pervading harmony as embodied in the manifold of perception; the senses are "bad witnesses" in that they report multiplicity as fixed and existent in itself rather than in its relation to the One. This theory gives birth to a sort of ethical by-product whose dominant note is Harmony, the subordination of the individual to the universal reason; moral failure is proportionate to the degree in which the individual declines to recognize his personal transience in relation to the eternal Unity. From the same principle there follows the doctrine of Immortality. The individual, like the phenomena of sense, comes out of the infinite and again is merged; hence on the one hand he is never a separate entity at all, while on the other hand he exists in the infinite and must continue to exist. Moreover, the soul approaches most nearly to perfection when it is least differentiated from elemental fire; it follows that "while we live our souls are dead within us, but when we die our souls are restored to life." This doctrine is at once the assertion and the denial of the self, and furnishes a striking parallel between European thought in its earliest stages and the fundamental principles of Buddhism. Knowledge of the self is one with knowledge of the Universal Logos (Reason); such knowledge is the basis not only of conduct but of existence itself in its only real sense.

Thus far the Ionian philosophers had held the field of thought. Each succeeding thinker had more or less assumed the methods of Thales, and had approached the problem of existence from the empirical side. About the time of Heraclitus, however, there sprang up a totally new philosophical spirit. Parmenides and Zeno (*see* ELEATIC SCHOOL) enunciated the principle that "Nothing is

born of nothing." Hence the problem becomes a dialectical a priori speculation wherein the laws of thought transcend the sense-given data of experience. It was therefore left for the later Ionians to frame an eclectic system, a synthesis of Being and Not-being, a correlation of universal mobility and absolute permanence. This examination of diametrically opposed tendencies resulted in several different theories. It will be sufficient here to deal with Anaxagoras, Diogenes of Apollonia, Archelaus and Hippo, leaving Empedocles, Leucippus and Democritus to special articles. The latter three do not belong strictly to the Ionian School.

Anaxagoras (*q.v.*) elaborated a quasi-dualistic theory according to which all things have existed from the beginning. Originally they existed in infinitesimal fragments, infinite in number and devoid of arrangement. Among these fragments were the seeds of all things which have since emerged by the process of aggregation and segregation, wherein homogeneous fragments came together. These processes are the work of Nous (νοῦς) which governs and arranges. But this Nous or Mind, is not incorporeal; it is the thinnest of all things; its action on the particle is conceived materially. It originated a rotatory movement, which arising in one point gradually extended till the whole was in motion, which motion continues and will continue infinitely. By this motion things are gradually constructed not entirely of homogeneous particles (the homoeomerê, ὁμοιομερῆ) but in each thing with a majority of a certain kind of particle. It is this aggregation which we describe variously as birth, death, maturity, decay and of which the senses give inaccurate reports. His vague dualism works a very distinct advance upon the crude hylozoism of the early Ionians, and the criticisms of Plato and Aristotle show how highly his work was esteemed. The great danger is that we should credit him with more than he actually thought. His Nous was not a spiritual force; it was no omnipotent deity; it is not a pantheistic world-soul. But by isolating reason from all other growths, by representing it as the motor-energy of the Cosmos, in popularizing a term which suggested personality and will, Anaxagoras pave an impetus to ideas which were the basis of Aristotelian philosophy in Greece and in Europe at large.

In Diogenes of Apollonia we find a return to Anaximenes. Diogenes (*q.v.*) began by insisting on the necessity of there being only one principle of things, herein contradicting the pluralism of Heraclitus. This principle is that of the universal homogeneity of nature; all things are at bottom the same. or interaction would be impossible. This universal substance is air. But Diogenes went much farther than Anaximenes by attributing to air not only infinity and eternity but also intelligence.

Another pupil of Anaxagoras was Archelaus of Miletus (*q.v.*). His work was mainly the combination of previous views. except that he is said to have introduced an ethical side into the Ionian philosophy. "Justice and injustice." he said. "are not natural but legal." He endeavoured to overcome the dualism of Anaxagoras, and in so doing approached more nearly to the older Ionians.

The last of the Ionians whom we need mention is Hippo (*q.v.*), who, like Xrchelaus, is intellectually among the earlier members of the school. He thought that the source of all things was moisture. and is by Xristotle coupled with Thales (*Metaphysics,* A 3).

IONIC ORDER: see ORDER.

IONIC THEORY: see ELECTRICITY? CONDUCTION OF: Conduction in *Gases;* ELECTRICITY: *Ions.*

IONOSPHERE, an electrically conducting sphere completely surrounding the earth. The name is derived from the presence of ions and free electrons produced by the sun's ultraviolet radiation. The ionosphere exists in the earth's outer atmosphere. above the stratosphere and mesosphere and extends from heights of approximately So to 300 km. (50 to 200 mi.). (*See* ATMOSPHERE.) It was more commonly known as the "Kennelly-Heaviside layer" in the period 1901–30. The ionosphere makes possible all long-distance radio communications using high-frequency waves. since it reflects the signals back to earth. keeping them from being lost in space.

Before 1901 it was thought that wireless (radio) waves were useful only for short-distance communications. since they were known to travel in straight lines. like light. However, the success of Marconi's transatlantic tests in 1901 led to theories developed independently by A. E. Kennelly and **O.** Heaviside that radio signals were reflected back to earth from an electrically conducting region in the earth's outer atmosphere. A similar region had also been proposed by Balfour Stewart shout 1882, to explain systematic changes observed in the earth's magnetic field. (*See* GEOMAGNETISM.)

Direct measurements of the ionosphere were not made until 1925, when. in England. E. V. Appleton and M. A. F. Barnett reported an experiment based on a wave-interference technique. and. in the United States, G. Breit and M. A. Tuve recorded radio echoes using a new system of transmitting short pulses of radio waves and receiving their echoes. In the latter experiment it was noted that pulses transmitted vertically with frequencies below 1 or 2 mc. per second were either reflected or absorbed by the ionized layers. whereas frequencies ahove 15 or 20 mc. usually passed completely through the atmosphere and were lost to space. This is because the higher frequency radio n-aves required a greater electron density for reflection. The time required for a pulse to travel to the ionosphere and back was a measure of the height of the reflecting layer.

This pulse technique has been developed to the point where equipment to record automatically the effective height of reflection for each frequency from 0.j to 20 mc. is in wide use throughout the world. As a result. knowledge of how the distribution of free electrons changes with place, time of day, solar activity. etc., is quite complete.

The ionosphere contains two principal regions of free electrons. The lower (E-region) normally occurs at heights of go to 120 km. (j j to 75 mi.), while the upper (I;-region) is usually found from 150 to 300 km. (100 to 200 mi.) above the earth. Rocket observations and theoretical calculations have indicated that the so-called layers oi free electrons are. in fact, broad maxima of electron density, and that the ionosphere is highly ionized throughout. The daylight value for the E-region maximum is roughly 10^5 free electrons per cm.^{3}, while in the daytime the F-region often has two maxima, known as the F,- and F_2-layers. The F_2-layer, which is above the F_1-layer and is more persistent. may have about 10^6 electrons per cm.^{3}, though this is highly variable.

Characteristics of ionospheric layers change with time of day. season of year and geographical location. Variations in the normal E- and F_1-layers are generally small. but abnormal or sporadic ionization in the E-region is rather common in summer. Fluctuations in the F_2-layer are often relatively large and irregular, and such fluctuations are particularly pronounced during magnetic storms. The 11-year sunspot cycle and other forms of solar activity also influence ionospheric characteristics.

The ionosphere controls long-distance radio communication by establishing upper and lower limits of usable wave frequencies. The upper limit is determined hy i t reflecting properties and the lower limit by absorption in the lowest part of the ionosphere. called the D-region. During periods of solar activity the enhanced ultraviolet and X-radiation from the sun increases the ionization in the D-region. causing an increase in the absorption of radio waves. and this results in poor radio communication on those channels that depend on ionospheric reflections.

IOPHON, Greek tragic poet. son of Sophocles. He gained the second prize in 428 B.C., Euripides being first. and Ion third. In the Frogs of Xristophanes (405) he is spoken of as the only good Athenian tragic poet. He wrote 50 plays, of which only a few fragments remain.

It is said that Iophon accused his father of being incapable of managing his affairs and that Sophocles was triumphantly acquitted. on reading the iamous chorus of *Oedipus at Colonus.*

I.O.U. ("I owe you"), a written acknowledgment of a debt. It usually runs thus:

To——. I. O. U.——

(Signed) ——. Date ——.

An I.O.U., if worded as above, or even if the words "for value received" are added, needs no stamp in Britain, as it contains no term of agreement. If any such words as "to be paid on such a day" are added it requires a stamp. An I.O.U. should be addressed to the creditor by name, though its validity is not impaired by such omission. Being a distinct admission of a sum due, it is prima-facie evidence of an account stated, but where it is the only item of evidence of account it may be rebutted by showing there was no debt and no demand which could be enforced by virtue of it. An I.O.U. is not negotiable in the technical sense. See NEGOTIABLE INSTRUMENT.

IOWA, popularly known as the "Hawkeye state," a north central state of the United States, is bounded north by Minnesota, east by the Mississippi river, which separates It from Wisconsin and Illinois, south by Missouri and west by the Missouri and Big Sioux rivers, which separate it from Nebraska and South Dakota. The state's total area is 56,290 sq.mi., of which 258 sq.mi. are water surface.

Various meanings have been ascribed to the word "Iowa": among the most common are "beautiful land" and "this is the place." It is commonly supposed that the name "Hawkeye" was that of an early Indian chief. The state is the 25th in size of the 50 states of the union. The state capital is Des Moines, and the state entered the union, Dec. 28, 1846, as the 29th state. The wild rose is the state flower and the eastern goldfinch the state bird. The state flag consists of three vertical stripes of blue, white and red. In the centre of the white stripe is depicted a spreading eagle which bears in its beak blue streamers. Inscribed upon the streamers is the state motto: "Our liberties we prize and our rights we will maintain" and the word "Iowa" is in red letters below the streamers.

PHYSICAL GEOGRAPHY

Physical Features.—Iowa lies wholly in the prairie plains region between the extremes of approximately 40° 22' and 43° 30' N. and 90° 08' and 96" 38' W. Since its surface was overrun by one or more of the great ice sheets of the glacial epoch, the largest portion of the state is prairie tableland. The lowest elevation, 480 ft. above sea level, is at Keokuk in the southeastern part of the state. From this point the land rises in gentle swells to the point of highest elevation, (1,675 ft.,) in Osceola county in the northwestern part of the state. The greatest departures from the prairie surface are in the northeast and southwest. In the northeast—the so-called driftless area of Iowa—cliffs rise almost vertically from the banks of rivers to heights of from 300 to 400 ft. From the summit of such cliffsto the crest of a divide, usually a few miles distant, is another ascent of 300 ft. or more, which terminates occasionally in knob-topped hills crowned with small cedar trees. In the west, southward from the mouth of the Big Sioux river, a line of moundlike bluffs rises abruptly to a height of from 100 to 300 ft. from the flood plain of the Missouri river. Because of glaciation, the northern half of the state is more broken and irregular and has more shallow lakes and ponds than the southern half.

A broad watershed, extending in a southerly direction from Spirit lake on the northern border, divides the state into two drainage systems. That to the east, comprising about two-thirds of the whole area, is drained by tributaries of the Mississippi, of which the Des Moines, the Skunk, the Iowa (and its tributary the Cedar) and the Wapsipinicon are the largest. These streams have long courses and moderate slopes. The region to the west of the watershed is drained by tributaries of the Missouri, such as the Big Sioux, the Little Sioux, the Boyer and the Nishnabotna.

Climate.—Iowa has a climate of great extremes. The mean annual temperature is 49° F.; the average range of extremes per year is about 135° F. The average mean annual temperature at Sibley in the northwest is 44°, while at Keokuk in the southeast it is 52.4°. Des Moines, located nearer the centre of the state, has an average mean annual temperature of 50.9°.

Rainfall is very unequal in its distribution throughout the year, as between the same periods of different years and as between the different parts of the state. While the mean annual precipitation is 31.44 in., about 71% of this falls during the six months from April 1 to Oct. 1. May, June and September are generally the wettest months. Within any one year the precipitation is usually less in the western part of the state than it is in the eastern part; the western part also has a greater percentage of its rain in the spring and summer than has the eastern part. Though the average frost-free growing season is from May 2 to Oct. 7, killing frosts may occur later or earlier. Injury to crops from drought and hot winds occurs infrequently, but harmful effects from excessive rainfall, hailstorms and prolonged excessive heat are more common.

Soil.—The fertile soil of Iowa, because of its depth and porous nature, is capable of withstanding the extremes of wetness and dryness remarkably well. Perhaps no other state in the union has such superior soil for agriculture; no other state has so many acres of grade A land or so large a proportion—from 85%–90%—of its land suitable for cultivation.

The soil is of four kinds: till (or drift), alluvial, loess (or bluff) and geest (or gravelly earth). Dark drift, composed chiefly of clay, sand, gravel, boulders and lime, is both the soil and subsoil of the greater part (about 66%) of the state and is especially predominant in the north and northwest. Alluvial soil, composed of material washed from other soils and decayed vegetable matter, covers about 6% of the surface of the state. This type of soil is found in the river bottoms, particularly in the valley of the Missouri, and varies much in fertility. Loess soil, chiefly a mixture of porous clay and carbonate of lime, forms the bluffs bordering the bottom lands of the Missouri and is common in the northeast. In fertility loess is not inferior to the better drift. Geest is found particularly in the northeast, but it covers less than 1% of the area of the state.

Vegetation and Animal Life.—When the first settlers came to Iowa they found the rolling prairies covered with deep, coarse grasses, berries and wild flowers. Forests of birch, maple, hickory, oak, elm, walnut, ash and cottonwood trees grew in the river valleys and in scattered areas. The Cedar river derives its name from the red cedar, the only evergreen native to the area. Native grasses and the original timber, except in a few places, have been destroyed; yet, trees and plants, some native and some immigrant, grow in profuse variety. The prairie rose, aster, honeysuckle, primrose, shooting star, violet, blue phlox, trillium, bloodroot and many types of ferns are common.

Situated along the Mississippi and Missouri flyways, Iowa is a haven for birds of many types. The robin, eastern goldfinch, starling, junco, blue jay, chickadee, red-winged blackbird, woodpecker, crow and meadow lark are frequently seen. The wild turkey, once plentiful, is almost extinct; the ring-necked pheasant, imported into the state, is now a major game bird. Owls and hawks are the principal birds of prey.

Wolves were once numerous in the region, but they have since disappeared. Except for the white-tailed deer, large game animals are rare. Among the small wild animals found are the beaver, muskrat, raccoon, skunk, jack rabbit, cottontail rabbit, ground hog, gopher and chipmunk. Although more than 100 kinds of fish have been seen in the area, the most common are the catfish, bullhead, carp, buffalo, sucker, walleyed pike, smallmouthed bass, rainbow, brook and brown trout, crappie and bluegill. There are about 25 varieties of reptiles, of which three (all rattlesnakes) are poisonous.

State Parks and Historical Sites.—The state conservation commission has jurisdiction over state parks, reserves and monuments; state forests and forestry; and state waters. Providing for the protection, propagation and preservation of fish, game and fur-bearing animals is an important function of the conservation commission. It maintains more than 120 wildlife refuges comprising about 35,000 ac. and more than 160 public hunting grounds totaling approximately 91.000 ac. Nearly 100 lakes, artificial and natural, are also the responsibility of the commission.

State parks include Backbone (near Strawberry Point); Dolliver Memorial (near Fort Dodge); Geode (near Burlington); Lacey-Keosauqua (near Keosauqua); Lake Ahquabi (near Indianola); Lake Darling (near Fairfield); Lake Macbride and Palisades-Kepler (both near Cedar Rapids); Lake Wapello (near Ottumwa); Ledges (near Boone); Nine Eagles (near Leon); Pike's Peak (near McGregor); Pilot Knob (near Forest City); Rock Creek Lake (near Kellogg); Springbrook (near Guthrie Center); Stone (near Sioux City); Waubonsie (near Sidney); and Wild Cat Den (near Muscatine).

Various historical sites attract thousands of visitors annually. Among these are the Amana colonies, which were established in 1855 as experimental religious communities; the Old Capitol, which is now the administrative office of the State University of Iowa; Plum Grove farm, at Iowa City, the home of Robert Lucas, Iowa's first territorial governor; Effigy Mounds National monument, at Marquette (established 1949), which contains burial mounds of prehistoric Indians; Fort Atkinson State park; former Pres. Herbert Hoover's birthplace at West Branch; the grave of Julien Dubuque at Dubuque; and the Anton Dvorak monument at Spillville.

HISTORY

Early Inhabitants. — The name "Iowa" was taken from the tribal name of a group of Siouan Indians who occupied the area when it was first seen by white men — the Frenchmen, Father Jacques Marquette and Louis Jolliet, in 1673, and Father Louis Hennepin, in 1680. In the century following the visits of these early travelers, explorers and missionaries did little to disturb the Indians of the region. During those years, however, the Ioway tribe was pushed westward and largely supplanted by the tribes of Sauk and Fox, who had previously been driven from Michigan by the French.

First White Settlements. — No permanent white settlement had been established in Iowa when the French, who had held it since 1682, relinquished control to the Spanish in 1762. During the period of Spanish control, there was some penetration and exploitation of the area. The lead mines near the Mississippi river were a major attraction, and to these mines came a French Canadian, Julien Dubuque, who in 1788 obtained an Indian grant giving him the right to carry on mining operations near the present site of the city which today bears his name. Although Dubuque received confirmation of his grant from the Spanish governor, the wealth he sought eluded him and he died bankrupt in 1810. Louis H. Tesson in 1799 and Basil Giard in 1800 also received Spanish grants in Iowa, but were similarly disappointed.

Iowa was retroceded to France in 1800 and, as part of the Louisiana Purchase in 1803, became United States territory. During 1804–05 it was a part of Indiana territory; it was made a part of Louisiana territory from 1805 to 1812. Indian hostility forced the abandonment of the first American post in Iowa, Ft. Madison, near the mouth of the Des Moines river, during the War of 1812. After the conclusion of peace in 1815 the Sauk chief, Black Hawk, nourished a bitter hatred toward settlers, and in a final attempt to recover lands in Illinois, he instigated a war against the United States in 1832. Black Hawk's defeat resulted in the cession of nearly 9,000 sq.mi., the first of many Indian land cessions between 1832 and 1851. From 1812 to 1821 Iowa was a part of Missouri territory; from 1821 to 1834 it was a part of the unorganized territory of the U.S. After Black Hawk's war, settlers began to pour into Iowa. In 1834 it was a part of Michigan territory; in 1836 it was a part of Wisconsin territory. Government land surveys were not begun until 1836, making the first settlers technical trespassers on the public domain. Ostensibly to protect their holdings, the settlers formed voluntary associations or "claim clubs." Although proceedings of the associations relating to land claims were later recognized by U.S. authorities, they were often dominated by speculators rather than farmers.

Statehood and Early Problems. — Iowa was separated from Wisconsin in 1838 and the question of applying for admission into the union as a state was voted on as early as 1840. The measure was defeated then and again in 1842 by those who wished to avoid an increase in taxes. Finally, in 1844, a convention was held at Iowa City, a constitution framed and application for admission to the union made. Congress, however, rejected the application because it disagreed with the proposed boundaries of the new state. A second constitutional convention was called at Iowa City in 1846; it drew up the present boundaries of the state and prohibited the organization of banks of issue. Congress approved the second constitution and Iowa was admitted to the union in 1846, being paired with Florida, a slave state, to maintain the balance of power between the North and the South.

Burlington had served as temporary capital of the territory until 1839. In that year, Iowa City was designated as the capital city but was replaced by the present capital, Des Moines, in 1857.

Statehood by no means solved all problems faced by Iowa pioneers. The Spirit lake massacre of 1857, in which about 40 settlers were killed, provided grisly proof that Indians were still a danger to isolated settlements. Elsewhere, lawless elements defied regularly established authorities, and as a result vigilance committees were formed. From 1846 to 1860 there were approximately 45 lynchings in which 70 victims were summarily put to death. Sectional feeling, running rampant over the nation, also created problems in Iowa, resulting in a shifting of political allegiances. Although the Democratic party had been in power since statehood, the state supported the Republican party after the latter's formation in 1854. The American Civil War claimed the lives of more than 12,000 Iowans.

Issues and Reforms. — Economic expansion characterized the years following the American Civil War. From 1860 to 1910, for example, more than 9,000 mi. of railroads were constructed in Iowa. Yet there was considerable agrarian discontent during this period, as some of the farmers felt that they did not share adequately in the general prosperity. Thus, farmers' organizations and third parties, such as the Patrons of Husbandry (the Grange). the Greenback party and the Populist party, developed significant follonings. Though not markedly successful in electing candidates, such movements forced the major parties to adopt reform programs and to enact progressive legislation.

Particularly important issues in Iowa were tariff reform, railroad-rate regulation and the prohibition of the manufacture and sale of intoxicating liquors; but the reformers in these areas had indifferent success. The tariff question split the Republican party when its more progressive members supported the "Iowa Idea"; *i.e.*, the expansion of trade through tariff reciprocity and downward revision of rates. Advocates of railroad-rate regulation were never able to accomplish all their aims, although a railroad commission was established as a result of their efforts. Prohibition was steadily debated from 1882, when it was attempted unsuccessfully. until the repeal of the prohibition (18th) amendment to the U.S. constitution in 1933. In that year the general assembly passed laws legalizing the sale of beer with 3.2% alcoholic content and established a state monopoly for the sale of intoxicating liquors, with a state liquor control commission in charge.

Reformers in Iowa achieved their most important victories in the field of welfare legislation. In 1913 the general assembly passed an employers' liability and workmen's compensation act and a mothers' pension act. The Perkins law of 1915 provided free treatment for crippled children of indigent parents. In 1917 a child welfare station for the study of children's problems was established at Iona City.

The depression of the 1930s had the same effects in Iowa that it had in other areas, and the demand for relief legislation was met on both a state and national level. Concern for the aged found expression in a system of old-age pensions begun in 1935. In 1936 the Iowa employment security commission was created to encourage industry to provide more stable employment, maintain a free public employment service and grant benefit payments to those unemployed. A large-scale construction project to provide a system of dams for the upper Mississippi river was begun in 1931 and continued throughout the following decade. The agricultural program of the New Deal was a response to distress in the farm belt of which Iowa is such a significant part. The Iowa state planning board was created in 1937 to deal with vari-

ous problem areas, and it continued in service until 1939.

The state contributed more than 260,000 men and women to the services during World War II; of these, more than 8,200 lost their lives. The first women's army corps training camp was established at Ft. Des Moines, and navy fliers were given training at Ottumwa and Iowa City. In 1948 voters approved a bonus for veterans of World War II.

GOVERNMENT

Iowa's present constitution was adopted in 1857, the constitution of 1846 having been superseded chiefly because it prohibited banking corporations. The constitution may be amended by an affirmative vote of both houses of two successive legislatures, followed by a majority vote of the electors of the state voting on the proposed amendment. Suffrage is granted to all citizens of the United States (except idiots, insane persons and those convicted of an infamous crime) who are at least 21 years of age, have resided in the state for six months and in one county for 60 days preceding an election. The franchise was conferred on Negroes by an amendment adopted in 1868, and on women by the federal amendment adopted in 1920.

The supreme executive authority in Iowa is the governor. Other elective executive officials are: the lieutenant governor, secretary of state, treasurer, auditor, attorney general and secretary of agriculture. All officers must be citizens of the United States and have the age and residence qualifications of voters. The governor and lieutenant governor must, in addition, be at least 30 years of age and must have resided in Iowa for at least two years preceding election. All are elected for two-year periods.

The governor has extensive appointive power, oversees the making of the budget and may veto acts of the general assembly, although such acts may be passed over his veto by a two-thirds majority of both houses. The lieutenant governor is ex-officio president of the senate and takes the office of governor in case of the death, resignation or removal from office of the chief executive. The governor, secretary of state, auditor, treasurer and secretary of agriculture make up the executive council. This ex-officio board canvasses state election returns, supervises the incorporation of building and loan associations, appoints the board of mine inspectors, allocates space in the capitol and other buildings used by the state government to the various offices and departments and has other supervisory duties.

In addition to the elective offices a number of subordinate administrative offices have been created by the legislature. These offices, filled by appointment, include those of the adjutant general, the commissioner of public health, the superintendent of public instruction, the commissioner of insurance, the industrial commissioner, the labour commissioner, the commissioner of public safety, the superintendent of banking and the comptroller.

Much of the administrative work of the state government is performed by boards or commissions, usually bipartisan. Except for the commerce commission and the state board of public instruction, to which members are elected, membership on these boards is appointive. Among the other administrative boards are the state highway commission. the board of parole, the conservation commission, the board of control of state institutions, the Iowa development commission, the liquor control commission. the employment security commission, the real estate commission, the board of regents, the state tax commission and the department of social welfare.

The state legislature, called the general assembly, is composed of a senate and house of representatives which meets in odd-numbered years. Senators, who must be at least 25 years of age, are elected for a term of four years, one from each of the 50 senatorial districts, the terms of half of the members expiring every two years.

Representatives are elected for a term of two years, one from each of the 99 counties, with an additional one from each of the counties (not exceeding nine) having the largest population. The ratio of representation and the apportionment of the additional representatives from the larger counties are fixed by the general assembly.

The judiciary consists of a supreme court of 9 judges, and a district court of 70 judges, with 1 to 6 judges in each of the 21 districts. The supreme court has original jurisdiction in certiorari and mandamus cases, and appellate jurisdiction in cases sent to it from the lower courts. It also has the power to pass on the constitutionality of state laws. The district court has general, original and exclusive jurisdiction in all civil, criminal and probate matters not expressly conferred on an inferior court, and may hear appeals from inferior courts, boards or officers. Supreme court judges are elected for terms of six years and district judges for four years.

Each of the 99 counties has its own administrative boards and officers. The boards of supervisors consist of not more than seven members who are elected for three-year terms and have the care of county properties and the management of county business, including highways and bridges. The boards also fix the rate of county taxes within prescribed limits and levy the taxes for state and county purposes. Other county officers are: auditor, treasurer, clerk, recorder, sheriff, attorney, engineer, coroner, assessor and superintendent of schools.

The relationship between municipalities and the state government is unitary; there is no real "home-rule." Although four cities. Camanche, Davenport, Muscatine and Wapello, were given special charters prior to 1857, all municipal governments have only the powers given them by the general assembly. Cities are of two types: those with a population of more than 15,000 and those with a population of from 2,000 to 15,000. All other incorporated places, except the special-charter cities, are classified as towns. Local adoption of the commission-manager plan of municipal government was authorized by the general assembly in 1915.

Finance and Taxation.— In 1929 a state tax commission was established for the purpose of centralizing the tax structure. Although the commission worked toward an integrated system, taxation has remained, in large part, a series of semi-independent levies. The tax sources for the state, with the percentage of total revenue in the second half of the 20th century, were: motor vehicle license, motor carrier and gasoline tax (38%); sales and use tax (34%); income tax: individual and corporation (13%); liquor profits and beer tax (5%); cigarette tax (3%); insurance premiums (2%); inheritance tax (2%); and miscellaneous taxes (2%). The state's revenue from all sources was about $350,000,000 annually. Of this amount, about one-sixth was derived from the federal government and about 70% from state tax sources. The state's expenditures totaled approximately $355,000,000, but there was no state debt. In the second half of the 20th century approximately 25% of the state's revenues was appropriated for education, nearly 38% was allocated to highways, more than 13% to public welfare and slightly more than 5% to health and hospitals. The state's income at this time was about three and one-half times as great as it had been prior to World War II; expenditures had increased at about the same rate. Iowa's per capita income ranked it 24th among the states in 1950 but it fell to 27th place toward the end of the next decade. It was only slightly below the national average, however.

Iowa has not levied a general property tax for the financing of the state government since 1941. There are, however, property taxes levied on a local level. This revenue is used primarily for schools, roads, municipal and county government and various local projects.

POPULATION

The population of Iowa in 1850, four years after it had obtained statehood, was 192,214. Its population ranked 27th among the 37 states and territories that then composed the union, and was classified as nearly 95% rural. The previous decade had been the period of the most rapid growth in Iowa's history—the population increased almost 346% from 1840 to 1850. At the beginning of the 20th century, the state had advanced to 10th in rank of population with a total of 2,231,853 persons by the 1900 census. The state was still largely rural in character: about three-fourths of the people were classified as nonurban dwellers. The next

ten years saw an actual decline in the state's population—the 1910 census showed a drop of 0.3% from the census of 1900. The 1950 population indicated a total of 2.621.073 persons lived within the state, making it the 22nd in size of population among the states. The rural population was slightly more than 52% of the total at that time. Of the 1960 population. 1.462.512 or 53% lived in incorporated places of 2.500 or more. as compared with 46 9% in 1950. when these places constituted the urban area. The urban population, under a new definition set up in 1950. included also the thickly settled suburban area, or "urban fringe," adjacent to Des Moines. Sioux City, Davenport, Cedar Rapids. Dubuque. Omaha and Waterloo (standard metropolitan statistical areas). By 1960 these areas housed 33.2% (915,762) of the total population. In 1960 Iowa had a population of 2.757.537, an increase of 136,464 or 5.2% over 1950, and ranked 24th in population.

*Iowa: Places of 5,000 or More Population (1960 Census)**

*Populations are reported as constituted at date of each census. †Name changed from Valley Junction in 1938.

Note: Dash indicates place did not exist during reported census, or data not available.

The population per square mile in 1960 was 49. as compared with 49.7 for the U.S. as a nhole. By 1960 the urban population was increasing. Distribution by colour and nativity, according to the 1950 census. was as follon s: 96% native white: 3 2% foreign-born white; and 0.8% nonnhite. Along with the rest of the U.S. the percentage of persons 65 years old or over was increasing. being 10.5% in 1960. The percentage of the population 14 years old and over that was in the labour force (54.8% in 1950) was steadily decreasing.

EDUCATION

History and Administration.— The first schools in Iowa were private. In 1830 a private school was opened in the Half-Breed tract. now Lee county. In 1834 free tax-supported schools were legally authorized for the area and by 1838 there were more than 40 schools established. When the Iowa territory was formed (1840) a law was passed defining the means of establishing free schools. The educational system has as its basis a law passed by the state legislature in 1858. Education was made compulsory by the general assembly in 1902. Since that time. legislation has extended the school year to at least 24 consecutive weeks for children betneen the ages of 7 and 16 unless they have completed the eighth grade or are over 14 and employed. In 1911 the legislature authorized large, centrally located, consolidated schools to replace small, scattered ones. Part-time schools for employed children between 14 and 16 were provided for in 1919. In the second half of the 20th century Iona had the distinction of having the lowest percentage of illiteracy in the union. At that time. the state was spending $299 annually per pupil or slightly more than the U.S. average. This represented almost three times as much per pupil as had been spent prior to World War II.

At the head of the Iona system of public schools is the state superintendent of public instruction, assisted by the state board of public instruction. The superintendent is, by law, the executive officer of both the board of educational examiners and the board of vocational education. The county administration is in the hands of a popularly elected board of five officers who, in turn, appoint a county superintendent of public instruction for a three-year term. Each school district has its separate board of education or trustees.

School revenue is derived from the state's permanent school fund. which grew out of land granted to the state by the federal government and from local or district taxation.

Colleges and Universities.— Iowa has about 50 institutions of higher learning. which are governed by the state board of regents. This nine-member board is appointed for six-year terms by the governor with the approval of the senate. Schools supported by the state include the State University of Iowa (Iowa City), Iowa State University of Science and Technology (Ames) and State College of Iowa (Cedar Falls).

The State University of Iowa was established by an act of the legislature in 1847. Instruction was begun in the spring of 1855. The law department was added to the college of liberal arts in 1868, the medical department in 1870. the dental department in 1882 and the department of pharmacy in 1885. All these later became colleges. The graduate college was added in 1900 and the college of engineering in 1905. The school of education. created in 1907. became the college of education in 1913; and a school of commerce, established in 1914, became the college of business administration in 1959.

In addition to these nine colleges, a preparatory department was maintained from the founding date of the university until 1879: a homeopathic medical department, later a college, from 1876 to 1919; andacollegeof fineartsfrom 1911 to 1915. Within the college of liberal arts are the schools of fine arts. journalism, religion and social nork. In 1949 the school of nursing became the college of nursing.

The extension division was organized in 1913, the Iowa child welfare research station in 1917, the institute of hydraulic research in 1931, the institute of public affairs in 1949, the bureau of labour and management in 1950; the institute of gerontology in 1951 and the institute of agricultural medicine in 1955.

The central building of the university campus is the Old Capitol, which was turned over to the university when Des Moines became the state capital in 1857. The medical centre includes general. children's and psychopathic hospitals; the hospital-school for severely handicapped children; medical laboratories and the medical research centre.

Among the privately supported educational institutions in Iowa are: Briar Cliff college (Sioux City, Roman Catholic. 1930); Buena Vista college (Storm Lake. United Presbyterian Church in the U S.A., 1891); Central college (Pella, affiliate of Reformed Church in America, 1853); Clarke college (Dubuque, Roman Catholic, 1843); Coe college (Cedar Rapids, affiliate of United

Presbyterian Church, 1851); Cornell college (Mount Vernon, affiliate of the Methodist Church, 1853); Drake university (Des Moines, related to the Disciples of Christ, 1881); Grinnell college (Grinnell, nonsectarian, but related to Congregational Church, 1846); Iowa Wesleyan college (Mount Pleasant, affiliate of Methodist Church, 1842); Loras college (Dubuque, Roman Catholic, 1839); Luther college (Decorah, affiliate of Evangelical Lutheran Church, 1861); Marycrest college (Davenport, Roman Catholic, 1939); Morningside college (Sioux City, Methodist, 1889); Parsons college (Fairfield, affiliate of United Presbyterian Church, 1875); St. Ambrose college (Davenport. Roman Catholic, 1882); Simpson college (Indianola, affiliate of Methodist Church, 1860); University of Dubuque (Dubuque, affiliate of United Presbyterian Church, 1852); Upper Iowa university (Fayette, nonsectarian, 1857); Wartburg college (Waverly, American Lutheran Church, 1865); Westmar college (Le Mars, affiliate of Evangelical United Brethren Church, 1900); and William Penn college (Oskaloosa, Friends, 1873).

HEALTH AND WELFARE

The Iowa department of public health, established in 1924, is headed by a commissioner, who is required to be a physician with special training in public hygiene and sanitation. The department is concerned with the major causes of sickness and death, mental health and the prevention and control of communicable diseases. Major health programs are administered by the division of maternal and child health, the division of dental hygiene, the division of cancer control, the division of gerontology, heart and chronic diseases, the division of public health engineering and industrial hygiene, the division of public health nursing and the division of public health education.

The charitable, penal and reformatory institutions of the state are supervised by a board of control of state institutions which has three members appointed by the governor. The institutions include: a soldiers' home at Marshalltown; a school for feebleminded children at Glenwood; a hospital for epileptics and school for the feeble-minded at Woodward; four hospitals, or mental health institutes, at Clarinda, Independence, Mount Pleasant and Cherokee; a juvenile home for destitute, neglected or homeless children at Toledo; the Annie Wittenmyer home for children at Davenport; a training school for delinquent boys at Eldora; a similar institution for girls at Mitchellville; a men's reformatory at Anamosa; a women's reformatory at Rockwell City; and a state penitentiary at Fort Madison. The state also maintains a school for the deaf at Council Bluffs, one for the blind at Vinton and a combination school and hospital for handicapped children at Iowa City.

In 1907 the general assembly passed a law that established the indeterminate sentence for certain criminal offenders. The governor appoints a board of parole of three members, one of whom must be an attorney, and of which not more than two may be members of the same political party. A bill calling for the sterilization of certain mental defectives was passed in 1929. The provisions of the bill are carried out by an ex-officio board of eugenics.

In 1937 a state department of social welfare was created to administer old-age assistance, aid to the needy blind, aid to the disabled (since 1950), child welfare and the care of dependent children and general relief in the state. The state board supervises the county boards of social welfare. The employment security commission manages a system of old-age and retirement insurance, which went into effect in 1946.

THE ECONOMY

Agriculture. — The superior quality of the soil and the warm, moist months of spring and summer make Iowa one of the foremost states of the union in the production of corn (maize), oats, hay and soybeans. Much of the produce is utilized in the further production of poultry, hogs, dairy cattle and sheep. Of the total farm acreage of approximately 35,000,000 ac., more than 60% was under actual cultivation in the second half of the 20th century. The average size of farms was about 185 ac., and the average value of farm land per acre was nearly $200. There was a pronounced trend toward larger holdings.

In the second half of the 20th century, cash receipts from farm marketings and government payments averaged more than $2,000,000,000 annually, more than $1,500,000,000 of which came from livestock and livestock products, and about $375,000,000 from crops of all kinds. Corn is the most important crop, and Iowa ranks first among the states in corn production with almost half the cultivated area of the state devoted to its culture. In the quarter-century after 1935 the total average annual yield was increased almost 400%. After corn, the most important Iowa crops are oats, barley, soybeans and hay.

By the second half of the 20th century the value of Iowa livestock was greater than that of any other state and twice as great as the valuation in 1920. Hogs, cattle, sheep and lambs are the principal types of stock raised. Dairy products and poultry are also vital parts of the state's agricultural program. The average egg production during 1950–60, for example, exceeded 4,000,000,000 eggs per year; Iowa farmers sold 1,500,000,000 lb. of whole milk annually in the same period and the state was first in the amount of cream sold.

Industry. — Although Iowa is famous for its agriculture, a considerable amount of industry has been attracted to the state by the Iowa development commission. During the second half of the 20th century Iowa industries employed more than 160.000 persons and paid more than $600,000,000 annually in salaries and wages. The estimated total value added by industry in a typical year of the 1950s was 3.81 times as great as that of 1929.

Most of Iowa's industrial plants are engaged in the processing of foods of various kinds. Meat-processing plants are the most important, the largest pork-processing plant in the United States being located in Iowa. Of secondary importance are dairy products-processing establishments and poultry-processing plants. Machinery manufactured in the state includes tractors, combines, corn-pickers and hay-balers. The largest aluminum-rolling mill in the United States is located at Davenport and the nation's largest manufacturer of fountain pens is at Fort Madison. Des Moines, Cedar Rapids and Waterloo are the state's leading industrial centres.

Mineral **Production.**—Iowa's first settlement was a mining camp, but this event proved to be no index to future mineral production. The early lead and zinc mines around Dubuque are little worked, and these products are of small significance in comparison with the state's total mineral output. During the second half of the 20th century, Iowa was among the first ten states in its production of gypsum and cement, but ranked 29th among the states in the value of all of its minerals (1958).

Transportation. — From the close of the Civil War to 1920, the railroad was Iowa's most important means of transportation, although river traffic was of considerable importance during the 19th century. It was in those years that the "Big Four" railroads (the Chicago, Burlington and Quincy; the Chicago and North Western; the Chicago, Milwaukee, St. Paul and Pacific; and the Chicago, Rock Island and Pacific) established control over almost three-fourths of the railroad mileage (about 8,900 mi.) in the state. Since 1920, however, the railroads have steadily declined in favour of motor vehicles and airplanes.

Iowa has long had a state highway system, but it was not until 1919 that highways were classified as primary and secondary. In 1925 the state highway commission began its control of the primary road system. By the second half of the 20th century there were about 8.700 mi. of highway in the state primary system. Motor vehicle registrations increased from 437,000 in 1920 to more than 1,200,000 by 1960. Iowa was receiving about $35,000,000 in federal funds annually under the national highway program initiated in 1956.

The creation of the Iowa aeronautics commission by the general assembly in 1945 testified to the increasing importance of air travel. The number of licensed pilots increased from 1,882 in 1940 to more than 16,000 after World War II; more than 1,600 privately owned planes were registered with the aeronautics commission and there were more than 200 airports and five commercial

Current statistics on production, employment, industry, etc., may be obtained from the pertinent state departments; the principal figures, together with the current history, are summarized annually in the *Britannica Book of the Year,* American edition. (P. W. GL.)

IOWA, STATE UNIVERSITY OF, an institution of higher learning. in Iowa City, Ia., was organized by an act of the legislature in 1847. *See* IOWA: *Education.*

IOWA CITY, a town on the Iowa river in east central Iowa, U.S., 57 mi. W. of the Mississippi river, the seat of Johnson county. Founded as the capital of Iowa territory in 1839 and incorporated as a town in 1353, Iowa City lost the state capital to Des Moines in 1857 but retained the state university and historical society. The university buildings, including the Old Capitol, now dominate the centre of the community. Iowa City was an important immigrant dispersal point during the late 1850s; from there in 1856 about 1,300 European Mormons proceeded to Utah, carrying their baggage in handcarts. Ohio, Pennsylvania and New York provided the largest number of early settlers, including Amish and Mennonite groups which in the mid-20th century still maintained their identities. By 1900 there were 2,622 Bohemians and Germans present and foreign born or their children made up 50% of the population; this proportion then declined. (For comparative population figures *see* table in Iowa: *Population.*)

Iowa City has a council-manager government, in effect since 1951. The residents mainly serve the needs of the state university, the university hospitals, a veterans hospital, Mercy hospital, Oakdale tuberculosis sanatorium and the hog, cattle and corn agriculture of the county. Aside from a toiletries plant and a brush factory there is little local industry. Lake Macbride State park and the Herbert Hoover birthplace lie to the north and east.

(A. G. Bo.)

IPECACUANHA (IPECAC), an expectorant and emetic, is obtained from the dried roots of *Cephaelis ipecacuanha* (Rio or Brazil ipecac) or of *Cephaelis acuminata* (cartagena. Nicaragua or Panamá ipecac). The former is indigenous to Brazil but also grows in Colombia, while the latter is obtained mainly from Colombia and Nicaragua.

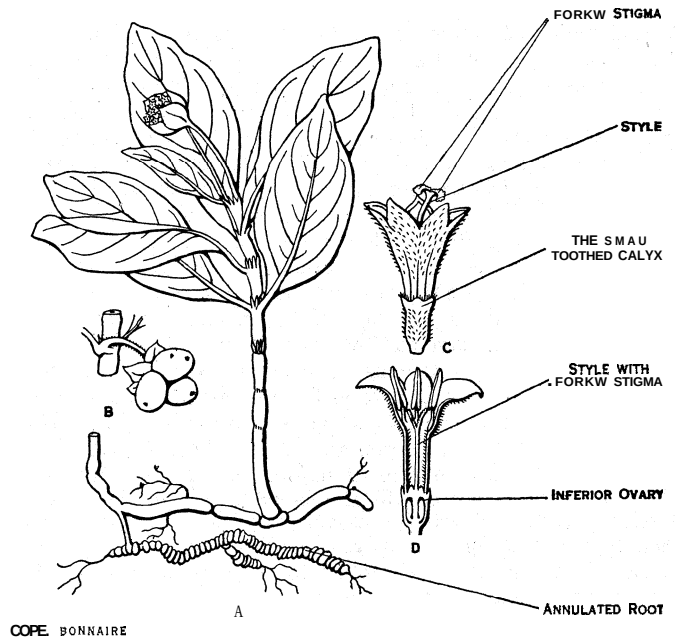
The *United States Pharmacopeia* recognizes both species. while the *British Pharmacopoeia* recognizes only *Cephaelis ipecacuanha.*

Ipecacuanha root occurs in pieces about two or three lines in thickness, of a grayish-brown or reddish-brown tint externally, having a ringed surface and exhibiting a white or grayish interior and a hard wiry centre. It has a faint, rather musty odour and a bitter taste. Cartagena ipecac differs from Rio ipecac only in its larger size and in being less conspicuously ringed. Ipecacuanha owes its emetic properties to the presence of the alkaloids emetine and cephaeline, which occur mainly in the cortical portion of the root.

Emetine is a white amorphous substance, which has a bitter taste. no odour, and turns yellow when exposed to air and light. Besides a number of other alkaloids of no known medicinal value, a substance known as ipecacuanhic acid. a mixture of several glucoside tannins! has been isolated from ipecac.

Ipecac is used in large doses as an emetic (it may be poisonous in excessively large doses) and in smaller doses as an expectorant and diaphoretic. Dover's powder contains 10% each of ipecac and opium. The active alkaloid, emetine, was formerly the mainstay in treating amoebic dysentery, but it has been largely replaced by synthetics and antibiotics.

Other plants to which the name of ipecacuanha has been popularly applied are American ipecacuanha *(Gillenia stipulacea).* wild ipecacuanha (*Euphorbia ipecacuanha*), bastard ipecacuanha (*Asclepias curassavica*), Guiana ipecacuanha *(Boerhaavia decumbens),* Venezuela ipecacuanha (*Sarcostemma glaucum)* and ipecacuanha des Allemands (*Vincetoxicum officinale*). All these possess emetic properties to a greater or less degree.



IPECACUANHA (CEPHAËLIS IPECACUANHA)
A. Plant showing annulated root
B. Fruits
C. Long-styled. flower
D. Longitudinal section through a short-styled flower

IPEK (properly PEĆ), a town in Kosovo-Metohija, Serbia, Yugos. Pop. (1961) 28,297. Peć was formerly the centre of the Serbian Church, the archbishop having been raised to the patriarchate by Stephen Dushan (1331–55). It was suppressed in 1459, restored in 1557 and finally abolished by the Turks in 1767. On the heights above the town stands the 13th-century monastery, the seat of the patriarchs until 1690, and the church, which dates from the 16th and 17th centuries, After the fall of Belgrade in 1521 many of the inhabitants migrated to Hungary, and in 1690 there was a second migration there led by the patriarchs.

IPHICRATES, Athenian general, son of a shoemaker, flourished in the earlier half of the 4th century B.C. He is chiefly known for the use he made of lightly armed troops (peltasts); he increased the length of their weapons, and improved their mobility by reducing their defensive armour. He also paid special attention to discipline, drill and manoeuvres. With his peltasts Iphicrates seriously injured the allies of the Lacedaemonians in the Corinthian War, and in 392 (or 390) dealt the Spartans a heavy blow by almost annihilating a battalion of hoplites (Diod. Sic. xiv. 91; Plutarch, *Agesilaus,* 22). He was later transferred from Corinth to the Hellespont, where he was equally successful. After the peace of Antalcidas (387) he assisted Seuthes, king of the Thracian Odrysae, to recover his kingdom. About 378 he was sent with a force of mercenaries to assist the Persians to reconquer Egypt; but a dispute with Pharnabazus led to the failure of the expedition (Diod. Sic. xv. 29–43). On his return to Athens he commanded an expedition in 373 for the relief of Corcyra, which was besieged by the Lacedaemonians (Xenophon, *Hellenica,* vi. 2). On the peace of 371, Iphicrates returned to Thrace, and fought for Cotys in a war against Athens for the Chersonese. The Athenians soon pardoned him and gave him a joint command in the Social War. He and two of his colleagues were impeached because they had refused to give battle during a violent storm.

Iphicrates was heavily fined. He died about 353.

IPHIGENEIA, daughter of Agamemnon (*q.v.*); not mentioned in Homer, but by some absurdly identified with the Iphianassa of II ix, 145, who was alive and well some ten years after Iphigeneia's supposed death. As she is constantly represented as connected in some way with Artemis, and as Iphigeneia ("mightily born," *i.e.*, "great princess") is a title of the goddess; as, moreover, she has substituted for her one of Artemis' beasts (see below), it is in no way impossible that originally she was a by-form of the goddess herself; but the question is obscure. Agamemnon had vowed to sacrifice to Artemis the fairest thing that should be born in a certain year, meaning the handsomest beast; but in that year Iphigeneia was born. Another story is that he or Menelaus had offended Artemis in some way. As a result, Artemis stayed the Greek fleet at Aulis on its way to Troy, by calm or contrary winds, and Calchas discovered that only the sacrifice of Iphigeneia would appease the goddess. Iphigeneia therefore was sent for on pretence of marrying her to Achilles; at the last moment the goddess relented and substituted a hind, bear, or bull for the victim, whom she spirited away to the land of the Tauri (Crimea). Here she became priestess of Artemis and as such had to sacrifice all strangers. At last Orestes (*q.v.*) and Pylades arrived; by a stratagem, she fled with them taking the image of Artemis, which Orestes had been sent to fetch. They left it somewhere in Greece; among places claiming to have the true statue and some remnant of the old rites of human sacrifice were Brauron in Attica, where a pretence was made of cutting a man's throat before the goddess, and Sparta, where boys were beaten till the blood came, in the ritual of Artemis Orthia. Ipnigeneia was variously said to have died and been buried at Brauron or Megara, and to have been transported to Leuce, where she was wedded to Achilles, or even to have been transformed into the goddess Hecate (*q.v.*).

See Stoll in Roscher's *Lexikon* (bibl.); *L.* R. Farnell *Greek Hero-Cults* (1921); H. J. Rose *Handbook* of *Greek Mythology* (1928).

I-PIN (SUI-FU; SÜCHOW), a Chinese river port at the junction of the Min and Chin-sha (upper Tangtze) rivers in southwest Szechwan (Ssuch'uanj province and head of navigation to small steamers on the Yangtze. Pop. (19j3) 177,500. It is the site of the Yangtze river crossing projected for the railroad being built in 1959 to connect Szechwan with Yünnan in the south. A highway runs northward to the salt centre of Tzekung (Tzu-kung). With its transportation facilities, it acts as the collection centre and export port for products of the Yünnan and Tibetan uplands, such as medicinal herbs and extracts, musk and metals, and as the dissemination point for salt, cotton and other manufactures to the surrounding mountain peoples. It is the nearest large city to the Liang Mountains Ti Peoples Autonomous Region inhabited by Yi (Lolo) tribesmen. A unique product collected at I-pin from the Lo-shan (Chia-ting) region up the Min is the lac produced by the exudation of a species of insects feeding upon the lac trees. (H. J. Ws.)

IPIRANGA, GRITO DO, the "cry of Ipiranga" (Ypiranga), so-called because Brazil's independence was proclaimed at this place by Dom Pedro on Sept. 7, 1822. Sentiment for independence had been growing since the preceding year when King Jodo VI returned to Lisbon, leaving his son Pedro as regent. When the Portuguese parliament limited the powers of the regency, the action was interpreted as an effort to reassert Portuguese rule in Brazil. A messenger sent to intercept the young regent returning to the capital from São Paulo met him on Ipiranga hill, where he vowed: "Independência ou morte!" (Independence or death!). He was proclaimed Pedro I, emperor of Brazil, Oct. 12, 1822. (R. E. P.)

IPOMOEA, a large genus of mainly climbing herbs or shrubs of the convolvulus family (Convolvulaceae, *q.v.*), with about 400 species. It includes the sweet potato (I. batatas), cultivated morning glory (I. *purpurea*) and manroot (I. *pandurata*).

IPSUS, BATTLE OF, 301 B.C. This, named "the battle of the kings," was the great clash in the wars of Alexander the Great's "Successors," which shattered Antigonus's attempt to reconsolidate the Macedonian empire. Hard-pressed in Thessaly by Demetrius, the son of Antigonus, Cassander turned the tables by a stroke of true genius. Keeping only a minimum of force, he despatched his ally, Lysimachus, to invade Asia Minor and arranged with Seleucus to advance from Babylon on Antigonus's rear. The combination and concentration against the heart of the opposing power succeeded, and forced Demetrius to evacuate Greece and sail home to his father's aid. The armies of Antigonus and Demetrius met the armies of Lysimachus and Seleucus at Ipsus in Phrygia. Antigonus had 70,000 foot, 10,000 horse and 75 elephants; the allies only 64,000 foot, 10,500 horse, but 480 elephants. At the outset of the battle Demetrius with the cavalry charged and dispersed the opposing cavalry, but, pressing the pursuit too far, found himself cut off by the enemy's elephants. But instead of assaulting Antigonus's army, thus stripped of his cavalry, Lysimachus demoralized it by threat of attack and by fire until it began to melt—part going over to the allies. Then only did Seleucus launch a strong body at the position occupied by the enemy's command.

Borne down by this charge, Antigonus died, crying vainly "Demetrius will come and save me." If the victory is memorable in military history as an outstanding triumph of the war elephant, its greater political consequence was to ensure the disappearance of any central power and the dismemberment of the Greco-Macedonian world.

IPSWICH, a city of Stanley county, Queensland, Austr., on the Bremer river, 23½ mi. by rail W. by S. of Brisbane. Pop. (1954) 38,953. It is the centre of a rich and populous agricultural>mining and manufacturing district. Coal outcrops on the surface and is worked on the banks of the river. Ipswich is the chief coal field in Queensland; and there are about 50 mines, which produce about 1,000,000 tons a year. There are woolen factories, saw-mills, foundries and large railway workshops at North Ipswich.

The first settlement, based on the presence of limestone, was made there in 1829; the town was incorporated in 1860. It grew considerably during the first half of the 20th century.

IPSWICH, a municipal, county and parliamentary borough and county town of Suffolk,Eng., 69 mi. N.E. of London by road. Pop. (1961) 117,325. Area 13.7 sq.mi. It is an ancient market town and port at the head of the Orwell estuary, and an important farming and industrial centre. Above the town the river is called the Gipping; the old name of Ipswich was Gipeswic. Ipswich harbour extends domnstream to Shotley point; there is a large wet dock and, excluding private constructions, the commissioners control more than 4,000 ft. of quayage. Imports are principally grain, sugar, timber, petroleum and caal; exports are agricultural machinery, railway supplies, grain, flour, fertilizers and oil cake. Ipswich is well known for its manufacture of agricultural implements and fertilizers, and a variety of other industries give it an unusually well-balanced economy.

It has many historic buildings: Christchurch mansion (16th century), in its park, is an art gallery and museum; Sparrowe's or the Ancient house (1567) has a pargetted facade; Wolsey's gateway (1536), a Tudor brick building, is the only remnant of the cardinal's foundation to supply scholars to his great college (Cardinal's college, now Christ Church) at Oxford. The Great White Horse hotel was the scene of one of Mr. Pickwick's adventures. Ipswich was the birthplace of Cardinal Wolsey and from 1747 to 1759 Thomas Gainsborough lived and painted there.

The older churches are all towered flintwork structures, wholly or mainly Perpendicular in style, with the exception of St. Peter's, which is principally Decorated, with a Norman font of Tournai marble. The grammar school, dating at latest from 1477, was refounded by Queen Elizabeth I in 1565. There is an Anglican bishopric of St. Edmondsbury and Ipswich. The parliamentary borough returns one member.

Prehistoric finds include a Roman villa and a Saxon settlement. In 991 the town was sacked by vikings. In 1200 King John granted the burgesses their first charter, the town to be held at fee-farm, with a guild merchant; the burgesses were definitely incorporated in 1464 and reincorporated in 1665 under a charter which remained in force up to its modification by the Municipal Corporations act of 183j. The cattle market and provision market are the prescriptive right of the corporation.

IPSWICH, a town of Essex county, eastern Massachusetts, U.S., 28 mi. N.N.E. of Boston, on both sides of the Ipswich river and fronting on Ipswich bay. (For comparative population figures *see* table in MASSACHUSETTS: *Population;* there are in addition about 2,000 summer residents)

The town was settled under the name of Agawam in 1633 and was incorporated in 1634 as Ipswich, being named for the English town. During the early days of the colony it was little inferior to Boston in wealth and influence, and frequently took an opposing position on public questions. Ipswich was the home of several of the leading writers of the colonial period, including Nathaniel Ward (1578–1652) and Anne Bradstreet (1612–72). Nearly 40 houses built before 1725 are still standing. The John Whipple house (1640) contains the collection of the Ipswich Historical society. The Choate bridge, built in 1764, is the oldest stone arched bridge in the U.S.

Ipswich has a selectmen-executive-secretary form of government in effect since 1955. (K. S. T.)

IQUIQUE, a city and port of Chile, capital of the province of Tarapacá (q *v*), 75 mi. S of Arica and 820 mi. N. of Valparaiso. Pop. (1960) 51.468. The Pacific coast runs due north and south and the city is built on a narrow level plain between the sea and bluffs, the latter rising steeply 2.000 ft. to the level of the desert plain of Tarapacá, celebrated for its rich deposits of nitrate of soda, which gives nay to the Atacama desert (*q.v.*). Facing the city is the low barren island of Serrano, which is connected with the mainland by a stone causeway 1,500 ft. long and shelters the anchorage from southerly storms. A mole extending from the northeastern end of the island affords further protection.

The city is laid out on the rectangular plan, with broad streets and large squares. Water is brought by pipes from the oasis-town of Pica. 50 mi. inland. Iquique is a city of commercial importance and is provided with banks, substantial business houses, newspapers, clubs. schools, railways. tramways, electric lights, telephone lines and steamship, air and cable communication with the outside world. It exports iodine and immense quantities of nitrate of soda obtained from the adjacent desert region.

A large number of vessels are engaged in the nitrate trade, and Iquique ranks as one of the two leading ports of Chile in the aggregate value of its foreign commerce. It is connected by rail with the inland town of Tarapacá and various mining centres. and through them with the ports of Pisagua on the north and Patillos on the south.

Iquique was an insignificant Peruvian fishing settlement until 1830 when the export of nitrate began. In 1868, the town was nearly destroyed by an earthquake, in 1875 by fire, and again in 1877, by earthquakes, a fire and a tidal wave. It was occupied by the Chileans in 1879 in the war between Chile and Peru, and was ceded to Chile by the treaty of Oct. 20. 1883

IQUITOS, Amazon river port in northeastern Peru, and capital of Loreto department, located 3° 45′ S. at an elevation of about 350 ft.. 2,300 mi. upstream from the Atlantic ocean. It is 640 mi. N N.E. of Lima. Pop. (1958 est.) j4.286. The climate is equatorial with an average rainfall of 103 in , but temperatures are not so high as in the middle latitudes—the warmest month (February) averages 78.3" F., and the coldest month (July), averages 74.1° F. The humidity is high, especially in the early morning hours.

Iquitos was founded as a Peruvian settlement in 1863 at a place occupied previously by an Indian village The Peruvians became interested in the region during the rubber boom of the late 19th century. and Iquitos became the chief shipping port for this part of the norld. In spite of the great distance from the Atlantic. ships draning 14 ft. can reach this place even at lon nater. The most prosperous period of rubber production was between 1906 and 1912, after which production dropped to only a fraction of nhat it had been. Population declined and for a long time this remote jungle region and the city which was its commercial centre remained stagnant.

Since 19jo there has been a renewed interest in the economic development of eastern Peru. Highways from Lima. including the Lima-Pucallpa highway, reach navigable water east of the Andes, and airplanes make the trip over the mountains in a fen hours. Iquitos has started to grow again in response to the increased settlement and production in its tributary area

The products, most of nhich continue to move out by steamer, include small amounts of rubber, balata, chicle, medicinal plants. tagua nuts, cabinet woods, cotton, rice, coffee, tobacco and hides. (P. E. J)

IRAKLION (HERAKLEION or CANDIA), the largest city in Crete, lies on the north coast, northeast of the central Mt. Psiloriti (Ida), and derives its name from the ancient Heracleum (Ἡράκλειον) which probably occupied the same site. Pop. (1961) 64,492. The town gained much importance as a trading centre after the construction of the new harbour, the airport and a number of motor roads. The chief exports are grapes, sultanas, olives and olive oil, nine, carobs, citrus fruit, almonds, soap and leather.

The Saracens, who captured the island between 823 and 828, made the city their capital, but they were defeated and massacred in 961 by Nicephorus Phocas. In 1204. after the capture of Constantinople by the crusaders. Crete was sold by King Boniface to Venice, but was occupied by the Genoese and only became Venetian territory in 1210. Most of the extensive Venetian walls of Iraklion still survive.

In 1669 the city was ceded to the Turks after a long siege. Francesco Morosini, later doge of Venice, commanded the defenders, and the finely sculptured fountain he erected still remains, though his loggia has been pulled down and the surviving Venetian churches have been desecrated. There is a modern cathedral, Armenian and Roman Catholic churches and also the interesting old church of St. Menas. A modern museum contains the finest collection in the world of Minoan antiquities from Knossos, 3 mi. S E., and from other Cretan sites, and there are interesting remains of later dates in the new historical museum. The Turkish mosques have been destroyed or converted to other uses. A monument commemorates Dhaskaloyannis, flayed alive there after the rebellion of 1770.

In a massacre that followed the Cretan rebellion of 1897, 17 British sailors were killed there, and Adm. Sir Gerard Noel forced the Turks to surrender the city. With the rest of Crete, after a period as a protectorate, Iraklion passed to Greece in 1912. During the German invasion in 1941 the city suffered heavily from aerial bombardments.

Iraklion is the capital of the department of Temenos; this department consists of the hilly country round Mt. Iuktas on the east and the valley of the Kairatos on the west, opening out into a coastal plain, perhaps the most fertile land in Crete except that of Messara. *See* also CRETE. (R. W. Hu.)

IRAN, the great plateau between the plain of the Tigris in the nest and the valley of the Indus in the east, the Caspian sea and the Turanian desert in the north and the Persian gulf and the Indian ocean in the south. surrounded on all sides by high mountain ranges with a great salt desert in the centre. The modern name Iran (in Middle Persian. Eran) is derived from the ancient *Aryana,* "the country of the Aryans." Eratosthenes limited the name of Ariana to the southeastern part of Iran. and excluded Persia. Media and Bactria, and therein he is followed by Strabo (ii, 78, 130, xv. 720 ff.; Pomp. Mela i. 3).

The term "Iran," having always been used by native Persians to designate their indefinitely bounded country, became current in western usage after 1927 as the name of the kingdom proper in recognition of its reinvigorated life and nenly asserted independence.

For the ethnography and history of .Iran *see* PERSIA.

IRANIAN LANGUAGES. The Iranian languages, of which the Persian branch is the most important, belong to the Indo-European family, within nhich Old Iranian and Sanskrit form the Aryan group (the terms "Aryan" and "Iran" having a common origin). How close Old Iranian is to Sanskrit may be judged from the translation into Sanskrit of the Avestan phrase *yō vō āpō vaβuhīš yazāitē ahurāniš ahurahe vahištābyō zaoθ-rābyō* ("he nho worships you, the good waters, the Ahurian [daughters] of Ahura, with the best libations"), which becomes *yō vō āpō vasvīṣ yajātē asurānīs asurasya vasiṣṭhabhyō hōtrā-*

bhyō; and the original Avestan words. undisguised by the alphabet, would be still nearer to the Sanskrit.

The principal phonetic distinctions of Iranian from Indian are: (1) original *s* becomes h in Iranian; (2) to Indian voiced and voiceless aspirates correspond respectively Iranian voiced stops or spirants; (3) Iranian has *z,* absent in Indian; (4) Iranian diphthongs ai, nu are found in Indian as *ē, ō,* etc. Compare the examples shown in the table.

Sanskrit	Avestan	Old Persian	Modern Persian
Sindhu (Indus)	*Hindu*	*Hindu*	*Hind*
Asura Medhās	*Ahura Mazdāh*	*Ahuramazdā*	*Hurmuzd*
bhūmī (earth)	*būmī*	*būmī*	*būm*
kratu (insight)	*xratu*		*xirad*
hasta- (hand)	*zasta-*	*dasta-*	*dast*
açva- (horse)	*aspa-*	*asa-*	*asp*

Later on the two branches, Iranian and Indian, diverged widely.

Three successive stages in the history of the Iranian languages —Ancient, Middle and Modern, in Persian. the principal branch of the group—correspond with epochs of national vicissitudes. Old Persian was used on the monuments of the Achaemenid dynasty (6th–4th centuries B.C.) destroyed by Alexander the Great. Middle Persian is known from the Parthian or Arsacid period (2nd century B.C.–3rd century A.D.) and even more from Sassanian times (C. A.D. 224–651), terminated by the Arab conquest and domination. With the Persian renaissance (9th century A.D.) Modern Persian appears, from which time it survives: with some unsubstantial changes: as a living language. Other Iranian idioms passed through stages similar to those of Persian.

Ancient Iranian Languages.—Of the Median language is known only one word (σπάκα, dog), preserved by Herodotus (i, 110) and several personal names. Of the Old Saka-Scythian group of languages (Scythian and Sarmatian) only personal names in Greek inscriptions, found in south Russia, have come down. The only ancient Iranian languages really known are Avestan and Old Persian.

The former is the language of the Zoroastrian sacred books. By early European scholars it was improperly called Zend, which term designates only the commentary to the Avesta, written in Middle Persian (see below). The age of the Avesta is dubious. Two parts of it are clearly distinct: the so-called Gathas are more or less at the same linguistic stage as the most ancient Vedic hymns of Old Indian. These archaic poems composed by the prophet of Iran, Zoroaster (*q.v.*), are authentic documents of his religious reform. The greater part of the Avesta, the so-called recent or younger Avesta, is a collection of texts of varying antiquity and is characterized by a gradual simplification and a lax use of the grammatical forms. At the time of its codification (4th–6th centuries A.D.) Avestan had long been a dead language known to the priests alone. In its present state the Avesta has the size of the *Iliad* and Odyssey put together. The original home of Avestan is uncertain but must no doubt be sought in eastern Iran. It was long taken for the language of Bactria, but later arguments were advanced for localizing it in ancient Khwarizm (Khiva). The Avestan alphabet was evolved from the late Pahlavi script (see below); before this, the Avestan texts are thought to have been transmitted orally.

Old Persian was used in the cuneiform inscriptions of the Achaemenid kings. The text is usually accompanied by translations into Elamite and Akkadian (Assyro-Babylonian). The most important document is the famous inscription of Darius the Great (522–486 B.C.) on the rock of Behistun. near Kermanshah, which was first read and published by Sir H. Rawlinson in 1846–47.

Middle Iranian.—This term describes the state of Iranian languages from the 3rd to the 10th century AD.. although in the case of Persian the transition from the Middle to the Modern phase had been completed by the 8th century. The Middle Iranian languages are Parthian, Middle Persian, Khwarizmian, Sogdian and Saka. Linguistically all except the second are closer to Avestan than to Old Persian.

Parthian was the official language of the Xrsacid period but is attested chiefly in later Sassanian inscriptions and Manichaean texts. The Parthian hymn cycles, composed by the Manichaean missionary Mar Ammo in the second half of the 3rd century A.D., rank among the highest literary achievements of the Middle Iranian period.

Middle Persian, the official language of the Sassanians. is found in their inscriptions as well as in Manichaean and Zoroastrian books. Of the former by far the most important is the great inscription of Shapur I (*c.* A.D. 262), a historical record of the war against the Romans, with parallel versions in Parthian and Greek.

The Middle Persian Manichaean literature (3rd–10th centuries) shares with the Parthian and Sogdian Manichaean texts the advantage of being written in an easily readable Aramaic alphabet, whereas the Zoroastrian books (largely commentaries on the Avesta and treatises on religious subjects, composed down to the 9th century) are nritten in the highly ambiguous Pahlavi script and abound in Semitic ideograms. The extant Pahlavi literature has been computed to amount to 628,000 words (E. W. West). The Manichaean texts, discovered in central Asia at the beginning of the 20th century, are much less numerous but have shed much light on the reading of Pahlavi books.

Khwarizmian is found only in glosses and sentences embedded in mediaeval Islamic lam books. The language may be a descendant of Avestan (see above).

Sogdian, the native language of the province centred on Samarkand, is available in three distinct Semitic alphabets, one being employed for lay documents and for Buddhist texts; one for Christian and the third for Manichaean literature. Each group, moreover, is characterized by dialectal variations. Sogdian traders and missionaries. travelling and settling in colonies along the route connecting Sogdiana with China, raised their language to the status of a lingua franca of central Asia between the 4th and the 10th centuries. A great deal of Sogdian literature was still awaiting publication in the middle of the 20th century.

Saka is known in two varieties. One, richly attested, was once the language of the kingdom of Khotan in Chinese Turkistan and hence is known as Khotanese. The other (of which only one Buddhist fragment survives) was connected with Tumshuq (Chinese Turkistan). From the end of the 8th century B.C. nomadic tribes of Sakas periodically emerged from central Asia into what is now south Russia (the Black sea coastal area. the Don basin and the northern Caucasus), the Scythians being the earliest-known wave of these invasions. Phonologically, the Iranian language which is closest to Khotanese is the present-day Wakhi in the Pamirs. A special affinityhas been noted between Khotanese, Ossetic, Khwarizmian, Sogdian and Pushtu (see below). The amount of Khotanese literature that has been recovered (largely Buddhist, but including some documents of lay content) is hardly less than what has survived in Pahlavi. The language is permeated with Indian elements. The study of Khotanese, still in its initial stage in the 1950s, seemed bound to have a profound effect on philologists' understanding of Iranian in all its branches.

Modern Languages.—A11 Iranian languages in actual use in the 20th century display in different degrees a tendency toward an analytic stage (simplification of the sounds and, in morphology, the use of new auxiliary tenses, etc.). Of these languages by far the most important is the literary Persian, as found in the extensive Persian literature and in the present-day speech of the more educated classes of the Persian-speaking countries.

Modern Persian is a direct descendant of the southern forms of Middle Persian, but has borrowed many words in the northwestern form and nymerous Arabic and Turkish elements. It is written in Arabic characters. Though Modern Persian is one and the same language, local variations, spoken in Persia, Afghanistan, India and Russian Turkistan (Tajiki), are considerable.

Parallel to literary Persian, special dialects are in use in most Persian towns and villages. The dialects of Fars, Luristan, Khurasan and Kerman belong to the same southern group as the literary Persian. On the other hand, numerous and different vernaculars represent the remains of former northwestern idioms.

Such are the local dialects of the Caspian provinces, the language of the Kurds (spread over a vast area and sporadically found in northern Syria and even close to Ankara in Asia Minor),

the language of the Baluchis and of isolated groups (as those of Kashan, Siinnan, etc.).

Among Modern Iranian languages of the "eastern" group are the Afghan language (Pushtu, *q.v.*), the various dialects of the Pamir group (Shughni, Wakhi, Munjani, etc.), Yaghnobi (a modem descendant of Sogdian) and Ossetic (spoken in the heart of the Caucasian mountains south of Vladikavkaz, a survivor of the once powerful Sarmatian group of Saka spoken in south Russia).

BIBLIOGRAPHY.—Detailed monographs on the Iranian languages, with a bibliography complete to the end of the 19th century, will be found in vol. i of *Grundriss der iranischen Philologie,* ed. by W. Geiger and E. Kuhn (Strasbourg: part i, 1895–1901; part ii, 1898–1901; supplement on Ossetic, 1903). Later Important works are: C. Bartholomae, *Altiranisches Wörterbuch* (Strasbourg, 1904) and *Zum altiranischen Worterbuch* (Strasbourg, 1906); A. Meillet, *Grammaire du vieux perse,* ed. by *E.* Benveniste (Paris, 1931); and R. G. Kent, *Old Persian* (New Haven, 1950). Middle Persian and Parthian texts have been edited by W. B. Henning from 1932 onward; *see* also A. Ghilain, *Essai sur la langue parthe* (Louvain, 1939); and Mary Boyce, *The Manichaean Hymn-Cycles in Parthian* (London, 1954). For Shapur's inscription *see* M. Sprengling, *Third Century Iran, Sapor and Kartir* (Chicago, 1953). For the relation of Khwarizmian mith Avestan *see* W. B. Henning, *Zoroaster* (Oxford, 1951; New York, 1952); and A. A. Freiman, *The Khorezmian Language* (in Russian) (Moscow and Leningrad, 1951). Sogdian texts have been published by F. W. K. Müller, W. Lentz, R. Gauthiot, E. Benveniste, W. B. Henning and O. Hansen; *see* Ilya Gershevitch, *A Grammar of Manichean Sogdian* (London, 1954). Khotanese texts have been edited chiefly by E. and M. Leumann, S. Konow and H. W. Bailey; *see* for instance S. Konow, *Primer of Khotanese Saka* (Oslo, 1949); and H. W. Bailey (ed.), *Khotanese Buddhist Texts* (London, 1951) and *Khotanese Texts 11* (Cambridge, 1954). For the languages spoken in Afghanistan and the Pamirs *see* G. A. Grierson, *Linguistic Survey of India,* vol. x (Calcutta, 1921); G. Morgenstierne, *An Etymological Vocabulary of Pashto* (Oslo, 1927) and *Indo-Iranian Frontier Languages,* 2 vol. (Oslo, 1929, 1938); and I. I. Zarubin's numerous studies, in Russian, on the Pamir languages. On Ossetic *see* V. I. Abayev, *Ossetic Language and Folklore* (in Russian) (Leningrad, 1949). For Modern Persian and Kurdish dialects *see* V. A. Zhukovsky, *Materials for the Study of the Persian Dialects,* 3 vol. (in Russian) (St. Petersburg, 1888–1922); V. F. Miller, *Tati Studies* (in Russian) (Moscow, 1905–07); O. Mann and K. Hadank, *Kurdisch-persische Forschungen,* 7 vol. (Berlin, 1906–30); A. Christensen, *Contributions à la dialectologie iranienne,* 2 vol. (Copenhagen, 1930–35); B. V. Miller, *The Talyshi Language* (in Russian) (Moscow, 1953).

The best theoretical grammar of Modern Persian is C. Salemann and V. A. Zhukovsky, *Persische Grammatik* (Berlin, 1889). More practical are D. C. Phillott, *Higher Persian Grammar* (Calcutta, 1919), and Ann K. S. Lambton, *Persian Grammar,* 2 parts (Cambridge, 1952–54). Dictionaries include: J. A. Vullers, *Lexicon persico-latinum,* 2 vol. and an annex (Bonn, 1855), complete and important for research work; Baron J. Desmaisons, *Dictionnaire persan-français,* 4 vol. (Rome, 1908–14); S. Haim, *New English-Persian and Persian-English Dictionary,* 4 vol. (Tehran, 1930–36). (V. F. M.; IA. G.)

IRANIAN RELIGION: see AVESTA; ZOROASTER.

IRAQ or AL-'IRAQ), a former kingdom (proclaimed a republic on July 14, 1958), formed out of the three Turkish provinces (vilayets) of Basra. Baghdad and Mosul after World War I. The boundaries between Iraq and its neighbours Syria, Jordan. Turkey, Iran (Persia), Kuwait and Saudi Arabia were gradually settled between 1922 and 1937. The northern frontier is crossed only by difficult tracks; the eastern frontier is crossed by only one easy route over the Paitak pass to Kermanshah; south of the mountain zone passage is hindered by soft desert and marshes. The southern and western frontiers offer no obstacles other than those of desert conditions.

PHYSICAL FEATURES

Geographically Iraq may be divided into three regions which correspond mith the geological structure of the land: the southern and western deserts ending at the Euphrates escarpment; the central lowland, comprising the delta lands south of Baghdad and the Jazira (*i.e.,* island) between the Tigris and Euphrates north of Baghdad with the northeastern plain and foothills; and the mountainous region of Iraqi Kurdistan. The frontiers with Kuwait, Saudi Arabia and Jordan are in the desert region. That with Kuwait follows for 60 mi. the Batina. a narrow depression which extends right across the Arabian peninsula. Elsewhere these frontiers follow a line of wells or are arbitrarily traced over featureless desert. In this desert region are three main divisions: the Dibdiba, a gently undulating steppe desert with a slightly sandy surface extending in a southeasterly direction from Abu Ghar wells across the Batina into Kunait: the Hajara, the "stony desert." to the northwest; and the Wadiyan to the frontiers with Jordan and Syria, a series of long wadis with a stony or gravel surface. The only notable oases are at Rahhaliya and Shifathah (or Shithathah) about 30 mi W. of Karbala. Fifteen miles southeast of Shifathah is an imposing ruin, Qasr Ukhaidhir, dating probably from the 6th century A.D. A metalled road nith a bitumen surface crosses the Wadiyan from the Jordan frontier via Rutba wells (where there is an Iraqi police fort and travellers' resthouse) to Ramadi. This road was constructed in 1941 but the route had been in general use for motor traffic between Baghdad and Damascus since 1923. The Iraq Petroleum company's pipelines cross from Haditha on the Euphrates to the Mediterranean.

The central lowland includes tracts with varying characteristics; lower Mesopotamia from Basra to Baghdad; the Jazira, a preponderantly desert area from the right bank of the Tigris to the Syrian and Turkish frontiers; and the "Assyrian" plain and foothills betaeen the Tigris and the mountainous region to the east and north. From Falluja (nhere the two rivers are no more than 50 mi. apart) the Euphrates follows a generally southerly course to Shinafiya. 150 mi. below in a direct line Hence it turns east to join the Tigris below Qurna. The northern part of this region is irrigated by canals from both rivers; the southern is a vast area of marshland and lakes. The Jazira—most of ahich is included in the new province named al-Badiyat al-Jazira (the Mesopotamian desert)—is the southeastern part of the almost wholly desert region between the Tigris and Euphrates south of the southern foothills of the Turkish mountains. In the north are occasional low ranges of hills of which the most prominent are the Jabal Sinjar nest of Mosul and the Jabal Mak-hul, an extension of the Jabal Hamrin west of the Tigris and parallel to its course. Rainfall from these and other hills is collected in streams which flou into the Tigris or into the depression known as the Wadi Tharthur which runs parallel with the Tigris for the full length of the Jazira. This depression receives Tigris floodnaters as part of a scheme of flood control and water storage. Hatra (Hadhr), an interesting Parthian ruin, lies 55 mi. S.S E of Mosul. Narrow belts of cultivation are found along the banks of both rivers. East of the Tigris the central lowland north of Baghdad is divided into four regions by the Jabal Hamrin and the Little and Great Zab rivers. South of the Jabal Hamrin is desert traversed in a north-south direction by the Adhaim river nhich is dry for eight months of the year. The Khalis canal takes off the Diyala river about 30 mi. K.E. of Baquba, and the land commanded by it and its subsidiaries is extensively cultivated. There are belts of cultivation also along the Tigris and the Diyala to Baghdad.

The Jabal Hamrin rises to about 1,500 ft. above sea level at the Fatha gorge. uhere the Tigris divides it from the Jabal Makhul, and loses height to about 700 ft. near the Diyala. The main pass, which takes the main road between Baghdad and Kirkuk, is the Injana or Abu Ghuraib, 6 mi S.E. of the break made by the Adhaim. The railway crosses at the Kurderuz pass 10 mi. E. of Deli Abbas which carries also the main road into Iran. The Khanaqin plain on the left bank of the Diyala is fertile and well watered. The roughly rectangular region between the Jabal Hamrin, the Diyala river, the Kurdish foothills and the Little Zab river is broken by numerous ravines and by tributaries of the Diyala and the Adhaim, but there are cultivated areas and stretches of good grazing. Northnest of Kirkuk is an area bare of vegetation beneath which are the oil fields.

Between the Little and Great Zab rivers is the Arbil (Arbela) plain all of which is cultivated with wheat and barley. To the southwest is the Jabal Qara Chauq and between it and the Tigris a formerly prosperous triangle nhich is now sparsely populated grazing land. The Mosul-Xrbil road crosses the Great Zab hy a steel bridge at Eski Kellek. The Mosul plain between the Great Zab and the foothills north and east of Mosul has a rich soil and is well cultivated; except in the extreme northwest cultivation is dependent entirely on rainfall. Iraqi Kurdistan forms a moun-

tainous crescent on the northeast through which the frontiers with Iran and Turkey are arbitrarily traced. It is a region of rugged mountains, impassable gorges and fertile valleys and plains, watered by the Great and Little Zab, the Khabur, the Diyala (known as the Ab-i-Sirwan on both sides of the Iranian frontier) and their tributaries. Many of the mountain slopes are well wooded and summer grazing is plentiful. Passage throughout the region is difficult. A motor road connects Kirkuk with Sulaimaniya (Suleimaniye) via the Tasluja pass and extends to Halabja in the south and to the edge of the Pizhdur country in the north, crossing the Little Zab at Dokan. An ancient route from Arbil to Ruwandiz and the Iranian frontier was made fit for motor traffic in 1932 after four years of work. There are also passable roads from Mosul to Dohuk with branches to Zakho and Amadiya.

Climate. — There are three climatic regions which are identical with the geographical regions mentioned above: the southern and western deserts, the central plains and the mountainous districts of the north. Throughout the country there are two pronounced seasons, the summer and the winter. Summer begins in May and lasts until October. During these months the sky is cloudless, the atmosphere dry and rain extremely rare. The prevailing northwest wind, the shamal, brings relief because of its dryness. In Baghdad the average mean maximum temperature exceeds 100° F. during June, July, August and September; but at night during those months it drops to between 69° F. and 76° F. In Mosul the nights are somewhat cooler. The highest recorded absolute temperature was 125° F. at Shaiba near Basra and at Diwaniya, both in August, which is normally the hottest month. The highest recorded temperature in Baghdad, however, was 121° F. on July 21, 1943; in Mosul 124° F. on July 21, 1937. Winter comes suddenly and lasts from November to April. Northwest winds prevail but are frequently interrupted by depressions from the Mediterranean; with the southeast winds which blow in front of them come cloudy skies, rain and cold Frosts may occur in any of the five months from November to March except perhaps in the extreme south; Shaiba has only once recorded 32° F. in November. The lowest recorded temperature in Baghdad was 18° F. on Jan. 5, 1942; in Mosul 12° F. on Jan. 3, 1925. Almost the whole rainfall occurs in the winter and spring. December, January and February are the wettest months, but, except in the north, the mean of each of these three months nowhere reaches 2 in. Precipitation in the mountains is considerably higher than in the plains, and an average of 40 in. has been recorded at several stations there. In Baghdad, the average over the period 1937–48 was just over 6 in. a year; in Mosul (1923–48) nearly 16 in. a year. Snow falls every year in the Kurdish mountains, and continuous snow cover down to 3,500 ft. has been noted in January, as a-ell as deep snow on sheltered plateaus at 5,000 it. Elsenhere in Iraq snow is rare; the average days on which snow fell in Mosul from 1923 to 1948 mas 0.6 per annum. In Baghdad, for the period 1937–48, it was o 3 days per annum.

Dust storms may occur at any time of the year; the light alluvial soil is easily broken up into fine dust when the ground is dry. Thus they are more frequent in southern and central Iraq than in the north. In the western desert, where the surface is harder. they are infrequent.

Autumn is more marked in the north than in the south, but is short everywhere. Spring, uhich occurs in April, lasts for less than a month and is noticeable for a slight rainfall, generally accompanied by thunder.

Flora and Fauna. — Biogeographically Iraq is usually included in the Mediterranean region, a term which has been used to cover not only countries of the Mediterranean basin but those as far east as Iran. The flora and vegetation of a few areas of Iraq have been studied in some detail, but other areas have never been touched by botanists. The most convenient botanical divisions are: (1) the western and southern desert; (2) the marshes, riverbanks and canals; (3) the plains of lower Iraq; (4) the submontane area; and (5) the Kurdish mountains.

In the driest parts of the desert there is almost complete sterility, and no hydrophytic vegetation is found west of the Euphrates. The depressions are generally saline and support a halophytic vegetation. Most of the persistent perennials in the desert are low, bushy shrubs or subshrubs, much branched and compact. Their prevailing gray colour is caused by a protective covering of gray hairs. Some have an impermeable surface of tough cuticle, often with a hairy covering as well. The rnarshes and riverbanks support dense communities of rushes, reeds and reed grasses. Willows and poplars are found on the riverbanks and, as an undergrowth, in addition to numerous annuals, grasses and sedges, there often occurs a species of tamarisk. The tamarisk may extend a long distance from the margins of streams. A shrubby member of the pea family (Prosopis *stephaniana*) is very common and in places forms dense thickets 7 ft. high. It is found everywhere in Iraq and extends to the Kurdish valleys. The licorice plant is common. From 34° N. lat. southward to Basra there are many areas, cultivated in the past, which are now neglected; the vegetation there can be regarded as only seminatural. Such areas become covered fairly densely with *Prosopis* and the gorselike camelthorn. Licorice may also be present where water is close at hand; and in the spring grasses and other low annuals sprinkle the ground. Saline areas are common, and some halophytes may occur which afford valuable grazing. Farther north salinity is less common; and the plain from Hillah to Samarra, including the region around Baghdad and the Diyala river, though treeless and muddy, develops a spring vegetation bright with flowers and green grass.

Climatic conditions become more favourable toward the north, but generally the vegetation of the desert lands varies according to the soil. In saline districts it is poor in species; where there is a calcareous substratum it is richer and of a different constitution; another type appears where sand predominates. The submontane district, with its longer winter and greater rainfall, has a steppelike vegetation often dominated by tufted perennial herbs and prickly plants, with a dense covering of annuals and small perennials in spring. In the Kurdish mountains altitudinal zones are clear. Between 2,000 ft. and 6,000 ft. is a forest zone with oaks as the common species. The Aleppo pine also occurs in restricted localities. The ground vegetation is varied and rich. Above the tree limit (6,000 ft.) many interesting plants are found, some forming compact thorn cushions and others being aromatic herbs.

The lion, once common in Iraq, appears to have become extinct about 1910. The oryx, wild ass and ostrich were once common, but their decrease or disappearance, like that of the lion, follon ed the introduction of the breech-loading rifle. The jungle cat and the smaller eastern wildcat, hyenas and jackals are not uncommon. The small Persian mongoose is widely spread in the southern areas. The common otter is not rare. At least six species of gerbils (desert rats) have been found. The brown and eastern black rat are found in Basra, but only the latter extends upcountry. The eastern house mouse is common. The Iraqi hare. a pale-coloured animal, is widely distributed. Marica's gazelle is found in the deserts and drier parts.

Large numbers of birds pass through Iraq. The resident birds include babblers, bulbuls, scrub warblers and sand grouse. In the hilly country the seesee, a miniature partridgelike game bird, is fairly common; and in thick scrub or cultivation the black partridge abounds. The houbara is widely spread, but the great and little bustards are confined to the northern districts. There are many birds of prey, including several eagles and two vultures. Geese winter in the marshes, and large flights of ducks come to Iraq for the cold weather. Several species of snakes are found, but only three, so far as is known. have poison fatal to man. There are numerous varieties of lizard. The true fresh-water fishes of the Tigris and Euphrates are dominated by the carp family. The Tigris salmon, one ot the small-scaled forms, is recorded as attaining the aeight of 300 lb. The lower reaches of the rivers are invaded by marine species. The Ganges shark has been found as high as Baghdad. (K. C. B.)

HISTORY

For the earlier history of what is now Iraqi territory see MESOPOTAMIA. See also, for its history in relation to the many empires of ahich it has formed a part, BABYLONIA AND ASSYRIA; CALIPHATE; PERSIA; and TURKEY.

Nationalist Movement. — Throughout the 19th and early 20th

centuries, Iraq remained as when first conquered by the Turks—a neglected outpost of the empire, governed by successive Turkish pashas for the benefit of themselves and the central government at Constantinople. Almost continuous misrule and maladministration, relieved only by the vigorous but futile attempts of Midhat Pasha (governor of Baghdad vilayet from 1869 to 1872) to bring order and a renewal of prosperity, added fuel to the slowly rising fires of Arab nationalism. The nationalist movement in Iraq, while lagging behind similar movements in the Arab nationalist centres of Damascus and Beirut in Syria. received additional stimulus when the Young Turks failed to live up to the hopes which they had aroused among the Arabs by the revolution of 1908. In the increased agitation for autonomy, or for decentralization, between 1908 and 1914, important roles were played by local Arab leaders, including Talib Pasha an-Naqib of Basra and Mohammed al-Gailani of Baghdad, and by the Arab army officers who dominated the secret Arab societies, particularly al-Ahd (the League). with affiliations in Egypt, Syria and Constantinople. Although the nationalists in Iraq were handicapped by the isolated position of the country, by the lack of educational facilities and of a middle class and by the existence of personal rivalries and religious antagonisms, the Arab movement was firmly established in Iraq at the outbreak of World War I.

British Military Occupation.—On Nov. 6, 1914, following the declaration of hostilities between Great Britain and Turkey, the Anglo-Indian expeditionary force "D." under Brig. Gen. W. S. Delamain, landed at Fao. This Turkish fort at the southernmost part of Iraq was speedily captured.

In sanctioning the capture of lower Iraq and eventually Baghdad and all of Iraq, British policy was never clearly defined nor worked out in advance and the decision to dispatch the expeditionary force was reached, with some misgiving—particularly about Indian Moslem reactions to war with the sultan-caliph—only after intensive consultations between London and Delhi. Its objectives were to reassure the sheikhs of Nuhammareh and Kuwait, to counter the threats of German and Turkish penetration of Persia with consequent danger to India and to protect the south Persian oil fields.

By Nov. 22, 1914, the Anglo-Indian forces had reached Basra and were firmly established on the Shatt al-Arab, thereby ensuring the safety of the refinery of the Anglo-Persian Oil company on the island of Abadan, Persia. (A detailed account of the advance to Baghdad and beyond, following the extension of the original objectives of the expedition, appears under MESOPOTAMIA, OPERATIONS IN.) Baghdad was occupied on March 11, 1917, by Sir Stanley Maude. The conquest of the remainder of the country was undertaken by Lieut. Gen. Sir William R. Marshall, who assumed command on the death of Sir Stanley Maude from cholera. The Euphrates was occupied up to Ramadi by late Nov. 1917 and up to Ana by March 1918. When the Russian troops withdrew from northeastern Iraq after the collapse of Russia, British forces pushed northward, occupying Khanaqin in Dec. 1917 and Kifri in April 1918. Kirkuk was taken in May 1918. The armistice of Mudros, Oct. 30, 1918, by which Turkey dropped out of the war, found General Marshall's forces 14 mi. from Mosul. Cnder orders received from the war office and on the authority of clauses vii and xvi of the armistice, General Marshall continued to push on. Mosul was occupied on Nov. 7, in spite of the indignant protest of the Turks.

British Policy and Iraqi Nationalism.—Arab nationalism in Iraq during the war flickered feebly as a result of the rigours of Turkish military rule, of the uncertainty about British policy and of fears that, whatever the outcome of the Mesopotamian war, the Turks might return.

The end of the war, nevertheless, brought encouragement to the nationalists. The promises that alien institutions would not be imposed and that participation would be accorded them in their civil affairs, which had been made in the proclamation of March 19, 1917, issued in General Maude's name after the capture of Baghdad, had then been assessed as the exuberance of wartime propaganda. When, ho ever, the Anglo-French declaration was published in Baghdad an Nov. 8, 1918, after the defeat of the Turks, the nationalists took heart. This declaration stated in part: "France and Great Britain have in view . . . the establishment of national Governments and Administrations drawing their authority from the initiative and free choice of indigenous populations . . . ."

The principal effect of the declaration, magnified by the fact of its appearance close upon the publication in the Iraqi press on Oct. 11 of Woodrow Wilson's fourteen points, withheld until that date by official orders. was that it apparently confirmed the promises in Maude's proclamation, in David Lloyd George's speech of Jan. 5, 1918, and in the Allied propaganda associated with the Arab revolt. Expectations ran high that national aspirations were about to be realized.

Such pronouncements were at variance with the earlier policies of the British government as expressed in the conversations in 1915–16 between the amir Husain of the Hejaz and Sir Henry MacMahon, the high commissioner in Egypt and in the Anglo-French (Sykes-Picot) agreement of 1916, the existence of which was unknown to the Arabs until the Bolsheviks revealed it in Dec. 1917. By this agreement Mosul was recognized as being in the French sphere of influence.

If the end of the war thus found British policy confused, the ensuing months were not fruitful in bringing order to the complexity of interests, aspirations and problems. In Iraq, Sir Arnold Wilson, acting civil commissioner during the absence in Tehran of Sir Percy Cox, felt obliged to formulate policies which would counteract the British government's indulgence of the nationalist aspirations. Such tendencies. which he held to be dangerous to the best interests both of the British empire and of the inhabitants of Iraq, could, in his opinion, be offset by fixing the patterns of administration and by maintaining British control with gradual participation of qualified Iraqis. This administration, although it brought greater efficiency, honesty and order than ever known before in Iraq, had no great welcome; it was too ambitious, and it was alien. Moreover, the plans for future government as proposed by Sir Arnold were held to be insufficient by the nationalists when measured against the promises of the British government and against their own aspirations.

These aspirations had continued to expand. A plebiscite, proposed by Sir Arnold and sanctioned for the spring of 1919 by the British government, not only failed to give the expected support to Sir Arnold's point of view but gave new stimulus to Iraqi self-determination. The establishment of an Arab government under the amir Faisal in Damascus with British support encouraged Iraqi officers of the Sharifian army to look across the desert to Iraq. In the name of the amir Abdullah ibn Husain whom they had elected king of Iraq on March 8, 1920, at Damascus, they supported with arms, men and money the local demands for Arab government at Baghdad. In Iraq, anti-British sentiment and local discontent of every variety in the towns and religious centres and among the tribes, landlords and unemployed former officials were skilfully stimulated and pressed into the service of the nationalists. Publication in Baghdad on May 3, 1920, of the news that Britain had accepted the mandate for Iraq was cited as a further proof that Great Britain could not be counted on to keep its promises.

By the time an announcement was made in Baghdad, June 20, 1920, concerning the establishment of an Arab government with British advisers, the moment had passed when the nationalists could have been restrained by a statement. An outbreak of lawlessness at Rumaitha, June 30, became the signal for a general rising.

The Rebellion.—In face of the rebellion which spread the length of the Euphrates and to the Baquba, Diyala and Kifri areas, but not to Mosul or Arbil, the restoration of peace and order was the first necessity. Reinforcements, numbering 4,883 British and 24,508 Indian troops, together with an air squadron, were brought from India. By Oct. 1, when Sir Percy Cox landed at Basra as high commissioner, the rebellion had been broken, although it did not finally collapse until late October. The rising, costly in lives and money for both sides, had a profound effect on Iraq's political life. To Iraqis it became a national war of independence, although

the immediate policy of the British government was not changed and its future policy was altered more in method of application than in objective. Iraqis who lost their lives in the rising became heroes and martyrs, while participation became the basis of later political preferment. To Sir Percy, on the other hand, the rebellion was a blow to the speedy realization of the self-government promised in June. By Nov. 11, however, he was able to announce the formation of the provisional Arab government for Iraq with the revered and aged religious dignitary, Abd ur-Rahman al-Gailani, naqib of Baghdad, as head of the council of state, with a membership representing all classes and sects. The provisional government gave its attention to the immediate pacification of the country; to the repatriation of Iraqi officers from Syria and the Hejaz; to administrative reorganization; and, as steps toward the creation of a permanent government, to the drafting of an electoral law and the inauguration of an assembly.

Faisal's Coronation.—As the head of this permanent government, the amir Faisal, expelled in July 1920 from Syria by the French authorities, became the preferred candidate, supported by the returned Iraqi officers, by Gertrude Bell, who had become oriental secretary in Baghdad, and by Winston Churchill, secretary of state for the colonies. The final stamp of approval was given him at the Cairo conference, called by Churchill (March 12 to 24, 1921) with the principal British political and military officials of the middle east in attendance.

On June 23, 1921, Faisal arrived at Basra, accompanied by three aides-de-camp, by Col. (later Sir) Kinahan Cornwallis, his personal adviser, and by a party of Iraqi notables. Three weeks later, on July 11, the council of state passed a unanimous resolution declaring Faisal to be king of Iraq on the condition that his government should be "constitutional, representative and democratic and limited by law." The high commission asked for a referendum to be carried out by the ministry of the interior. It was accordingly announced that the votes, which were cast by organized groups, were 96% in favour of Faisal. Kirkuk voted against Faisal, while Sulaimaniya took no part. The coronation took place at Baghdad, Aug. 23, 1921. Abd ur-Rahman al-Gailani became the first prime minister.

Facing the new king were a multitude of problems: consolidation of his position against considerable opposition, especially from the Shi'ite divines and the pro-Turks; establishment of the proper balance between the ardent nationalists and his British patrons; reconciliation of the bitter mutual antagonisms between townsmen and tribesmen, between the Shi'ite and Sunnite sects and between Arabs and Kurds; the settlement of frontiers with Turkey and Saudi Arabia; and, above all. the clarification of Iraq's relations with Great Britain through the negotiation of an Anglo-Iraqi treaty.

The Treaty of 1922.—Both the king and the British government had referred to the treaty before and after Faisal's coronation. It was soon clear, however, that a treaty did not mean the same thing to both sides.

In Iraq the fact had been obscured that the mandate was to be continued. The announcement, however, of H. A. L. Fisher before the League of Nations, Nov. 17, 1921, that the treaty was not "intended as a substitute for the mandate" renewed the anti-British and antimandate agitation. By early Aug. 1922 the agitation showed such virulence as to convince the high commissioner that both the peace of the country and the success of British policy would be imperilled if nationalist activities were not checked, a step which the king appeared unable or unwilling to take. Accordingly, when King Faisal was suddenly stricken with a dangerous attack of appendicitis on Aug. 24, the day following an anti-British demonstration at the palace, Sir Percy Cox gathered the reins of power into his own hands. He immediately issued a proclamation outlining the circumstances and serving notice that further sedition would be severely punished. The leading agitators were deported to Hinjam in the Persian gulf. Two of the Shi'ite clergy were induced to depart for Persia. By the time the king was able to resume his duties in early September, the crisis had passed. On Oct. 10 the council of state ratified the treaty, affirming the previous resolution of June 25 that it must be approved by the national assembly.

Consequently, ratification of the treaty, with the four subsidiary agreements governing the employment of British officials, military assistance and judicial and financial controls, did not take place until 1924 when, after the repeatedly postponed elections, the constituent assembly was opened March 27. In the debate which began immediately on the treaty and the agreements, it was apparent that because of the resurgence of nationalist activities and the heavy financial burdens imposed by the agreements, even the protreaty deputies would be reluctant to vote for its approval. The British government. therefore, after giving assurances that certain of the financial obligations would be reconsidered after ratification, announced that if the treaty was not approved by June 10, the day before the question of Iraq was to be considered by the League of Nations, the treaty would be regarded as having been rejected. The regular session of the assembly on June 10 adjourned without taking action. Then the prime minister, Jafar al-Askari, fully apprised of the issues at stake, gathered the deputies in a special session. Before midnight, after stormy debate, the treaty was ratified by a vote of 37 to 24, with 8 deputies abstaining. The organic law or constitution received unanimous approval on July 10. The assembly was dissolved on Aug. 2, after approving the electoral law on the same day.

The treaty was accepted on Sept. 27, 1924, by the League of Nations as regulating future Anglo-Iraqi relations. Ratifications were exchanged between Great Britain and Iraq during the winter of 1924.

The Treaty of **1926.**—The protocol of April 30, 1923, which had been attached to the treaty of 1922, had provided that the treaty should expire upon Iraq's becoming a member of the League of Nations and in any case not later than four years from the ratification of peace with Turkey. A new situation arose, however, when the League of Nations undertook to settle the Turco-Iraqi frontier dispute as the final step in establishing peace with Turkey. Under the terms of the peace treaty of Lausanne, Switz., July 24, 1923, when Turkey refused to abandon its claims to the Mosul area, the dispute had been referred to the League. On receiving the report of the special commission which it dispatched to Mosul (January–March 1925) to investigate the rival claims, the council of the League decided, on Dec. 16, 1925, in accordance with the decision of the Permanent Court of International Justice on Nov. 21, 1925, and subject to certain conditions, that Mosul vilayet south of the Brussels line (so-called because drawn by the council at Brussels, Belg.. Oct. 29, 1924) should be awarded to Iraq.

The most important of these conditions provided that a new treaty should be negotiated, ensuring continuance of the mandatory regime for 25 years or until Iraq had entered the League. While public opinion in Iraq did not oppose the extension of the treaty in exchange for the retention of Mosul, the rise of a strong demand for amendment to the subsidiary agreement and for periodic reviews of Iraq's fitness to join the League resulted in the inclusion of these conditions in article iii in the new treaty. The treaty, after signature on Jan. 13, 1926, was approved by the Iraqi parliament on Jan. 18 and by the British parliament on Feb. 18.

The Treaty of 1927.—In the autumn of 1927 the king sought in London British recommendation of Iraq for membership in the League and a new treaty ameliorating the obligations of the subsidiary agreements, in accordance with article iii of the 1926 treaty. The British government was unresponsive. The advent of the second Labour government in Great Britain facilitated a change in policy. On Sept. 14, 1929, Air Vice-Marshal Sir Robert Brooke-Popham, acting high commissioner following the death of Sir Gilbert Clayton, informed King Faisal that he had been authorized to announce that the British government was prepared to support Iraq's candidature for admission to the League in 1932, would not proceed with the treaty of 1927 and expected to negotiate a new treaty of alliance to regulate Anglo-Iraqi relations after the admission of Iraq into the League.

The Treaty of 1930.—The declaration, published on Sept. 19, evoked both approval and an immediate demand that the treaty be negotiated forthwith. Negotiations began on April 1, 1930. The treaty was approved by the ministers on June 28 and signed on

June 30, after a new judicial agreement and various annexes had been initialled.

The new treaty provided for "a full and frank consultation in all matters of foreign policy" which might affect common interests. Each party undertook not to adopt a policy inconsistent with the alliance or which might create difficulties for the other (article i).

In the event of war, each of the contracting parties was to come to the other's assistance. The aid of Iraq would "consist in furnishing to Great Britain on Iraq territory all facilities and assistance . . . including the use of railways, rivers, ports, aerodromes, and means of communication" (article iv). Air bases were to be leased to Great Britain on the terms set forth in the annexure (article v). All responsibilities previously assumed by the British government with respect to Iraq were to devolve upon the Iraqi government (article viii). The treaty was to come into force only when Iraq entered the League of Nations and was to continue for a period of 25 years from the date of its admission to membership.

The substance of the new relationship was, as in the previous treaties, contained in the subsidiary documents. The annexure regulated the leasing of the air bases and provided for the continuance of military assistance to Iraq. It gave Great Britain the right to move troops and supplies by all possible means across Iraq.

The first of the notes signed and exchanged on the same day, June 30, assured to the representative of the British government precedence over representatives of other powers at the court of the king of Iraq. The second note provided for a separate financial agreement, while the third stipulated that Iraq should normally engage British subjects for posts requiring foreign officials. The fourth note stated the intention of the Iraqi government to ask for a British advisory military mission.

The judicial agreement abolished the special judicial regime established in 1924 but guaranteed the employment of British legal experts in important specified posts.

Admission to the League of Nations.—The League in considering the candidature of Iraq evinced some doubt as to Iraq's administrative, political and social progress. Concern was also expressed for the future of minorities. When Great Britain, however, authorized its representative, Sir Francis Humphrey, high commissioner at Baghdad, to accept responsibility for the future conduct of Iraq, the council of the League agreed on Jan. 28, 1932, to admit Iraq, subject to the condition that it give a declaration guaranteeing minority rights, the administration of justice, international law and other safeguards. The declaration was signed on May 30, and on Oct. 3, 1932, Iraq was admitted to membership in the League as the first of the A mandates to achieve statehood as envisaged under article 22 of the covenant of the League.

By the time the mandate had been legally terminated, the transfer of administration into Iraqi hands had already largely taken place, having been accelerated from the end of 1929. Nevertheless, British officials continued to hold responsible advisory positions in various ministries.

Reign of Ghazi I.—The sudden death of King Faisal at Berne, Switz., on Sept. 8, 1933, brought the accession of his 21-year-old son as Ghazi I. The young king came to the throne on a wave of popular approval engendered by his open support of the Iraqi army's part in the Assyrian incident of Aug. 1933 in upper Iraq, in which nearly 600 of the Assyrians were slain. Yet it was not Ghazi's fortune to possess the experience, discipline, statesmanship and vigour which had stood his father in good stead. Nor did Ghazi become, as had his father, the common rallying point for the many diverse groups of the new state. Under King Ghazi, the existing trend toward political instability increased, marked by the new factor of interference from the army, which held not only that the government's policy toward the army was unsatisfactory but also that the discrepancy between the progress made by Turkey under Mustafa Kemal Atatiirk and that made by Iraq was the result of Iraq's lack of a strong leader.

The first of such interventions occurred in the coup d'état of Oct. 1936 when Gen. Bakr Sidqi, after bombing Baghdad and assassinating Jafar al-Askari, forced the resignation of the cabinet and the appointment of Hikmat Sulaiman as his prime minister. Bakr Sidqi was assassinated by a soldier on Aug. 16, 1937, after which Jamil al-Midfai came into office. The latter was replaced by Nuri as-Said after a bloodless coup carried through by army officers on Dec. 24–25, 1938. Nuri as-Said was obliged to suppress an alleged coup by an army group on March 21, 1939, and another on Feb. 20–21, 1940.

Notwithstanding the deterioration of order and of administrative efficiency, progress in a number of directions could be observed in the five and a half years of King Ghazi's reign. The Kut al-Amara irrigation barrage, begun in 1934, was pushed to completion. Development programs, for which oil royalties had been earmarked, were carried out. Pipelines from the Kirkuk oil fields to the Mediterranean were opened in Jan. 1935. The railroads were purchased from Great Britain and the construction begun of the Baiji-Tell Kiichiik section, the only missing railway link between Iraq and Europe. More schools were built, and larger numbers of students were sent abroad. Commerce improved generally over that of preceding years.

In foreign relations, the long-standing boundary dispute between Iraq and Persia was terminated and demarcation initiated for the Iraqi-Saudi Arabian boundary. The Syro-Iraqi boundary was amicably altered to include Jabal Sinjar within Iraq. Iraq, with Turkey, Iran and Afghanistan, signed the pact of nonaggression and consultation, at Saadabad in Iran on July 8, 1937. Arab solidarity was stressed in the nonaggression treaty with Saudi Arabia (1936) to which the Yemen later adhered, and by participation in the London round-table conference on Palestine in early 1939.

World War II.—The accession of the four-year-old son of King Ghazi, as King Faisal II, following his father's death at Baghdad in a motor accident on April 4, 1939, brought uncertainty at a time when internal and external crises required a strong hand. The regent, Abd ul-Ilah, uncle of the king, and Nuri as-Said as prime minister, supported the alliance with Great Britain on the outbreak of World War II in 1939, severing diplomatic relations with Germany. Nevertheless, the rapid growth of anti-British feeling, stimulated by axis successes and pervasive axis propaganda, caused the situation to deteriorate rapidly in 1940 and early 1941. Many Iraqis were convinced that in British military reverses lay the long-awaited opportunity to free Iraq of the remnants of British control. British policy in Palestine had long been opposed by most Iraqis, and Haj Amin al-Husaini, mufti of Jerusalem, who had taken refuge in Iraq, lost no opportunity to keep the opposition alive. Army officers, dominated by four colonels calling themselves the Golden Square, were particularly anti-British, not merely because of their antagonism to British policies in the Arab world but also because the Iraqi government, which they held to be under the thumb of the British, did not grant sufficient precedence to army demands for arms and reorganization. Rashid Ali al-Gailani, personally ambitious and convinced that his way to power and wealth was barred by the British, attached his fortunes to the army group and with it to the axis. On April 7, 1940, under pressure from the four colonels, the regent dismissed Nuri and appointed Rashid Ali in his place.

The army officers showed their hand in late Jan. 1941, when the regent sought to secure, in view of Rashid Ali's connections with the axis and his reluctance to break relations with Italy, his resignation as prime minister. The attempted coup d'état was checked, and, on Jan. 29, Rashid Ali was obliged to give way to Taha al-Hashimi. The army, however, encouraged by axis successes in the Mediterranean and by promises of assistance, maintained its pressure. On April 2 the regent, faced with an army demand to reinstate Rashid Ali, fled from Baghdad. The army group assumed control, appointing Rashid Ali premier.

Sir Kinahan Cornwallis, who had been named ambassador to Baghdad on Feb. 26, had hoped to solve the crisis without the use of force. On April 7, however, a higher national defense council was set up. The replacement of Abd ul-Ilah as regent by as-Sharif Sharaf by the parliament, under threat of force, followed on April 9. On the same date Rashid Ali formed his new cabinet with members known to possess axis connections.

Notified by his government of the dispatch of troops, the ambassador thereupon informed Rashid Ali that the British government intended to call upon Iraq to carry out provisions of the

treaty of 1930 by providing transportation from Basra across Iraq for British troops to meet the threatening military situation in the near east. Although Rashid Ali acquiesced, objections were raised when the troops began to arrive and an announcement was made that a second group was to be expected. Iraqi troops with artillery were concentrated about the British air base at Habbaniya on April 29–30 as a precautionary measure. When the commander of the Iraqi troops presented the local British commander with an ultimatum, the latter ordered the royal air force into action on May 2 and, though facing very considerable odds, forced the enemy to raise the siege by May 7. Axis aircraft and arms arrived by way of Syria, but in insufficient quantities. A small British mobile force then crossed the desert. Rutba was reoccupied on May 9, Falluja on May 20 and Baghdad on June 1, after the request for an armistice on May 30, when Rashid Ali and a number of his associates had fled from Baghdad. The regent Abd ul-Ilah returned to Baghdad on June 1, setting up a new government on June 3, with Jamil al-Madfai as premier. In Oct. 1941 the latter was succeeded by Nuri, who remained in power until June 1944.

Throughout the remainder of the war, Iraq not only observed the terms of the Anglo-Iraqi alliance but also actively participated in the war. Over its communications systems, expanded by military construction, considerable quantities of materials were sent to the U.S.S.R. Its resources of food and material were also drawn upon, with adverse effects on its own internal economy. Diplomatic relations with Vichy were broken off on Nov. 16, 1941, as were relations with Tokyo on Nov. 18. 1941. War was declared on Germany. Japan and Italy on Jan. 16. 1943. On the same day, Iraq signified its adherence to the United Nations declaration. Previously, on May 1, 1942, Iraq had been declared eligible for lend-lease. A constitutional amendment in 1943 attempted to prevent a repetition of the political unrest which had characterized the years 1936–41 by empowering the crown to dismiss a prime minister. Before this, a government could be dismissed only by a vote of no confidence in the chamber, and no election had been free enough to establish a chamber independent of the cabinet. In 1943 Nuri circulated a confidential memorandum in which he proposed the merging of Syria, Lebanon, Palestine and Transjordan into a Greater Syria, to be linked with Iraq. His subsequent discussions with the Egyptian government led to the formation in 1945 of the Arab league (*q.v.*).

After World War II.—Iraq emerged from World War II with its financial position improved. The country, moreover, possessed all that was needed for raising the standard of living, but the Sunni Arab group of politicians that entrenched itself in government was not particularly efficient. By 1946 there had been 32 cabinets in 25 years recruited from about 50 persons. In Nov. 1946 Nuri as-Said accepted his ninth term as premier. The ban on political parties, imposed in 1937, was lifted, and in Feb. 1947 elections were held.

Salih Jabr, the first Shi'ite Arab to become premier, went to England to sign at Portsmouth, in Jan. 1948, a 20-year treaty under which Great Britain might continue using the air bases at Shuaiba and Habbaniya until peace treaties with all former enemy countries had come into effect and might subsequently maintain technical staffs and equipment there. But under nationalist and Communist pressure this treaty was denounced, and the government resigned. A "caretaker" government sent Iraqi troops to join in the Arab league's intervention in Palestine (May). Muzahim Amin al-Pachachi became premier after the elections in June but was succeeded in Jan. 1949 by Nuri as-Said. Nuri withdrew the Iraqi troops from Palestine and was now supposed to be sponsoring the "fertile crescent" plan for union with Syria (as opposed to Greater Syria); and during his government the doubling of the Kirkuk-Tripoli pipeline was completed. Two coalition governments followed his resignation (November); the second, in March 1950, authorized Iraqi Jews to renounce their nationality and emigrate (see Area *and* Population, below); in May it adopted plans for building a pipeline from Kirkuk to the Syrian port of Baniyas. In Sept. 1950 Nuri formed yet another government; this, in Aug. 1951, concluded an agreement with the Iraq Petroleum company and its subsidiaries, under which Iraq was to get 50% of the companies' profits (see Petroleum, below). Mustafa al-Umari's government, which succeeded Nuri's in July 1952, had to resign in November when riots broke out in Baghdad after four of the five political parties pressed for replacement of the two-stage electoral system by direct voting. Gen. Nureddin Mahmud, whom the regent asked to form a government, declared martial law, arrested 200 Communists and then abolished the two-stage system. A general election in Jan. 1953, in which every male over 20 years had a vote, gave an absolute majority to Nuri's supporters in the parliament, and Jamil al-Madfai formed a government with Nuri as minister of defense. On the following May King Faisal II attained his majority and assumed the royal prerogatives. In September. on the government's resignation, a new cabinet was formed by Fadil Jamali. This government lifted the martial law that Nureddin Mahmud had imposed; but Jamali had to resign in April 1954. In August Nuri formed a government again. He dissolved the 135-seat chamber of deputies and at the Sept. 12 general election won 113 seats.

All political parties were dissolved on Sept. 22 and measures were taken to deprive the Communists of citizenship pending deportation.

On Feb. 24, 1955, a Turkish-Iraqi treaty of mutual defense was signed at Baghdad. joined on April 4 by Great Britain (thus terminating the Anglo-Iraqi alliance of June 30. 1930), by Pakistan on Sept. 23 and by Iran on Oct. 12. On Nov. 21–22 the allies set up a permanent council, with its secretariat in Baghdad, a permanent military committee and a permanent economic committee. The U.S. maintained a close association with the organization through political and military observers. From Nov. 1956 to May 1957 Iraq was under martial law introduced during the Suez canal crisis. In June 1957 Ali Jawdat al-Ayubi succeeded Nuri as premier, and was in turn succeeded by Abdul Wahab Marjan in December. On Feb. 14, 1958, a union between Iraq and Jordan was proclaimed. Revolt broke out in July of that year and King Faisal II was killed. A republic was established with Gen. Abdul Karim Kassem, revolutionary leader, at its head. The new government quickly dissolved the Iraq-Jordan union.

(P. W. I.; X.)

AREA AND POPULATION

The country's total area is 171,599 sq.mi., including 91,112 sq.mi. for 14 settled provinces (liwas) and 80,487 sq.mi. for 3 desert provinces. The Jazira desert is a roughly triangular area between the Tigris and Euphrates and the Syrian frontier; the Northern desert (Badiyat ash-Shimaliya) extends from the Euphrates along the Syrian frontier to Jordan's frontier up to the latitude of Najaf; the Southern desert (Badiyat al-Janubiya) lies between the Euphrates and Saudi Arabia.

The census of 1957 gave the total population as 6,538,109, including the 14 settled provinces, the desert provinces, those not registered, and those abroad.

Iraq possesses a variety of peoples and religions. In 1947 4,251,680 (88.3%) of the population was Moslem, divided between the Sunni and the Shi'a sects in the proportion of about 5 to 8. There were 149,653 (3.1%) Christians (Nestorians, Chaldaeans, Syrian Orthodox and Catholics, Armenian Gregorians and Catholics, Greek Orthodox and other Uniates and Protestants), Yezidis, Sabians and Jews. The Jewish community of 118,099, of whom 77,542 were in Baghdad, was reduced to about 15,000 by emigration to Israel. In northern and central Iraq and on the upper Euphrates the Sunnites outnumber the Shi'ites by about six to one; in the middle Euphrates, lower Tigris and lower delta the Shi'ites outnumber the Sunnites by about ten to one. Of the Christian population, 62% is found in the Mosul province and 21% in Baghdad city.

The Moslems are Arab, Kurdish. Turkish or Persian, with a small number of Indians. The non-Moslems are Assyrians, Yezidis, Sabians (Mandaeans), Chaldaeans, Armenians or Jews. The Arab population comprises all the inhabitants of southern Iraq with the exception of several thousand Persians (many of whom are found in the holy cities of Najaf, Karbala and Kadhimain); in northern Iraq Arabs form a minority confined to the Jazira, the

riverain strip of the Tigris and the Mosul plain. The patriarchal organization of the nomadic tribes (*badu'*) persists among both seminomadic and settled rural Arabs, although the extensive development of pump irrigation has done something to break down the system. It has been estimated that about one-quarter of the total population of Iraq live in towns, one-tenth are truly nomadic and the remainder are either settled or semisettled cultivators.

The Kurds inhabit the mountainous crescent to the north and east, divided from their fellow Kurds in Syria, Turkey and Iran by Iraq's frontiers with those countries. To the west they have penetrated from their mountain home far into the plains, particularly in the provinces of Kirkuk and Arbil where Kurds and Kurdish ways dominate a region formerly held by Arabs and Turks. The total Kurdish population was estimated at about 800,000 in 1955. The tribal system remains strong in the remoter mountain districts. although even there there is some fragmentation. In the plains and the broad valleys around Sulaimaniya there are considerable areas where the tribal organization has been abandoned. Some tribes no longer make their seasonal migration, although the shepherds of the plains and foothills are seminomadic. The Kurds have never taken kindly to administrative control, and their traditional impatience with authority finds its excuse in their situation as a minority in the Arab state of Iraq.

The Turks (about 80,000 in 1955) are distributed in a number of small towns and villages along the old trade route from Baghdad through the plains and the northern Jazira to Turkey.

The majority of the Assyrians (Nestorians) in Iraq entered the country as refugees in 1918, having been driven from their homes in the Hakari district after revolting against the Turks. The exclusion of this district from Iraq in the frontier settlement of 1925 created a serious resettlement problem. By 1955 probably about 16,000 were left near Amadiya and Ruwandiz, in villages around Mosul or working in the big towns.

The Yezidis live in the Jabal Sinjar and the Shaikhan district north of Mosul. They, like other non-Moslem communities, have a tradition of autonomy dating from Ottoman days and cannot reconcile themselves to becoming citizens of a modern state, fearing particularly a weakening in the hold of their esoteric religion.

The Christian communities, although recognized by the government as possessing competence in matters of personal status, are, with the exception of the Assyrians and the Armenians, almost entirely Arabized. The majority are town dwellers, but there are many villages of Chaldaeans and other Christians intermingled with Moslem Arabs and Kurds in the Mosul plain and in the Dohuk and Amadiya districts. The Assyrians and Armenians preserve their language and traditions, but those in the towns are bilingual.

The official language of Iraq is Arabic, spoken throughout Iraq by the Moslem and Christian Arabs and by many Kurds and other minorities of the northern provinces. Kurdish, an Indo-European language akin to Persian, is spoken by all Kurds; in the mountainous parts of Kurdistan they have no other language except, in some districts, Persian. The Kurmanji dialect of Kurdish is spoken along the Great Zab river; south of it two closely allied dialects, the Sorani and the so-called Sulaimani; and Gorani by the unorthodox communities of Sarlis, Kakais and Shaveks and by some of the southernmost tribes. Syriac is spoken by Assyrians and Chaldaeans, but most of these people speak Arabic or Kurdish also. Persian is largely spoken in Najaf, Karbala and Kadhimain. The Turks speak Turkish.

Education. — In 1953–54 there were 1,451 state and 98 private elementary schools with, respectively, 258,333 and 22,045 pupils and 8,819 and 702 teachers; 134 state and 63 private secondary schools with, respectively, 34,810 and 11,653 pupils and 1,720 and 959 teachers; 11 vocational schools with 1,874 pupils and 90 teachers; 11 teachers' training colleges with 1,744 students and 78 teachers. There were also 12 institutions of higher education with 5,255 students and a teaching staff of 234. The percentage of illiterates amounted in 1947 to 91.5%.

GOVERNMENT AND ADMINISTRATION

Constitution. — Until the 1959 revolution Iraq was governed under the constitution of 1924, as amended in 1925 and again in 1943. The constitution provided for a hereditary monarchy, vested in the heirs of Faisal I, a council of ministers and a parliament. The king was head of the state, confirming laws and supervising their execution. He chose the prime minister and, if it was in the public interest, dismissed him. Parliament consisted of the senate and the chamber of deputies. Members oi the senate were appointed by the king for a period of eight years, one-half retiring or being reappointed every four years. Their number could not exceed one-quarter of the number of deputies. Members of the chamber of deputies were elected on the basis of 1 to every 20,000 male Iraqi subjects. The non-Moslem communities had to be represented in the chamber. The cabinet consisted of at least seven members, including the prime minister on whose recommendation the king appointed the other ministers. The ministries were those of foreign affairs, finance, the interior, social affairs, defense, justice, education, economics, communications and works, and development.

There were four kinds of courts of justice. civil, criminal, religious and tribal. The religious (Shari') courts dealt with matters of personal status affecting marriage, dowry, divorce, etc., and some matters affecting religious endowments (*waqf*) Shari' courts, both Sunnite and Shi'ite, existed wherever there were civil courts. The spiritual councils of the Christian and Jewish communities provided analogous courts for them The government, following the example of the former mandatory power, recognized tribal custom and gave official status to it, so that in the tribal areas tribal arbitration and tribal courts, convened by an administrative official, took the place of law courts.

Iraq was divided into 14 settled provinces (liwas) and 3 desert provinces. Each *liwa* was administered by a *mutassarif* who, apart irom being the chief executive officer oi the liwa under the minister of the interior, was also the agent and representative of the other ministers In each *liwa* there was an administrative council under the chairmanship of the *mutassarif* Each liwa was divided into two or more *qadhas* under a *qaimmaqam* and each *qadha* into two or more *nahiyas* under a mudir.

Defense. — By 1955 Iraq had three combat divisions, three operational tank battalions and six air squadrons, two of them jet. In April 1954 the United States agreed to provide Iraqi armed forces with modern weapons and equipment in order to modernize its existing units and to create a new mechanized division.

ECONOMIC CONDITIONS

Agriculture. — Iraq is primarily an agricultural and pastoral country. Agriculturally it may be divided into two zones: the rainfall zone, corresponding roughly with the higher-lying northern area; and the irrigation zone beginning south of the Jabal Hamrin, in which crops depend upon irrigation by flow or lift.

The agricultural land in 1952–53 amounted to 6,384,400 ha., 27% of the settled area; i.e., excluding the deserts. This land was divided into 125,045 holdings; there were 66,042 holdings of less than 10 ha., 25,982 holdings from 10 ha. to 25 ha., 28,747 holdings from 25 ha. to 200 ha., 3,345 holdings from 200 ha. to 1,000 ha., 825 holdings from 1,000 ha. to 5,000 ha. and 104 holdings of more than 5,000 ha. Of the agricultural land about two-fifths (2,520,000 ha. in 1952–53) was cultivated annually.

There are two flood periods: December–March, caused by winter rains, and March–May, caused by the melting of the snow in the upper reaches of the rivers. There are correspondingly two cropping seasons, winter (*shitwi*) and summer (*saifi*). The winter crops, sown in the autumn and watered by the winter rains or by irrigation, are harvested in the early summer. Summer crops are sown in spring and harvested in late summer. The principal winter crops are wheat, barley and some oilseeds; the summer crops are rice, cotton, sesame, maize and millet. Cotton has long been grown for local purposes and its cultivation for export received the encouragement of the department of agriculture and of the British Society for the Cultivation of Cotton. The principal cotton areas are in the Baghdad, Diyala and Hillah canal zones, around Kut on the Tigris and, on a smaller scale, on irrigable lands in the Mosul *liwa*. Tobacco is grown in the Sulaimaniya and Arbil *liwas*. The most important date-producing area is a strip 120 mi. long and 3 mi. wide along the Shatt al-Arab, which produces more than half of the total crop. Other important growing areas are on the lower and middle Euphrates (al-Qurna to Nasiriya and in the Hillah and Diwaniya *liwas*); around Karbala, with the desert oases of Shifatha and Rahhaliya; along the Tigris in the Baghdad *liwa;* in the Diyala area; and around Badra and Mandali, where the choicest variety is grown. Iraq produces about 80% of the world's supply of dates. Fruit and vegetables are grown mainly in the Diyala area and in the north, though there is local production throughout Iraq. The Baquba area is renowned for the quality oi its oranges. Beans and other leguminous plants are fairly widely cultivated, but there is no surplus for export. The production of the principal crops according to the government's statistical abstract is shown in Table I.

Three types of sheep are bred in Iraq; all are fat-tailed. Goats are bred throughout the country, but the majority are found in the north. Many sheep and goats range in mixed flocks with the nomadic or seminomadic tribes, moving from winter pastures in the plains or desert to the mountains or riverain areas for the summer. Cattle are kept in the riverain areas where there is permanent pasture. Two breeds are common, of which the southern is superior both in size and in milk yield. In the marshlands of the lower Tigris and Euphrates

TABLE I.—*Agricultural* Production
(in 000 metric tons)

Crops	1934–38	1950	1951	1952	1953	1954	1955

Dates	260	305	350	370	350	350	...

and elsewhere in southern Iraq the water buffalo is kept both as a draught animal and for its milk. Camels, mostly bred by the nomads of the desert, are of the single-humped variety. They are kept for their milk, hair and for transportation and are exported to Egypt for slaughter. Donkeys are common throughout the country and are used everywhere as pack or riding animals The usual breed is black or dark brown but a large white riding donkey of Tejdi origin is often seen. Thoroughbred Arab horses are raised by several tribes. Horses of inferior breed are used to pull carts and carriages. In the Kurdish districts ponies and mules are used, the latter mainly for pack transport. In 1954 the following estimates of livestock were published: sheep 10,000,000; goats 3,000,000; cattle 1,510,000; buffaloes 718,000; horses 300,000; mules 500,000; asses 1,000,000; camels 362,000.

Irrigation. — Although yields of the principal crops fluctuated in response to weather conditions, floods and attacks by locusts and other pests, an extension of acreage under crops was steadily maintained both by greater mechanization and by increased irrigation. In 1954 disastrous floods occurred which emphasized the urgency of completing irrigation and flood-control works planned earlier and undertaken through the six-year development scheme,?1951–57 *(see* below). Under this scheme ten dams were to be constructed on the Euphrates and on the Tigris and its affluents which would control floods by storing surplus rvater to be used for irrigation. The total area thus irrigated by the schemes on the Tigris and its tributaries was estimated at 1,224,000 ha. and that of the Euphrates schemes at 552,000 ha., an increase of about 70% in the cultivated area. On April 2, 1956, the Wadi Tharthur scheme on the Tigris was inaugurated at the Samarra barrage, providing in addition access across the river to a projected hydroelectric plant. On April 5 the Habbaniya system on the Euphrates, begun in 1912, was completed by the inauguration of the Ramadi barrage. Almost immediately this was put to the test by an unexpected flooding of the river on April 17, brought under control within a few hours.

Development Plan. — In 1950 a Development board was established to prepare a general economic and financial plan for the development of the resources of Iraq and to raise the standard of living of the people. The board of eight members was constituted under the chairmanship of the premier. In 1953 a ministry of development was set up and the minister became the board's representative on the council of ministers. It had its own budget and its revenues, originally the total revenue received from the oil companies, were amended in 1952 to 70% plus such other sums as might be allotted by parliament and the proceeds of any loans, domestic or foreign. A distinction was made between capital and small projects, the latter being financed by the board but carried out by the appropriate ministry. The six-year plan, 1951–57, based on a report of a mission from the International Bank for Reconstruction and Development which envisaged an expenditure of 168,500,000 Iraqi dinars, was superseded in 1954 by a five-year plan, 1955–60. The latter called for an estimated expenditure-of 303,306,100 Iraqi dinars.

Industry. — A law of 1929 designed to encourage industry by exemptions from customs and taxes was superseded in 1950 by a law which granted important privileges to factories which were power-operated, employed 90% or more of local workers, cost at least 5,000 Iraqi dinars to erect and used more than half Iiaqi capital. But Iraqi industry, in spite of substantial expansion between 1946 and 1954, remained small. The presence of deposits of copper and copper pyrites, of iron ore, chromite and magnesite had been indicated but no use was made of them by mid 20th-century and the raw materials of industry were almost entirely agricultural products. Factory employment was concentrated in and around Baghdad with 31,600 workers in 1954 out of an estimated 70,000. Three cotton ginneries established before World War II continued to operate and a spinning and weaving factory went into production in 1947. One factory in Mosul produced rayon cloth from imported yarn. Three factories produced about 500,000 metres of woollen cloth which was all used locally. Boots and shoes were produced by hand but there were several factories using electrically operated machinery. Other important industries were: jute spinning and weaving and the manufacture of jute gunny bags, tanning, soapmaking and the manufacture of tobacco products, beer, alcohol and alcoholic drinks (arrack from grapes and dates), bricks and cement (200,000 tons a year). One factory made spun-concrete pipes by a modern process. The amount of electricity used in industry increased from 9,000,000 kw hr in 1946 to 88,000,000 in 1954 exclusive of that used in the petroleum industry. Total production of electricity in 1954 amounted to 390,034,000 kw.hr., including 246,948,000 kw.hr. at the Kirkuk oil fields but excluding about 70,000,000 kw.hr. consumed by the pipeline stations.

Petroleum. — The existence of oil in Iraq has been recorded since ancient times (Gen. vi, 14). Modern development may be said to date from 1914 when the Ottoman government granted a concession in Iraq to an Anglo-German group which formed the Turkish Petroleum company. After World War I this concession was divided between British, U.S., Dutch and French interests, which took equal shares of 23.75%, and the Armenian agent C. S. Gulbenkian, who took 5%. This company, later named the Iraq Petroleum company, was granted a concession for 75 years by the Iraqi government in 1925. Oil was struck at Baba Gurgur, near Kirkuk, in 1927. In 1931 the terms of the concession were revised and the I.P.C. was granted sole rights to exploit petroleum in regions east of the Tigris (except the transferred territories) covering an area of 32,000 sq.mi. In return the company agreed to construct a pipeline to the Mediterranean with a capacity of not less than 3,000,000 tons per annum. This was opened in 1935; it bifurcates at Rutba to Haifa in Israel and Tripoli in Lebanon. Flow in the Haifa branch was cut off by the Iraqi government in 1948. A new 30-in. pipeline from the Kirkuk fields to Baniyas in Syria was completed in 1952. When the I.P.C. concession was revised the British Oil Development company was granted a concession over land to the west of the Tigris. The oil found was both too viscous and too high in sulphur content for profitable exploitation by the original company, and the concession was transferred to the Mosul Petroleum company, a subsidiary of the I.P.C., in 1936. A third company, the Basra Petroleum company, also associated with the I.P.C., obtained a concession for 75 years from 1938 covering the old Basra vilayet, and a pipeline to Fao from Zubair (Zobeir) was completed in 1951. A fourth company, the Khanaqin Oil company, a subsidiary of the Anglo-Iranian Oil company, operated the Naft Kaneh field about 30 mi. S. of Khanaqin. The output is largely consumed in Iraq, being refined at Alwand, 3 mi. from Khanaqin. The total output of all fields in Iraq amounted to 4,298,000 metric tons in 1938; it was 4,680,000 tons in 1946 and 6,479,000 tons in 1950; by 1954 it rose to 29,784,000 tons and was estimated at 33,700,000 tons in 1955.

The oil royalties in 1955 amounted to 73,700,000 Iraqi dinars.

A new agreement with the I.P.C. of Feb. 1952 stipulated that the government would receive its equal share of profits determined, before deduction of foreign taxes, on the basis of fixed values and costs of petroleum. This agreement was further modified in Iraq's favour in March 1955. The enormous increase in government revenue from this source (*cf.* 5,350,000 Iraqi dinars in 1950) reflected these more favourable terms as well as the great increase in production. As part of the 1952 agreement the government was entitled to take 12.5% of crude oil produced and to develop its own export market.

Foreign Trade. — The chief exports of Iraq (excluding petroleum and products) are barley, wheat, rice, dates, wool, hides and skins, and cotton. Quantities and values fluctuate somewhat with the size of the crop but there was a generally upward tendency after World War II to the mid-1950s. Imports showed a more striking rise, the increase being marked in iron and steel, machinery and vehicles, chemicals and pharmaceuticals, tea and sugar. Table II gives values of imports and exports, excluding petroleum and products.

TABLE 11. — Foreign Trade
(in 000 Iraqi dinars)

Item	1938	1948	1949	1950	1951	1952	1953	1954
Imports	9,361	45,523	40,501	37,595	50,871	61,795	68,709	74,111
Exports	3,690	8,662	12,426	21,603	28,927	19,965	19,866	18,580

Finance. — The unit of currency is the Iraqi dinar, at par with the pound sterling. Currency circulation in March 1955 amounted to 43,400,000 Iraqi dinars (4,600,000 Iraqi dinars in 1938). Principal sources of income, other than oil revenues, are indirect taxes. In 1952–53 the main items of revenue were: customs and other indirect taxes (32.9%), oil revenues (42.7%), taxes on land and produce (7.6%) and direct taxes on income and wealth (5.9%). The principal items of expenditure were: defense (30.9%), police (7.4%), education, non-elementary (5.0%) and public health (6.3%). Allocation of funds from the oil revenues to the Development board was noted above. A summary of revenue and expenditure is given in Table III.

Communications. — Basra, which lies about 85 mi. up the Shatt al-Arab, is the only port of Iraq. The river is of sufficient depth for large ocean-going vessels. Major improvements in the facilities of the port were made during World War II. The Tigris is navigable between Basra and Baghdad for vessels drawing not more than four

feet. In 1954, 484 ocean-going ships totalling 1,541,434 n.r.t. entered Basra, unloading 475,101 metric tons and loading 746,896 tons of merchandise.

Iraq State railways were operating three main lines in 1950 totalling 1,698 km. The standard gauge from Baghdad to the Syrian frontier at Tell Küchük follows the original trace of the Berlin-Baghdad railway as planned by the Germans before World War I. However, the first passenger train left Baghdad for Haydarpasa (Istanbul) only on July 17, 1940.

The metre-gauge line from Baghdad to Kirkuk, which was extended to Arbil (269 mi.) in 1949, serving the important wheat-growing area in the northern plains, has an extension of 18 mi. from Jalula (Jalawla; formerly Qaraghan) to Khanaqin, 5 mi. from the Iranian frontier. The metre-gauge line irom Baghdad to Basra (353 mi.), originally built as a military railway by the British between 1915 and 1918, has branch lines from Hindiya to Karbala (32 mi.) and from Nasiriya to Ur (10 mi.). A rail and road bridge at Baghdad, connecting the two metre-gauge systems, superseded the train ierry over the Tigris in 1950. The traffic on Iraqi railways amounted in 1955–56 to 676,000,000 passenger-kilometres and, for goods, to 837,000,000 ton-kilometres.

In 1955 Iraq had about 19.300 km. of roads of which a quarter was hard-surfaced. In 1957 there were 25,900 licensed passenger motorcars and 14,390 commercial vehicles.

Iraq lies on one of the main air routes between Europe and the iar east. Baghdad and Basra have modern airports which are used by British, U.S., French, Dutch, Swedish and other air lines. In 1954 a total of 6,991 aircraft landed at the Baghdad and Basra airports.

In 1954 Iraq had 203 post and telegraph offices, 225 telephone exchanges and 115,000 mi. of telegraph and telephone line. Radiotelephone communication is available to most countries in Europe and to the United States. A broadcasting station operated by the government is at Baghdad. (K. C. B.)

IRBIL, also known as Arbil, Erbil or Arbela. an important foothill town in northeast Iraq, about 48 mi. E.S.E. of Mosul in 36° 15' N. and 44° W.; pop. (1957) 34.73'1. largely Kurds. The long unbroken history of Irbil, attested by the accumulation of building debris which forms the high citadel mound, is explained by its position as a centre of communications and by the fertility of the countryside, which is for the most part adequately watered and produces good cereal crops. It is the commercial and administrative centre for the *liwa* (province) of the same name, bounded west by the Tigris, north and south by the Great and Little Zab rivers, and east by the Iranian frontier.

The city was known to the Sumerians in the 3rd millennium B.C. as Urbillum, and later, as Arba'ilu, ranked among the principal cities of Assyria; it housed a famous shrine of Ishtar (*q.v.*), and Sennacherib (*q.v.*) dug a canal, partly underground, to supply it with water from the Great Zab. In Achaemenid times it lay on the royal road through Nineveh from Sardis to Susa and Alexander the Great defeated the last Achaemenid, Darius III, on this road about 31 mi. W. of Irbil *(see* GAUGAMELA [ARBELA], BATTLE OF). Under the Parthians, Arbela became the capital of the petty kingdom of Adiabene, approximately the modern *liwa* of Irbil; the city apparently retained its religious importance: since many Parthian kings were buried there. In the late Xbbasid period it was a considerable town and a fine minaret of this era still stands in the plain below the deserted citadel, whose western side is skirted by the older part of the town; more modern buildings now extend across the plain. A tarmac road from Mosul to Kirkuk and Baghdad passes through Irbil, whence there is a branch through the Rawanduz gorge to the Iranian frontier. A metre-gauge railway runs from Irbil through Kirkuk to Baghdad.

IRELAND, JOHN (1838–1918), **U.S.** Roman Catholic prelate, was born at Burnchurch, County Kilkenny, Ire., on Sept. 11, 1838. In 1849 he was taken to the United States by his parents, who settled at St. Paul, Minnesota Territory. After being educated in France for the priesthood, he returned to the United States in 1861; he was ordained at St. Paul and in the following year he accompanied the 5th Minnesota Volunteer Infantry south as chaplain. Subsequently he became rector of the cathedral at St. Paul. His appointment in 1875 as bishop of Nebraska was changed at the urgent request of Bishop Thomas Langdon Grace so that he might remain at St. Paul as bishop-coadjutor with the right of succession; at the same time he was made titular bishop of Maronea.

His liberal views gave him a wide influence and reputation both within and without the church, and he came to be looked upon as a leader of the "American" as distinguished from the "Roman" party in the clergy. Several of his administrative acts, notably his plan for the partial taking over of control of the parochial schools by the local authorities, were strenuously opposed. He was prominently identified with the planting of Catholic communities or colonies in the northwest, with the establishment of the Catholic university at Washington, and with the Catholic total abstinence movement. He published *The Church and Modern Society* (1896). He died at St. Paul on Sept. 25, 1918.

IRELAND, JOHN (1879–), English composer, was born at Bowdon, Cheshire, on Aug. 13, 1879, the son of Alexander Ireland, editor and proprietor of the *Manchester Examiner.* He studied at the Royal College of Music. His pianoforte trio (1908) was followed by the sonatas in D minor and A minor for violin and piano and a second trio in one movement. In 1913 appeared an orchestral work, *The Forgotten Rite.* His piano works include *Decorations* (1914), *Rhapsody* (1915), four preludes (1911) and a series entitled *London Pieces* (1917–20). Other works include three trios (1908–38), *A London Overture* (1936), *Overture Satyricon* (1946) and songs and church music.

IRELAND, WILLIAM HENRY (1777–1835), forger of Shakespearian manuscripts, born in London. was the son of Samuel Ireland, an engraver and author, and dealer in rare books and curios. In 1794 young Ireland, with his father, visited Stratford, where he met John Jordan, a local poet who had forged the will of Shakespeare's father. Seeing his own father's credulous interest, Ireland copied, in ink which had all the signs of age, Shakespeare's style and handwriting, and produced leases, contracts with actors, notes, receipts, a profession of faith and even a love letter to Anne Hathaway with an enclosed lock of hair, to the delight of his unsuspecting father, and the deception of many scholars. Ireland invented an ancestor "William Henrye Irelaunde," to whom the documents had been bequeathed by Shakespeare in gratitude for rescue from drowning. At last the discovery of a whole new play named *Vortigern* was announced. Sheridan purchased it for Drury Lane theatre, and an overflowing house assembled on April 2, 1796, to sit in judgment upon it. But its one representation was greeted with shouts of laughter. Samuel Ireland the elder had published in 1795 the *Miscellaneous Papers and Legal Instruments under the Hand and Seal of William Shakespeare; including the Tragedy of King Lear and a small jragment of Hamlet* (dated 1796). He had the fullest belief in their authenticity, but the hostile criticism of Edmund Malone and others, and the unsatisfactory account of the source of the papers, made him demand a full disclosure from his son. Ireland at last confessed his fraud, and published (1796) an *Authentic Account of the Shakespearian MSS.,* and in 1805, a more elaborate *Confession,* entirely exculpating his father and making a full admission. The disgrace seems to have hastened the elder Ireland's death (July 1800). Ireland died on April 17, 1835.

The more interesting publications on the Ireland forgeries are: *Inquiry into the authenticity of certain Papers, etc., attributed to Shakespeare, by* Edmund Malone (1796); the elder Ireland's *Vindication of his Conduct* (1796); *An Apology for the Believers in the Shakespeare Papers* (1797), and a *Supplemental Apology* (1799), both

by George Chalmers. *Vortigern* was republished in 1832. The elder Ireland's correspondence with regard to the forgeries is preserved in the British Museum, with numerous specimens of his son's talent.

IRELAND, an island to the west of Great Britain, extending from lat. 51° 26′ to 55° 21′ N., and from long. 5° 25′ to 10° 30′ W. The 100-fathom line lies only a little way beyond its western coast, thus showing it to be "the last outpost of Eurasia against the oceanic depths of the Atlantic" (G. A. J. Cole). Its minimum distance from Great Britain is 13½ mi. between the Mull of Kintyre (Scotland) and Torr head. The narrowest crossings of St. George's channel are about 50 mi. in the south and 70 mi. in the north. Of its two political divisions, the Republic of Ireland has an area of 27,136 sq.mi. and a population of 2,814,703 (1961); Northern Ireland has an area of 5,459 sq.mi. and a population of 1,425,462 (1961). There are separate articles on IRELAND, NORTHERN and IRELAND, **REPUBLIC** OF.

PHYSIOGRAPHY

Geological Structure and Physical Features. — The common description of Ireland as a basin or saucer-shaped island is misleading. It is true that the central areas are low and that the main upland masses are marginal, but the interior is not a true plain and the uplands are far from forming a continuous rim around it. The main highland areas are evident extensions of similar features present in Great Britain. The northwest highlands of Donegal have the same northeast to southwest trend as the Scottish Highlands, the uplands of the Newry axis repeat many of the features of the southern uplands, and the Leinster chain is clearly akin to the highlands of north Wales. Similarly the Kerry-Waterford ranges belong to the east-west system which can be traced in south Wales and Exmoor, is deeply buried across southern England but reappears in Belgium. The three great series of earth movements that determined the relief of Europe all affected Ireland. The southwesterly trend in Donegal, Newry and the Leinster chain is due to the older Caledonian folding which created the now much-reduced mountain masses of Scotland and Scandinavia. The east-west uplands of the south and many of the hills of the so-called plain are the results of the later Armorican folding. The great Tertiary disturbances which produced the alpine folds of southern Europe and the gentler folding of the English weald showed themselves in Ireland as in western Scotland in the volcanic activity which created the basalt plateau of Antrim. They also probably effected the separation of Ireland from Great Britain. The minor surface features over much of the country are products of the Ice Age. The most striking geological difference between Ireland and its larger neighbour is in the absence of rocks of post-Carboniferous age. The New Red Sandstone beds, so prominent a feature of the English midlands, the chalk and the still more recent clays of southeastern England are represented only by very thin and localized deposits in the northeast.

The western Caledonian areas of Donegal and Connaught consist largely of low plateaus from which rise higher areas with isolated peaks (west Connaught) or ridges (Errigal range in Donegal) separated by deep valleys. The plateaus are usually peat-covered moorlands. The granite uplands are sharply distinguished by their smooth, rounded outlines from the bare, steep and conical peaks eroded from the quartzites. At the coast the quartzite beds form the most magnificent cliffs in Europe, 2,000 ft. high on Achill Island and Slieve League. The eastern Caledonian regions of Newry and Leinster, though of the same age, differ in character. The former, stretching from Dundrum bay almost to the Shannon, is a region of low hills except in the granitic Mourne mountains. The Leinster chain is a range 70 mi. long and rising to more than 2,000 ft., the most continuous highland area in Ireland. Its granite core is cut by deep, glaciated valleys such as that of Glendalough.

The Armorican areas of the southwest consist of simple folds, the resistant Old Red Sandstone forming parallel ridges with softer Carboniferous rocks flooring the valleys between. They include the whole region from the valley of the Barrow west to the Kerry coasts. Lower ridges of the same character cross the southern parts of the central lowland. The lowland itself has a rock floor of almost undisturbed Carboniferous beds, covered with drift of varying thickness. In the north, drumlins, low rounded humps of drift shaped beneath the ice sheets, occur in a wide belt from Belfast lough and Dundalk to Sligo bay and again in an area behind Clew bay. Eskers, long winding ridges of gravel, moulded by streams of melt water from the ice sheets, are found south of the drumlin belt. Most of the lowland drift is either compact boulder clay or gravelly clay with many limestone fragments. The latter type weathers into the most fertile soil of the plain. To the west, in Clare and Galway, considerable areas have little or no drift cover.

The basalt plateau of the northeast has steep edges, cut into attractive coastal glens in east Antrim and with the well-known columnar cliffs of the Giant's Causeway on the north. The depressed central area forms the basin occupied by Lough Neagh and the valley of the Bann. The Irish rivers are generally sluggish streams wandering through marshes and lakes across the drift-covered surface of the central lowland. As they approach the sea they become more vigorous as their rate of fall increases. The hydroelectric station at Ardnacrusha utilizes the power thus generated in the 16 mi. of the Shannon above Limerick. The station at Ballyshannon on the lower Erne has a similar situation. In southern Ireland the river courses are more obviously related to the underlying structure of the country. The Bandon, Lee and Blackwater follow the axes of the downfolds. The curious right-angled bends in their lower courses appear to be reminders of an older river system with a north-south direction, such as is still followed by the Barrow. Underground streams are widely developed in the limestone areas of the west, the hidden connection of loughs Mask and Corrib being a notable example.

Climate. — The dominant factors in the climate of Ireland are its insular position and the prevalence of southwesterly winds. These together account for its low temperature range (15°–20° F.), its abundant and frequent rains and the general decrease of both temperature and rainfall from southwest to northeast.

Mean winter temperatures are around 45° on the west coast and 42° on the east, summer temperatures about 60° in the southwest and 57° in the northwest. The hours of sunshine average more than 6.5 on June days in the southeast but less than 5.5 over all the west. These variations though slight are sufficient to affect agricultural practice. The check to winter growth is less in the west than the east, and lack of sun restricts wheat and barley growing to the southeast, ripening being uncertain elsewhere.

Rainfall is generally ample, if not excessive. Less than one-sixtieth of the country has a mean annual rainfall of less than 30 in. and about one-fifth has more than 50 in. The highest rainfalls are of course recorded in the western coastal mountain regions (both Kerry and Connaught record more than 90 in.). A marked feature of Irish rainfall is its frequency. The number of days with rain ranges from 175 to 250, but the showers are usually interspersed with sunny periods. From the agricultural standpoint the raininess of the early autumn is a great handicap, frequently delaying the harvest for weeks. This factor is mainly responsible for the prominence of potatoes, oats and grass in Irish farming. On the other hand, outdoor grazing is available for stock throughout the country for at least ten months. (T. HER.)

Flora and Fauna. — The absence from Ireland of many plants and animals found in Great Britain and farther east has three possible explanations. They may never have reached there, the British-Irish land bridges having disappeared before the British-continental one; they may have died out, as some certainly did during the Ice Age and as others at the limit of their geographical range probably have since; or they may be undiscovered, which is unlikely except for a few small creatures. The variety of Irish vegetation is only about three-fifths that of the British, while among animals the most conspicuous absentees are the dormouse, common and water shrews, five species of bat, the nightingale, all reptiles and amphibians except the brown lizard, smooth newt, natterjack toad (a relict species) and common frog (which was probably introduced). Animals endemic to Ireland are the Irish stoat and hare, the Irish jay, Irish coal tit, dipper and red grouse, six species of char and three of pollan (Lough Neagh, Lough Erne

and the Shannon). Endemic plants include mosses and liverworts and two marsh orchids.

There have probably been two land bridges at various periods joining Ireland to Great Britain, one across the southern part of the Irish sea and one joining Donegal to the Scottish isles. Across the southern one came species from the continent which comprise the Lusitanian-Mediterranean element now growing most luxuriantly in the west, especially in Kerry. There oak forest is found on sheltered hillsides with *Arbutus*, *Ilex*, etc. *Pinguicula grandiflora* (not found in Great Britain) and *Euphorbia hiberna* (found only in Devon) are very abundant, and there is an immense quantity and variety of ferns and mosses giving the vegetation an almost subtropical appearance. There too are the only stations of the natterjack toad and the Kerry slug *(Geomalacusmaculosus)*, and the district is very rich in insects. *Melampyrum sylvaticum*, *Ranunculus fluitans* and a species of snail, all now confined to the northeast, were perhaps among the latest forms to cross the northern land bridge. From America, via the Bering strait, came North American forms; *e.g.*, *Spiranthes romanzoffiana*, now found only round Lough Neagh, *Sisyrinchium angustifolium*, now only in the west, and a kind of fresh-water sponge.

After the warmth of the Pliocene period, when possibly the Lusitanian and American elements existed, the climate became cooler and the polar ice caps descended, driving plants and animals before them. The mammoth, spotted hyena and giant deer or Irish elk inhabited Ireland in late glacial times, and remains of reindeer, brown bears, wild boars, lynxes, arctic foxes, European wildcats and lemmings have also been found. Red deer are now protected in the Kerry mountains, the wolf was not exterminated until about 1786, and the fox, badger, otter, Irish hare, pine marten and Irish stoat were all present when man arrived in Mesolithic times or before. During one of the warm periods which interrupted the Ice Age, spruce, silver fir and Scotch pine were dominant, and a heath and rhododendron belonging to the Lusitanian element were widespread. ,The native spruce, silver fir and rhododendron are now extinct, and the Scotch pine died out in Neolithic times but has been replanted, with other conifers. At a late stage in the Ice Age when the ice did not cover the southern quarter, a northern flora dominated the country, containing among others *Astragalus alpinus* (now extinct), *Juniperus communis* (now in the north and west only) and *Arenaria ciliata* (now confined to limestone hills in Sligo and not found in Great Britain). When the final mountain glaciation took place the dwarf willow, now only on the mountains, was abundant in the lowlands, and *Dryas octopetala*, which dominates the Burren at sea level, grew at 300 ft. Many arctic-alpine plants died out as the climate became warmer. Later remains show that *Naias flexilis*, an American plant, was widespread, but it is now found only in the west. There the three elements reach their best development and are most markedly mixed on the Burren, where frost never touches the bare limestone hills and humidity is high.

The alder succeeded the Scotch pine in dominance. During the Atlantic period peat was formed over vast areas. Many woodland insects and other animals were destroyed then. The oak followed the alder and is still the chief tree of the woods. The forest plants and animals have mostly retreated to the glens, where pine martens and squirrels (exterminated in the mid-17th century and reintroduced at the beginning of the 19th) are still to be found. The vast grasslands of the east and centre have been reclaimed from forest. Everywhere the hedgehog, lesser shrew and field mouse are common, but the rabbit (introduced in the 13th century) and the brown rat (in the 18th century) are now pests. At higher levels the natural cover of the flat or sloping impermeable soils is blanket bog, while where the ground is well drained heath and scrub predominate with oakwood on sheltered slopes. A typical lowland bog is composed mainly of *Sphagnum*, cotton grass, beak rush, bog bean, sundew, etc., in pools and hollows, and *Calluna* with bilberry, cross-leaved heath, *Scirpus caespitosus* and often *Rhacomitrium* on the hummocks. Curlews, gulls, certain kinds of beetle and other insects are the most conspicuous animals of the limited bog fauna. On the mountains, isolated patches of alpine plants can be found, and hares, badgers, ring ouzels, ravens, choughs and peregrines are the chief mountain animals. The great auk, capercailzie and eagle are extinct. Many sea birds as well as choughs, ravens and peregrines breed on the cliffs and on the islands, and the Atlantic seal is familiar round the coasts. The common seal is less often seen, but various whales, the common porpoise and dolphins occur round the shores. The basking shark is seen off the west coast in spring. Several kinds of wild duck and other birds nest round the lakes. Salmon, trout and other fish are abundant in the rivers and the lakes contain char and other species. (X.)

ARCHAEOLOGY

While the broad outlines of Irish archaeology have been reasonably well established, much of the detail of the various phases of its prehistory still had to be worked out at mid-20th century. Systematic excavations were helping to fill in the gaps in knowledge, but many minor points of chronology and problems of the derivation of a number of cultural features from outside the country and their development within it were still matters for speculation and debate. Despite these uncertainties on smaller issues, however, the conspicuous place in Europe occupied by Ireland in Bronze Age and early Christian times is well attested. During the Bronze Age the initiative and skill of the native metalworkers is shown in weapons and implements of bronze and ornaments of gold, many examples of which were traded to Great Britain and the continent of Europe. In early Christian times metalworking again achieved extraordinary distinction in the production of objects for secular and ecclesiastical use, while there was a parallel growth of manuscript illumination of equal merit. This period also witnessed the flowering of sculpture, exemplified chiefly by a series of great stone crosses erected at ecclesiastical sites all over the country. A second revival of the craft of the metalworker, which appears to have suffered a temporary decline during the viking raids from the 8th to the 10th centuries, took place in the 11th century, and the contemporary fashion of enshrining the relics of the native saints left a large number of beautiful shrines in silver and bronze.

Another aspect of Irish archaeology which deserves special mention is the extraordinary wealth of field monuments of every kind scattered over the countryside. Although many must have been destroyed in the course of ages the proportion of the original number surviving is still very high, mainly because of a traditional respect for ancient things and traditional fear of disturbing them. These monuments include great numbers of megalithic remains: tombs of many types, ranging in size from small dolmens to enormous passage graves, and stone circles and other structures which are probably ritual in origin. From later times the defended dwelling place, whether taking the form of the stone-built cashel or the earthen ring fort, is still to be counted by tens of thousands. Remains of an explicitly Christian character—monastic settlements, churches, inscribed slabs and crosses—are also abundant. When to this rough inventory is added a host of miscellaneous monuments of all periods it will be evident that there is an almost unlimited field for survey, excavation and research.

The Mesolithic Age.—The human occupation of Ireland does not begin until a late date in the prehistory of Europe. The island seems to have been uninhabited throughout the whole of the Ice Age; at least, no trace of an interglacial colonization has been found anywhere within its borders. The earliest relics of man appear in the remains of a culture of Mesolithic affinities, evidence of which has been found at Cushendun, Larne, Rough Island and other places on the northeast coast of the country and, later, at further coastal sites in County Louth and County Dublin. This culture has been divided into two phases called Early and Late Larnian after the type site at Larne, County Antrim. As the majority of the sites associated with the culture are secondary and as most of them are on beaches, the relics they have yielded consist entirely of implements of stone and flint.' Early Larnian is characterized by microliths, scrapers and blades allied to those of the Mesolithic cultures of the adjacent areas of Britain, and its descent is probably to be traced to the British Upper Palaeolithic. It existed at a period when the northern land bridge connecting

the two islands was still intact and may be roughly dated to 6000 B.C. Late Larnian is regarded as a local evolution of this culture developing after the severance of the land bridge, and its equipment of flint tools tends to be of a more massive type. The people of both these phases were dependent for subsistence chiefly on hunting and fishing, supplemented by minor food collecting activities such as seasonal visits to the seashore for shellfish. It would seem that groups of these people survived in lakeside and riverside settlements until the coming of the Neolithic agriculturalists and pastoralists sometime before 2000 B.C.

The Neolithic Age.—Neolithic culture elements appear in the country in a variety of associations, and their discovery and recognition has been the fruit of comparatively recent excavation and field work. The most important of these elements is the pottery found both in funerary and habitation sites. In its most widely distributed form it appears as wide-mouthed, round-bottomed bowls, closely related to the contemporary Neolithic A ware of Britain but showing local developments of rim form and ornament. Of this type is the funeral pottery which is found in the first megalithic tombs erected in Ireland, the "horned cairns" which are found over the northern part of the country, and also occurs in graves of other types in the south. It was discovered in large quantities at a remarkable earthwork at Lyle's hill, County Antrim, and in a series of habitation sites at Lough Gur, County Limerick. At the latter place houses, round and rectangular in plan, were revealed, and evidence pointed to an economy based largely on cattle raising supplemented by a limited amount of agriculture. Another strain in Irish pottery is related to the Neolithic B wares of Britain and has an ultimate Baltic origin. It probably reached Ireland from Scotland and has been found mainly in northern areas. A third pottery type, which makes its first appearance in Neolithic but survives into Bronze Age times, is a flat-bottomed pot of coarse fabric. It appears in quantity at Lough Gur, is known from some other districts, and is probably related to the "grooved ware" of Britain.

As has been mentioned already, the megalithic graves which are so widespread and numerous in Ireland had their beginnings in this period in the horned cairn group which extends over the greater part of the territory north of a line from Carlingford lough to Blacksod bay. A typical tomb of this class consists of a narrow corridor formed of large upright stones and normally subdivided into a series of chambers by pairs of jambstones having sill stones set in the ground between them. The corridor was roofed with a line of lintels and the tomb was approached through a semicircular forecourt formed by the two curving arms of a façade of upright stones. The whole was probably originally covered by a low cairn, wedge-shaped or oval in plan. Some of the western examples (*e.g.*, Creevykeel, County Sligo) have circular, open courts enclosed within the structure of the tomb itself. These tombs were generally situated on high ground, but their builders, unlike those of the later passage graves, did not favour hilltop positions. Cremation was the usual burial rite in them. Although none so far excavated has produced metal objects, tanged-and-barbed arrowheads and other finds from some indicate that this type of tomb continued in use into Bronze Age times. Although the immediate continental locality from which these graves were derived is still undecided, there can be no doubt that they must be ultimately traced to a Mediterranean origin.

Apart from the pottery the artifacts associated with the Irish Neolithic culture are chiefly implements and weapons of flint and stone. Characteristic of these are leaf-shaped flint arrowheads which are often of extremely fine workmanship. Another implement which appears to be typical of certain settlements by inland waters is a pointed flake of flint or chert, widening toward the base, where it is provided with a rudimentary tang. Since it is the type implement of a number of stations situated in the valley of the lower Bann river, County Antrim, it has been named the "Bann flake," and it seems to have evolved from the Mesolithic Larnian of the same region.

It is apparent that during the Neolithic phase of Irish prehistory a number of diverse cultural influences were in operation in the country, but the actual time covered by the period was probably relatively short and the phase is best regarded as a brief preface to the Bronze Age into which it shades imperceptibly.

The Bronze Age.—The early Bronze Age, which began soon after 2000 B.C., was a continuation of forces already at work in the

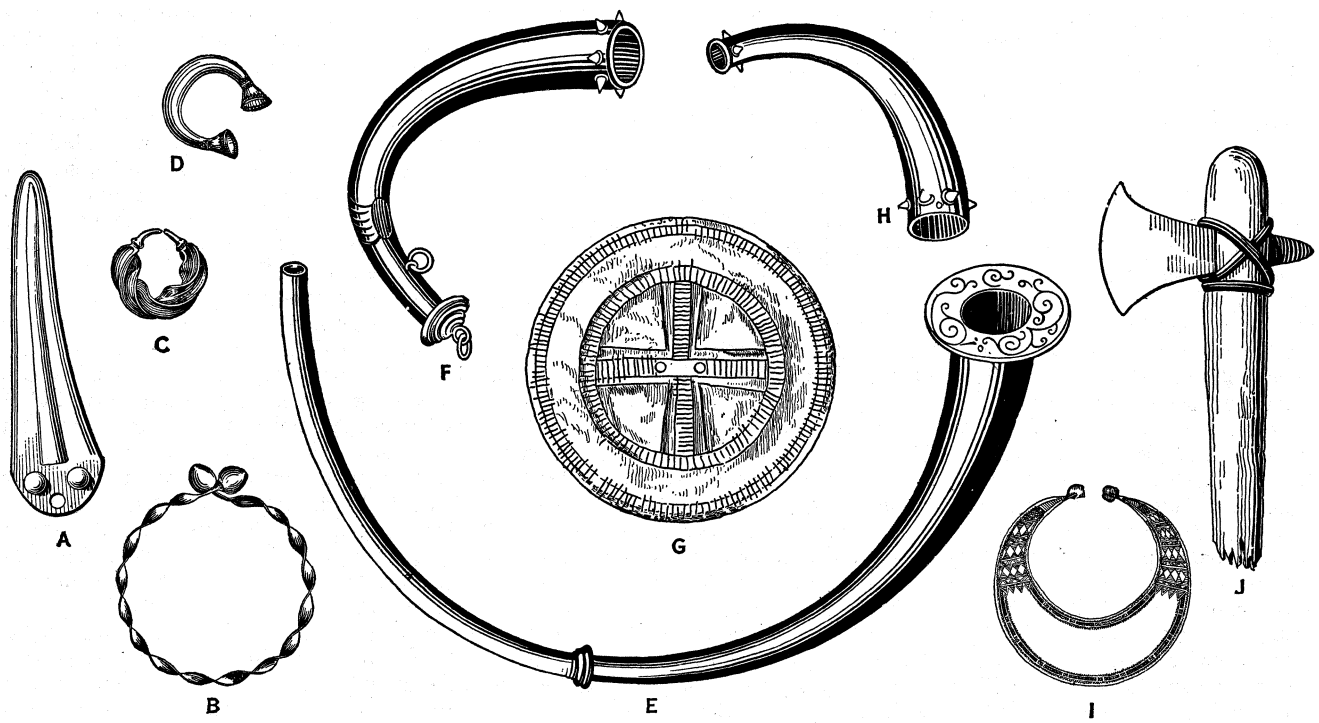

FIG. 1.—METAL ORNAMENTS AND IMPLEMENTS OF THE BRONZE AGE IN IRELAND

(A), Copper halberd blade, a characteristic weapon of the early Bronze Age; (B) gold torque, evidently a neck ring; (C) one of a pair of gold earrings formed of four flat narrow fillets joined at their inner edges in torque pattern; (D) gold open ring of the type probably used as currency; (E) bugle-horn shaped trumpet made in two portions soldered together; (F) cast trumpet, 34⅝ in. on concave side; (G) circular gold plate or "sun disk," probably worn on breast; (H) trumpet, 24 in. along curved edge; (I) gold lunula or "moon disk" worn around the neck; (J) copper hatchet, secured to a wooden handle by strings of hide or gut

preceding period, strengthened by fresh ones which made their appearance about that time. Of the latter, one of the most important is the Beaker culture which was formerly thought to be wholly unrepresented in Ireland. However, the Lough Gur site, already mentioned in connection with the Neolithic, produced considerable quantities of the very distinctive pottery of the culture, and other finds of it have been made in megalithic graves in Derry, Tyrone, Sligo and Dublin. The beakers found are of mixed British and continental affinities and their presence presumably indicates an immigration of people the extent of which cannot yet be gauged.

One of the chief determining influences which gave Ireland its important position during the Bronze Age was the gold in which at the time the alluvial gravels of certain parts of the present County Wicklow must have been very rich. The metal was probably obtained from the gravels of the mountain streams of the area for no evidence of ancient mining has been found there and the parent auriferous vein has never been discovered. Gold in commercially remunerative quantities is no longer to be found in the district. But the large number of early gold ornaments found in Ireland proves that in the first stages of the Bronze Age there was a considerable store of the metal at the disposal of its inhabitants; and the wide dispersal of gold ornaments of Irish provenance over the continent of Europe showed that this metal formed an important material of trade.

The chief gold ornaments that have come down from the early stages of the Bronze Age are crescents and disks of thin gold sheet, with a slight geometrical ornament engraved or embossed upon them. These are of Irish origin, wherever found. At a later stage in the Bronze Age, when Ireland had become a receiver rather than a giver in the matter of culture, the twisted torque was introduced—a collar consisting of a bar or ribbon of metal, twisted into a screw and curved into a loop, the ends being drawn out and bent abruptly so as to hook into one another. Later still, as the Bronze Age was drawing to its close, a peculiar form of ornament of a problematical kind came into use. This is in the shape of an open ring with the ends terminating in disks, or in expanding solid or hollow conical knobs. Various conjectures have been made as to the use of these objects; one of the most probable is that they were used as currency.

Of the Bronze Age implements many types are similar to those found elsewhere in northern Europe, but some have distinctive character. The flat copper hatchet is probably indigenous to the country, from which it spread over the continent. The copper halberds are especially remarkable. They are a kind of dagger-axe, being in essence triangular dagger blades mounted at right angles at the end of a long handle. These show an evident connection with Spain, where this form of weapon reappears. About the middle of the Bronze Age Ireland seems to have lost its initiative in civilization; the later types of hatchet-heads, etc., were imported into the country, rather than exported abroad. To the last, however, the Irish metallurgists of the Bronze Age retained their skill and their appreciation of beauty and symmetry; some of the late spearheads, for example, are of admirable workmanship. For one class of objects Ireland was the source of supply for Europe till the end of the Bronze Age—the horn-shaped trumpets, made by the *cire* perdue process, which are found in many places on the continent; there is one represented as lying by the side of the well-known statue of the "Dying Gaul," often erroneously called the "Dying Gladiator," by the Greek sculptor Epigonus.

Megaliths.—As we have seen, the first megaliths to be built—the "horned cairns"—were constructed in the Neolithic period, but the full development of the megalithic idea is to be found in the Bronze Age. Of the tombs, the passage graves, while not the most numerous, comprise some of the most impressive antiquities in the country, and there can be little doubt that they are the result of direct influences from Brittany and the Iberian peninsula. They are generally grouped in cemeteries on hilltops, the most noteworthy of these concentrations being those beside the river Boyne and at Loughcrew, both in County Meath, and at Carrowkeel in County Sligo. The largest and the most famous tomb is the enormous tumulus of Newgrange, one of the Boyne group. It covers an acre of ground and encloses a great cruciform chamber built of corbelled slabs of stone, many of which are richly decorated with a geometric ornament of spirals, chevrons and lozenges. The chamber is approached by a lintelled passage of massive stones, and the whole mound, which is about 40 ft. high, is surrounded by a continuous curb of great stones laid end to end. The mound was originally encircled by a ring of large pillar stones, most of which have, unfortunately, been destroyed. The Boyne group includes two other great tumuli which approach Newgrange in dimensions. Of these, that of Dowth possesses two independent chambers the stones of which bear decoration similar to that found in Newgrange, while the other mound, called Knowth, has its curb profusely ornamented with a wide variety of patterns of this peculiar art, which seems to have served a magico-religious purpose. Further examples of the art occur in the Loughcrew cairns, at Knockmany and Sess Kilgreen, both in County Tyrone. and in a grave at Fourknocks, County Meath, near the Meath-Dublin border in the neighbourhood of Naul.

Other megalithic tombs take the form of gallery graves and dolmens, both of which are found in great numbers.

In all these tombs the dead are generally cremated and the commonest funeral pottery is a small, elaborately decorated bowl or vase called a food vessel, since it is thought to have contained food offerings for the dead. Irish graves of all types tend to be very poor in grave goods in comparison with those of some other European countries, but stone beads and pendants, flints and an occasional metal object sometimes accompany the interments.

Toward the end of the Bronze Age the typical grave consists of a small rectangular cist composed of four upright slabs covered by a capstone, the whole sunk in the ground to a short distance below the surface. Here, too, cremation is the usual burial rite, a large urn of coarse and poorly baked clay being often inverted over the pile of burned bones.

The few human bones found in Irish Bronze Age sites indicate that the population of the country during this period belonged to the Mediterranean race—a relatively short, dolichocephalic (long-headed) and dark-complexioned people, to be seen today in their fullest purity in Spain. This population was apparently dominant all through the Stone and Bronze Ages, for the few skulls of round-headed individuals that have been found are to be taken as those of casual wayfarers. Of the language of this people we are absolutely ignorant. Some of the river names, which cannot be explained with the aid of Celtic, may belong thereto; and a few inscriptions in the Ogham character, found in the Pictish regions of Scotland, may possibly preserve some words of this tongue or of a cognate dialect. These inscriptions have defied all attempts to decipher them.

Scandinavian and other foreign objects of the late Bronze Age found in Ireland speak of an oversea trade with eastern and southern Europe; the centre of activity shifted eastward in the course of the Bronze Age. We may assume that the technical skill displayed in the bronze objects which have survived was likewise shown in the objects in wood and in textiles, which no longer exist. Here, as elsewhere, because of the decay of organic materials, only a very incomplete picture of ancient civilization can be reconstructed. The Bronze Age was illiterate, so that no literary documents have survived, even indirectly; though it is very likely that there is a considerable body of Bronze Age material embedded in the vast body of Irish literary and oral tradition.

The **Iron** Age.—The early inhabitants remained in undisturbed possession of the country till about 400–350 B.C. It is possible that there were occasional immigrations such as a gold-producing country would naturally attract; but if so these became absorbed in the aboriginal population and cannot now be isolated. But in the 4th century a much more formidable immigration took place, doubtless only one phase of the movements of peoples in central Europe, of which the Gaulish sack of Rome in 390 B.C. and the attack on Delphi about 100 years later were outstanding incidents. The Celtic people seem to have had their origin in the regions between the headwaters of the Rhine and the Danube. There they developed their peculiar linguistic characteristics, language being the chief if not the only common mark of Celticism in the modern world. They seem early to have become acquainted with

the ironsmith's craft, and with the aid of their iron weapons they subdued one by one the petty peoples of the area of Europe north of the Alps. Over these peoples they spread a veneer of Celticism; they Celticized them in speech, in religion and in organization, but could not make any very great modification in their racial affinities. This explains the racial diversity which underlies the superficial unity of the Celtic peoples and which makes it difficult to determine to what people the term "Celtic" most fittingly belongs. (See CELT.)

A community — or more probably, several communities — of this people effected an entrance into Ireland about the middle of the 4th century B.C. They were probably few in numbers, but they had the advantage of a superior military organization and, especially, of iron weapons. In time they effected a complete revolution in the life of the country. Their Celtic speech completely ousted the aboriginal tongue. New gods and new methods of government, new arts and new crafts were introduced. The aborigines were reduced to vassalage, which, though mitigated with the establishment of Christianity, was never completely terminated until conqueror and conquered alike were subdued by the Norman. It is possible that the newcomers were a tall, fair people of Nordic extraction who contrasted physically with the aborigines. The contrast was maintained, as we cannot doubt, by restrictions on intermarriage.

In the literature which a little later began to come into being, an aristocratic product, the distinction between fair and dark people is of paramount importance. Every person who is spoken of with respect, save for a number of individuals of exceptional character who "prove the rule" much more clearly than in most cases of the kind, is described as being tall and fair, with long, flowing locks. Every person who for any reason is spoken of with disdain is described as being short, dark and with close-cropped hair.

The culture which the newcomers brought into the country belongs to the later stage of the iron culture of Europe, which goes by the name of La Tène (*q.v.*). The earlier phase of the European iron culture, called Hallstatt, is not represented in Ireland save by a few stray objects which came in by way of trade or by mere accident and do not indicate a permanent settlement. This enables us to assign a date to the Celtic invasion with tolerable exactness. The legends of the landing of the invaders, attracted by the country's store of gold, may at least be historical in that they represent the landing as taking place in the southeast corner of the island, the place where the gold-bearing gravels are to be found.

The actual remains of the pagan Iron Age in the country are, comparatively speaking, scanty. They include a number of types of bronze objects, some peculiar to Ireland and several of very problematical use; some spearheads and other objects of iron; and, most remarkable of all, a few large stones, probably sepulchral gravemarks, bearing sculptured ornament of the geometric-floral type associated with the art of La Tène period. In other respects the pagan Iron Age was of very great importance in the history of Ireland. At this time the literature began to come into being, though the documents which transmit it to our time are of much later date and show clear evidence of editorial manipulation. The oldest written relics are the Ogham inscriptions, which preserve early forms of the Irish language not otherwise illustrated. Such of the inscriptions as have been deciphered contain nothing but names, with words denoting relationship linking them together. The Ogham alphabet is a cipher, based upon an abbreviated form of the Roman alphabet and doubtless originally intended not for writing at all but for secret communication by means of the fingers. The letters are combinations of strokes, in number from one to five (representing the fingers), disposed in various positions around a central line. (See OGHAM SCRIPT.)

Probably many of the numerous ancient fortifications are also to be attributed to this period. These are as a rule circular enclosures, surrounded by one, two or three ramparts of earth or of stone. Others, however, are much more complex in their plan. Very little is known of these enclosures, which are common everywhere. Some of them are as early as the Bronze **Age;** others, certainly, are quite late in date (perhaps A.D. 700–1000), for inscribed stones are used as building material in their construction. Some are burial enclosures; some, perhaps, sanctuaries; others cattle pens and the majority fortified steadings. Probably many were erected as defenses against wolves. They are often in positions strategically worthless and show a singular carelessness with regard to facility of water supply if they were expected to stand a siege.

Christian Remains. — We may safely date the beginning of Christianity as a power in Ireland at somewhere about A.D. 350–400. There probably were individual Christians even before this date, but they cannot have made much impression on the life of the community. But after about three centuries we begin to find definite traces of a specific Christian art. The earliest church buildings, and for a long time the most important ones, were built of wood, not of stone, and these have all disappeared through fire and decay. Stone building was in a rudimentary stage of development throughout the country; the extensive forests supplied the most obvious and the most easily worked building material. Probably also carved wooden plates did duty for sepulchral memorials; wooden tomb "stones" are still to be seen in some of the country graveyards. Early remains very likely lie hidden in some of the monastic sites, but these are effectually sealed from the excavator by modem interments. The viking raids of the 9th and 10th centuries must be responsible for the disappearance of many of the earliest works of art.

The only remains of wooden constructions are the fragments of framed houses found in some of the lake dwellings (commonly called in the country "crannogs")—artificial islands made by piling earth and stones on the bottoms of the shallower lakes and, after securing them with a revetment of stones or wattlework, erecting a dwelling house in the middle. These structures began in the Bronze Age, were much in use (to judge by the remains found within them) about the 7th century, and were not wholly abandoned until about the end of the 16th century. The fragmentary structures which they bear are insufficient for us to gauge fairly the skill of the ancient builders in wood. Certain features of the earliest stone churches are evidently translations, so to speak, of constructional details proper to wood into stone, where they are merely otiose. The arch is not used for the larger openings in the earliest structures, though its use for small windows shows that its principle was understood from the first. The stones are set without mortar or at most in mud. There is much variety in the character of the masonry, but this depends on the skill of the local masons and on the materials at their disposal and is of no chronological significance. After the Irish missions to the continent began, the stone building in the country began to improve notably. The Romanesque style was introduced and successfully practised; some very remarkable buildings were produced especially in the 12th century, such as King Cormac's chapel at Cashel, the nunnery church at Clonmacnoise and the cathedral of Clonfert.

There has been much controversy about the round towers found in many places, but it has been generally decided that they do not possess the historical or architectural importance once attributed to them. They are simply the detached campaniles of the churches with which they are invariably associated; they were erected during the time of the Scandinavian raids, when watchtowers and keeps were as necessary as belfries to the churches which had treasures to guard.

The *scriptorium* was one of the busiest centres of industry in an ancient monastery. A sufficient number of manuscripts survives to prove the nature of the work there carried on. The oldest manuscript completely in the Irish language, Lebor *na Huidre* (The Book of the Dun Cow) (so called from the animal from whose hide its vellum was said to have been manufactured), was written at Clonmacnoise some time before A.D. 1106 but is founded on much earlier exemplars, now lost. These literary manuscripts however concern us less than the illuminated books, of which a considerable number was produced; those that survive date from the 7th century to the 11th. The documents thus enriched are psalters, service books and, especially, Gospels. The enrichments

consist not so much in miniatures as in an artistic treatment of the letters of the text itself; these are worked with great ingenuity into fantastic knots and monograms and decorated with applied ornament of great beauty. In the Book of Kells (probably of the early part of the 9th century) the art attains its high-water mark; some pages of this manuscript, especially the monogram of the name of Christ at the beginning of the Gospel of St. Matthew, rank among the finest illuminations in existence.

The art of these illuminations is one with the art of the metalworker and the sculptor, differing only in the medium employed. It is a provinciai phase of the great decorative art practised by Celtic and Teutonic peoples alike, though with differences of idiom, in the 6th to the 12th centuries. It consists of devices founded on such geometrical devices as spirals and interlacements and on figures of animals or parts thereof, often conventionalized almost out of recognition.

Like the art of illumination, that of the metalworker was almost wholly devoted to the service of the church, save for ornamental pins and brooches, of which a number of very fine specimens have survived. Of these the best-known is the (falsely so called) Tara brooch, a work probably of about A.D. 800. It was found on the seashore at Bettystown, south of Drogheda, and is now preserved in the collection of the Royal Irish academy. On the reverse side is elaborate chasing, founded mainly on spiral forms; on the face are sunk panels filled with ornament in extremely delicate filigree.

The more specifically ecclesiastical works in metal may be classed under the headings of bells, shrines, chalices and processional crosses. The bells used by the early Irish ecclesiastics were adaptations of cattle bells, like those in Switzerland and elsewhere. They are rectangular, not round, in horizontal section. The earlier specimens, including the famous bell of St. Patrick at Belfast, are of iron (sometimes brazed on the surface); the later are cast bronze. Bells are usually without ornament, save occasional decorative treatment of the handle; a few specimens are engraved with simple decoration. One is inscribed, and can be dated A.D. 908.

The shrines are of several different varieties, depending upon the nature of the object to be enshrined. Caskets for bones were made in the form of the ordinary church building of the time (understood to be the form in which the Temple of Solomon had been designed); or else in the shape of the part of the body from which the bone came. The best-known example of the latter type is the shrine of St. Laichtin's forearm, in the Royal Irish academy's collection, a work of the 12th century. Those meant for books were flat, square boxes of the size and shape of the volume which they were intended to contain. The books were not preserved in these shrines for perusal; they were holy relics and were not meant to be taken from their receptacles. Had they not been thus preserved they would have perished, for the book which had belonged to a notable saint was accredited with miraculous powers; strips were cut from it to make amulets, water was poured over it to acquire healing virtues and, according to Bede, books from Ireland were in especial request in England, for scrapings from their pages were a remedy against snake venom. Shrines for bells and crosiers, again, took the form of the object enclosed within them.

The solitary decorated chalice which has survived from the days of Celtic Christianity far surpasses the best of these objects in artistry. It was found near Ardagh, County Limerick, and is now in the Royal Irish academy's collection. It is richly decorated with bands of chased and filigree panels, and its beauty is enhanced by the use of enamel, crystal, mica, glass and amber. It is a worthy companion to the Book of Kells, with which it is probably contemporary.

The one processional cross that has survived is the so-called Cross of Cong, made at Roscommon in or about 1125 to enshrine a fragment of the true cross and now in the National museum, Dublin. Its late date is reflected in the character of its ornament; the pure interlacements and other geometrical decoration of the Ardagh chalice give place to patterns founded on contorted animal figures. The cross head, which alone remains, is about 2 feet high. It rises from the jaws of a foxlike animal head. The surface is covered with bronze plates, enriched with silver and enamel, and with applied panels of openwork or what may be called false filigree representing animal figures in fantastic knots. In the centre of the face is a large crystal, behind which it may be presumed that the relic, or what is left of it, is still lying. On the sides are inscriptions in Latin and in Irish, explaining the purpose of the cross and asking for prayers for all those concerned in its manufacture. The back had an inlaid saltire, presumably of gold, which some sacrilegious thief has picked out.

Numerous remains of sculptured ecclesiastical art in stone exist in Ireland, beginning about the middle of the 8th century. They take the form of sepulchral slabs, carved crosses and the sculptured decoration of church buildings. At Clonmacnoise there is a valuable series of slabs commemorating inmates of the monastery. These sometimes bear the names of persons known from other sources and are therefore datable; it has been found possible to determine a sequence of styles from these, extending over four centuries. Of much greater importance are the standing crosses, erected in various important ecclesiastical centres. These are in some cases memorials of individuals, such as the fine cross erected at Clonmacnoise by Abbot Colman in memory of his friend and patron Flann, king of Ireland, who died in A.D. 914. Others seem to mark the limits of the monastic enclosure. Others are dedicatory, erected, perhaps, in fulfilment of vows; among these is the Cross of Patrick and Columba at Kells, County Meath. The earliest standing crosses are perfectly simple, being merely stones carved into a cross form. But about the beginning of the 10th century a much greater elaboration began. The so-called Celtic cross had by now been evolved—a Latin cross with a circular wheel surrounding the centre, probably an attempt to suggest a halo of glory. The surface of the shaft and head of the cross is usually divided into panels, each containing either ornamental devices or else figure subjects. The great majority of the latter which have been identified represent biblical scenes, chosen for their homiletic value—the fall of man, the sacrifice of Isaac and so forth. A few scenes which cannot be identified may possibly represent local events familiar at the time of the erection of the monument but now forgotten.

Foreign Influences.—Two important foreign influences profoundly affected the life of Ireland during this period. The first was that of the Scandinavians, who began their piratical raids in the latter part of the 8th century. For more than 200 years they continued their depredations and did incalculable damage to the material welfare and to the morale of the country. But on the other hand they imported their own peculiar variety of north European art, and from this and the native style there sprang a hybrid which produced works of great beauty: the Cross of Cong is one of these. Nevertheless, despite the hold which the Scandinavians had upon the country, comparatively few objects of definitely Scandinavian type have been found there. Only one Scandinavian cemetery has been discovered, and the number of runic inscriptions is far less than analogy with other Scandinavianized countries would lead us to expect.

Beginning in 1170 came the Anglo-Norman invasion, which completely overturned the traditional life of the country. From that date onward foreign methods and ideas impressed themselves with increasing intensity. The immediate result of the invasion was the total extinction of the traditional arts. Typical of the resultant chaos is that strange product, Irish Gothic architecture. There is nothing like it anywhere else. It is a curious jumble of styles and periods, and the mouldings, which in English Gothic afford an infallible guide to chronology in ambiguous cases, are either totally absent or else share in the general eccentricity. The Romanesque style had been voluntarily adopted and had a healthy natural growth in the country; the Gothic style was violently forced on the country from without and was never assimilated.

More prominent and characteristic remains of mediaeval Ireland are the numberless castles. At first wooden towers (*bretesche*) erected on earth mounds (motte), these developed along lines parallel to those followed by castles in England. They are thus hardly monuments of Irish archaeology pure and simple, but of

the archaeology of an extension of England. Naturally none of the temporary wooden towers survives, though the place name Brittas, which is not infrequent, preserves a reminiscence of them, "Brittas" being a corruption of bretesche. There are numerous *mottes* still in existence, however, such as the splendid example at Castletown Geoghegan, County Westmeath. The castles of Ireland are of all sizes and dates, from the great structure at Trim, founded in 1173, down to the humble "peel towers" — small square structures of two or three stories — some of which are not earlier than the 17th century. The history of Ireland after the Norman invasion is a history of decay and degeneration, and it is vividly reflected in all the remains of antiquity that have come down out of those troubled centuries.

HISTORY

Earliest Inhabitants — The earliest-known remains of human habitation in Ireland are assigned by archaeologists to the period of the transition between the early and the late Stone Age. This period, it is held, was preceded by intense glacial conditions, covering the whole island and extending also over Britain as far south as the estuaries of the Severn and the Thames. The Neolithic and early Bronze periods which follow are well represented in Ireland, but their data belong rather to archaeology than to history. The later Bronze Age in Ireland, though it has no documents, native or extraneous, has left evidences sufficiently abundant and vivid to be considered historical. To it belong numerous tombs of massive structure, surmounted by great tumuli of earth or stones, the stone slabs in some of them being carved with a great variety of designs, symbolic or ornamental — evidence of a settled population under opulent rulers. Bronze was abundant. There were rich copper mines, but no tin mines, and the tin which was needed to make bronze must have been an article of import, no doubt from Cornwall, during the whole of the Bronze Age and later. The distinctive feature of this period in Ireland was the production of native gold, of which it is certain that there were comparatively rich deposits in the Wicklow mountain region. Irish gold ornaments of the Bronze Age have been found in various parts of Britain, in northern France and in Luxembourg, Hanover and Denmark. In Ireland the principal finds have been in districts far away from the gold-producing region. Finds of the ancient apparatus of bronze founding are likewise recorded in places far away from copper mines and from seaports through which tin could be obtained. The facts point to a development of commerce, internal and external.

To the Celts of Gaul, and through them to the Greeks, the ancient inhabitants of Britain and Ireland appear to have been known by the common name of "Pretani." The two islands, Albion and Iverna, are called in Greek the Pretanic Islands. In Latin and first, so far as is known, by Julius Caesar, the name "Brittani" (becoming later Britanni and Brittones) is substituted for Pretani and used distinctively of the people of the larger island, to which the name "Brittania" (Britannia) was given. "Pretani," represented in early Irish by "Cruithin," was the name of the people who in later times are known as Picti, Picts. Hence it may be inferred that during the Bronze Age the Picts were the chief people of Ireland as well as of Britain, and this inference is amply confirmed by ancient Irish traditions.

Celtic Colonization. — Such archaeological evidence as we have seems to indicate that the earliest Celtic migrations to Ireland took place during the 4th century B.C. In the absence of skeletal material, no positive statement as to the racial characteristics of these early migrants can be made. That is, no one from the then-literate part of the world saw them, and there is no indirect evidence available since they cremated their dead. The language they spoke formed one group within the Indo-European family, to which the Germanic, Italic, Slavic and other groups also belong.

Later Celtic immigrants introduced the La Tène stage of the Iron Age culture into general use in Ireland. They are likely to have arrived in small colonies, settling first in maritime districts and along the larger rivers.

The Celts established small states, the nucleus of each state (tuath) being a convenient place of assembly to which the freemen could resort, like country people to a local market, without having to lodge away from home. The chief who presided over such an assembly was entitled king. He also performed the functions of judge and leader in war. Besides the common assembly of freemen (oinach), there was a curia or senate (aireacht) of nobles, which met in the king's house. The nobles who composed it were known as the companions (celi) of the king — they may be compared with the king's hetairoi in Homer. In ancient theory, a tuath provided an armed levy of 3.000 men, but in the period of contemporary documents much smaller states are indicated. Each tuath formed a separate jurisdiction. A freeman was a citizen *(urrad)* in his own *tuath,* but a noncitizen (deorad) in any other tuath, having, however, a legal status which did not belong to a foreigner *(allmurach, muirchuirthe).* Common jurisdiction (cairde) for legal proceedings could be made operative by agreement between states. It was the tendency of these small states to group together under hegemonies, the king of one state of the group having a certain authority over the kings of the other states. Such groups could become permanent. The chief salient feature of the early Celtic regime is the division into five major groups of states, the five fifths of Ireland, so firmly fixed in tradition that in later times, when the country was divided into four provinces, these were called and are called at present by the Irish word meaning "fifths." The five fifths were:

Ulster (Coiced Uloth, "the fifth of the Uluti"), extending on the west as far south as Loch Boderg on the Shannon, on the east as far south as Drogheda; it was thus much larger than the later province. Its capital (*i.e.,* the seat of the chief king) was Emain, "the Navan," close to the city of Armagh.

North Leinster (Coiced Lagan Tuad-Gabair, "the fifth of the Lageni north of Gabair"). Capital: Temuir (Tara).

South Leinster (Coiced Lagan Des-Gabair, "the fifth of the Lageni south of Gabair"). Capital: Dinn Rig, on the Barrow.

Munster (Coiced Muman, "the fifth of Muma"), nearly coextensive with the counties of Limerick, Cork and Kerry, with part of Waterford. Capital: Temuir Erann, near Ardpatrick, County Limerick.

Connaught (Coiced Connacht, "the fifth of the Connachta"), including the present Clare but not extending east of the Shannon. Capital: Cruachain (Rathcroghan), in County Roscommon,

Social Order. — The population consisted of free, unfree and slaves. The freemen in the main were the freeholders of land, but their franchise extended also to the men of certain professions and skilled crafts. In the early Christian period, all ecclesiastics and all who received education in the schools of Latin were free. From this and from Caesar's statement of the immunities of the Gallic druids and their pupils, it may be inferred that the Irish druids and their pupils were freemen. The unfree were tenants of land, labourers and craftsmen of inferior kinds. Among the landed freemen, the nobles were distinguished by a higher measure of wealth and by having a sufficient number of clients (*celi,* "com-

panions"). The nexus between chief and client was formed by a personal contract which was terminable by either and was terminated by the death of either, differing thus from the hereditary connection of feudal lord and vassal. The clients were freeholders and retained their ownership of land. The chief advanced capital, usually in the form of cattle, to the client, protected his interests in court or assembly and was his leader in war. The client repaid the capital with large interest, attended on the chief at the assembly, followed him to war, supplied him with labourers for certain works and rendered him certain reliefs and fixed dues of hospitality. There were two classes of clients, free (*soercheli*) and subject (doercheli). A subject client received from the chief, in addition to an advance of capital, his own "honour price" (that is, the legal valuation of his franchise or status) and so ceased temporarily to be a freeman; he paid a tribute in meat, vegetables and malt for the support of the chief's house.

FIG. 2—ANCIENT IRISH HISTORY. THE "FIVE FIFTHS"-OF IRELAND ABOUT THE BEGINNING OF THE CHRISTIAN ERA

Ancient Ireland was divided into fifths, each ruled by its own king: Coiced Uloth (Ulster), with Ernain Macha as capital; Coiced Connacht (Connaught), with Cruachain as capitai; Coiced Lagan Tuad-Gabair (North Leinster), with Ternuir (Tara) as capitai; Coiced Lagan Des-Gabair (South Leinster), with Dinn Rig; and Coiced Muman (Munster), with Temuir Erann as capital

Normally, each freeman was a member of a fine or joint family, consisting of descendants of the same great-grandfather—in other words, extending to second cousins. For some purposes a wider extension of the joint family, as far as fourth cousins, was recognized. If a man died without issue, his property was divided in regulated shares among the members of his *fine*. In case of homicide, the compensation fixed by law was divided in like manner. A fine could be made liable for the undischarged liabilities of any of its members. When a kingship became vacant, any man whose father, grandfather or great-grandfather had been king was eligible to succeed. The power of election belonged to the freemen in assembly, but it seems to have been usual for them to accept a choice made first by a meeting of the nobles.

The Druids.—Druidism, known only in Transalpine Gaul, Britain and Ireland, but not recorded in Britain outside Anglesea, and the northern Pictland, is likely to have originated in Ireland. J. Pokorny's view, supported by Irish tradition, is that among the pre-Celtic inhabitants there existed a class of seers and sorcerers from which, under the Celtic regime, the druids were developed. The druids may be described as an association of professional wise men, philosophers in the early Greek sense, claiming to be experts in all the higher branches of knowledge. They professed special knowledge of the gods, the other world, the future life, the form and measurement of the earth, the movements of the heavenly bodies, the history of men; and they were accepted as authorities in matters of religion and law. They also claimed occult and prophetic powers. In the Roman world, after their suppression by the state, and in Ireland, after its conversion to Christianity, they were chiefly remembered as prophets and magicians. The notion that they were the priests of a particular religion is of modern growth. In Christian Ireland the druids continued to exist, but with a change of name and with limited scope. They were called filid, a name which in time became restricted to the meaning of poets (see IRISH **LITERATURE**: Gaelic) but which originally, signifying seers, denoted one of the functions of the druids. They no longer had authority in matters of religion but they long continued to practise occult rites of divination. In matters of learning they were displaced from the ground covered by the Latin teaching of the ecclesiastical schools. They remained the authoritative exponents of the national history, literature and law. In Gaul, notwithstanding the division of the country into so many independent states, the druids formed a single society, with annual conventions and an elected president. In Ireland the filid did not present this organized form, but they maintained an effective unity through a long course of centuries. They provided a single code of law for the whole country. They followed a common literary usage in writing and in minutely regulated rules of prosody which they all accepted. What Caesar tells of the long course of education of the Gallic druids and of the instruction given orally and in verse is paralleled in the filid. Like the druids, they enjoyed civil immunities. Their persons were sacred. The influence of druidism remains operative and distinctive in Irish history throughout mediaeval times. It can be traced in the conversion of the Irish to Christianity, in the development of the monastic schools, in Irish law, in the form and content of Irish literature, in lasting pedantic tendencies, but chiefly in a sense of national unity not dependent on political coherence.

Origin of the Monarchy.—The sagas of the Ulster cycle point to a rivalry for the hegemony of Ireland between the Ulster and the Connaught kings. In time the Connaught dynasty gained ground. Its kings crossed the Shannon and occupied Uisnech, dominating the fertile midland plain, probably in the and century. In the 3rd century they annexed the Boyne valley and made Tara their capital. These conquests broke up the pentarchy and gave a decided headship to the kings of Tara. Of them the most celebrated in tradition is Cormac, perhaps the first clearly historical personal figure in Irish history, reigning between the years 250 and 300. About this time, taking advantage of the disorder of the Roman empire, the Irish undertook plundering incursions into Roman Britain. A panegyric of Emperor Constantius in 290 speaks of the Britons as being already "accustomed" to Irish raids. Contact with the Roman military power had effects in Ireland. In imitation of the Roman walls in northern Britain, the Ulster kings protected their diminished territory by a massive earthwork, of which the remains are traced extending, with intervals of lake and forest, across the island from Dundalk bay to Donegal bay. A great quadrangular earthwork called the Dorsey, anciently *Doirse* Emna (the Gates of Emain), built no doubt in imitation of a Roman legionary camp, guarded the main road leading from Tara to the Ulster capital. The Roman military organization seems to have led to the formation of the *fiana*, permanent bodies of professional soldiers, peculiar in Ireland to this period. In the earlier heroic tradition there is no military organization. Later, the Irish law does not recognize the military profession, and no permanently formed Irish military forces are seen until the introduction of the galloglasses from western Scotland in the 13th century (see below). About A.D. 350, the Connaught-Tara dynasty captured Emain and annexed the greater part of Ulster. It reached the height of its power under Niall of the Nine Hostages at the beginning of the jth century. His sons took possession of the western part of Ulster, and their kindred now ruled all the northern half of Ireland except the eastern strip from the mouth

of the Bann to the mouth of the Boyne. The chief kings of this kindred, Dal Cuinn, were recognized as kings of Ireland until 1002.

The high kingship or monarchy was an acknowledged primacy, symbolic of the sense of national unity, rather than a politically operative institution. Its powers are nowhere found defined. It claimed no tributes from the suffragan kings except from the kings of Leinster, who denied the legality of the claim and yielded the tribute only to superior force. The assembly over which the high kings presided was held annually at Tailtiu, in the Boyne valley, and was regarded in a sense as national, but there is no instance recorded of its acting as legislative or administrative authority for all Ireland, in the manner in which the assembly of Carman, for example, acted for all Leinster.

In Munster the 4th century saw the rise of a strong dynasty, of the Eoghanacht sept (clan), whose traditions indicate a relatively late immigration from Gaul. Under its rule, the bounds of the older fifth were pushed out and reached in the 5th century an extent approximately the same as the modern province of Munster.

From the 5th century onward, the five major kingdoms of earlier tradition were replaced by seven. Of these, the older Ulster formed three—the kingdom of Ailech on the west, the kingdom of Airgialla (Oriel) in the middle and the kingdom of the Ulaid (Ulidia or Ultonia) on the east. The others were Connaught and Munster, both nearly coextensive with the modern provinces; Mide (Midia, Meath), comprising the greater part of older North Leinster and a small part of Ulster; and Leinster, consisting of the remainder of the two ancient Lagenian fifths. This division subsisted with little change down to the 11th century and is described in detail in the Book of *Rights* (10th century). The grouping, however, was in some particulars theoretical rather than actual. Eastern Ulster is to be regarded as containing three kingdoms of equal status—Dalriada, of which the kings ruled also in Scotland; Ulaid, the successor of the ancient Uluti; and Dal Araidi, a kingdom of the Picts. Osraige (Ossory), nominally in Leinster, does not appear subject to the king of Leinster. In each major kingdom or group kingdom, the component states or petty kingdoms were of two kinds, tributary and nontributary. The nontributary states were those whose kings were of the same sept as the superior king, though their pedigrees may have branched apart for centuries. In Munster, for example, about half the number of component states were ruled by kings of Eoghanacht lineage, and these were not tributary to the king of Munster, who was also of that lineage. Distributed all over the country were remnants of ancient subjugated tribes, the *Aithech-thuatha,* made tributary and held in political subjection.

Oversea Raids and Migrations.— From about the middle of the 3rd century, Latin writings bear constant evidence of Irish raiding expeditions, and the older Latin name Hiberni or Iverni is almost wholly replaced by a new name, Scotti, which appears to be a Celtic word meaning "raiders." Linked with the Scotti are found the Atecotti, also a Celtic word meaning "the very ancient folk," and probably distinguishing the Irish of pre-Celtic origin from the dominant Celts. Toward the end of the 4th century, large bodies of Atecotti were enlisted in the Roman service under Emperor Honorius. Irish tradition fully reflects the evidence of Latin writers. As the Roman power weakened in Britain, Irish raids were followed by migratory settlements. There is abundant evidence of Irish settlers all along the western seaboard of Britain from Argyll to Devon. Irish dynasties sprang up in Wales and lasted there for centuries. In the jth century, the kings of Dalriada, a small kingdom in the northeastern angle of Ulster, extended their power over the Irish settlers in Argyll and the neighbouring islands, their descendants ultimately, in the 9th century, becoming kings of Scotland. Crimthann, king of Munster, is said to have held a fortress in Britain. Branches of his sept settled in Wales and Cornwall. Niall of the Nine Hostages, who was high king at the end of the 4th century, is identified by W. Ridgeway with "the Scot" who, in Claudian's poem, "mobilized all Ireland" against Roman Britain. In his reign, St. Patrick was carried to Ireland as a captive and with him in the same raid, as his confession says and his epistle repeats, "so many thousands of men." At the head of a later expedition, Niall was killed at sea by a Leinster prince. His successor, Nath-i, heading another raid, died on the continent.

THE MIDDLE AGES

Introduction of Christianity.— There is evidence of Irish Christians, apart from the thousands of enslaved Christian captives, before the first Christian mission to Ireland. In 429, at the instance of Palladius, deacon of the Roman church, St. Germanus, bishop of Auxerre, was sent by the pope, St. Celestine, to combat the Pelagian heresy in Britain. It was doubtless in answer to an appeal made through Germanus that, in 431, "Palladius was sent, their first bishop, to the Scots believing in Christ." After a short stay in Ireland, Palladius passed over to northern Britain, where he died soon after his arrival. In 432 Patrick, a disciple of Germanus, was sent as bishop to Ireland. He was a Briton, son of a decurion under the Roman government, and probably a native of Gwent in Monmouthshire. He was carried off as a captive in the reign of Niall and became a slave in northeastern Ulster. After six years he escaped. His birth may be dated in 385, his capture in 401, his escape in 407. His mission in Ireland succeeded rapidly. In 438 he was favourably received at the court of the high king, Loiguire, son of Niall. In 439, doubtless in answer to a request sent to his patron Germanus, three bishops were sent to his assistance, Secundinus, Auxilius and Iserninus, the last also a disciple of Germanus. Patrick chose for his own see Armagh, beside the ancient Ulster capital. Secundinus had his church near Tara, the seat of the high king; Auxilius, near Naas, also a royal seat in Leinster; Iserninus, driven out at first by Enda, king of Leinster, was restored later by Enda's son Crimthann, a Christian convert, and fixed his see at Aghade, near Rathvilly, where Crimthann lived. There is evidence that Patrick chose Baislex (Basilica Sanctorum), near Cruachain, the capital of the kings of Connaught, as the see of a bishop for that kingdom.

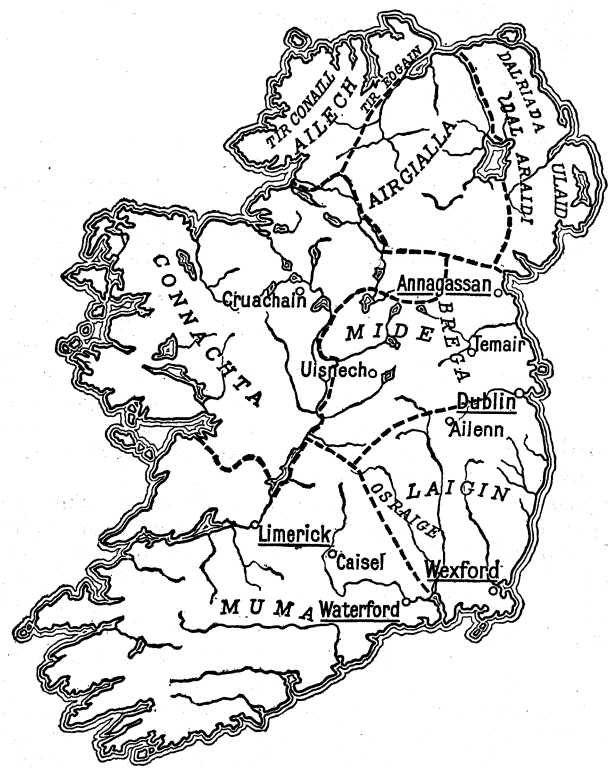

FIG. 3.— MAP OF THE SEVEN MAJOR KINGDOMS OF IRELAND, A.D. 500–900
These were Allech (Donegal); Alrglalla (Londonderry, Arrnagh and Monaghan); Ulaid (Antrim and Down); Connachta (Connaught); Murna (Munster); Mide and Brega (Meath); and Laigin (Leinster)

In the story of St. Patrick's reform of Irish law one might see an influence transformed by tradition into an event. A druid fore-

told to Loiguire: "He shall free slaves, he shall raise up men of lowly kin." In the written laws, two centuries later, a slave class no longer exists. St. Patrick's epistle condemns the enslavement of Christians. The earlier racial distinctions between conquerors and conquered, between Pict and Celt, survive only in antiquarian tradition, and all become known by the common name Goidel (Gaels) or Fir Erenn (Men of Ireland).

The Ascendancy of the **Ui Neill.**—The descendants of Niall, Ui Neill, acquired territories in the regions annexed by conquest to their ancestral kingdom, Connaught. The other branches of their kin remained in Connaught. Loiguire was succeeded as high king by Aillill Molt of a Connaught branch. Niall's descendants combined against Aillill, who was defeated and killed in the battle of Ocha, A.D. 483. Thenceforward, until 1002, the high kingship was held exclusively by the line of Niall. One group of his descendants, the "northern Ui Neill," held western Ulster. Another group, the "southern Ui Neill," dominated Mide, the main part of the old North Leinster fifth. In 563 the Pictish territory west of the Bann river was annexed by the northern Ui Neill. In 575 the high king, Aed, son of Ainmeri, held an assembly at Druim Ceta, on the border of that territory, and decisions were adopted limiting the privileges of the *filid* and regulating the relations of the kingdom of Dalriada in Ireland to the kings of Dalriada in Scotland and to the kings of Ireland. In 637 Domnall, king of Dalriada, invaded Ireland from Scotland. He was defeated in the battle of Mag Roth (Moira) by Domnall, king of Ireland.

After the battle of Ocha, the high kingship passed without any regularity from one branch to another of the Ui Neill, being held by descendants of five of his sons. In 734 Flaithbertach, of the line of Conall, son of Niall, was deposed by Aed Allan, of the line of Eogan, son of Niall. Thenceforward the succession was confined to two branches, the kings of Ailech, descendants of Eogan, and the kings of Mide, descendants of Colman, these being, respectively, chief kings of the northern and southern Ui Neill, and the high kingship was held by the kings of Ailech and Mide in a regular alternation, interrupted only twice, by the reigns of Congalach, king of Brega, 944–956, and of Brian Boroimhe (Boru), 1002–14.

Development of Monastic and National Culture.— The great development of Latin learning and of the monastic schools takes its origin from St. David's school of Menevia in Wales about A.D. 500. The kingdom of Dyfed (Demetia), in which this school was situated, had originated as an Irish colony and remained in close intercourse with Ireland. St. David was partly of Irish ancestry and his school attracted many from Ireland. Among its earliest pupils was St. Finnian, who founded the monastery and school of Clonard about 520. Clonard became the parent of other noted monasteries, notably Clonmacnoise and Bangor, and, through its most famous pupil, St. Columba, of Derry, Durrow, Kells and other foundations in Ireland, as well as of Iona.

The language of these schools was Latin. The Latin classics were held in high esteem and in some instances survived because of Irish zeal. When Theodore set up the teaching of Greek in Canterbury, he was beset by students from Ireland "like a wild boar surrounded by a troop of furious wolves." Scribes were continually at work providing copies of books. In the decoration of the more precious books, the art of illumination was highly developed. On the humanistic side, monastic learning was influenced by the traditions of druidism. In the 7th century a fusion of the two cultures came about. In its early years a monastic chronicler introduced a framework of Irish history into his redaction of the Chronicle of Eusebius. A young noble, Cennfaelad, of the line of Niall, wounded in the battle of Moira (637), became a student in Tuaim Regon, where schools of the monks and the *filid* existed side by side. He broke away from the old druidical tradition by writing down the mnemonic formulas of Irish law. Cennfaelad, who died in 679, also wrote a number of poems on historical events and a short tract on the grammar of Irish. During the 7th century an Irish written literature in prose and verse was extensive.

The Irish Missionaries.— In 563 Columba, then 43 years of age, a descendant of Niall and a pupil of Clonard, having already founded the monastery of Derry on the site of the present city, ied a colony of monks to the island of I (Iona), granted to him by the king of Dalriada. This was the beginning of the Irish missions overseas, the "surplus product" of the monastic schools. The work of Irish missionaries among the Picts, Angles and Saxons belongs to the history of Britain. The continental missions began with Columban of the monastery of Bangor in Ulster, who, with a few companions, arrived in France about 574. Their range extended in time over a large part of France, the Netherlands, Germany, Austria, Switzerland and Italy.

The early missionary movement had its natural sequel in the sphere of learning. The part taken by Irishmen in the Carolingian revival of learning belongs to Irish history inasmuch as it exhibits the mental training given in Irish monastic schools and the scope and character of their studies. Clement the grammarian had a kno ledge of Greek. Dicuil wrote a geography of the world in which he shows that his countrymen had travelled as far as Egypt and had discovered Iceland. Dungal, theologian and grammarian, wrote for Charlemagne an explanation of the solar eclipse of 810. Virgilius taught the existence of the Antipodes. Eriugena, for his knowledge of Greek and the boldness of his philosophical speculation, is the most prominent intellectual figure of his time. At Glastonbury, under Irish masters, St. Dunstan studied arithmetic, geometry, astronomy and music. Irish monasteries, in Ireland and abroad, were also prominent in the cultivation of music.

The Paschal Controversy.— The Irish church, in the dating of the Easter festival, followed a method introduced by its founders. Irish missionaries abroad found a different method under papal authority. About 631 the Roman computation was introduced in the southern parts, in northern Ireland somewhat later. Iona held out longest for the Irish tradition. even in opposition to its abbot, the celebrated Adamnan, and did not adopt the Roman Easter until 716, 12 years after his death.

Rural Economic Development.— The Irish laws point to a large development of rural industry in the period in which they were first written, preceding the Norse incursions. They deal minutely with the enclosure, subdivision and fencing of lands for tillage, the measurement and valuation of land, the management of crops and domestic animals, and innumerable details of husbandry, including milling. dyeing, spinning and weaving, dairying, malting, meat curing, etc. The principal crops were wheat, barley, oats, flax and hay. Dyestuffs were grown. Irish hounds were in high repute. St. Patrick, in his escape from captivity, joined a company of Irish traders whose chief merchandise was hounds. Watermills were owned and worked jointly by landholders.

Norse Invasions and Settlements.— The first appearance of the Norsemen on the Irish coast is recorded in 795, their first inroad in 807. Thenceforward there were frequent plundering raids, sometimes far inland. By degrees the Norsemen took possession of all the islands of Scotland, of Caithness, Argyll, Galloway and of the Isle of Man. In 841 they seized and fortified two ports, at Annagassan, between Dundalk and Drogheda, and Dublin. About the same time a fleet under Thorgest passed up the Bann to Lough Neagh. He afterward sailed round to the Shannon and took possession of Lough Ree in like manner. Thorgest was captured in 845 and put to death by Mael-Sechnaill, king of Mide, who in 846 became king of Ireland. Large invading forces were defeated in 847. The turning point of these invasions was reached in the reign of Aed Findliath, high king from 862 to 879, who forced the Norsemen to abandon all their stations in the northern parts of Ireland. At the same time the Norse kings of Dublin reached the height of their power, waging war in England and Scotland, and so nearly dominating Ireland that in 873, 876 and 878 the high king was unable to hold the assembly of Tailtiu. Waterford in 914 and Limerick in 920 were occupied by the Norsemen without opposition. In 917 Niall Glundub, high king, endeavoured to dislodge them from Waterford but they defeated a Leinster army coming to his assistance and forced him to withdraw. In 919 Niall led an army against Dublin, and in a battle where the Phoenix park now lies he was defeated and killed. The permanence of the Norse settlements in Dublin, Waterford and Limerick became assured. Landed colonies spread out from Dublin and Waterford. Without quite abandoning piracy, the

vikings became traders in close intercourse with the Irish, and their commercial towns formed a new element in the life of the country, typified in Wexford, which did not appear in warfare until the siege of 1169. The combination of war and commerce led to a recrudescence of slavery, and imported slaves are mentioned in the Book of *Rights* (about A.D. 900).

About 964 Mathgamain, king of Dal Cais, one of the petty kingdoms of Munster. became king of Munster, displacing the ancient Eoghanacht line. In 968 he defeated the Norse of Limerick and captured their city. In 976 he was captured and put to death by two Eoghanacht princes, one of whom, Mael Muaid, became then king of Munster. In 978 Mael Muaid was defeated and put to death by Brian, brother of Mathgamain. Brian, having gained the kingdom of Munster, steadily increased his power. His claim to suzerainty over Leinster forced the Leinster king into close alliance with the Norse of Dublin. In 999 their united forces were defeated by Brian at Glen Mama, near Dublin, and they agreed to become his allies and supporters. In 1002 Brian became king of Ireland by the submission of the high king Mael Sechnaill II. The Irish and Norse accounts agree in bearing witness to the high character and good government of Brian. The kings of Dublin and Leinster, however, chafed under his suzerainty. In 1013 Sigurd, earl of the Orkneys, had for a Christmas guest the Norse king of Dublin, Sigtrygg, and a compact was made between them. Sigurd was to gather from all parts the greatest possible host of Norsemen and to bring them before Easter to Dublin, where they were to be joined by the forces of Dublin and Leinster to give battle to Brian; if they were victorious, Sigurd mas to have the kingdom of Ireland. Brian learned of these preparations and met the Norse army at Clontarf, near Dublin, on Good Friday, 1014. He was joined by the deposed high king, Mael Sechnaill. The Norsemen and their Leinster allies were defeated and Earl Sigurd was slain, but a viking chief, who had taken refuge in a wood, sallied out in the rear of the Irish army and killed Brian in his tent.

Though the battle of Clontarf removed the prospect of a Norse conquest, it brought a period of unsettlement. All the chief dynasties had lost their prestige, and, except in Connaught, new rivalries and fresh pretensions to power, based on force and careless of tradition, arose everywhere. Brian's son Murchad, who had already gained a reputation hardly less than his father's, had fallen in the battle. Of the sons who survived, none was able to sustain Brian's power. Mael Sechnaill was restored to the high kingship and held it until his death in 1022. After him for half a century there was no acknowledged king of Ireland.

Then followed the period of the high kings "with opposition"; *i.e.*, not acknowledged by a minority of the provincial kings: Toirdelbach, grandson of Brian, 1073–86, and his son Muirchertach, 1086–1114, kings of Munster; in opposition were Domnall Ua Lochlainn, king of Ailech, who died in 1121; Toirdelbach Ua Conchubair, 1118–56, king of Connaught; Muirchertach Ua Lochlainn, 1156–60, king of Ailech; and Ruaidri Ua Conchubair, 1166–74, king of Connaught. The centralized feudalism established in England by William the Conqueror had an apparent influence on the policy of these kings. One after another they sought, for the most part without success, to set aside the ancient tradition of local autonomy and to exercise direct authority outside their hereditary jurisdictions. Thus Toirdelbach Ua Conchubair in 1118 divided Munster into two coequal kingdoms; in 1125 he deposed the king of Mide and appointed three kings in his stead; in 1126 he made one of his sons king of Dublin and Leinster; and in 1129 he built the first castle in Ireland, commanding the passage of the Shannon at Athlone.

The last effort to establish Norse domination was made by Magnus, king of Norway. who in 1098 arrived with a strong fleet and restored the Norwegian sovereignty over the Scottish islands, Cantire and the Isle of Man. In 1102 Magnus, then in Man, threatened an invasion of Ireland but agreed to a year's truce. In 1103 he landed on the Ulster coast, where he mas killed.

The period of political ferment which followed the success of Brian over the ancient chief dynasties was also a period of new growth in religion, literature and the arts. The movement for religious reform, mainly in the direction of a Catholic uniformity and the removal of abuses in matters of ecclesiastical discipline and observance, was led by Gillebert, bishop of Limerick, and Cellach (Celsus), bishop of Armagh and primate, in the beginning of the 12th century, and by the successor of Cellach, Maelmaedoc Ua Morgair, better known as St. Malachy. The outstanding feature of the abundant literary output of this time is enthusiasm for ancient national tradition. It became customary to compile tomes, each forming a kind of library of traditional lore, comprising sagas, poems, genealogies, etc. A number are still extant.

(E. MacN.; JA. Hn.)

The Anglo-Norman Invasion.— As early in his reign as 1155, Henry II of England had through his envoy, John of Salisbury, received from Pope Adrian IV the grant of Ireland "as an inheritance," on condition that he should reduce to order the Irish church and state. The so-called "bull," *Laudabiliter*, which defines this grant, rests on the sole authority of Giraldus Cambrensis; how far it is genuine is one of the puzzles of history. but the general submission of the Irish to Henry later would imply that some such papal privilege was in the air.

Henry had to put his project aside for the time, and, when the invasion came, it was a feudal one and directed from south Wales, which was full of Norman adventurers. The first invaders, Maurice Fitzgerald, Robert Fitz Stephen, Raymond "le Gros" de Carew and others, were sons or grandsons of the famous Welsh princess Nesta and vassals of Richard FitzGilbert de Clare, earl of Pembroke, called "Strongbow" in Irish tradition.

Their opportunity came when Dermot MacMurrough, king of Leinster, expelled by his enemies, decided to seek aid in England and arrived in Bristol with his beautiful daughter Eva (Aoife) in Aug. 1166. He was referred to Henry, found the king in France, was graciously received and given permission to raise forces in Britain. Returning to Wales, he won FitzGilbert over by the offer of his daughter's hand with apparently the succession to Leinster. He also enlisted "the sons of Nesta" in his cause, and they found volunteers among the Welsh and Flemings of south Wales and Pembroke. Returning to Leinster, where his son Donal Kavanagh, whom Giraldus calls illegitimate, was holding out for him, he held his ground until successively Fitzgerald, Fitz Stephen, Raymond and finally Lord Richard himself arrived, the latter landing at Waterford in Aug. 1170 with 200 knights and 1,000 men-at-arms.

The successes of Dermot, backed by these professional fighters, were rapid; Danish Waterford was taken, the marriage of Eva and the earl celebrated, and by a rapid march Dublin also was captured and a relieving force under the high king scattered, late in 1170. Leinster and Ossory were reduced, but the death of Dermot the following May made the situation difficult. The Irish regarded his son Donal as the true heir, but FitzGilbert considered himself king of Leinster, and anyway in feudal theory was, in virtue of his wife. lord of the province. But he was hemmed up in Dublin in midsummer by a national levy raised by Roderick (Ruadri, or Rory O'Connor), king of Connaught, and though this attack was repelled it was uncertain whether he could hold his own. Therefore when Henry, fearful lest a new Norman state should arise across the Irish channel, resolved to come to Ireland, Strongbow placed his conquests at his suzerain's feet.

Henry landed near Waterford on Oct. 17, 1171, with an imposing army, but a conquest in arms was not necessary, and in fact the peaceful submission of the Irish leaders was prompt and widespread. The king marched to Lismore and Cashel and finally to Dublin, where he spent the winter, leaving Ireland on April 27, 1172. In this short period he managed to set up the rough essentials of a government. At Dublin and elsewhere he received the homage of all the kings of Ireland except those of Connaught and Ulster. To Strongbow he granted the land of Leinster; he confirmed the Geraldines and others in their fiefs, and annexed to the crown the Danish kingdom of Dublin. He gave the capital to "the men of Bristol," took the Ostmen under his protection and appointed Hugh de Lacy governor of the colony. He did not scruple to confer on De Lacy the whole of Meath, though its native king, O'Melaghlin, had recently submitted, and the grant illustrates the inevitable clash of feudal and Irish law. Meanwhile during

the winter the Irish bishops met at the synod of Cashel and, after enacting various reforms, declared (according to Giraldus): "Divine offices shall be celebrated according to the forms of the Church of England, for it is just and right that as Ireland has received her lord and king from England, she should accept reformation from the same source." This of course was an inspired assurance of the task with which the papacy had commissioned Henry. The submission of the church was complete, nor was it a packed assembly, for though Christian, bishop of Lismore and papal legate, seems to have been on Henry's side, Laurence, archbishop of Dublin, and the native prelates of Cashel and Tuam were present. Thus Ireland was presented to the English crown as a papal fief; such was the basis of its authority till 1541, and the Irish themselves accepted the fact.

Meanwhile the adventurers were attacking Desmond, though its king had submitted to Henry; De Lacy was organizing Meath, and John de Courci conquered in Antrim and Down a principality for which he could show no royal patent. Strongbow enfeoffed Leinster deeply with Normans, giving the barony of Naas, for instance, to Maurice Fitzgerald. Strongbow died in 1176, leaving only a daughter, who later married William, the earl marshal, and brought to him "the land of Leinster." Ulster and Connaught were unconquered, and in 1175, by the treaty of Windsor, Henry acknowledged Rory O'Connor as king of Connaught under him.

English Overlordship.— At the Council of Oxford in 1177 Henry created his son John *Dominus Hibernie* and granted Desmond to Robert Fitz Stephen and Milo de Cogan. Eight years later (1185) John himself visited Ireland. A fresh series of grants was made, and William de Burgh and Theobald Walter "le Botiller" got wide lands in north Munster and Theobald de Verdun about Dundalk. The resentment of the Irish was shown in the assassination of Hugh de Lacy, and the lesson was taken to heart later in John's reign when Cathal Crovderg O'Connor, brother of Rory, was confinned in the kingdom of Connaught and Donnchad O'Brien in that of Thomond west of the Shannon.

Under John the lordship of Ireland was united with the English crown, and to this king belongs the credit of first establishing a civil government at the expense of the conquistadors. He dispossessed De Courci and gave the earldom of Ulster to Hugh, brother of Walter de Lacy, earl of Meath; but he soon repented of making this family too great, and in a personal campaign in Ireland in 1210 expelled them both. During his short stay in Dublin he organized a permanent government under a justiciar, and "with the common consent of all men of Ireland ordained that the laws and customs of the realm of England should be kept therein."

After his defeat over Magna Carta, John had to restore the De Lacys, and the feudal caste under Henry III bent its energies upon the subjection of Ireland. When Richard de Burgh got a grant of all Connaught despite the claims of Felim O'Connor, conquered it and divided it among his followers (1235), and Maurice Fitzgerald acquired a claim to Tyrconnell, a complete conquest seemed probable. But during this period two great native dynasties arose in Ulster, the O'Neills and O'Donnells, and they repelled the Norman attacks, finding a new and potent weapon in those professional fighters, the galloglaigh or galloglass (a word meaning "foreign soldiers"), Hebrideans of mixed Gaelic-Norse blood who now began to flock into the north. On Connaught, however, the De Burghs kept firm hold, leaving to the O'Connors only a few cantreds of Roscommon. The power of this family was increased when in 1264, after the extinction of the De Lacys, Walter de Burgh was created earl of Ulster. The native Irish, though only partly successful, now broke the spell of Norman victory. Brian O'Neill was elected high king and raised a Gaelic confederacy, but was defeated and slain at Downpatrick in 1260. But the next year the MacCarthys overthrew a colonial army at Callan and thenceforth ruled undisturbed over southwest Munster, their chief taking the name MacCarthy More. So when Edward I, in 1276, granted to Thomas de Clare the "land of Thomond," Turloch O'Brien took up arms, and the De Clares were finally expelled in the war which ended in 1318.

In the early years of Henry III the central government was steadily built up. Magna Carta was sent over, the whole framework of English law was introduced, and Ireland had an administration under the justiciar and a parliament of peers and prelates, while the county organization was extended over the planted areas.

Great numbers of the Gaels had fallen under Norman lords, and, while some were already villeins *(betaghs)* under the old system, and remained so on the new manors, many of the colonists tried to reduce all Irishmen to the same level. Those living among the English and suffering from a denial of English law strove to procure it, but though the government was not unwilling the colonists opposed emancipation. The Irish who lived under brehon law (*q.v.*) had less desire to exchange it for English law, but under the pressure of the new domination they naturally aspired to have its legal advantages. The chiefs especially sought to have their tenures legally established under the crown, a benefit which, except in a few minor cases, had been denied them. The royal government was to blame for not embracing the Irish within the law by edicts rigidly enforced, but, indeed, to reconcile and blend two peoples so far apart in language and tradition was a huge task which only a resident monarchy could have achieved.

Under Edward I a second attempt was made to create a real central authority, and a series of justiciars, of whom John Wogan, viceroy from 1295 to 1307, was the ablest, extended the area of common law and did something to reduce the feudal liberties. The baronial interest, however, was too strongly entrenched, and Edward had to placate it, so he added to the ranks of the magnates by giving "the land of Decies and Desmond" to Thomas, head of the Munster Fitzgeralds. Wogan's greatest achievement was to summon a parliament in 1297 in which knights and the common clergy were included and nine shires and five liberties sent representatives. In 1310 the towns also sent deputies, and thus Ireland received a legislative body which lasted till 1800. It was an Anglo-Irish assembly in which the native people had no spokesmen.

A series of disasters now shook the ill-founded state to its very base. Fresh from his victory at Bannockburn, Robert Bruce dispatched his brother Edward to win the crown of Ireland, which a league of Irish chiefs under Donal O'Neill, *Rex Ultonie,* offered to him. When Edward Bruce landed with an army of veterans near Larne in May 1315, almost all the natives rose in arms, and not a few of the older stock of the Englishry joined him. He defeated Richard, the "red earl" of Ulster, at Connor. On May day, 1316, he was crowned king of Ireland on a hill near Dundalk, "the Gaels of Erin proclaiming him king of Ireland," says the *Annals of Loch Ce.*

The English cause was at last saved; Bruce failed to take Dublin, Felim O'Connor, at the head of a great Irish confederacy, was defeated and slain by a colonial levy at Athenry in Aug. 1316, and a new viceroy, Roger Mortimer, put spirit and energy into the government. Bruce himself was overwhelmed at Faughart, near Dundalk, by an army under John de Bermingham, and fell in the battle (Oct. 1318). The Scottish fire was thus quenched and Edward II recovered a kingdom he deserved on every count to lose. Little or no vengeance was taken, and Mortimer was instructed to admit the aggrieved Irish to English law and liberty, an edict again without much effect.

The Irish Revival.——For a time all seemed fair, and the peerage between 1316 and 1329 was strengthened by the creation of new earldoms—that of Kildare, given to John, head of the Leinster Geraldines; that of Desmond, given to Maurice, head of the Munster Geraldines; and that of Ormonde, given to James Butler. In Ulster, the true key of the colony, the power of the earls now covered the whole coast from Carlingford to Derry. But an element of discord was found in the older colonists, who resented the dominance of the great lords, claimed that succession should go to heirs male instead of heiresses who conveyed lands to English absentees, and began to form clans of their own *(naciones et cognomina)*. In 1333 the young earl of Ulster, William, was murdered by his own tenants, the Mandevilles, near Belfast, leaving only a daughter who later was married to Lionel, duke of Clarence. The O'Neills became supreme in mid-Ulster and the

greater part of Antrim and Down, where they founded a new state, Clandeboy.

Connaught was at the same time lost to the English interest. Two cousins of the murdered earl, Ulick and Edmund de Burgh, seized on the family lands and founded, respectively, the Burkes of Clanricarde and Mayo, known to the Irish as MacWilliam Uachtair, "the upper MacWilliam," and MacWilliam Iochtair, "the lower MacWilliam." Though they maintained a certain English tradition of law and land tenure, spoke French and boasted their continental descent, they were obliged amid so Irish a population to speak Gaelic and marry Irish wives.

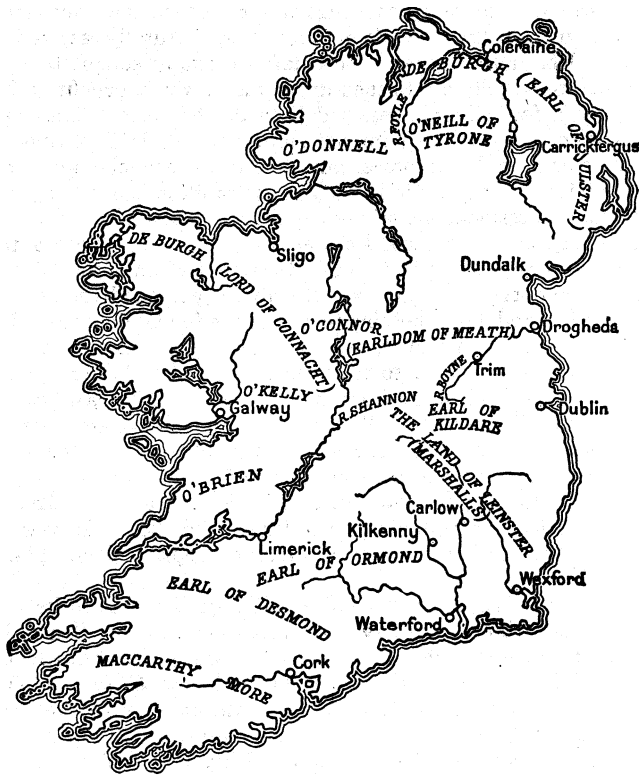

FIG. 4. — MAP OF MEDIAEVAL IRELAND, SHOWING THE LANDS OF THE RULING FAMILIES WHEN THE ENGLISH POWER WAS AT ITS HEIGHT, *c.* 1330 In addition to the counties governed directly from Dublin, several great earldoms had been created at this date; but that of Meath, belonging to the Lacya, had, owing to the extinction of this family, fallen into two portions, that of W. Meath (De Verdun) and that of Trim (Mortimer)

As a result of such events an Irish revival alike in arms, language, law and civilization displayed itself in every part of the island, and the Gaels recovered large parts of Ulster, the midlands, Connaught and Leinster. Even in the latter province the MacMurroughs became the terror of the lowland English, and the descendants of Donal Kavanagh resumed the title "king of Leinster." Absenteeism there had left the lordships of Carlow and Wexford open to Irish attack.

Efforts to Restore English Lordship.--Only a great army led by the king in person could have reconquered Ireland, and the young Edward *III* had thoughts of going there, but he soon abandoned Ireland for Scotland and France. The colony dwindled, and an Anglo-Irish parliament at Kilkenny in 1341, summoned without leave by the earl of Desmond, expressed its resentment against "the English by birth" who misgoverned Ireland, and complained of the decay of the revenue and the loss of a third of the land to the Irish. The capacity of this "middle nation," "Irish to the English and English to the Irish," to turn into temporary rebels was often to puzzle England.

Finally a royal prince was sent, and Lionel, duke of Clarence, ruled as viceroy for six years (1361–67). The Statutes of Kilkenny are the one memorial of his rule. These enactments defined the "English" or "obedient" land as the counties and liberties of Louth, Meath, Trim, Dublin, Carlow, Kildare, Kilkenny, Wexford, Waterford and Tipperary. The decay of the colony was attributed to a general lapse into Irish language, law and usage, to intermarriage and fosterage and to the maintenance of Irish bards. Therefore the English were forbidden to make such alliances with the Irish or to use brehon or "March" law, and, along with the Irish who dwelt peaceably among them, were ordered to take English surnames, speak English and follow English law and custom.

The purpose of these statutes was to preserve as large an area as possible for England at the cost of abandoning the rest. The king's sovereignty over the whole island was not renounced, but the independent Irish were thenceforth treated as "Irish enemies," outside the pale of English law and loyalty and unable to plead in or profit by the civil courts, to marry or to purchase, possess or inherit land among the English. Up to the end of the 16th century the chiefs were held to have no right to their lands except by prescription and usurpation.

But nothing could recall the "degenerate English" from friendly intercourse with the *meri Hibernici.* The old Gaelic civilization, badly shattered in the 13th century, recovered much of its strength in the 14th, and, with its music and poetry, the charm of its language and its women and the aptness of its law, laid an irresistible spell on the older Englishry.

The marriage of Lionel's only daughter to Edmund Mortimer, earl of March and lord of Trim, carried to him the earldom of Ulster, and this great lord went to Ireland as viceroy in 1380, but died prematurely. Buying off the more powerful Irish chiefs by paying them "black rents" to keep the turbulent clans in order was now the poor device of the colonists, whose most dreaded foe was Art MacMurrough, king of Leinster. More than anything else, this chief's activities brought about the first royal visit since 1210. Richard II arrived at Waterford in Oct. 1394 with a large army, attended by Roger Mortimer and other peers, and stayed in Ireland till May 15, 1395. His general policy for the "Irish enemies" was to secure their homage and confirm them in such lands as they had not "usurped," but with one exception; Art MacMurrough and his Leinster *urraghts* or vassals were to be induced to evacuate Leinster for other parts of Ireland and leave the province open to a new English plantation. This was achieved in both cases on paper; almost all the ruling chiefs, headed by Niall O'Neill, *Princeps Hibernicorum Ultonie,* came in and did, liege homage and entered into indentures with the king.

But on Richard's departure MacMurrough refused to fulfil his extraordinary bargain. Robert Mortimer, left behind as viceroy, was slain by the Wicklow Irish in 1398, and Richard in fury hurried over to Ireland again in 1399. His armies could do nothing against the light-armed Irish in their forests, and the king returned to England.

There is little of importance to record of the dwindling "English land" during the Lancastrian period. An occasional strong viceroy, such as John Talbot, afterward the famous earl of Shrewsbury, could do little against the "Irish enemy," the "degenerate English" and the "English by blood," who resented government from Westminster. A hope of uniting the Celts and Englishry was found in Edmund Mortimer, now earl of Ulster, who went to Ireland as viceroy and received the homage of O'Neill and other chiefs but died of the plague in 1425. The old English and the Gaels transferred their affections to his nephew, Richard, duke of York, and in the wars of succession in England were almost to a man for the White Rose.

The Great Earls. — In reality three great earls now ruled Ireland. The greater part of counties Limerick, Cork, Kerry and Waterford with their towns had come under the absolute rule of the earls of Desmond; James "the White," 1st earl of Ormonde, had extended the power of the Butlers in Tipperary and Kilkenny; and the earls of Rildare were dominant in Leinster. The three families worked together, dominated the Dublin government in spite of an "English interest" headed by Talbot, took the lead of an Anglo-Irish home rule party and built up a rampart of feudal independence that later took the Tudors almost a century to break down.

"Aristocratic home rule" may till 1495, and indeed till 1532,

be written over Anglo-Irish history. The Wars of the Roses were to the old English an occasion to secure colonial independence. Richard, duke of York, who became lord lieutenant in 1449, played up to the enthusiasm that was at once displayed for his person and name. All Ireland believed him to be the true heir to the English crown and greeted with enthusiasm the hereditary claimant, who in return was expected to rule Ireland by Irish ideas. Hence, when he arrived as a defeated refugee in 1459, the Irish parliament greeted him almost as a king, but proceeded to declare that the land of Ireland was bound only by the statutes of its own estates. When his son Edward ascended the English throne, Ireland seemed to have the king of its choice, and the earldom of Ulster was merged in the crown. James, earl of Ormonde, taking the Lancastrian side, was executed after Towton, and his house attainted. His two brothers, successively earls, spent their lives in England, and a junior branch of the Butlers took practical possession of the Ormonde lands.

King Edward had little love for an oligarchy which ruled Ireland under the guise of Yorkist loyalty, and all Ireland was appalled when a new viceroy, John Tiptoft, earl of Worcester, got Thomas, earl of Desmond, attainted "for treasons, alliances and fosterages with the Irish enemies" and had him beheaded (1468). But Edward was not in a position to go further; after this exhibition of bloodletting, the government had to be left to the Anglo-Irish, and Thomas, earl of Kildare, ruled as deputy till his death in 1477.

Under his son, Gerald, called by the Irish "Garret More" (the Great), the Kildare supremacy reached an almost royal height. Although only deputy for English princes who bore the empty titles of lords lieutenant, Gerald was, in effect, actual ruler of Ireland. The old English were for him, his sister was wife to the Irish chief Conn O'Neill, various daughters of his married Irish chiefs, and the Dublin parliament was at his beck and call. He had the revenues of Ireland and the appointment to offices; these went to his supporters and Irishmen ruled Ireland. So things stood when Richard III fell at Bosworth.

ENGLISH DOMINATION, 1485-1800

The Kildare Supremacy, 1485–1534.—To the Ireland of 1485 the victor of Bosworth seemed a pure usurper, and a Plantagenet restoration was long hoped for. But by 1499 Henry was strong enough to attack the Anglo-Irish oligarchy. He removed Kildare and sent as deputy, in Oct. 1494, Sir Edward Poynings, who had Kildare attainted in a parliament at Drogheda and then proceeded to the task of restoring the royal power. The Acts of the Irish Estates of 1460, which proclaimed the legislative autonomy of Ireland, were annulled, and in their stead was passed the famous measure known to history as Poynings' law, enacting that no parliament might meet in Ireland till the king, notified by the Irish council of the necessity and the measures proposed, gave his approval under the great seal of England.

Among other acts of the parliament of Drogheda, one directed a ditch to be made around the nearer parts of Meath, Dublin, Kildare and Louth. Within this "Pale" alone, and in the towns and a few strips of coast elsewhere, were English law, speech and loyalty regarded as secure. Outside were the great earldoms, the "degenerate English" and the "Irish enemy." To break the power of the first, to recall the second to their allegiance and to conquer or conciliate the third was to be the threefold task of the Tudors in Ireland. But it could not be undertaken yet. When Poynings departed in 1496, Kildare was restored and a general pardon was issued.

"This people of Ireland," said a later observer, "did ever, both English and Irish, love to be ruled by great persons." Garret More, who ruled Ireland till his death in 1513, was such a personage. As deputy he controlled Dublin and the Pale, his earldom made him supreme in Leinster, and by vassalage, fee or marriage he attached numbers of Irish chiefs to him, of whom the greatest were Conn O'Neill and Hugh O'Donnell. But his loyalty was dubious, and in his later years he was intriguing with Scotland against the young Henry VIII. His son Gerald, called "Garret Oge" (the Younger), succeeded to this hereditary power, but to maintain it became an ever-harder task. To the hostility of the Butlers was added that of Thomas Cardinal Wolsey, who urged Henry against so overgrown a subject as "the king of Kildare." Gerald was again set aside, and the earl of Surrey went to Ireland as lord lieutenant for two years, in 1520–22. His reports, backed by such tracts as D'Arcy's *Decay* of *Ireland,* told the same tale: Kildare, "using the sword the king had committed to him to extinguish the fame and honour of any other nobleman within the land"; the Irish speech and habit universal, even in the Pale; the "March English" everywhere imposing on their tenants coynye

and livery, quarterings of kern and galloglass and other such "Irish exactions"; the Irish, independent under their chiefs. Though Gerald was restored once again, the Butler-Wolsey alliance grew more dangerous, and when the divorce question began and Henry conferred the vacant earldom of Ormonde on Sir Thomas Boleyn, grandson of the last earl, and made Sir Piers (the Red) Butler earl of Ossory, it seemed impossible for him to escape. Yet so astute a man might have weathered through even yet but for a young and foolish son. Recalled to London in 1534, Gerald instructed his heir, Thomas, Lord Offaly (called "Silken Thomas"), to be ruled by the wise heads of the council. The Butler faction spread the rumour that Kildare had been done to death, and Offaly at once flew to arms. His father did, indeed, die in the Tower, but with mortification and dismay; a new deputy, Sir William Skeffington, arrived, and Thomas, while barring himself from pardon by offering Ireland to the emperor and declaring himself of the pope's sect against the heretic Henry, finally had to surrender at discretion, and in 1535 was executed at Tyburn with five uncles.

Settlement Under Henry VIII.—The new policy in church and state could now be carried through, and thenceforth English viceroys and obsequious Anglo-Irish officials directed the government. Lord Grey "managed" the parliament of 1536–37, which declared Henry supreme head of the church and voted the dissolution of the abbeys. It is certain that almost no desire for such reformation existed in Ireland; lords and chiefs might accept bribes of monastic lands, but even at the end of the reign scarcely any

abbeys had been dissolved outside Leinster, and not till 1607 could those of Ulster be confiscated. Within the region of the Pale the abbeys were centres of English education, speech and civility; outside, they were the home of Gaelic culture, and civilization in general suffered by their extinction. George Browne, an Englishman, was sent over as archbishop of Dublin to preach the royal supremacy and, before the end of the reign, about 14 or 15 of the older bishops temporized and accepted it, in the belief that the church was still Catholic.

On its civil side the new policy had much support, not only from Piers Butler, who was at last created earl of Ormonde in 1536, but from great numbers of the rural tenantry, desirous of being released from the exactions of the great lords. To recall the old English to their natural allegiance was no insuperable task, and had the Tudors never abandoned the old faith it is probable that they would have commanded the entire loyalty of the "first conquerors." When, however, the Reformation began in earnest the old English grew steadily alienated, and the introduction of new colonies became the royal policy.

Toward the Gaelic chiefs Henry adopted the plan of surrender and regrant, by which they could surrender the lands they held and receive them back on tenure of knight service to the crown. To the great ones he offered to grant titles, but in return they must accept him as supreme in church and state. Sir Anthony St. Leger, who came as deputy in 1540, pointed out that a new title must be found for the crown in Ireland, "for of long continuance Irishmen have supposed the regal estate of this land to consist in the bishop of Rome and the lordship of the kings of England here to be but a governance under the obedience of the same." Accordingly a parliament was summoned in June 1541, and six Gaelic chiefs approved the act that made Henry king of Ireland.

By the skilful handling of St. Leger, Manus O'Donnell accepted Henry as his lord and king, renounced the pope's authority, consented to serve the deputy with an agreed number of horse and foot and to accept whatever title the king should give him. Conn O'Neill surrendered his ancestral claims, accepted Henry as king and in 1542 was made earl of Tyrone; Murrough O'Brien became earl of Thomond and Ulick Burke earl of Clanricarde.

Edward VI and Mary (1547–58).—Under the two Protectors the Reformation was pushed on apace, and the anger of the common people at the destruction of monasteries and the plunder of the church was now shared by the great. George Dowdall of Armagh, though one of Henry's bishops, defended the mass, and only five Protestant bishops held their ground, of whom the most active was the Englishman John Bale of Ossory, a Genevan reformer.

On her accession, the Catholic Mary retained the title of queen of Ireland, but had to leave the abbey lands to the grantees. St. Leger became deputy again, Dowdall returned and, as a part of the general reconciliation, the exiled Gerald was restored to the earldom of Kildare. But in spite of religious unity, there was little peace. Henry had begun the policy of trying to rule the further provinces through the new earls, but these were opposed by the vested interests of those who preferred the old order, in which the O'Brien or MacWilliam was but an elected captain of his "nation," holding for life, not a hereditary official landlord. This was especially seen in the north, where Shane O'Neill, claiming to be Conn's eldest legitimate son, came out as champion of the old Gaelic order, preferred being "the O'Neill" to any English title, and opposed his brother Matthew, baron of Dungannon, whom he declared to be a bastard. The conflict of state feudalism and Gaelicism became general. In Leix and Offaly, where Gila Patrick O'More and O'Connor Faly were sovereign, a determined stand was made against the extension of English law, and after a long border war the government decided to annex and partly plant these areas. Lord FitzWalter, afterward earl of Sussex, replaced St. Leger in 1556, and with him a policy of confiscation and plantation was adopted. The two lands were shired as king's and queen's counties and divided into an eastern, more fertile area, in which Englishmen were to be planted, and a western area, which was to be left to the natives holding by common law tenure.

The Elizabethan Settlement.—Elizabeth succeeded to the throne in Nov. 1558, and under the earl of Sussex the state religion was established by law. In a parliament of 1560, which represented ten counties and 28 towns, the Acts of Supremacy and Uniformity were passed and recusancy fines were imposed. Outside Dublin the supporters of the established church were a handful, and it soon became clear that the old English were even more determinedly Catholic than the Irish. As loyal subjects their position was strong, and a constitutional resistance was successfully waged by the lawyer class, which was strong in the commons, the town corporations and even the government.

Ireland, with its feudal and Gaeiic lordships, was a standing offense to a centralizing monarchy, and to extend the shireland and introduce sheriffs, garrisons and English law became the avowed object of the government. But every such extension, which had to proceed piecemeal, met the opposition alike of the chiefs and the old English lords; the resistance of the Gaelic population was the more deadly of the two, for its military resources were greater, its native civilization was dearly cherished and its hatred of the Saxon was deeply rooted. The greatest of these captains, Shane O'Neill, was, in native eyes and almost in fact, king of Ulster. From the four counties, Tyrone, Derry, Armagh and Antrim, where he was overlord, his ambition was to rule the whole province, and after Matthew, baron of Dungannon, had fallen in an affray, and his son Hugh was taken to be educated with the earl of Leicester and in Elizabeth's court, Shane had the field to himself. He proceeded to subject O'Donnell on one hand and the Scots of Antrim on the other, and, having been invited to the English court in 1562, he so flattered the queen with his Irish tongue that he returned in triumph as "the lord O'Neill" When Sir Henry Sidney arrived as deputy in 1565 the power and influence of Shane overshadowed all Ireland, but in a rash attack on Hugh Duv (the Black) O'Donnell, chief of Tyrconnell, he was routed at Farsetmore, and, flying to his enemies, the MacDonnells, was murdered by them in 1567.

The Desmond *Wars.*—Desmond was an old English regality as Tyrone was a Gaelic state. The new earl, Gerald, was deeply suspicious of the "forward policy" which menaced his palatine authority. He and Thomas, earl of Ormonde, were hereditary enemies, and after a pitched battle at Affane, in 1564, they were summoned to London, where Desmond spent many years of semi-captivity till 1573. The Geraldines, therefore, took as captain the earl's cousin, James Fitzmaurice Fitzgerald, who planned a league which should defend at once the earl's liberties and the Catholic faith. Exclusion from office under the oath of supremacy alienated the Catholic English of the Pale. Catholic services were maintained by the friars while Jesuits and secular priests, trained in seminaries on the continent — later to grow into the Irish colleges in Spain, France and the Netherlands — returned to Ireland in increasing numbers. The bull of Pius V excommunicating Elizabeth and releasing her subjects from obedience gave sanction to rebellion. It was unfortunate that at such a time the government allowed Sir Peter Carew, a Devon gentleman, to get legal possession of wide lands in Carlow and Cork by virtue of very musty pedigrees. With him began the age of the adventurers and land speculators, the Raleighs and the rest, and old English and Irish felt that even their property was insecure. Fitzmaurice was accordingly able, in 1569, to kindle a widespread revolt in Munster and Leinster, which Sir Philip Sidney, Carew and Sir Humphrey Gilbert stamped out with a severity that set the note for future "pacifications." Fitzmaurice submitted in 1573.

Six years later he was the leader of a new war in Munster. The continental side of it was organized by the Spaniard Matthew de Oviedo, later titular archbishop of Dublin, but, though the pope offered spiritual assistance, Philip gave little or no material aid. and Fitzmaurice had only a small band with him when he landed in Kerry in 1579. With him was the English Jesuit Nicholas Sanders, who proclaimed a plenary indulgence for all who would fight against "Elizabeth, pretended queen of England." There was a widespread rising, but the only man who could have made it formidable disappeared when Fitzmaurice fell in a petty affair at Castleconnell. The earl himself was driven into rebellion, and 800 Italians, sent by the pope, were besieged at Smerwick by the deputy and, after surrender, pitilessly massacred. Desmond was

hunted down and killed and the south was pacified by the usual methods. Confiscation was thenceforth to follow the horrors of war, and while the earl and his chief followers were attainted, about 600,000 ac. were declared forfeit. In the end about 200,000 ac. were granted to newcomers like Sir Walter Raleigh.

Ireland was now so "pacified" that even in the year of the Armada it scarcely moved. Sir John Perrot, deputy from 1584 to 1588, encountered in the parliament of 1585 a strong and well-led Recusant party, but though Archbishop Adam Loftus urged enforcement of the penal laws, the astute and politic viceroy refused to test men's consciences. He mas empowered by this parliament to make, with the chiefs and gentry of the west, "the composition of Connaught," by which they were confirmed in their immediate demesnes with rents from the rest of their "countries" in lieu of feudal and Irish regalities, on condition that they serve in arms, pay rent to the crown and hold by English tenure. The result was that Connaught, under its Gaelic and Norman proprietors, remained, on the whole, loyal up to 1640.

The Tyrone War.—One of the last acts of Perrot was to have the young Red Hugh (Aodh Ruadh) O'Donnell kidnapped and sent to Dublin castle as a hostage for the loyalty of his father, Hugh Duv. The results were disastrous; up to now, the O'Donnells had been allies of the state, but the alliance was now shattered. After five years Red Hugh escaped to become the O'Donnell and the hero of Gaelic Ireland. Ulster was the last stronghold of the Celtic order which the state had determined to extirpate, and the northerners had always been the proudest and most warlike of the Irish. When, therefore, under the new shiring order, a sheriff was set over Fermanagh, it was not long before his firm methods drove Hugh Maguire into revolt, whereupon this chief was proclaimed traitor.

Red Hugh was naturally for Maguire, but it was uncertain what part Hugh O'Neill, now earl of Tyrone, would take. He, too, had to fear the extension of English order, which would menace his hereditary lordship; he resented the religious and civil oppression of his country, and when, finally, he threw in his lot with O'Donnell in 1594, the government had to face the greatest opponent and the most formidable rising it had yet met. Tyrone and O'Donnell talked mainly of their ancestral rights and of religious tolerance, but at the same time they wrote to Philip asking for 6,000 men and begging that an archduke might be sent as king.

Finally, the victory of the Yellow ford on the Blackwater, in Aug. 1598, over Sir Henry Bagenal, made O'Neill a hero of the Counter Reformation. While Red Hugh overran Connaught, Tyrone descended into Munster, the new colony vanished like a dream, and a league of Irish and old English, under James Fitzgerald, the so-called sugan (straw-rope) earl of Desmond, took the field (see FITZGERALD). In 1599 the earl of Essex went to Ireland with a large army but failed to restore order. In 1600 the insurgents throughout all Ireland were reckoned at nearly 20,000, but O'Neill knew they could not take cities or hold the sea without Spanish aid.

Charles Blount, Lord Mountjoy, finally proved the Scipio to the Irish Hannibal, and the tide was turned less by battles than by devastation and massacre. At last Don John d'Aquila arrived with 4,000 men, the Ulster chiefs marched to meet him, and the issue was decided at Kinsale. A rash attack by O'Donnell ended in the rout of the Irish; D'Aquila surrendered, O'Donnell, sailing to Spain for more aid, died there, and O'Neill cut his way back to the north. Finally he submitted to Mountjoy in April 1603, and going to court was pardoned and restored by the new monarch, James I, while Rory O'Donnell, brother of Hugh, was created earl of Tyrconnell. (See O'NEILL.)

With this fight Celtic and Norman Ireland passed. A new Irish nationality had emerged, Catholic by conviction, a blend of English and Irish in origin and, in the upper ranks, English-speaking. How to reconcile this with a Protestant government was the problem.

James I, 1603–25.—On the religious question the policy of James was a guarded toleration. The royal prerogative was still supreme, especially in Ireland, and a series of viceroys, such as Arthur, Lord Chichester (1605–IS), exercised it in the interests of that large majority which it seemed now almost hopeless to convert. The opposition of the Catholic party, led by the lords of the Pale and the lawyers, was constitutional and loyal; it was impossible to debar recusants from parliament, even if the oath of supremacy barred them from government, and in the older towns this party was so strong that up to 1624 every one had a Catholic mayor. Could James and this moderate element have had their way all might have been well, but the ultramontane spirit on one hand and the Puritan on the other made plain sailing difficult. The established church in Ireland was for strong measures, and, on the other hand, when James proposed a simple oath of allegiance for recusants, by which they should repudiate the supposed right of the papacy to depose heretic kings, two papal briefs in 1606 declared the proposed oath unlawful for Catholics.

There was also Roman Catholic opposition to the new university at Dublin, founded by Elizabeth in 1591. A centre of disinterested learning would have been a force for reconciliation, but that it was not so intended was generally understood; it was spoken of as "the college of the heretics near Dublin," and though at first there were no tests, Catholics preferred to seek education abroad. The statutes of Archbishop William Laud confined its advantages to members of the established church, and, though a few Catholics frequented it, disabling tests till 1793 barred them from fellowships and degrees. Trinity college became, however, an active centre of learning.

The Plantation of Ulster.—Though the earls of Tyrone and Tyrconnell had been restored in 1603, their new position was full of difficulties; Ulster was now shireland, subject to sheriffs and garrisons hateful to its ancient lords, and Tyrone, involved in disputes with bishops, officials, grantees and his former vassals, complained that strong forces at Dublin were against him. At last the aged chieftain resolved to quit the field. Whether he and O'Donnell were guilty of plots to raise a new rebellion cannot be proved. In Sept. 1607, along with Tyrconnell and nearly 100 more chiefs of the north, he left Ireland forever. The "flight of the earls" was a mortal blow to the Catholic interest and the old Gaelic tradition. Celtic Ulster was now to become the most British of the provinces, and the lament of the Four Masters over the passing of the earls is indeed the swan song of the Gaelic world. With these devoted scholars, who laid down their pens in 1616, were silenced also the voices of the Gaelic brehons, poets and historians, and by 1700 only the Irish language, which the gentry was then forsaking, remained a visible memorial of a world that went back 2,000 years.

A plantation of Ireland was now urged on the ground that, without a strong Protestant population, neither would the state be safe nor the state church have congregations. The earls and their adherents were found guilty of treason, and by legal processes six counties were declared escheated. By the final plan (1609) the escheated lands were divided between undertakers, servitors and natives. Undertakers, mainly English, were to lease only to English and Scottish tenants and to take the oath of supremacy. Servitors, mainly Scots, might take Irish tenants, but if so their rents to the crown were increased. Native Irish grantees were to pay quitrents twice as large as the undertakers, but need not take the oath. Of these a good number received grants of thousands of acres, and several junior branches of the O'Neills and Magennises, etc., survived as large landlords, though no longer as Irish chiefs. But the colonists entered upon the best lands, and the lesser ranks of Irish were reduced to the position of tenants at will, for Sir John Davies, the solicitor general, found, by a most iniquitous decision, that they had had no freehold rights under their attainted lords. The town of Derry was given to the City of London, and the London companies received grants which gave them practically all that county.

The practical success of the plantation was great, and for the first time a large part of Ireland was not merely owned by Saxon landlords but was tilled and farmed by Scottish and Protestant farmers. The Irish population was numerous in the mountainous parts, and its natural disaffection was kept alive by hopes that Tyrone or another would return, but on the surface, at least, the Irish seemed no longer a danger.

The success of the Ulster scheme led to plantations in north Wexford, Longford, Leitrim and eisewhere, where, though the natives were treated with more equity, again the object of the crown lawyers was to find that most of the Irish were not freeholders but tenants at will. The new English were dominant; adventurers and speculators such as Richard Boyle, earl of Cork, and other moneyed men displaced the old aristocracy; 39 new boroughs, carefully rigged, could be counted to cffset the old towns, and several of the old Irish, such as the earl of Thomond, had become Protestant.

In the parliament of 1613–15, summoned by Chichester to ratify the Ulster plantation, the government engineered a small majority, partly through the new close boroughs, but the minority could claim that it spoke for 21 counties and 28 ancient boroughs in this first general representation of the kingdom. After failing to get its choice as speaker, the opposition petitioned the crown, and James saw a deputation of old English peers and commoners who complained of religion, the new boroughs and the rigging of elections. James thoroughly enjoyed himself and declared, "What if I had created 40 noblemen and 400 boroughs?—the more the merrier," and, as regards religion, "the pope is your father in *spiritualibus* and I *in temporalibus* only; you are but half-subjects and therefore only entitled to half privileges." The upshot was that 11 boroughs were disfranchised; James spoke some fair words and continued the *laissez faire* policy on religion; and parliament voted a large subsidy. The recusants, though called "old English Irelandized," were, in fact, loyalists with a religious grievance, but they had their left wing, and this veered steadily toward armed protest. The continent of Europe was full of Irish exiled soldiers and priests, and among these both the old English and the old Irish had their heroes. In spite of its troubles, Ireland benefited economically from a period of peace. Agriculture recovered; the settlers brought in their skill and enterprise; and the manufactures started by men like the earl of Cork made Ireland something of an industrial country.

Charles I, 1625-49.—With the second Stuart came the idea of raising men and money in return for religious concessions. The deputy, Lord Falkland, was allowed to promise various concessions, known as "the graces," such as that Catholics might practise at the bar and that where land titles, like those of the Connaught gentry under the Composition of Connaught, were lacking in legal confirmation 60 years' possession was to be held good against the crown. From agents of the Catholic party Falkland secured a pledge of subsidies amounting to £120,000. But when the agents reached London they found a strong antipapist spirit there, under pressure of which Charles gave way. He dropped "the graces" but exacted the subsidies, though no parliament was called to ratify them.

To make Ireland first prosperous and then to use it in the royal interest against Puritan opposition was the idea of Thomas Wentworth, later earl of Strafford, viceroy from 1633 to 1640. He set himself to break the power of the great and the monopolists, making the Court of Castle Chamber into a star chamber for Ireland. While he wrested power from the anti-Irish clique in Dublin, he had no sympathy with Irish or Catholic complaints and looked on religious concessions merely as policy. Similarly, his aim in making Ireland rich and prosperous was that out of a surplus revenue he might enrich his royal master, and the first-rate army that he raised largely from Catholics and natives was destined, if need be, to serve in Britain. Among the strongest measures of this satrap were extracting subsidies of £50,000 from parliament and then denying all but the least important of "the graces"; forcing the juries of Connaught to find a title there for the king, with a view to a fresh plantation; and attacking the London companies. But the policy of "Thorough," as Strafford called it, ultimately failed, and when he was assailed in England all the interests he had offended in Ireland joined in the general impeachment that brought him to the scaffold in May 1641. His army was disbanded and the control of the government passed under Puritan lords justices.

A rising in Ulster was inevitable. The Irish there had local leaders of the old stock, such as Sir Phelim O'Neill, and still more abroad, where Owen Roe O'Neill, nephew of Tyrone, was in Spanish service. In the south the native party found a leader in Rory O'More, who planned a union of the old English, with their religious grievances, and the Irish who had lost vast estates. A plot to seize Dublin castle failed, but the rising in Ulster was general (Oct. 1641) and thousands of colonists were murdered, died of ill treatment or fled.

For the suppression of the Irish war the English parliament at once voted an army, but in order to find the money offered to the adventurers or subscribers of £1,000,000 the pledge of 2,500,000 ac. of profitable lands which were to be confiscated. Naturally, the dread of confiscation, coupled with a belief that the Puritans meant to extirpate their religion, drove more and more Irish to arms. A Catholic confederacy was formed at Kilkenny in May 1642 "to defend religion and the king against sectaries, and establish the Catholic religion as fully as at any time since Henry VII"; soon Richard Preston, earl of Desmond, and Owen Roe arrived from abroad, the first to lead the confederate armies, the second the Ulster forces.

The story of the next seven years is a complicated one. Though the confederation of Kilkenny organized a Catholic parliament and government, it did not succeed in welding together the parties of which it was composed. So while the Irish, whose chief figure was Owen Roe O'Neill, commanding an Ulster army, and the old English, supported by Preston, commanding a Leinster army, debated at Kilkenny, parliamentary armies operated in the north and south and Dublin was held by James, marquess of Ormonde, commanding an army of Protestant royalists. The confederation gained some recognition abroad, and in 1645 John Baptist Rinuccini, archbishop of Fermo, arrived as an accredited papal nuncio. Ormonde, who could count on some sympathy from the old English, sought to hold Ireland for the king and the Protestant interest by fomenting dissension among the confederates and by offering agreements on behalf of the king, which he had neither the power nor the intention of honouring. The nuncio used all his influence to hold the confederates together and to support the Irish, the stronger party, particularly after O'Neill had smashed the parliamentary army under Sir George Monroe at Benburb in 1647. By now the king's cause was already lost and Ormonde, preferring "to surrender Dublin to English rebels than to Irish ones," handed over the capital to Col. Michael Jones, the parliamentary commander, and left Ireland in 1647. After the execution of the king Ormonde returned to recover Dublin for the young Charles, but he was defeated by Jones. The papal nuncio left Ireland in Feb. 1649. O'Neill died in November. Oliver Cromwell's campaign of indiscriminate massacre broke the back of Irish resistance, though it lingered till 1652.

The Cromwellian Regime.—Ireland had been conquered by an English faction to which Irish Catholics were odious, and now it had to pay for its own conquest. Not only the adventurers but also the conquering army were to be paid in Irish land. Under the rule of Charles Fleetwood and by an act of settlement ten counties were appropriated to soldiers and adventurers. Later others were added. The English parliament, which disavowed any intention to "extirpate that whole nation," divided the population into ten classes, of which the first five were excepted from pardon for life or estate; even those who could prove their innocence and loyalty to the Commonwealth found it hard to retain more than a portion of their estates. But such a plan involved a removal of the occupiers, and by a scheme of transplantation the former landowners with their families and retainers were ordered to move into Connaught, where land was provided for them, generally though not always of inferior quality. The chief effect of the Cromwellian plantation was to impose a new English and Puritan landlordry on Ireland.

Charles II and James II, 1660–88.—The monarchy was restored in Ireland by the Cromwellians Roger Boyle, earl of Orrery (previously Lord Broghill) and Sir Charles Coote, and this gave the keynote to the resettlement. The Irish had lost all at the hands of sectaries and republicans and supposed that theirs would be the favoured side, but the real division was now between English and Irish, and Charles had to say to them, "My justice I must

afford to you all, but my favour must be placed upon my Protestant subjects." Ormonde as lord lieutenant made a great fight for his fellow countrymen, and finally by the English Act of Settlement the Cromwellian party consented to surrender one-third of the lands in dispute, but 5,000 claims were left unheard. Roughly, the old proprietors now held one-third of Ireland; in population the Catholics were about 800,000 to 150,000, but in the corporations, parliament and government they scarcely counted at this time. Much, however, was done to restore Catholics to the corporations, and their numbers and influence grew steadily. The popish plot of 1678 brought on a terrorism to which Archbishop Oliver Plunket fell a victim, but on the return of reason toleration was resumed and the Irish later looked back on Charles's reign as a golden age.

In James II Ireland found a king who could be trusted to restore the faith and might be induced to repeal the detested Act of Settlement. For more than a year the earl of Clarendon acted as viceroy, but his royal brother-in-law balanced him by Richard Talbot, whom he created earl of Tyrconnell, an Irishman and Catholic who first as lieutenant general and then as sole lord deputy increased and remodelled the Irish army, officered it with Catholics, secured the garrisons and admitted his coreligionists into the council, the corporations, the shrievalty and highest legal offices. Ireland for a time was truly a Catholic kingdom, and Tyrconnell planned an independent parliament to repeal at once the penal laws and the Act of Settlement. From the military point of view his mistake was in not securing Ulster, and so, when James's cause collapsed at the end of 1688, though a great Irish army was in the field, Derry, Enniskillen and other places became cities of refuge for a Protestant population ready to fight for William.

In March 1689 James himself landed from France, with officers, money and arms from Louis XIV, but no men. Catholic Ireland could provide these in plenty, but only on terms. When James, in May 1689, summoned what was practically a Catholic parliament to Dublin, he announced liberty of conscience for all and some relief for sufferers by the Act of Settlement, but parliament totally repealed the hated act and restored the heirs of those dispossessed since 1641. An act of attainder was passed which included about 2,400 persons supposed to be supporters of the prince of Orange. As for religion, Catholics and Protestants were to pay their tithes to their own clergy.

Settlement Under William III and Anne.—The successful stand and relief of Derry was a prelude to the wider operations in which first Marshal F. H. Schomberg and then William himself landed at the head of professional armies. On the other hand, a French force arrived to help the Irish. The battle of the Boyne was won and lost on July 1, 1690, and James returned to France, leaving the Irish to ruin themselves in his cause. At least the gallantry of Patrick Sarsfield and the heroic stand of Limerick illuminated the last fight of Catholic Ireland as a nation in arms. At Aughrim in July 1691 the issue long hung in the balance until the French commander, the marquis de Saint-Ruth, fell, and the Dutch general Godart van Ginkel, who was in command of the English forces, carried the hill. Tyrconnell died, and Sarsfield finally capitulated on terms at Limerick on Oct. 13. By the Articles of Limerick the Irish Catholics were guaranteed the religious liberty they had enjoyed under Charles II, and all officers in arms and those under their protection in the five western counties covered by the terms were to retain their estates and professions under a simple oath of allegiance "and no other." William was to have the terms ratified by parliament and do his best to get those who had been attainted restored to their estates; this latter clause was omitted in the signed articles but restored by William. Officers and men who would not take the allegiance oath might depart for France; 7.000 did so, and among the flower of the Irish aristocracy that sailed away was Sarsfield. William was a tolerant man and, after all, the Irish had but served the king de *jure;* but he now had to divide his prerogative with parliament, and, while he strove to keep the spirit of the treaty, the parliaments of both islands ratified it in less than the letter. Irish opinion has always called it "the violated treaty." The English Whigs meant to keep the Irish Protestants in the saddle, and a Test act of 1691 was extended to Ireland and excluded Catholics from the Dublin parliament. In 1697 this body ratified what remained of the treaty, but William had to drop the omitted clause and abandon the stand he had made for justice. Finally, in 1699, the English houses confirmed the settlement by which about 750,000 ac. passed to new owners. Thus the third conquest of Ireland within a century was achieved. The most illustrious names of the Irish nation disappeared from their country by attainder, death or voluntary exile. Those that remained owned only about a seventh of the soil. The middle classes suffered exclusion from the corporations, trades and professions, and the penal laws began with acts of the Dublin parliament in 1695 and 1698 which debarred conscientious Catholics from wearing arms, teaching publicly and practising the law.

English arms and statutes had given the Protestant ascendancy the title deeds of Ireland but at the cost of its own political and economic subjection. Under Charles II English acts had debarred Ireland from the colonial trade and prohibited the import of Irish cattle into England. Now an act of 1699 ruined the export trade in Irish woollens; Ireland retained the provision trade with Europe and America, and William encouraged the linen industry.

The Penal Laws.—The new ascendancy, full of memories of 1641 and 1689, was bent on treating the Jacobites like a beaten enemy. The land settlement as made under Charles II and William was final, and Catholic landowners had to keep what little they had and no more. The penal code, by which the majority was rendered powerless to rise again, was passed mainly in 1702–15. The acts that concerned the landowners forbade them to acquire freehold other than by inheritance or to take leases of more than 31 years at a crushing rent. By the Gavelling act if the eldest son conformed he succeeded to the whole estate; otherwise it was equally divided. This, more than anything else, served to extinguish this class, whose members either conformed or were impoverished by subdivision. The Catholics in general were barred from trades and professions, education, office (great or small), juries, the electoral vote, the right to arms and a horse.

Feeling against the Presbyterians of the north was hardly less strong in the Episcopalian ascendancy. A Test act was passed against them in 1703, but after the accession of George I the "Regium Donum" was restored to their ministers and a Toleration act allowed them to worship freely and hold petty offices. Though these Protestants were debarred from parliament and from the government of the country, their lot could not be compared in severity with that of the Catholics, with whom, however, they shared the grievance of riches paid to a church they both detested.

The Hanoverian **Succession.**—With the Hanoverian succession the last hopes of the Jacobites faded away. For the old Irish nation the next half-century was a time of oppression, despair and decay; the great exodus of the gentry and the more adventurous spirits to join the continental armies was balanced by emigration of the poorer Protestants ruined by heavy rents and the commercial acts. The penal laws steadily crushed the upper classes, and by 1780 about 4.000 of them had conformed. The old landlords had been the protectors of the Gaelic poets and scholars, and as they decayed or joined the ascendancy the old native culture declined, but a new group of poets took the place of the old aristocratic literati, using popular language and sharing the lives of the peasantry. Such histories as W. E. H. Lecky's, however excellent on Anglo-Ireland, fail to discern the strong current that ran, half underground, among the Gaelic-speaking people of poetic memories and hopes for a future in which now the Stuarts, now the French, would come over to restore "the Dark Rosaleen." Such feelings were not merely poetic; they were kept alive by unjust laws and what was perhaps the worst land system anywhere in Europe.

The Protestant ascendancy of Ireland now began to resent its political and economic subjection to English interests. The constitutional and legal benefits of the Glorious Revolution had not been extended to Ireland; while in England the sovereignty of parliament had been established, the Irish parliament was shackled by Poynings' law. Ministers were responsible only to England, and in 1719 by the Declaratory act the imperial parliament affirmed its right to legislate for the sister island. The Dublin legislature

became a mere dependency, hardly representative of even the Anglican minority.

How to keep Ireland at once dependent and secure was a question the imperial government solved for 50 years by putting power successively into the hands of such men as Archbishops Hugh Boulter and George Stone, both Englishmen, who managed the country in the English interest. The regime had its merits; government was cheaply run, the national debt kept low, and the surplus revenue was used to beautify Dublin and develop the country. Economic progress made itself visible, an influential class of rich Catholic merchants appeared, and the wane of Protestant bigotry on the one hand and the ultramontane spirit on the other made toleration possible.

The Patriot Movement.—A political party now appeared among the Protestants, inspired by John Locke, William Molyneux, Jonathan Swift and George Berkeley, which found its leaders in Henry Flood and Henry Grattan. On the other hand, the British government was ready to make concessions. The viceroy, Viscount Townshend (1767–72), was instructed to offer an octennial bill limiting the duration of parliament, and Lord Harcourt continued the policy with the purpose of procuring troops from Ireland for the war with America. After the defeat of the British at Saratoga (1777), the "restrictive acts" had to go; at the same time the imperial government encouraged the Irish Protestants to relax the penal code, and in 1778 Catholics were allowed on a simple form of oath drawn up by the Catholic association to inherit land and take leases like Protestants, while the Gavelling act was repealed. Events of the American Revolution put Ireland for the first time into Irish hands, those of the Protestant ascendancy, and 80.000 volunteers raised under Lord Charlemont boasted themselves "the armed property of the nation." Free trade with the colonies was won by Flood, and Grattan moved the famous declaration; "No power on earth but the king, lords and commons of Ireland is competent to bind Ireland." The volunteer convention at Dungannon emphasized these demands, and the view was general that without legislative autonomy there was no security for Irish rights. The imperial government gave way and an act of the Irish parliament was confirmed, amending Poynings' law and providing that bills duly enacted and sent to England should be returned without alteration under the great seal and receive the viceroy's assent. At the same time the Test act for Protestant dissenters was repealed, and by Luke Gardiner's Relief bill of 1782 Catholics were allowed to purchase lands freely and have their own schools.

The Irish Constitution, 1782–1800.—The constitution of 1782 was completed by the Renunciation act of the next year, by which England admitted the claim of the people of Ireland to be bound only by their own laws and courts. But Irish ministers were still appointed by and were responsible to the imperial authority; they could not be turned out by vote of the majority, and though John Fitzgibbon (later Lord Clare) and the rest were Irishmen, Grattan, Flood and their party remained a mere opposition, and legislative autonomy without responsible government and electoral reform proved vain.

Popular support was needed for the new constitution and Flood and Charlemont sought it in a more representative parliament still confined to Protestants, while Grattan aimed at an extension of the franchise to Catholics and the admission of their gentry to parliament. But both were thwarted by the narrow clique which under Fitzgibbon controlled the government and resisted pressure alike from Ireland and England. William Pitt's failure to carry a commercial treaty and the Regency dispute emphasized the difficulties created by the constitution, but it might have survived long (for Ireland as a result of commercial freedom, bounties and John Foster's corn law was progressing rapidly in wealth. manufactures and agriculture) had not the war with France brought on a situation which grew ever tenser. French principles spread among the Presbyterians, the Catholic association passed into the hands of bold politicians, and agrarian discontent vented itself in the Defenders, a Catholic society formed in opposition to the Peep-of-Day Boys (*q.v.*). Clare held that either the Protestant ascendancy must remain intact or give way to a union, for general enfranchisement would fill parliament with disloyal dissenters and Catholics and imperil the imperial connection. The British government preferred Catholic relief to reform, but finally, faced with the question of how to hold Ireland against the French menace, Pitt chose to buttress up the unreformed Irish house which Clare and John Beresford could "manage," and after 1798 decided on a union. The approaching crisis was accentuated in 1795 when, after British pressure had compelled the Irish government in 1793 to admit Catholics to the electoral franchise, the viceroy, Lord Fitzwilliam, failed to carry final emancipation and to break the Clare-Beresford junta. The Society of United Irishmen, formed originally by Theobald Wolfe Tone on constitutional lines, now became revolutionary and entered into negotiations with France for an Irish republic, while the founding of the Orange society intensified the religious feud. Insurrection acts and the suspension of *habeas corpus* bridled a country which was becoming an armed camp, and the peril of a French invasion had to be faced. The Brest expedition of 1796–97 had failed to land troops at Bantry bay, but Tone still hoped for foreign aid, and a determined French invasion would undoubtedly have set Ireland ablaze. The Ulster Presbyterians were more feared by the authorities than was the Catholic south, and when in 1797 Gen. Gerard Lake "disarmed the north" by the most savage methods the back of a national rising was broken. The military forces were small, but 30,000 yeomanry led by the gentry sufficed to break the rebellion when it came. It was but a partial one, for the government had seized the leaders, and though June 1798 witnessed a Presbyterian rising in Down and Antrim and a far more dangerous one of the Catholic peasantry in Wexford, both failed, and Tone, who was on board the "Hoche," surrendered with it and ended his life by his own hand in prison. (*See* TONE, THEOBALD WOLFE.)

After this the union was inevitable. Many of the ascendancy became convinced that only such a measure could maintain them in power over the Catholic majority; the Presbyterians were disillusioned by the events of the rebellion, and the Catholic population had been cowed into submission. Pitt and his Irish agents, Clare, Viscount Castlereagh and Lord Cornwallis, had effective arguments for all—the Catholics could only be sure of emancipation from the imperial assembly, only union could save the Protestant establishment, and free trade would compensate the commercial classes. Several Catholic bishops declared for union in the inspired belief that emancipation would follow it, but it is very doubtful how far they spoke for their whole people. There was little to fear from the Irish parliament, where the majority was corrupt and unrepresentative, where the ministry could survive defeat after defeat and where patronage and bribery were at the government's disposal. Grattan and the poor remnant of the patriots made a brave fight, but the union became law by acts of both parliaments in May 1800.

Thus ended the patriot parliament. The ascendancy, for which it spoke exclusively, had been created by the revolutions of the 17th century. It had ruthlessly exploited the helpless Catholic population in the interests of a small Protestant minority. Yet in the later stages at least it produced men of ability and generosity who identified themselves with the country of their adoption and strove to temper the harsh lot of its people. Dublin's Georgian buildings, beautiful even in decay, are a monument to the 18th-century ascendancy. (E. Cu.; U. G. F.)

THE UNION (1800-1921)

Resistance to Pitt's campaign for a legislative union had been so strong in the Irish parliament that the measure was carried only by the undisguised purchase of votes, either by cash or by the bestowal of honours. But opposition to it among the landowners and the lawyers did not last long, and after a few years the agitation for a repeal of the union was being generally opposed, even by those who had protested vehemently against the extinction of the Irish parliament. On the other hand, the support for the union which Pitt and Castlereagh had gained from most of the leading Catholics was quickly lost. Bishop Francis Moylan and others had used their great influence on behalf of the union, in expectation that Pitt would redeem his promise to introduce

Catholic emancipation at once by an act of the joint legislature in London. The Catholics had already gained important concessions since the establishment in 1795 of the Royal Catholic college at Maynooth as a national seminary for training Irish priests. They could no longer be educated in France and the Low Countries, since the Irish colleges there, which had kept the Catholic Church supplied with priests for generations, had been suppressed under the penal laws by the Revolution. The bishops had been appalled by the antireligious campaign in France. and they had also seen the Irish regiments of the French army disbanded, their officers enlisting in other armies to fight against revolutionary France. Pitt had not only endowed Maynooth but had given active help to the French clergy who escaped from imminent danger of death. He had promised to admit the Irish Catholics to full civic rights, which the ascendancy in Dublin had persistently denied to them; and they had little sentimental regard for the Irish parliament, which was determined to uphold Protestant domination.

But Pitt's failure to carry out his promises produced a sense of betrayal and humiliation, and the Catholic Church had no further sympathy with the new experiment. Wolfe Tone's attempts to bring a French expeditionary force to assist a national uprising had been actively opposed by the Catholic bishops, who dreaded revolutionary ideas. But Robert Emmet's abortive rising in Dublin in 1803, though it had much less chance of success and was little more than a local riot, had a stronger sentimental appeal. The promised emancipation of the Catholics had been withheld because the king considered that their admission to parliament would be a violation of his coronation oath. Pitt had resigned the premiership as a gesture of loyalty to his promises, but he soon returned to office and refused to raise the Catholic question again.

Economic Effects of Union. — While the hopes of the Irish Catholics had thus been defeated, the economic and social consequences of the union for Ireland were soon found to be disastrous. Dublin ceased to be the metropolis in which the landowners had their town houses and their lavish social life. Many activities that had been connected with the Irish parliament either ceased or languished when London became the political and social centre. The most gifted and most public-spirited members of the community who were still elected to parliament now had to spend most of their time in London, while those who were no longer legislators soon tended to become absentee landlords. Trade and industry declined rapidly, especially in Dublin, and the sudden increase of absenteeism had an unexpected effect upon Irish agriculture when prices rose abnormally during the Napoleonic wars.

Ireland's population in 1800 was 4,500,000. Of these, fewer than 500,000 were Protestants and about 900,000 were dissenters, who were chiefly in the eastern half of Ulster. Almost all the landowning class was Protestant, and Catholics had not been allowed even to buy land until the recent relaxation of the penal laws. The great majority of the 3,150,000 Catholics were either labourers or tenant farmers who held their land on short leases without any security of tenure or protection against increase of rents if they improved their holdings. When the landlords became absentees, they left their estates in the hands of agents who had no social responsibility and were concerned only with extorting the utmost profit from the land. A swift rise of prices during the Napoleonic wars made it more profitable to multiply the smallholdings. by dividing the estates, and so increase the rent rolls.

With no alternative occupation the competition for smallholdings was extremely keen, and the landlords were not required to provide farm buildings or even cottages. Any young labourer who could build a miserable hut for himself could therefore attain at once all that could be expected by any tenant farmer. While high prices continued, the subdivision of farms increased everywhere, with rents steadily rising and no outlay of capital on improvements. There was no inducement to delay marriage until later in life, and the population rose very rapidly with young marriages and large families. The standard of living was miserably low. On smallholdings of less than ten acres it was scarcely possible to grow an3 crops other than potatoes, which provided the only food for a whole family throughout the year. Even milk and butter were luxuries seldom seen. Any small crops of grain had to be sold to pay rent and tithes which were exacted regularly; and the few cattle or pigs which could be kept on the little holdings were the chief source from which such payments had to be met.

Catholic Emancipation. — The Catholic peasantry and labourers, who formed the bulk of the population, suffered acutely when prices fell after the Napoleonic wars. Dublin declined rapidly after the extinction of the Irish parliament, and many industries in all parts of the country decayed. But a new Catholic middle class was slowly emerging, since the mitigation of the penal laws. Education was no longer forbidden, and churches could be built without breach of the law. There were no Catholic secondary schools, however, and the merchants and others who had formerly sent their sons to school in France now sent them to the few Catholic colleges which had been opened in England, since they found refuge there from the Revolution. Catholics were already admitted to Trinity college, Dublin, and they could now become lawyers and doctors. The young barristers who had benefited from these new advantages became the most active leaders of the demand for full civic rights.

Among them was Daniel O'Connell, who had been at school in Douai until the French Revolution and had completed his legal training in London. One of his uncles, Gen. Count Daniel O'Connell, had been the last colonel of the now disbanded Irish brigade in France, and Daniel had been brought up in County Kerry by another uncle who had for years conducted a flourishing contraband trade with the continent but had now become a loyal supporter of government since the Revolution. Among the young Catholic barristers who infused new life into the Catholic committee, Daniel O'Connell soon displayed outstanding gifts of popular leadership and great courage in asserting the Catholic claims. He had imbibed the new doctrines of democracy and equality and also the nationalism which had spread since the French Revolution. His attempts to revive and broaden the agitation for Catholic rights brought him into collision with Dublin castle, but he showed great skill in confining his agitation to strictly constitutional demands. By exploiting his legal rights as a defending counsel, he converted the law courts into a platform for political agitation.

Grattan had continued at Westminster to press for Catholic emancipation, but he and other Protestant reformers were prepared to make concessions which O'Connell as a fervent Catholic would not accept. Sympathy with the Catholic grievances was widespread in England, and by 1815, when O'Connell had created a really formidable popular agitation in Ireland, emancipation probably would have been carried in the house of commons if the Catholics had agreed to a government veto upon the appointment of Catholic bishops. But O'Connell objected so vehemently to any government interference with religious matters that he preferred to allow his agitation to collapse. His nationalism also was so intense that he regarded repeal of the union as being more important than Catholic emancipation, which he knew that an Irish parliament must concede. His defiant methods and his democratic claims aroused alarm among the Protestant landowners who had formerly resisted the union but now feared that an Irish parliament would be overwhelmed by a Catholic majority.

O'Connell's personal magnetism and his unrivalled success as an advocate had brought new energy to the popular movement. In 1823 he revived the Catholic agitation, with the help of some brilliant younger leaders, by forming a Catholic association which was financed by subscriptions of a penny a month. A concerted revolt against payment of tithes to the established Church of Ireland was developing widely, and the demand for emancipation assumed a wider aspect, with O'Connell as the national leader asserting the people's rights against an oppressive system. Although sympathy with the Catholic claims was now widespread in England, King George IV refused to allow the question to be raised. In 1826 the peasantry in Waterford showed its independence by voting against the powerful Beresford family on its own domain. In 1828 O'Connell himself stood for Clare, as a Catholic who would not take his seat until the anti-Catholic oath was

abolished. His triumphant election compelled the duke of Wellington and Sir Robert Peel to carry the Emancipation act of 1829, which admitted Catholics to parliament and to most public offices.

Demand for Repeal of the Union. — When the Whigs had obtained power soon afterward, O'Connell attempted to agitate by similar methods of mass meetings and popular organization for repeal of the union. His efforts were defeated by vigorous repression, and for about ten years he gave the Whigs a chance to fulfil their promises of enlightened reforms. But the house of commons had neither the time nor the knowledge to attend to Irish problems, which required drastic remedies, and the ascendancy still controlled Dublin castle and kept Catholics out of almost every office. Property, as well as land, was still mainly in Protestant hands, and the Catholic population was more impoverished than ever, while its numbers continued to expand. By 1841 there were about 8,200,000 people in Ireland, and the increase had been chiefly in all the overcrowded and infertile counties of the west. Destitution had become so prevalent that landowners were already doing their utmost to encourage emigration and to reduce the number of holdings.

After a decade of disappointment O'Connell derided to revive the repeal agitation in 1840. It came to life swiftly when the Young Ireland leaders, Gavan Duffy and Thomas Osborne Davis, founded the weekly newspaper the Nation and threw their energies into organizing monster meetings in all parts of Ireland. Action in parliament was disregarded, while the popular demonstrations assumed a more definite character. A climax was reached in Oct. 1843 when Feel mobilized troops and artillery to suppress the monster meeting arranged at Clontarf, outside Dublin. O'Connell and the principal leaders were tried for seditious conspiracy and imprisoned, but were soon released after an appeal to the house of lords. O'Connell's method of popular agitation within the law had proved unavailing, and his strength was now broken by age and the disease which caused his death in 1847.

The Great Famine. — The younger leaders demanded a bolder policy of revolt, and open friction between O'Connell and the Young Ireland movement had developed before the country was suddenly confronted by national famine in 1846. The potato crop, which was as indispensable to the people as rice in India, failed everywhere as a result of the blight, which was still an unknown disease. In 1846 and 1847 the blight was more general and devastating, and, with typhus following upon famine, vast numbers died. Emigration became the sole hope of escape, and there was a catastrophic decline of population. Every little farm had to support a family, but without potatoes the people could not survive. Out of less than 700,000 holdings, about 300,000 were smaller than 3 ac. and another 250,000 were between 3 and 15 ac. Attempts to relieve the universal distress were ineffective. Large supplies of maize were imported by the government and by charitable agencies, and many temporary schemes of relief work were organized to provide employment. Subscriptions poured in from the United States and other countries. But emigration was the chief escape from death by starvation and pestilence, and the population, which had risen to about 8,500,000 by 1845, had fallen by 1851 to 6,550,000.

O'Connell's cautious policy after his release in 1844 had made the Young Ireland leaders restless, while the popular agitation died down. The great famine intensified their conviction that unless the union was repealed there could be no constructive improvement. There was now a much wider difference between the economic conditions and needs of the two countries, and Irish needs were overridden or ignored, even when famine was depopulating the country. Young Ireland demanded that the export of grain and cattle should be forbidden while the people starved, and that the state should finance new industries and railaays to give employment. But these demands conflicted with the sacred principles of free trade and private enterprise, and the house of commons generally ascribed Irish misery to the results of political agitation. In desperation the Young Ireland leaders began preparations for an armed rising to achieve national government. They were encouraged by the bloodless revolution in Paris which overthrew Louis Fhilippe early in 1848. But the government forced a premature outbreak in June, and the leaders were either deported as convicts to Tasmania or escaped to the United States.

Rise of **Fenianism.**—For about 20 years after the great famine, political agitation was subdued, while emigration continued to reduce the population every year. The landowners had also suffered severely from inability to collect rents, and there was a wholesale transfer of estates to new owners. Their first concern was to reduce the number of smallholdings and to substitute grazing for tillage on larger, consolidated farms. Evictions were widespread, and cottages were burned down at once by the landlords to prevent other impoverished tenants from occupying them. The flow of emigrants to the United States was now encouraged by invitations from relatives and friends who were already there. And in England, also, the new industrial cities and shipping centres attracted large settlements of hopeless and embittered exiles from Ireland. Among them, both in the United States and in England, the Fenian movement spread widely as a secret revolutionary society which aimed at securing Ireland's political freedom by exploiting every opportunity to injure English interests. Fenianism became a serious menace when it was reinforced by many Irish-Americans who had served on both sides in the American Civil War. W. E. Gladstone at last recognized the necessity for drastic Irish reforms, and in 1869 he disestablished the Protestant Church in Ireland. The next year he introduced the first Irish Land act which conceded the principles of secure tenure and compensation for improvements. In 1870 the Home Rule association was founded by Isaac Butt, a prominent Unionist lawyer who had been converted by the famine experience to the necessity for Irish self-government.
