The right of petitioning the crown was recognized indirectly as early as Magna Carta in the famous clause. *Nulli vendemus, nulli negabimus aut differemus, rectum vel justitiam* ("To no one will we sell, to no one will we deny or delay, right or justice" art. 40.), and directly at various later periods, *e.g.*, in the articles of the house of commons assented to by Henry IV, by which the king was to assign two days in the week for petitions *(Rot. Parl.* 8 Hen. IV, p. 585). The case of the seven bishops in 1688 confirmed the right, and finally the Bill of Rights in 1689 declared "that it is the right of the subjects to petition the king. and all commitments and prosecutions for such petitioning are illegal." At first, petitions to the crown appear to have been for the redress of private and local grievances, or for remedies which the courts of law could not grant (Erskine May. *Parl. Pr.,* 11th ed., p. 532). As equity grew into a system, petitions of this kind not seeking legislative remedies tended to become superseded by bills in chancery. Statutes were originally drawn up by the judges at the close of the session of parliament from the petitions of the commons and the answers of the crown. Under this system of drafting, it was found that the tenor of the petition and answer were not always stated correctly. To obviate this inconvenience, demands for legislation came in the reign of Henry VI to be drawn up in the form of bills which the crown could accept or reject, but could not alter. *(See* W. R. Anson. *The* Law *and Custom of the Constitution,* 1886). In the same reign. the words "by authority of parliament" were added to the words of enactment, and from the time of Henry VII public legislation has been by bill and not by petition. The right to petition is thus closely interwoven with the history of parliamentary legislation.

Petitions to either house of the legislature seem to have been later in origin than petitions to the crown. They are not referred to in the Bill of Rights, but the right of petition is a convention of the constitution. Petitions to the house of lords or the whole parliament can be traced back to Henry III. No petition to the commons has been found earlier than Richard II, but from the time of Henry IV petitions to the commons have been freely made.

The political importance of petitioning dates 'from about the reign of Charles I. The development of the practice of petitioning had proceeded so far in the reign of Charles II as to lead to the passing in 1661 of an act (13 Car. II St. 1 c. 5) against "tumultuous petitioning." It provided that no petition or address should be presented to the king or either house of parliament by more than 10 persons; nor should anyone procure more than 20 persons to consent or set their hands to any petition for alteration of matters established by law in church or state, unless with the previous order of three justices of the county or the major part of the grand jury.

Up to 1688, petitions to either house usually dealt only with some specific grievance. From that time dates the practice of petitioning with regard to general measures of public policy. Petitioning as a device of political agitation became very common in the later 18th century, and afforded a basis for radical organizations seeking parliamentary reform. The number of petitions presented annually increased 2j-fold between 1780 and 1830, and culminated in the monster petitions for electoral reform in 1830–32 and the great Chartist petitions of 1839, 1842 and 1848. *(See* CHARTISM.)

In modern conditions, the presentation of public petitions plays little effective part in parliamentary affairs. Most fail to conform to the very strict tests of technical validity. Petitions to the houses of lords or commons must be framed in the form prescribed by the standing orders, must be properly superscribed and must conclude with a prayer. Petitions to the commons must be in writing, must contain none but genuine signatures and must be free from disrespectful language or imputations upon any tribunal or constituted authority. They must be presented by a member of the house, except petitions to the house of commons from the corporation of London. which may be presented at the

bar by the sheriffs. The rules as to petitions to the house of lords are similar. Applications for leave to bring before either house bills for private or local and personal matters must under the standing orders of both houses be made by petition. and the same rule obtains as to applications for leave to be heard in opposition to such bills. *See* PETITION OF RIGHT; PRIVY COUNCIL, JUDICIAL COMMITTEE OF; REPRESENTATION.

United States.—The right under the 1st amendment to the U.S. constitution to petition the government for redress of grievances is one of the basic guarantees of U.S. liberty, being closely associated historically with freedom of assembly. The political theory of the American Revolutionary era emphasized strongly that the colonists were entitled to all the historic guarantees of English liberty. As one such right, freedom of petition found its way into several of the state constitutions drafted in the Revolutionary period; while Thomas Jefferson in the Declaration of Independence significantly listed the flouting of "petitions for redress" as a major grievance against the British king. In 1789. the 1st congress incorporated the right of petition. along with freedom of religion. press. speech and assembly. in the first of a series of proposed amendments submitted to the states. Ratification of the 1st amendment thus made freedom of petition an integral part of the so-called federal Bill of Rights. *(See* also BILL OF RIGHTS. UNITED STATES; CIVIL LIBERTIES.) Thereafter, virtually all the states incorporated guarantees of petition in their own constitutions.

The right to petition has been exercised constantly in U.S. political life. both congress and the various state legislatures having well-defined procedures for receiving, tabling or referring materials of this kind. Virtually the only constitutional argument of consequence involving petition occurred when the national house of representatives in 1836 adopted a so-called "gag rule" against the receipt of abolitionist petitions condemning the institution of slavery. Antislavery Whigs under the leadership of John Quincy Adams thereafter attacked the "gag rule" *(see* GAG Laws) as a violation of the right of petition as guaranteed in the 1st amendment and finally forced its repeal in 1844.

See G. H. Barnes, *The Antislavery Impulse, 1830–1844* (1933); Samuel F. Bemis, *John Quincy Adams and the Union* (1956).
(A. H. K.)

PETITION OF RIGHT. This term is now specifically appropriated in English law to the peculiar procedure by which a subject may sue the crown. At common lam the crown—a term which is. in constitutional law, merely an abstraction for the king in his official capacity—could not be sued in the king's courts: the king was, historically, the supreme lord of those courts, administering justice therein between his subjects, and as the supreme lord he was not amenable to their jurisdiction. His writs could not run against himself. Hence a practice arose. uhere a subject's real or personal property had come into the possession of the king or his servants without legal title. for the subject to "petition" the king in council praying for its restoration. The king then might or might not in his discretion. refer the suppliant's petition to one of his courts, usually the old court of exchequer, with a writ directing the judges to do what is just. Although the procedure of petition of right has now been regulated by statute, the discretion of the king, or rather of his ministers, is still absolute and no one can sue the crown directly except by the crown's grace and favour.

Originally the scope of a petition of right was confined to issues of fact. Where the subject relied on some title appearing by record, such as letters patent issued by the crown. he could proceed by what was known as a *monstrans de droit* or "manifestation of right." Another method, known as a traverse of inquest of office, allowed a subject in certain cases, such as escheat or forfeiture, to challenge the king's title to land or chattels These antiquities are of little importance today in vieu of the Petition of Right act, sometimes known as Bovill's act, of 1861

The Petition of Right act (1861) creates no right nor abolishes any prerogatives. It merely regulates procedure, providing that anyone seeking to sue the crown shall file a petition, in effect a statement of claim, with the home secretary, who invariably refers it to the attorney general for advice. If he advises that there is substantial "cause of action," the home secretary endorses it with his *fiat.* If he refuses it, the subject is without remedy. The discretion of the secretary of state is absolute. In practice the *fiat* is rarely refused, unless the claim appears purely frivolous.

Once the *fiat* is granted, the proceedings are like an ordinary action between subject and subject. The crown must enter an appearance within 28 days. It can, however, avail itself of many prerogatives in practice and pleading at the expense of the subject, most importantly the prerogative as to "Discovery," succinctly expressed "The law is that the Cromn is entitled to full discovery, and that the subject as against the Crown is not." This means that the suppliant cannot, as in an ordinary action between subject and subject, compel the other party, *i.e.,* the crown, to produce for inspection documents which may be essential to prove his case. So too with "amendment.!' The crown may amend its answer to any extent but the subject cannot amend his petition with the same freedom as a plaintifi may amend his pleadings in an ordinary action. Furthermore the crown may claim "privilege" in respect of any attempt by the suppliant to compel a witness to disclose "matter of state." though this prerogative is not peculiar to procedure by petition of right. In all these respects the crown has an immense advantage over the suppliant. On the other hand, the suppliant has one great advantage, nhich the plaintiff in an ordinary action does not possess. in that his claim cannot be barred by the cronn pleading the Statute of Limitation of 21 James I by which statute action of contract must be brought within six years Another peculiarity of proceedings by petition of right is that the subject cannot demand. as of right. trial by jury even where. had it been an action between subject and subject, he might have done so. The suppliant, if successful. is entitled to his costs; if unsuccessful. he is liable to pay the costs of the crown. a statutory exception to the common-law rule that it is "beneath the dignity" of the crown either to pay costs or to receive them.

Judgment is given in the ordinary way. But the "execution" of the judgment is quite another matter. The courts cannot decree execution against the crown and its servants. The act of 1861 provides, however, that, where judgment is in favour of the suppliant. it shall be "certified" by the court to the treasury which shall then satisfy it out of the public funds.

Scope of the Remedy.—For a long time it appears to have been held. although the matter is not free from doubt, that the remedy would only lie to recover possession of real or personal property in the hands of the crown. But in the leading case of *Thomas* v. *the Queen* (1874) 44 L.J.Q.B. 9, the courts held that a petition of right would lie for unliquidated damages for breach of contract. It has since been held that it will also lie for the recovery of duty overpaid to the revenue authorities (*In re Nathan,* 1884. *12* Q.B.D. 461), for compensation for the requisitioning of premises for national defense *(The De Keyser Case,* 1920. A. *C.* 508), and for such "implied contracts" as "Quantum Meruit" and "Money had and received." Petition of right will, however, never lie to enforce a contract or service with the crown, whether civil or military, for it is the crown's prerogative to determine such contracts at its pleasure *(see* PREROGATIVE).

On the other hand, the scope of the remedy is subject to considerable limitations of which the most important is the exclusion of any redress against the crown for "wrongful." *i.e.,* tortious acts such as. for example, negligence, trespass or the infringement of a patent. The only remedy open to the subject in such a case is to sue. in an ordinary action. the particular officer of the crown nho was responsible for the wrongful act or omission. The subject is far better protected in France and Germany. under whose law the state is responsible, and can be sued in the ordinary way for the torts of its servants. Moreover. in England the rule of *respondeat superior* by which a person wronged can sue the employer, whether an individual. a partnership or a company, for the wrongful acts of his servants does not apply in the case of

torts committed by the servant of a governmental department. In such a case not only can the crown not be sued but neither can one sue the immediate superior of the servant committing the wrongful act The postmaster general, for example, is not liable for the negligence of a post-office engineer. Further, the servant of the crown, although personally liable. was given the advantage. as against the plaintiff. of a "Statute of Limitations" of a very peculiar and invidious kind, knoun as the Public Authorities Protection act of 1893, which required all actions for tort against "public authorities," including servants of the crown as well as local authorities to be brought not. as in the case of an action between subject and subject, in six years but in six months. And if plaintiff was a day too late in bringing his action, he not only lost it but was subjected by the act to penalties, in the matter of special costs, not known to the common law.

Reform. — The decision of the courts in the famous case of *Dyson* v. *the Attorney-General* (1911) 1 *K.B.* 410 that a subject might apply directly to the courts, without recourse to a petition of right, for a '(declaration," *i.e.*, a "declaratory judgment," as to whether the crown was illegally invading his rights (in that case the question was whether the plaintiff was bound, under penalty, to answer certain questions contained in "forms" issued by the revenue authorities), and that the courts could declare the action of the crown illegal, was a great victory for the rights of the subject. But that decision was specifically made subject to the qualification that no such declaration could issue where the proper remedy was by petition of right. The advocates of reform of the law therefore directed their agitation to two things: (I) that the subject should no longer be dependent on the grace of the executive where he conceives himself to have what amounts to a cause of action against the cronn. but should be enabled to sue the crown in the same way as he can sue a fellow subject; (2) that the crown. thus made directly suable, should be liable in tort. In some of the commonwealth countries, most notably in Australia, this reform was effected by statute. In Scotland the law is equally enlightened.

See H. Morgan, *Remedies Against the Crown (1926).* (J. H. Mo.; X.)

PROCEEDINGS AGAINST THE STATE IN THE UNITED STATES

The rule that the sovereign was immune from suit at the hands of the private citizen is an accepted principle of U.S. law. Both the federal government and the states, whose sovereignty had not been surrendered to the national government, were clothed with this immunity. The constitution authorized the supreme court to take original jurisdiction in all cases "in which a State shall be a Party." and in 1793 the supreme court in *Chisholm* v. *Georgia,* (2 Dall. 419), held that it could take cognizance of a suit by a citizen against a state. This decision, contrary to the general expectation of the framers of the constitution, so aroused the nation that in 1798 the 11th amendment to the constitution was adopted which re-established the original theory that the states were immune from suit by private citizens. No such procedure as the petition of right was known to American law. Claimants against the United States were originally referred to auditors of various governmental departments and, in the event of unsatisfactory treatment, were obliged to petition congress. Such petitions were ordinarily disposed of before committees, which might recommend a pecuniary grant from congress. In a few instances congress by special legislation authorized suit to be brought against the government and the claims would be adjudicated in the courts. The unsatisfactory character of this method of dealing with claims against the government led in 1855 to the establishment of the court of claims. At first the court was simply authorized to hear claims and by appropriate bills refer them to congress for payment. In 1863 the court was authorized to give judgments subject to revision by- the secretary of the treasury. The secretary was shortly thereafter deprived of this power and the court is now empowered to render final judgments against the United States subject to an appeal to the supreme court. The jurisdiction of the court of claims illustrates that in the United States suits against the government are governed by much the same principle as that underlying the English procedure by petitions of right.

A few of the states have established courts of claims upon the model of the C.S. court of claims, but in most states the procedure of enforcing claims against the state government is by petitioning the legislature. (J. M. LA.; X.)

PETITOT, JEAN (1607–1691), French-Swiss painter of miniature portraits in enamel, was born in Geneva, the son of the sculptor Faulle Petitot. He was apprenticed to a jeweler from 1622 to 1626, but about 1633 he went to France, and there probably became the pupil of Jean and Henri Toutin, the originators of the art of painting miniature portraits in enamel. In or before 1637 Petitot went to England. where he was patronized by Charles I and his court; a handful of miniatures are known from this period, all copies of portraits by Sir Anthony Van Dyck. Petitot formed high expectations of his stay in England but the Civil War disappointed his hopes, and he returned to France. There he enjoyed for many years the patronage of Louis XIV and his courtiers. A complete catalogue of Petitot's enamels would comprise many authentic portraits of the king, his family and the most celebrated figures in his entourage, the majority based upon paintings by fashionable artists. Petitot worked in partnership with Jacques Bordier until the latter's death in 1684. On the revocation of the Edict of Nantes in 1685. Petitot, as a Protestant, was imprisoned until, worn out by fever and old age, he signed a recantation. In 1687 he was allowed to return to Geneva and was received back into the Reformed Church. He died at Vevey, Switz., in 1691.

Although priority in the discovery of the art of painting enamel miniature portraits belongs to the Toutins, it was Petitot who by his incomparable facility raised the art to a pitch never surpassed. While relying primarily on original portraits by others, he preserved to a remarkable degree the character of the presentation which he was transforming into a small jewellike roundel. The most important collections of his works are in the Victoria and Albert museum, London, and the Louvre, Paris. His style, much imitated in his own time. called into being a vast number of 18th- and 19th-century copies or imitations. Petitot's journal gives many details about his life.

His son JEAN LOUIS PETITOT (1653–after 1699) painted portrait enamels in a style closely resembling his father's. (G. Rs.; X.)

PETITS CHEVAUX (Fr. for "little horses"), a gambling game played with a mechanical device consisting of a board perforated with a number of concentric circular slits, in which revolve. each independently on its own axis, figures of jockeys on horseback, distinguished by numbers or colours. The bystanders having staked their money according to their choice on a board marked in divisions for this purpose, the horses are started revolving rapidly together by means of mechanism attached to the board, and the horse which stops nearest a marked goal wins, every player who has staked on that horse receiving so many times his stake.

Figures of railway trains and other objects sometimes take the place of horses.

PETN (pentaerythrityl tetranitrate, $C_5H_8N_4O_{12}$; pentrite) was first prepared by L. Vignon and F. Gerin in 1901, but was not in systematic use prior to World War II. It is a powerful and sensitive high explosive. Its structural formula is $C(CH_2ONO_2)_4$. The manufacture involves the nitration of pentaerythritol with concentrated nitric acid and a subsequent washing to eliminate acid. Pentaerythritol, $C(CH_2OH)_4$, is synthesized by the reaction of acetaldehyde with formaldehyde, catalyzed by calcium oxide. PETN is a white crystalline powder, melting point 139° C.. specific gravity 1.7;. It is insoluble in water but is soluble in acetone and several other organic solvents. It finds use as an ingredient of detonators (*q.v.*) and as the charge of the detonating fuze Primacord; for use as a bursting charge of military devices it is usually mixed with other ingredients, largely T.N.T., to reduce its sensitivity to percussion and to make it suitable for loading by casting. *See* DETONATORS ; EXPLOSIVES.

PETŐFI, SÁNDOR (1823–1849). one of the greatest Hungarian poets. was born at Kiskoros. Jan. 1. 1823. Petofi had an eventful youth; he studied at eight different schools. joined for a short time a group of strolling players and enlisted as a private soldier, but because of ill health was soon dismissed from the army. He traveled extensively in Hungary, mostly on foot. As a schoolboy he displayed a keen interest in the stage and in literature, and his first poem was published in 1842. After years of vicissitudes and misery. in 1844, on the recommendation of Mihály Vorosmarty. then the leading Hungarian poet, he became an assistant editor of the literary periodical Pesti *Divatlap.* His first volume of poetry, Versek, appeared in the same year, and made him famous at once, though the tone of his poems scandalized many. In 1847 he married Julia Szendrey who inspired his best love poems.

Petőfi played a leading role in the literary life of the period preceding the outbreak of the Hungarian revolution of 1848. After 1847, together with Mór Jókai, he edited the magazine *Életképek.* A fervent partisan of the French Revolution, an admirer of Jean-Pierre de Béranger and Hégésippe Moreau, he castigated in violent terms the social conditions of his country, attacking the privileges of the nobles and the monarchy. Politically he was an extreme radical, an inspired agitator, but he was lacking in experience and failed to obtain a seat in the diet. His poems were glowing with political passion, and one of them, "Talpra magyar". ("Rise Hungarian"), written on the eve of the revolution, became its anthem. During the revolution he became the aide-de-camp of Gen. József Bem, then head of the Transylvanian army, who had great affection for the somewhat unsoldierly but enthusiastic poet. Petofi disappeared during the battle of Segesvár, July 31, 1849. Public opinion refused to believe in his death and for many decades hoped to see him return.

Petofi's poetry meant a revolution in Hungarian literature. Opposed to the fashionable literary conventions and mannerisms, he introduced a direct, unpretentious style. and a clear, unornamented construction adapted from national folk songs. This simplicity was the more arresting as it was used to reveal extremely subtle emotions and political or philosophical ideas. His poetry is characterized by realism, humour and descriptive power and imbued with a peculiar vigour. Of his epic poems the Jdnos *vitéz* (1845), an entrancing fairy tale is the most popular Petofi's popularity has never diminished in Hungary, and were it not for the barrier of language his name would probably take its place with those of Burns and Heine in world literature. In his homeland his poetry and his personality have remained the symbols of the people's desire for freedom.

A critical edition of Petofi's works by B. Varjas Béla was published in six volumes, 1948–56.

See J. Horváth, *Petőfi* (1922); *G* Illyés, *Petőfi* (1954). (N. KI.)

PETRA, a ruined site in Jordan, lying in a rock basin on the eastern side of the Wadi 'Araba, the great valley that continues the rift of Jordan southward to the Gulf of Aqaba. The descriptions of Strabo (Geography, xvi, p. 779), Pliny (*Natural* History, vi, 32) and other writers leave no doubt as to the identity of this site with the famous capital of the Nabataeans (*q.v.*) and the centre of their caravan trade. The country around is assigned by tradition to the Horites, *i.e.*, probably "cave-dwellers," the predecessors of the Edomites. The tombs at Petra offer some evidence of the early Nabataean settlement. Two types of tombs may be distinguished, the h'abataean and the Graeco-Roman. The former start from the simple pylon-tomb of pre-Hellenic age (about the 6th century B.C.); they then pass through various stages evolving to the full Nabataean type, nhich retains all the native features and at the same time shows characteristics which are partly Egyptian and partly Greek. The next stage in the evolution of the tombs gives tomb fronts terminating in a semicircular arch, a feature derived from north Syria, and there finally appear the elaborate façades from which all trace of native style has vanished. copied from the front of a Roman temple. After the period of the pre-Hellenic tombs we notice a period which combined Greek, Egyptian and Syrian elements, clearly pointing to the age of the Ptolemies. Toward the close of the 2nd century B *C.*, when the Ptolemaic and Seleucid kingdoms were equally depressed, the h'abataean kingdom came to the front; under Aretas III Philhellene (c. 85–60 B.C.) the royal coins began; at this time probably the theatre was excavated and Petra must have assumed the aspect of a Hellenistic city. It is to the long and prosperous reign of Aretas IV Philopatris (9 B.C.–A.D. 40) that the fine tombs of the el Hejr type may be dated, and perhaps also the High-place. Then the city became more and more romanized. In A.D. 106 Arabia Petraea ("Arabia belonging to Petra") was absorbed into the Roman empire, and the native dynasty came to an end. When the city was more prosperous than ever, at the time of Alexander Severus (AD 208–235), the issue of coinage came suddenly to an end. Meanwhile. Palmyra was growing in importance. and attracted much of the Arabian trade away from Petra, and the latter declined. It seems, however, to have lingered on as a religious centre. Christianity found its way into Petra in early times. The Christianity of Petra, as of north Arabia, was swept away by the Moslem conquest in A.D. 633–640. Under the Latin kingdom, Petra was occupied by Baldwin I; it was held by the Franks till 1189; fragments of the Crusaders' citadel are still standing.

PETRARCH (FRANCESCO PETRARCA) (1304–1374), Italian poet, the first humanist and the first modern lyric poet, was born at Arezzo, July 20. 1303, son of a notary Ser Pietro di Ser Parenzo of Incisa in Valdarno, and his wife, Eletta Canigiani. His father (who after 1312 is referred to as Petrarca, the surname which his son made famous), had been banished from Florence. on Oct. 20, 1302, probably as the result of personal differences with Albizzo Franzesi. a leader of the Blacks, and not, as his son allowed it to be understood, for political reasons, like Dante. Francesco remained at Arezzo for less than a year; then his family moved, to Incisa (where they stayed until c. 1310). to Piss (where perhaps he met Dante) and finally to Xvignon (1311), at that time the seat of the papacy, where his father hoped to find suitable employment. Owing to the difficulties of finding lodgings, the family settled at Carpentras nearby and there Francesco began his studies under the modest direction of Convenevole da Prato. In 1316, in obedience to his father's wishes, he went to Montpellier to study law. To this period. although they were certainly revised later. belong the earliest poems that have survived, those on the death of his mother (1318 or 1319: Epistolae *metricae,* i, 7). In 1320 he moved to Bologna and unwillingly continued his legal studies there until 1326. His knowledge and love of the classics increased and he was able to develop his acquaintance with the new vernacular poetry, perhaps even to experiment for himself. In 1326 he returned to Avignon, gave up his legal studies and took minor orders (which would allow him to enjoy benefices and canonries nithout ecclesiastical obligations).

For some years he enjoyed the life of the Avignon court where he soon made a name for himself thanks to the elegance of his culture and his first poetic attempts in Latin and the vernacular. His early youth. nhich had been mainly influenced by his love of God and virtue and his realization of the transitory nature of human affairs. was followed by a period of dissipation which coincides with the beginning of his most famous love affair (*Secretum meum,* iii, 6–7).

On April 6. 1327, in the church of Sta Chiara, he first saw Laura, the lady nho was to dominate his poetry, though not all his norks and still less his life. as the romantics would have us believe Such critics. followed by the positivists, have consistently tried to give a face and a name to the "lady" of the *Canzoniere* (she has been identified with Laura di Audiberto di Noves who married Ugo di Sade, Laura di Sabran, Laura di Chiabau, Laura Colonna, etc.). The reaction is seen in the opposite tendency to see in Laura a pure symbol or *senhal* (in the language of Provençal poetry), a personification of intellectual beauty and truth. But neither the particular images that are woven into the *Rime* nor the accepted transfigurations and poetic structure imposed by literary tradition are able to reduce her to a symbol or an allegory. Yet it is useless to try and find out who she really was since Petrarch maintained silence about everything that concerned her civil status, as though he considered it of no importance. Laura

lives only in his verse even though Petrarch drew his inspiration from a woman whom he had really known and loved.

At the invitation of Giacomo Colonna, a friend of his Bolognesi years, who had been appointed bishop of Lombez, Petrarch passed the summer of 1330 in that little Gascon town, "a most heavenly summer owing to the gaiety of the bishop and his companions," and then entered the service of Giacomo's brother, Giovanni, Cardinal Colonna, where he was to remain until 1347, "not serving a master, but rather a father or better still a most affectionate brother" (*Posteritati*). These were decisive years, crowded with travel alternating with periods of austere retirement, years of ambition but also of unpretentious, unremitting study and literary activity, particularly in the field of classical Latin (up to 1328). In 1333, he journeyed through France, Flanders, Brabant and the Rhineland. In Paris, thanks to a gift from Father Dionigi of Borgo San Sepolcro (his faithful friend and discreet confidant in spiritual matters) he was introduced to the *Confessions* of St. Augustine, a book which he was to use more and more as the breviary of his spiritual life; at Liège he transcribed, among other things, the Ciceronian oration *Pro Archia,* that great manifesto of the nature of poetry. These events seem almost to symbolize his mission as a stubborn advocate of the continuity between classical culture and the Christian message (as between a rich promise and its divine fulfillment) which justifies his position as founder and representative of European humanism and which can already be discerned in his two most ambitious and significant Latin works of this period, the *De viris* and the *Africa* (begun 1338 or 1339). And even before 1336 he had already begun to select, revise and copy those vernacular poems which he had been composing with increasing care during the preceding ten years.

The Mature Years.—Early in 1337 his dreams and aspirations which had been resolutely directed toward classical civilization found fulfillment in a visit to Rome. It was perhaps this deep emotional experience, which confirmed him in his faith, and the moral and religious doubts which had dramatically assailed him the previous year on his ascent of Mt. Ventoux with his brother Gherardo, that made him, when he returned to Provence, seek a refuge far from the restless, corrupt life of Avignon, full of memories of his most dissipated years (in 1337 his natural son Giovanni had been born). A few miles to the east he found the solitude of Vaucluse which was to serve as a retreat sacred to meditation and to poetry: his Helicon.

In Sept. 1340 there reached him simultaneous invitations from Paris and Rome to be crowned poet laureate, an honour which he had sought, not only from ambition but also in order that the rebirth of the cult of poetry might be celebrated after 1,000 years. For this reason he had no hesitation in preferring the Capitol to the Sorbonne and it was in the Capitol, on April 8, 1341, that he received a laurel wreath which he deposited as a symbolic gesture on the tomb of St. Peter.

From May 1341 until Feb. 1342 Petrarch was in Parma and later in the nearby solitude of Selvapiana; he then returned to Provence till the autumn of 1343. It is generally believed that at this time he passed through a "crisis" which, after a further period of dissipation in Avignon (his natural daughter Francesca was born in 1343), led him to a better-regulated life in which his spiritual need found expression in an intense concern for literary as well as moral problems. His inner torment, increased perhaps by his brother's decision to enter a Carthusian monastery, can be reduced to a conflict between his religious faith and his inability to adapt his own life to it: this is the situation so lucidly set out in the *Secretum* (42–43: "many times I thought to have shaken off my former yoke but it has bitten deep down to my bones . . . I shall die in my sin if help does not come from on High . . .").

It was therefore an evolution, both moral and literary, rather than a crisis, which made him realize that his love for Laura was wrong in spite of its purity and although it inspired him to do good, because it made him love his Creator for what he had created (and not the creature as the work of God) and was proof, therefore, of his attachment to this earth; an evolution which led him to break through the barriers of his too exclusive admiration for antiquity and to admit other and more authoritative voices. In the *De vita solitaria* (1346) the antinomy between classical and Christian culture appears almost completely resolved: "solitude," that great literary myth bequeathed by Petrarch to the humanist and modern worlds, becomes the point of contact between the *otium literatum* of the ancients and Christian asceticism; classical writers and heroes mingle with the prophets, saints and holy fathers, to such an extent that the first plan for the *De viris* was enlarged to include material from sacred as well as secular history.

Events which are fundamental to his biography as a man and a writer befell Petrarch during these years. He became sympathetically, even enthusiastically, interested in the efforts of Cola di Rienzo to realize the dream of popular government in Rome (an attitude which divided Petrarch ever more sharply from the curia at Avignon and in 1347 caused a break with Giovanni Cardinal Colonna). The terrible plague of 1348 caused the death of many friends including Laura herself (with poetic coincidence she died on April 6): the news reached Petrarch in Parma on May 19 and he noted it in his Virgil so that he might see it often and be reminded of the decay of all earthly goods. He met Boccaccio in Florence, a very important meeting, awakening in Petrarch a consciousness of his cultural and moral mission. He made a pilgrimage to Rome for the jubilee year (visiting his birthplace and discovering Quintilian) in 1350, the year to which Petrarch assigns his final renunciation of the pleasures of the senses.

Between these landmarks, his life unfolded, crowded with diplomatic missions and dedicated to study during periods of meditation: in the autumn of 1343 he was in Rome and then in Naples on a mission to Queen Joanna on behalf of the Colonna family; from Dec. 1343 until Feb. 1345 he was again at Parma (where he wrote the *Rerum memorandarum*) and then at Bologna and Verona (where he made his great discovery of Cicero's letters *Ad Atticum, Ad Quintum, Ad Brutum*); toward the end of 1345 he returned to Avignon and took refuge in his beloved Vaucluse for two years of great spiritual and literary activity (*Bucolicum carmen, De vita solitaria, De otio religioso*); in Nov. 1347 he left for Italy, probably on a mission in favour of Cola (whom the May revolution had placed at the head of the Roman republic) but the fall of the tribune made him change his plans; he went to Verona and then to Parma where, except for occasional visits and missions, he remained from March 1348 to March 1349 (in Aug. 1348 he was appointed archdeacon of the cathedral). He then made a more permanent home in Padua where the lord of the city, Giacomo Novello da Carrara, had obtained a lucrative canonry for him. But Giacomo was assassinated (Dec. 19, 1350) during Petrarch's jubilee pilgrimage to Rome and since he was prevented from returning to Parma by some disagreement with the bishop and the suspicious tyranny of the Visconti family, to whom the city had been ceded, he felt himself possessed anew by a longing for Vaucluse. Neither Boccaccio's visit in April nor the offer he brought of a chair in the university to be established in Florence under his guidance were able to hold him back. He left in May 1351, reached Avignon in June and went straight to Vaucluse. This fourth retreat was particularly productive: the arrangement of the *Canzoniere,* on which he had already resumed work in 1348 at Parma and Padua, began to assume a more definitive form; the idea of forming a corpus of his letters which had first come to him perhaps as early as 1345 and certainly by 1349 took shape in his plan for the first collection, the *Familiari;* he continued to work assiduously on his collection of *Metriche* begun in 1350; he embarked on his polemic against the doctors, the bitter enemies of humane letters; and he revised and rewrote various earlier works (*De viris, Secretum*).

The death of his closest friends, the suspicions of Pope Innocent VI (who had succeeded the friendly Clement VI in Dec. 1352), and his increasingly bitter differences with the curia at Avignon, finally decided Petrarch to leave Provence and to return to his own country. From the alpine frontier of Montgenèvre he addressed it with moving eloquence: "Hail O most sacred land, beloved of God, hail land whom the good can trust, the proud must fear . . . Eagerly I return to you after so many years to live with

you for ever; you will provide a haven of peace for my weary life." (Epistolae metricae, iii, 24). He found rooms in Milan where he remained, except for brief periods. during the next eight years (1353–61) in spite of harsh criticism for his acceptance of hospitality from ambitious tyrants and the enemies of Florence (the Visconti). Apart from the considerable missions entrusted to him by the Visconti (especially notable those to Venice in 1353 to negotiate peace with Genoa, to Mantua in 1354 and to Prague in 1356 where the emperor Charles IV accorded him royal honours, to Paris in the winter of 1361 on a visit to King John II after the peace of Bretigny), the Milanese period, the longest uninterrupted stay in one place during his whole lifetime, was one of the most fruitful. He completed the first proper edition of the Rime, applied himself with great fervour to the *Familiares,* made considerable progress with the De remediis, worked on the *Trionfi,* composed the Invectiva against Cardinal Jean de Caraman and the *Itinerarium* and revised and set in order with scrupulous care some of his earlier works.

Later Life.—During the spring of 1361, hoping to escape from the plague, he went to Padua on the invitation of Francesco da Carrara (son of his great friend Giacomo) remaining there until Sept. 1362 when, once more as a fugitive from the plague, he sought shelter in Venice, "the only stronghold in our times of liberty and peace and justice" (Senilium *rerum* libri, iv. 3). The *signoria* gave him a house on the Riva degli Schiavoni and Petrarch promised to bequeath all his books to the republic when he died. He was joined by his daughter Francesca with her husband the Milanese Franceschino da Brossano and their small daughter Eletta: the tranquil happiness of this little family gave great pleasure to their affectionate father. He was visited by his dearest and most famous friends (by the great chancellor Benintendi de' Ravegnani, by Paduan scholars, by Boccaccio, who in 1366 presented him with a long-desired Latin translation of the Homeric poems); he nas invited to play an honourable part in the life and politics of the city; he worked peacefully but with great concentration at the definitive versions of the *Rime,* the Familiares, the De *remediis* and the *Seniles.* Nevertheless the insult he received from four young Avverroists who called him "a good man . . . but illiterate and in fact an idiot" because he believed in Christian doctrines rather than those attributed to Aristotle, an insult which was ignored by Venetian public opinion, induced him to move back to Padua in 1367. He was to remain there until his death, dividing his time from 1370 onward between Padua and Arqui in the neighbouring Euganean hills where Francesco da Carrara had given him a little house, his last Helicon. He was still in demand as a diplomat: in April 1368 he accompanied the ruler and the bishop of Padua to meet the emperor Charles IV who aas on his way to Italy as an ally of the league against the Visconti; later he was in Pavia and Milan for the marriage of Violante. daughter of Galeazzo, to Lionello the second son of the king of England; in 1370 he was called to Rome by Urban V and he set off eager to see the fulfillment of his great dream of a new Roman papacy, but was halted at Ferrara by a stroke. Yet he did not stop working; in addition to revision he composed the De gestis Caesaris, the Invectiva against Jean Hesdin and the final sections of the Trionfi.

Petrarch died during the night of July 18–19, 1374, when he was working in his little study at Arqui, and was found the next morning, his head resting on a manuscript of his beloved Virgil.

WORKS

Petrarch's literary production as poet. historical moralist and outstanding representative of the new culture is enormous. The chronology of his writings is somewhat complicated and uncertain and is made more so by the scrupulousness with which he revised and rewrote, often very extensively. Included here is a summary list with notes and. when they exist, a reference to better editions than those in his collected works (Opera, 1554 and 1581).

Latin **Works.**—*Epistolae Metricae.*—A collection in three books of 66 epistles in hexameters, dating from the verses on the death of his mother (1318 or 1319) and the earliest epistle of 1333 to the last letters composed between 1350 and 1354; he appears to have worked on the collection in three distinct phases, about 1350, 1357 and 1363. The subject matter is, naturally, very diverse. intimate confessions, autobiographical anecdotes, letters of consolation and exhortation. moral reflections, literary propositions and rhapsodies, descriptions, panegyrics, etc. (*Poemata minora,* edited by D. Rossetti, 1831).

Africa.—Petrarch began this work at Vaucluse in 1338 or 1339, pursued it with greater vigour at Selvapiana in 1341, returned to it frequently but intermittently after 1343 but never completed it: its various parts were gradually put together but its nine books (iv and ix are very incomplete) were published only after Petrarch's death, by Paolo Vergerio in 1396. It is an epic poem in hexameters which relates the history of the Second Punic War. The episode of Sophonisba, sacrificed to political expediency by her ardent lover King Massinissa, is both pathetic and dramatic; the famous lament of the dying Magone on the decay and misery of everything on earth (it was the only passage made available during the poet's lifetime) is strictly Petrarchan in inspiration; and this sentiment, together with a desolate perception of the fugacity of time. pervades the whole work, tempering with Christianity the Roman classicism of Livy and Cicero who are widely used as sources and at times with too heavy a hand. (Critical edition by N. Festa. 1926.)

De *viris illustribus.*—The original plan of this work, begun in 1338 or 1339 and continued in 1341–43 as a series of biographies of famous Romans or people closely connected with Rome, was considerably modified between 1351 and 1353 so as to include famous men of all times beginning with Adam, thus achieving Petrarch's aim of emphasizing the continuity between the ideals of the Old Testament, of classical antiquity and of Christianity. Later he wrote fuller lives of Scipio and Caesar and finally, when he was in Padua, he took up the work again with the title *Quorundam virorum illustrium epithoma,* limiting it to 36 characters whose effigies were to be placed in a hall of Francesco da Carrara's palace; but he did not get further than the preface (the rest is the work of his disciple Lombardo della Seta who also completed the *Compendium* or Breve compendium of which Petrarch wrote only the first 14 biographies). (Edited by L. Razzolini, 1874–79.)

Secretum meurn.—This autobiographical treatise was composed between the autumn of 1342 and the winter of 1343 and revised between 1353 and 1358. Not intended for publication, it is a fundamental work for the understanding of Petrarch's inner life. It consists of three dialogues between Petrarch and St. Augustine in the presence of Truth: in the first, Petrarch's secret infirmity is identified with a sickness of the will which makes him aspire to a nobler life while lacking the knowledge and will power to achieve it; in the second, Petrarch examines his conscience with regard to the seven deadly sins and finds himself guilty of all of them except envy, but especially of accidia (the theological definition of the sickness of the will discussed in the first book); in the third, Petrarch convinces himself of the sinfulness both of love (even when pure and directed towards a chaste woman) and of the desire for glory: that is. of the two great passions of his life. But he wearily declares himself unable to reform. The work constitutes a self-analysis of pitiless sincerity and precise autobiographical references at one of the decisive moments of his life. (Edited by E. Carrara, in Petrarca, Prose, 1955.)

De vita solitaria.—Written in 1346 and later revised and enlarged (one addition is definitely of 1371), the treatise, in two books, provides the theoretical basis and the description of one of Petrarch's essential myths, that of the "solitary life," in which man is able to enjoy the consolations of nature and study together with those of prayer. (Edited by G. Martellotti, in Petrarca, Prose, 1955.)

De otio *religioso.*—Written in 1347 it was revised and considerably enlarged in 1357. It is a treatise in two books on the advantages of the contemplative monastic life. It takes up the theme of De vita solitaria from a more strictly devout attitude and is tinged with a sharp nostalgia for purity and spiritual peace (Edited by G. Rotondi, 1958.)

Familiarium rerum libri xxiv.—The idea of this collection of letters goes back to 1345 or more probably to 1349. The real

work of arrangement was begun between 1351 and 1353 (up to book viii) and the final version was completed between 1359 and 1360 (up to book xix); in 1363–64 Petrarch returned to it, adding four books, and continued to work on it until 1366. It consists of a selection of 350 letters (the earliest dated 1325, the latest 1366, although the collection is supposed to end at 1361) which are of great importance for an understanding of Petrarch's life, both spiritual and active, and for the history of his decisive influence on European culture. As Martellotti has observed, these collections of letters represent the final stage of that progress from the contemplation of the world of antiquity as a means of escape from unpleasant realities to an intense preoccupation with the present, and the study of antiquity as foreshadowing the moral truths of Christianity. (Critical edition by V. Rossi and U. Bosco, 1933–42.)

De renzediis *utriusque fortunae*.—This vast work, a part of which had been begun in 1354, had reached an advanced stage by 1360 and was finished in Oct. 1366 and published immediately. Petrarch probably returned to it later. It consists of two books containing 122 and 131 treatises, or discussions, between Reason, Pleasure and Hope and between Reason. Sorrow and Fear which contain respectively advice on how to attain good fortune and the remedies for bad, and which demonstrate the inconsistencies of pleasure and pain in a tone of bitter pessimism.

Senilium rerum libri.—Petrarch began his collection of the Senili after 1361 but never made a definitive arrangement as he did for the *Familiari*. The collection comprises 125 letters from 1361 to 1374 in 17 books.

Posteritati.—The first draft must be dated before 1367; there were important additions between 1370–72. It is an interesting autobiography in the form of a letter addressed to posterity. left unfinished and in draft form (it only goes up to 1351); it was to have formed the conclusion to the Senili. (Edited by E. Carrara and P. G. Ricci in Petrarca, Prose, 1955.)

De sui *ipsius* et *multorum ignorantia*.—Written 1367, published 1371, this is directed against the critics of Venice. Following St. Augustine Petrarch tries to show that rhetoric and poetry are the best spurs to moral action. (Edited by L. M. Cappelli, 1906.)

Other Latin *Works:* Prayers (1335–38). *Epistole* sine *nomine,* written 1342–58; collected 1359–60. (Edited by P. Piur, 1925.) *Rerum memorandarum* libri, 1343–45. (Crit. ed. by G. Billanovich. 1945.) *Bucolicum carmen,* 1346–48; definitive version 1364. (Edited by A. Avena. 1926.) *Salmi penitenziali,* 1347. (Edited by H. Cochin, 1929.) *Invectivarum* contra *medicum quendam* libri, 1352–55 (Edited by P. G. Ricci, 1950). *Invectiva* contra *quendam magni status hominem,* 1355. (Edited by P. G. Ricci, 1949.) *Itinerarium* breve de Janua *usque* ad Jerusalem, 1358 et seq. *Invectiva contra eum* qui *maledixit* Italiae, 1373. Epistole varie; 65 letters not included by Petrarch in his collections.

Italian Works.—Rerum *vulgarium fragmenta*.—This was Petrarch's title for the definitive collection of his Italian verse. his Rime. It consists of 366 compositions (317 sonnets, 29 *canzoni*, 9 sestine. 7 *ballate,* 4 madrigals) divided into two parts (263 poems described as in vita Laura; 103 in morte *Laura*). Naturally the first stage in the production of this work was the actual composition of the single poems (he did not include in the collection those written earlier than 1330); the second, before 1336, his first idea of making a selection; the third, between 1342 and 1347, the arrangement of the selected poems according to a certain criterion; the fourth, after the death of Laura, their division into two parts and the project of illustrating the story of his own soul (perhaps 142 lyrics on the period before Laura's death plus 29 after); the fifth, the first proper edition of the Canzoniere sent to Azzo da Carreggio in 1360 (about 174 plus 41); the sixth. a second edition in Jan. 1373 sent to Pandolfo Malatesta; the seventh, the definitive edition which is preserved in the Cod. Vat. Lat. 3195, partly autograph, partly transcribed by Giovanni Malpaghini under the poet's supervision. The choice of poems and the arrangement of the collection are governed by a most rigorous and exclusive standard of aesthetic taste, by a preference for an approximately chronological arrangement and by the poet's ever growing urge to express, through these verses which are chiefly concerned with his love for Laura, the story of his own soul, from the description of his falling in love to his anxious invocation to the Virgin; from his "youthful errors" to his realization that "all worldly pleasure is a fleeting dream"; from his love for this world to his final trust in God. The theme of his Canzoniere therefore, goes beyond the apparent subject matter, his love for Laura. For the first time in the history of the new poetry, lyrics are not considered as *nugae* or occasional verse as they had been from the troubadours to Boccaccio: Petrarch, in spite of frequent doubts and many changes of mind, still felt that the *schedulae* containing his verses were the threads holding together a marvelous new tapestry possessing its own unity and similar to that which he was constructing, on the Ciceronian model, from his letters. By selecting all that was most polished and at the same time most vigorous in the neo-Latin lyric tradition of the preceding two centuries, and filtering it through his new appreciation of the classics, he not only bequeathed to humanity the most limpid and yet passionate, precise yet suggestive, expression of love and grief. of the ecstasies and sorrows of man, but also created with his marvelous sensibility the form and language of the modern lyric. In fact, the history of the European lyric could be recounted in terms of action and reaction in the face of the Petrarchan experience. (Edited by G. Contini, 1949; commentaries by G. Carducci and S. Ferrari, 1899 and, 6th ed., 1957; edited by E. Chiorboli, 1924.)

Rime disperse.—This title (or sometimes Extravaganti) is used for those verbs which Petrarch did not include in his main collection, either because they nere not good enough or because they were not addressed to Laura. The authenticity of many is doubtful, in some cases no longer accepted. (Edited by A. Solerti, 1909.)

Trionfi.—A poem in *terza* rima probably conceived and begun in 1351 in imitation of Boccaccio's *Amorosa* visione and possibly of Dante's Divine Comedy. It was written in sections and continually revised during the following years (the earliest certain dates, 1356–60, are of the *Trionfo d'Amore*, the latest, Feb. 1374, is written in the margin of the Trionfo *dell'Eternità*). Petrarch left it unfinished and it was published posthumously. It is an historical and symbolical vision of the great theme of the *Canzoniere* raised from the autobiographical to the universal, that is, from the story of one man alone, Petrarch, to that of man in himself, or rather of the whole of humanity in its progress from earthly passion to fulfillment in God. Love triumphs over the greatest men, but is captured by Chastity; which in its turn, in the person of Laura. is overcome by Death; which is conquered by Glory; which is itself annihilated by Time: only in God does everything of beauty and everything of value, love for Laura and love for glory, shine eternally beyond all space and time, and heaven and earth are reconciled according to Petrarch's noble and constant dream. (Critical edition ed. by K. Appel, 1901; to be read in conjunction with the new sections, *Un* inedito petrarchesco, edited by R. Weiss, 1950.)

Conclusion.—This summary of the essential events of his life and sketch of the chronological and spiritual development of his works will have sufficed to show the exceptional importance of Petrarch in the poetry and culture of modern and Christian Europe; never before, perhaps. has a writer had so rapid, so decisive and so far-reaching an influence. This "presence" was so effective because it made itself continuously felt, through his spoken and written conversations with his friends and disciples, and his prodigious achievement as the discoverer of so many of the treasures of classical learning and beauty, both in those texts which he actually found and in those which he re-established by his sensitive and accurate interpretation. Through his sublime poetry, and his profound spiritual and moral meditations, his historical visions and reconstructions and in the devoted work for humane studies by which he solved the age-old problem of the reconciliation of the classical with the Christian world, Petrarch shows how in the substantial identity of human souls God provides the opportunity for meetings and contacts, for the affirmation of the same truths in different ages and under different skies. The words of his beloved St. Augustine which, during the ascent of Mt.

Ventoux, flashed before his mind's eye, "And men go to admire the high mountains and the immensity of the ocean and the course of the heavens . . . and neglect themselves," are truly symbolical of Petrarch's mission in life, of his thought and of his art. Never, since the great teachers of antiquity and the greatest fathers of the church, has man had so enthusiastic and sensitive an interpreter of his sorrows and his greatness, so subtle and so sympathetic an interpreter of his eternal uncertainty outside fulfillment in God. "I always feel a sense of unfulfillment in my heart," he wrote with Augustinian inspiration in the *Secretum*. It is for this reason that the figure of Petrarch towers over that age, from Boccaccio to Erasmus, which took its name from man. the age of humanism; for this reason that, from Bembo to Michelangelo and Ronsard, from Gongora and Milton to Klopstock, from Shelley and Heine to Leopardi, to Heredia, to D'Annunzio, the art which, better than any other, expresses with precision and yet with sensitivity the most constant and the noblest aspirations of man, sprang originally from the fount of Petrarchan inspiration.

PETRE, SIR EDWARD (1631–1699), Jesuit confessor of King James II of England. was born in Paris, the son of Sir Francis Petre, Bart., of Cranham, and his wife Elizabeth Gnge. Educated at the Jesuit college at St. Omer, he entered the order under the name of Spencer in 1652, but did not receive the full orders till 1671, when he was sent on a mission to England. In 1679 he succeeded his brother in the title and family estates. On the accession of James II in 1685 he became confessor to the king. whom he encouraged in the policy which ended by producing the revolution of 1688. The king contemplated making him archbishop of York, as the see was then vacant, but the pope, Innocent XI, who was not friendly to the order, would not grant a dispensation to hold it, and even directed Petre's superiors to rebuke him for his excessive ambition. On the outbreak of the revolution, Petre fled, and had no further relations with James II. After a visit to Rome, he became head of the Jesuit college at St. Omer in 1693, from where he was transferred to Walten in Flandersin 1697. He died on May 15, 1699.

PETREL, group of birds whose name is derived from their apparent habit of walking on the water as St. Peter is recorded (Matt. xiv. 29) to have done. They form with the shearwaters (*q.v.*) and albatrosses (*q.v.*) the order Tubinares, the name denoting the tubular structure of their nostrils. There are two families, Procellariidae and Oceanitidae.

Petrels are archaic oceanic forms, with great powers of flight, dispersed throughout the oceans of the world; some species apparently never resort to land except for the purpose of nidification. During the breeding season many of them are nocturnal in their habits, passing the day in holes in which they generally nest, the hen laying a single white egg, sparsely speckled in a few species with fine reddish dots. Of those species that frequent the North Atlantic the stormy petrel, or Mother Carey's chicken, *Hydrobates pelagicus,* is the commonest. Other Atlantic forms are Leach's or the forktailed petrel, *Oceanodroma leucorrhoa,* a larger but less common bird and Wilson's petrel, *Oceanites oceanicus,* the type of the family Oceanitidae, which is common on the American side. In the southern ocean petrels are most abundant, both as species and as individuals. The Cape pigeon or Pintado petrel, *Daption capensis,* is one that has long been well known to mariners, while those who voyage to or from Australia meet with many more species, some, as *Ossifraga gigantea,* as large as albatrosses, and several called by names having reference to their strong smell of musk. The colouring of petrels is sooty black, gray of various tints and white.

THE PETREL, AN OCEANIC BIRD THAT COMES TO LAND ONLY DURING THE BREEDING SEASON

PETRI, OLAUS and **LAURENTIUS,** two Swedish churchmen who played decisive roles in the reformation of the Swedish church. Born at Örebro in the diocese of Strangnas, OLAUS (or OLAVUS) PETRI (1493–1552) studied at Wittenberg (1516–18) and absorbed the reformed teaching of Luther and Melanchthon. When Gustavus Vasa was crowned king in 1523, Olaus had already attracted attention and criticism by his preaching. The Roman Catholic hierarchy were hostile to the king, who became a supporter of the reformed teaching. Laurentius Andreae, secretary and later chancellor to the king, was a friend of Olaus Petri, who preached the coronation sermon. Olaus rose in prominence and served briefly as chancellor (1531). Later he opposed the autocratic policy of the king, and both he and Andreae fell from favour and were condemned to death in 1540, the sentence being remitted for a heavy fine. Later he regained favour and was appointed pastor of Storkyrkan church in Stockholm where he died in 1552. Olaus provided most of the literature for the Swedish Reformation movement. including a Swedish New Testament (1526), hymnbook (1526), church manual (1529), the Swedish liturgy (1531) and many homiletical and polemical writings. His *Chronicle* is an important historical document.

LAURENTIUS PETRI (1499–1573) also studied at Wittenberg, returning to Sweden in 1527. He was appointed the first Protestant archbishop of Uppsala in 1531 and held this office until his death in 1573. His influence was very great, although he was less dynamic and forceful than his brother. The Swedish Bible of 1541, for which he was principally responsible, was as important for Swedish life and literature as Luther's German translation mas for the German-speaking peoples. His *kyrkoordning* (church order) of 1571 defined the practice of the church. particularly its relation to government, and went far toward establishing the independence of the church from the crown which has been characteristic of most of its history.

PETRIE, SIR (WILLIAM MATTHEW) FLINDERS (1853–1942), English Egyptologist, was born at Charlton on June 3, 1853, the son of William Petrie, C E.. and Anne, daughter of Captain Matthew Flinders (*q.v.*). He took an early interest in archaeological research, and between 1875 and 1880 studied ancient British remains at Stonehenge and elsewhere; in 1880 he published his book on Stonehenge. He mas much interested in

ancient weights and measures, and in 1875 published a work on *Inductive Metrology*. In 1880 he began a long series of important surveys and excavations in Egypt, beginning with the pyramids at Giza, following up his work there by excavations at the great temple at Tanis (1884), discovering and exploring the long-lost Greek city of Naucratis in the delta (1885) and the towns of Am and Dauhnae (1886), where he found important remains of the time when they were inhabited by the Pharaohs. Between 1888 and 1890 he was at work in the Fayum, opening up Hawara, Kahun and Lachish; and in 1891 he discovered the ancient temple at Medum. Much of this work was done in connection with the Palestine Exploration fund. By this time his reputation was established. He published in 1893 his *Ten Years' Digging in Egypt*, and was appointed Edwards professor of Egyptology at University college, London. In 1894 he founded the Egyptian Research account which in 1905 was reconstituted as the British School of Archaeology in Egypt. Perhaps the most important work of the school was at the site of Memphis (*q.v.*). Flinders Petrie was knighted in 1923. He resigned his professorship in 1933 and from 1932 to 1938 excavated in Palestine. Sir Flinders died July 28, 1942, at Jerusalem.

WORKS.—His chief general works on Egyptian subjects are: *Ten Years' Digging in Egypt* **(1893)**; *History of Egypt* (1894–1905); *Religion and Conscience in Ancient Egypt* **(1898)**; *Syria and Egypt* **(1898)**; *Hyksos and Israelite Cities* (1906); *Religion of Ancient Egypt* **(1906)**; *Arts and Crafts in Egypt* (1909); *Historical Studies* (1910); *Revolutions of Civilisation* (1911); *Eastern Exploration* (1919); *Prehistoric Egypt* (1920); *Social Life in Ancient Egypt* (1923); *Seventy Years in Archaeology* (1931); *Anthedon, Sinai* (1937); *Funeral Furniture and Stone and Metal Vases* (1937); *Egyptian Architecture* (1938); *Making of Egypt* (1939); *Egyptian Science* (1939). *A* principal work on Palestine is *Ancient Gaza* (5 vol., 1931–38).

PETROL ENGINE: see INTERNAL COMBUSTION ENGINES.

PETROLEUM. Petroleum exercises a deep influence on modern industrial civilization. Petroleum fuels power the engines of automobiles, buses. farm tractors and trucks as well as those of fishing craft, merchant ships, passenger liners and aeroplanes. Petroleum products lubricate engines. motors and machines, and petroleum cutting oils make possible much of the drilling and grinding basic to mass production. Petroleum fuels heat homes and buildings. Petroleum asphalt helps build modern highways. Either by self-consumption or by generating electricity. petroleum illuminants supply many people of the world with artificial light.

Products of petroleum are used to make synthetic fibres for clothing; synthetic rubber for tires and other uses; cleansing agents. such as soap and detergents; paints and plastics: and numerous ingredients used in fertilizers. insecticides, food processing and many medicines. Such peacetime applications of petroleum multiplied as scientists found new uses for the liquid's by-products. A whole new industry grew out of petroleum chemistry—the petrochemical industry.

Two world wars demonstrated petroleum's vital importance in war. World War I first focused attention on petroleum as a strategic material and World War II underscored its importance as a fuel and a lubricant. Petroleum also was made to yield toluol, an ingredient of T.N.T.; waterproofing greases essential to amphibious operations; inflammables for flame throwers, napalm, and fuel for rockets and jet engines.

Because of its importance in daily economic life and in war and national defense, oil became a significant factor in international politics. and petroleum development and the control of reserves over the world became important security measures.

Petroleum development. on the other hand. served to raise living standards in underdeveloped countries. Activity by pioneering companies was called a private Point Four. Underdeveloped countries found to be oil-producing were not the only ones to benefit. Greatly increased and more readily accessible proved oil reserves stimulated the building of refineries in many countries. This greater availability of the energy resource. petroleum, promised to play a dynamic role in the improvement of living standards for all peoples.

In this article petroleum will be considered in these separate sections:

I Origin and Characteristics
II. Methods of Production
III. Refining of Petroleum
IV. U S Petroleum Industry
V. World Oil Situation

I. ORIGIN AND CHARACTERISTICS

Most scientists believe oil was formed from the bodies of tiny plants and animals that lived in the sea hundreds of millions of years ago when the sea covered large areas of what are now land masses. The animals and plants lived and died by the billions, then sank to the bottom and mixed with mud and sand in layers called marine sediment.

Later, these sedimentary layers were covered by more mud and sand, which finally turned into rock. As ages passed. the sea withdrew, the earth's crust heaved and buckled and the heat and pressure caused by the overlying rock. together with decomposition of the organic life, is thought to have formed oil from the animals and plants in the deep-buried layers. Because of their mutual derivation from organic material, petroleum, natural gas and coal are known as fossil fuels.

Crude oil as it comes from the ground is a mixture of thousands of different chemicals. which range from extremely light gases to semisolid carbonaceous materials such as asphalt or paraffin wax. The gases are dissolved in the other components of the crude oil because of the extreme pressure to which petroleum is subjected in the ground.

Likewise, the paraffin wax is dissolved in the so-called paraffinic crudes but can be removed by combinations of refrigeration and filtration or by selective solvents. As a liquid, petroleum may be as thick and black as melted tar. or as thin and colourless as water, depending entirely upon the particular oil field from which it comes.

Chemically, crude oil is largely composed of hydrocarbons. compounds of hydrogen and carbon. In addition. crude oil often contains sulphur, either uncombined or present as a part of certain hydrogen-carbon-sulphur compounds.

II. METHODS OF PRODUCTION

Exploration.— Since oil is never found apart from marine sediments, oilmen first look for them. But they know that oil does not always stay where it was formed. The sediments are porous, and water or gas can push the oil through tiny holes in the rock or between grains of sand until it is trapped by nonporous rock. Oilmen look for these traps. which result from changes that have taken place in the earth's crust.

For about 40 or 50 years after the first commercial oil well was drilled in the United States (1859) little technical advice was sought in determining the location of well sites. Oil was discovered by drilling near seepages or other surface indications and by random drilling.

Scientific methods of search were later developed and used, though random drilling still yields occasional discoveries of considerable importance. About 1912, geologists started the mapping of rock outcrops to locate favourable places to drill. Within a few years most of the promising surface structures in the U.S. had been drilled to depths as great as possible with existing equipment and methods.

In the early 1920s the great era of subsurface exploration for oil began. Pit digging and core drilling were used in areas where identifiable key beds were not exposed sufficiently to permit surface mapping of underground structures. More careful logging of wells and improved methods of collecting and analyzing drill cuttings vastly increased the quantity and accuracy of available information. thereby permitting the geologist to extend his knowledge of structural conditions both laterally and vertically.

Palaeontologists effected a correlation of geological horizons between widely separated wells through a study of microfossils. In some regions mineralogists mere able to correlate the underground geological strata on the basis of the mineral content of the sediments.

Electrical. gamma-ray and neutron well logging all were of great

value to the geologist in correlations and in working out the details of subsurface structure. The great strides made in perfecting coring devices not only improved production and development techniques but also vastly increased the geologist's knowledge of deeply buried formations.

The many advances which were made along these lines. though not spectacular individually, cumulatively furnished a wealth of assistance to the geologist and served as the foundation of the study of subsurface geology.

Geophysical methods of exploration were introduced into the United States oil industry in the middle 1920s. (*See* GEOPHYSICAL PROSPECTING.) German scientists using the seismic method (setting off an artificial "earthquake" with a charge of dynamite and recording sound waves on a delicate seismograph instrument) were the first to use geophysical methods in oil finding successfully. They located the first salt dome in the U.S. Gulf coast area, these domes being favourable to the accumulation of oil in pools or reservoirs below ground. U.S. technicians greatly improved on the early instruments and methods and introduced several new methods until geophysical exploration became a routine field operation as well as a continuing major research project in the laboratories of the large oil companies. The seismic method has proved to be one of the most accurate.

Measuring magnetic force is another test for possible oil-bearing formations. This depends on iron. Some rocks contain more iron than others. The more iron a rock contains, the more magnetic it is. Generally. the sedimentary rocks. which may contain oil, are less magnetic than the harder rocks that never contain oil. Oilmen use a magnetometer in measuring the iorce of magnetism at the surface of the earth. This gives them a general idea of rock formations underground. They take many readings over a large area in order to find formations that might hold oil. Sometimes they tow a magnetometer behind an aeroplane. A navigation system based on radar tells exactly where the plane is at every instant. Thus the magnetometer readings can be pinpointed on a map. Airborne surveys cover large areas very quickly—on land or sea.

Gravity gives the same kind of help in the search for oii as magnetic force. The force of gravity varies from place to place, depending on the weight of rocks underneath. Sedimentary rocks are lighter than the others. Oilmen use an instrument called a gravimeter in measuring the pull of gravity at the surface. They plot the readings on a map in order to get a picture of rock formations far below.

During the early 1950s, laboratory and field work was being conducted on such projects as the mapping of geologic anomalies with radio waves and the adaptation of various physical instruments such as the electron microscope. the mass spectrograph and the X-rav to the detailed study of well samples and cores.

Highly specialized seismic techniques and equipment were developed to cope with the problems of exploration in the open waters of the continental shelf. It became possible to examine such an area with much greater rapidity than on land. much of this work utilizing radar. Gravity data mere obtained by placing the instrument in a diving bell or by recording the readings electrically. Substantial reserves of oil found off the coast of Louisiana and Texas on the flanks of salt domes were located by these methods.

Interpretation of geophysical data falls just short of being an exact science. It has been compared with the work of the medical diagnostician who bases his findings on the correlation of a number of laboratory tests including X-rays. The geophysicist assembles a series of scientific readings. These have been constantly improved but everything depends upon his experience and learning, his interpretation.

Despite great and continuing improvements in techniques, year by year oil is becoming harder to find. A study of United States wildcat wells over a period of years shows that the percentage of success has declined. It dropped from 13.16% in 1954 to 12.41% in 1955 even though 6j8 more exploratory wells were drilled during the latter year.

Early Production.— In the United States the subsoil is not owned by the government. as is the case in almost every other nation, but goes with the ownership of the land. The long-established law of oil and gas known as the "rule of capture" gives the owner of the oil-field land all the oil which he can reduce to his possession, whether or not all such oil originally underlay his particular tract. Upon discovery of a new field, therefore. in the early days every operator rushed to develop his property as rapidly as possible and produce it at maximum capacity so as to obtain the greatest possible share of the total oil recoverable from the field. Under such practices operators observed that the first wells obtained the highest recoveries. that unrestricted producing rates yielded higher recoveries and that more densely drilled tracts obtained more oil per acre than adjoining tracts with %-ider well spacing.

These observations led to the conclusions that rapid development, close well spacing and maximum producing rates resulted in maxi-

BY COURTESY OF CREOLE PETROLEUM CORP.

OFFSHORE OIL FIELDS. STORAGE TANKS AND WORKERS' HOUSES AT LAGUNILLAS ON LAKE MARACAIBO. VENEZ.

mum recovery. It was later established that these conclusions were unsound and that practices in vogue in the early years incurred gross economic waste and were detrimental to the maximum recovery of oil from the field as a whole. Therefore, regulations were provided on well spacing to protect the rights of the landowners and the public interest.

Underground Pressure.—Beginning in the mid-1920s geologists and petroleum engineers were able to piece together fragments of information which indicated a definite pattern of behaviour of gas, oil and water under the ground. They learned something about the accumulation of oil in porous strata. They learned how oil and gas were brought to the wells as a result of the natural reservoir energy of the gas and water which confined the oil under great pressures. The key element in modern conservation operations is the underground pressure which forces the oil through the oil-bearing strata to the bottom of the well, from which it may be lifted to the surface.

Because the natural gas that originally accompanies crude oil in the ground is under compression, it often can provide sufficient energy to move the oil through the porous rock to the bottom of the well, and sometimes up the well to the surface. Similarly, water associated with the oil may be under pressure and thus provide some of this energy.

Properly conserved, these two natural forces can expel a large amount of the oil in the formation. If these forces are inadequate, the oil may be moved to the surface by means of artificial lift, such as pumping. The proper use of the natural energy contributes greatly to the maximum production of oil. Its proper utilization, then, has become one of the primary steps in the U.S. conservation movement. In some naturally prolific fields, modern engineering methods will result in the production of more than 80% of the available oil.

In most cases, good engineering practices call for producing methods which do not permit the pressure in the reservoir to be reduced below a minimum amount. Sometimes pressure can be maintained by controlling the rate of oil withdrawal. but it is often necessary to use other means. Sometimes the produced gas is gathered and pumped back into the oil reservoir, where it helps to maintain pressure.

In some fields where a water drive exists, the injection of water into the reservoir provide5 an effective way of maintaining pressure and recovering more oil. Four mechanisms important in moving oil through the pores of the rock to the bottom of the well have been developed. (Some reservoirs may have a combination of these mechanisms, although generally one type predominates.) They are dissolved-gas drive, gas-cap drive, water drive and gravity drainage. When a field is active, application of such devices are said to relate to primary recovery, as distinct from secondary recovery methods applied after a field has practically stopped producing or has long since been abandoned.

Pumping.—Obviously, natural flow is the least costly way to produce oil. and the engineer does his best to keep the wells flowing. Under modern conservation methods. some fields are still flowing after 10 or 20 years of operation. However, when insufficient gas or water pressure is present to move oil from the reservoir to the surface, petroleum engineers and operators resort to pumping. This may occur in the first development of the field, or after most of the original energy has been depleted. At the beginning of 1954, there were 501,859 producing wells in operation in the United States. 442,394 of them utilizing artificial lift. More than 332,000, or about 66%, were classified as "stripper" wells. These are wells which are pumped infrequently, yielding on an average slightly over three barrels daily.

Secondary Recovery.—Some wells have ceased to produce or are producing at such a low rate that they are considered to be uneconomical. To recover some of the oil still remaining in the reservoir several methods, referred to as secondary recovery, are used. These consist of pumping water, gas or air into the producing formation, through what are known as service or input wells. This process supplements or restores the original reservoir pressure and re-establishes the energy drive. When this can be done, the oil moves toward the well bore.

Natural Gasoline and **Condensate.**—All crude oil is associated with natural gas in the ground. There are many fields. geologically similar to oil reservoirs. nhich contain natural gas with little or no oil. When there is oil, it is separated from the gas at the surface. Plants are built to recover from this gas a liquid known as natural gasoline or casing-head gasoline.

Many deep, high-pressure fields produce a substantial amount of straw-coloured oil knomn as condensate. This condensate is, in effect, a light crude oil, even though it is not a liquid in its underground state. Extensive research on methods of recovering this condensate has made it an important source of petroleum products.

Unitization.—Under U.S. property laws, each leaseholder has the right to produce his own property. Under many state conservation statutes, leaseholders are permitted to pool their interests. so that the reservoir can be produced as a unit. This practice, called unitization, is gaining wider acceptance throughout the oil industry.

Unitization is encouraged by federal regulations relating to the public domain and permitted by the laws of many states. It provides for the orderly, joint development of a field for the benefit of all. More oil is ultimately produced at less cost to the consumer. The landowner who leases his land to an oil company continues to receive his proportional share of royalties from oil produced from the entire field.

U.S. Interstate Oil Compact Commission.—Co-operating in effectuating state conservation measures in the U.S. is the Interstate Oil Compact commission, established by act of congress in 1935. This act enabled oil-producing states to co-operate in the exchange of information both in the production and in the conservation of their petroleum resources.

Estimates of Increases in Recoverable Reserves.—Water drive and gravity drainage proved the most efficient means for obtaining high recovery. One authority estimated in 1952 that modern production methods, as practised under the regulations of state conservation agencies, had resulted in an increase of 50% in the recoverable reserves. All authorities agreed that the figure is "very large," and that further improvements promise additional increases. A survey of Texas fields, made in 1954, estimated that fields of that state, which had produced 14,800,000,000 bbl. (much by early wasteful practices), had remaining reserves of about 26,200,000,000 bbl., 10,500,000,000 of which could be produced by secondary recovery. The survey also indicated that 53,400,000,000 bbl. left in the ground could not be recovered by knomn methods. The report suggested that the recovery for the state would average about 43%. Another study, published in 1955, covering the entire U.S., estimated 272,000,000,000 bbl. as the original oil content of the known commercial reserves. The sum of past production and primary and secondary reserves was given as 105,000,000,000 bbl., leaving 167,000,000,000 bbl. of oil unproducible by existing methods.

Conservation in East Texas.—One of the outstanding examples of conservation occurred in the fabulous east Texas oil field which in 1932 began to go to salt water and to lose its natural pressure. The field mas shut down and conservation methods devised, including the drilling of salt-water injection wells to bolster the pressure of the field. In 1956 there were 82 salt-water wells injecting over 400,000 bbl. daily into the field, and it was estimated that up to that time 1,947,300,000 bbl. of water had been injected back into the oil reservoir. Oil experts figured that the salt-water injection program had resulted in saving approximately 600,000,000 bbl. in the east Texas field alone.

Indeed. the majority of major fields in which the pressure was maintained reasonably close to the original pressure, either through conservation of the natural reservoir energy or through injection of gas or nater, recovered over 50% of their oil in place. Such recovery under efficient practice may be contrasted with the recovery of about 20% or 25% commonly expected from reservoirs depleted under inefiicient methods prior to 1930.

In fields that were produced by inefficient primary-recovery methods, secondary-recovery operations can be used to obtain substantial additional production. Ultimate recovery by primary and

secondary operations of 40%–60% is common under good secondary-recovery practice. Secondary recovery in depleted reservoirs is generally not so efficient as the equivalent fluid injection carried out as a pressure-maintenance operation in a ne field.

Difficulties Encountered. — Often practical considerations make it impossible to use the more efficient reservoir mechanisms. One of the most common problems is that the application of efficient reservoir-engineering methods generally requires unitization of the pool, or operation under conservation regulations that have substantially the same effect as unitization. In some oil fields in flush (natural-flowing) production it is virtually impossible to reconcile the interests of the various property owners so as to permit the adoption of a program for development and operation which would lead to maximum recovery from the whole field. As a last resort, the property owners may reach a satisfactory unitization agreement, but the arrangement of such agreements is sometimes extraordinarily difficult. Then too, there may be good economic reasons for not adopting pressure-maintenance operations in the early life of some fields.

In the case of smaller fields with reservoirs of poor quality, rapid production at the expense of high recovery may offer an acceptable pay out on the investment in the properties, whereas pressure-maintenance may result in too slow return of the capital tied up in the operation.

Finally, in many cases, technical reasons may make pressure-maintenance operations unattractive. For instance, in many reservoirs the viscosity of the oil is so high that only a small percentage of it can be displaced by the flow of any reasonable quantity of gas or water through the rock.

New Recovery Methods. — Although recovery varied greatly for individual fields, experts declared that many of the larger and more important fields in the U.S. discovered since 1930 were probably leaving little more than the residual oil unproduced. Most of the oil which mould not be produced under practices current in the latter 1950s was in older fields. Active research in laboratories and in the fields throughout the U.S. was being carried on to make greater recovery in these fields technically and practically possible.

Several methods of applying solvents in the field were under test. The use of LPG (liquefied petroleum gas) components to enrich injected gas gave results which suggested that under favourable conditions recoveries of the order of 80% might be obtained in practice. The possibility of using nonhydrocarbon solvents such as carbon dioxide were being studied. Vaporization of a part of the residual oil by gas injection at high pressure was also under test in the field.

Several thermal methods of increasing recovery were under investigation. Laboratory tests and theoretical studies demonstrated that any of these new recovery methods was capable of removing almost all of the oil from the rock through which it was operative. Only two barriers kept them from being widely used. One was the physical problem of controlling the fluid distribution in the reservoir in such a way as to operate throughout the productive section of highly complex and irregular reservoirs. The other was the high cost of the proposed methods compared with conventional producing methods.

Improved Drilling Methods. — Io 1925 the deepest well drilled was around 7,000 ft., and 5,000-ft. wells were uncommon. In 1952 a well 5,000 ft. in depth was considered relatively shallow, and many fields were producing from depths between 12,000 and 15,000 ft. In 1949 the first well to reach a depth of more than 20,000 ft. was drilled in Wyoming.

Early wells were drilled by the cable-tool system, and to reach depths of 3,000 to 4.000 ft. by this method was a slow and laborious process. Rotary-drilling methods were first used in 1901 in the Spindletop field near Beaumont. Tex. With the advent of better steels this method was greatly improved, and by the early 1920s it was the commonly used method for drilling nells.

The drilling of deeper wells was made possible by general improvements in the design. strength and power of drilling machinery; by metallurgical progress in the manufacture of alloy steels and advances in the fabrication of drill pipe, casing, tubing and pumping equipment; by scientific control of drilling fluids resulting in greater drilling speeds. drilling through formations previously impossible to penetrate with ordinary drilling muds and security from blowouts; and by improvements in cements and cementing practices and the development of techniques satisfactory under high subsurface pressures and temperatures.

The introduction of electrical well-logging equipment greatly assisted the correlation and evaluation of subsurface strata and consequently improved completion practices. The early techniques were applicable only before the casing was set, but later developments made logging possible through the casing and thus provided a means of evaluating formations behind the pipe in old wells.

Core-analysis equipment and techniques were perfected so that core samples of formations could be tested immediately upon their recovery at the surface and possible reserves recognized during the process of drilling. Complete truck-mounted laboratories provided this service at the well to any wildcatter, making available information as to porosity, permeability and fluid content of the core samples of the strata.

Examination of the drilling fluid under ultra-violet light and other special tests assisted in determining the fluid content of formations penetrated by the bit.

In 1956 the announcement of the securing by a U.S. concern of a licence to manufacture a turbodrill developed by Russian technicians created a stir among oilmen. Turbine drilling as compared with rotary drilling is faster and therefore cheaper, according to claims made by a Soviet engineer at the fourth Petroleum World congress at Rome in 1955. Efforts to perfect the turbodrill had been virtually suspended in the U.S. at the outbreak of World War II after years of testing. The Russians stated that 65% of Soviet drilling was by the turbine method.

In 1956 the world's deepest hole was reported to be the Richardson & Bass 1-L Humble-LL & E-State Lease 2414 in Louisiana, still drilling at 21,535 ft. The deepest producer was Shell Oil company's gas-condensate well at Weeks Island, La., producing from 17,558–84 ft. The deepest cable-tool well in the world was drilled in Chemung county, N.Y., by the New York State Natural Gas corporation to a depth of 11,145 ft. It was started June 8, 1948, and continued to June 3, 1953, when it was abandoned as dry. The drilling operation represented an expenditure of $195,000.

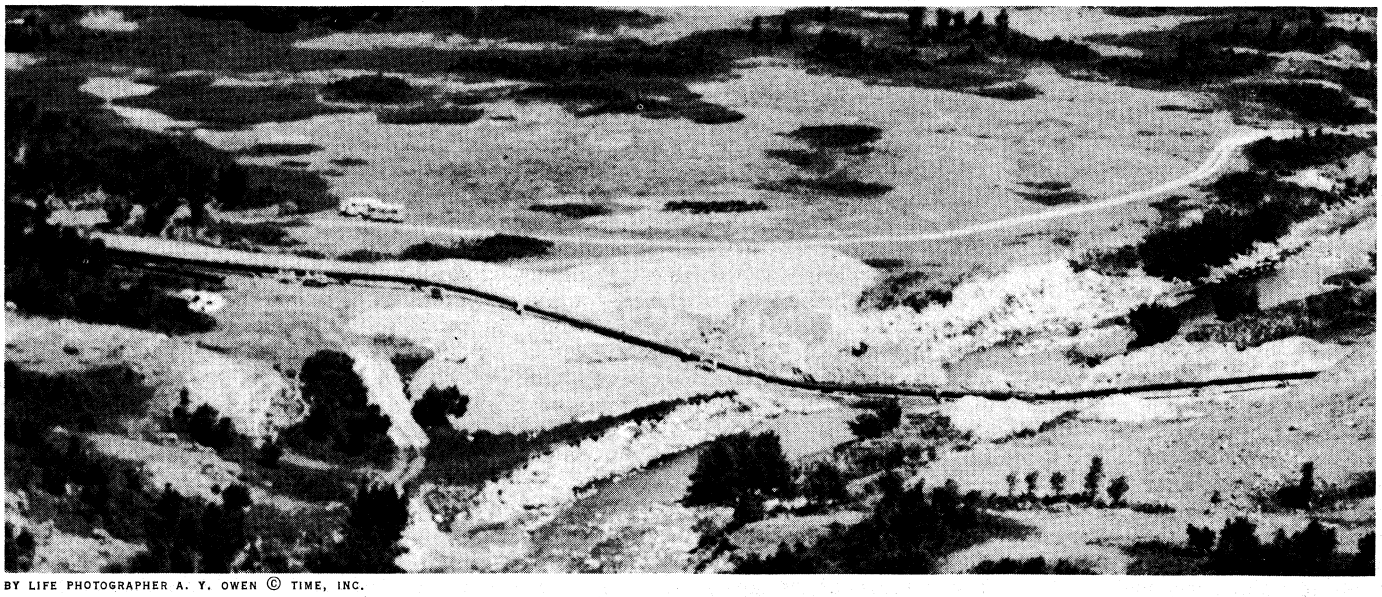
Offshore Drilling. — The opening up off the California coast of the pools of the continental shelf was made possible by the development of subsurface well-surveying instruments and directional-drilling techniques and their application to reserves under the deep coastal areas. The wells were drilled, from shore locations, on a slant to pools under water.

Drilling on the continental shelf in the Gulf of Mexico and experimentally in the Atlantic and in lakes, bays and shallow.-water areas of the Gulf roast and Venezuela was made possible by the development of suitable equipment for drilling from barges and special foundations. This opened the way to additional thousands of square miles of important prospective oil area and added substantially to crude-oil reserves.

The first discovery in the open waters of the Gulf of Mexico was the Creole field in 1938. World War II and litigation culminating in the supreme court decisions of 1947 and 1950 declaring the continental shelf federal property tended to restrict operations. Finally, in 1953, the federal Submerged Lands act restored to the states the title they previously had held and exercised. During this time, the industry poured $650,000,000 into the offshore fields of Louisiana and Texas. Gross revenue from all the oil and gas sold from the area was estimated at only $110,000,000. Yet this area from Brownsville, Tex.. to Key West, Fla., in water no deeper than 120 ft., constituted about 75,000 sq.mi. structurally promising for oil development.

For the drilling of wells in the Gulf tidelands, either exploratory or development, three general methods were used: the self-contained platform, the small platform-floating drilling tender and the mobile device. The small platform-floating drilling tender was most widely used.

To operate offshore, a base of operations on land must be provided. A permanent base is established in protected waters on



BY LIFE PHOTOGRAPHER A. Y. OWEN © TIME, INC.

SECTION OF THE TRANS-CANADA PIPELINE BUILT TO CARRY NATURAL GAS FROM ALBERTA OIL FIELDS TO CENTRAL CANADA

a navigable channel to the Gulf, and provided with an office, warehouse, communications centre. living accommodations, pipe racks and equipment and supply yard space, oil storage tanks and a slip. A complete offshore drilling unit requires three crew or personnel boats to transport up to 30 passengers and small supplies from the base to the rig. One boat is kept standing by the rig at all times for the evacuation of personnel in an emergency. Another is usually in transit and the third boat is kept in reserve at the base in case of a breakdown and for special unscheduled trips. A work boat is required.

In addition, tugboats are needed at certain times of the year, especially during the hurricane season, and also for short periods when equipment is being moved. Occasionally a deck cargo barge is used with the tug for carrying supplies and water. As an auxiliary to the drilling operation a dependable means of communication between the rig and the shore is necessary; therefore, each operation sets up its own FM radio and marine telephone facilities.

A survey of offshore operational costs published in 1952 showed that the investment made before drilling came to a minimum figure of $980,000 and a maximum figure of $4,050,000. Drilling costs were about $4,471 a day and about 100 days would be required. Tubular goods cost about $125,000 more. Drilling and production costs—estimated as about three to four times greater than uplands costs—were expected to be reduced materially as experience was accumulated in proving this vast potential oil reserve.

The Pipeline.— Not unlike the railways in operating technique, the modern pipeline system is an efficient, clocklike mechanism with dispatchers. district and division superintendents, "track-walkers" and section crews. Great improvements have been made in the pumping and power equipment at pumping stations. Diesel power is uidely employed for the powerful pumps, the performance is steady and continuous day and night, and the operation is almost automatic.

Since the early days. great changes have taken place in pipe material and in the joining of pipe. High-carbon steel was introduced. Methods were developed by which pipe was welded instead of joined by the ordinary screw couplings. In the gas fields, metallurgical science similarly enabled producers to pipe natural gas for long distances.

In the decade after 1927 the transportation of gas by pipeline was extended from a maximum distance of 250 mi. to distances of 1,000 mi. Electric arc welding, which permitted the handling of gas at high pressures; telescopic lines made up of sections of pipe of different diameters, the diameter increasing in the direction of flow as the pressure decreases; and automatic welding processes for field service, used in gas and oil fields, all came into vogue. The subsequent development of high tensile strength, thin-walled, large diameter pipe completely solved the problem of long-distance oil and gas transmission.

Coincident with the installation of gastight, long-distance natural-gas lines. pipeline systems were built to transport gasoline and distillates from the refineries to the main marketing centres. As in the case of natural-gas transmission, this was made possible by advances in metallurgy and in welding practices. Thus the pipeline began to supplement the railroad in the long-distance transportation of the refined products of petroleum. Large quantities of gasoline that would otherwise require the loading, hauling, unloading and return of hundreds of tank cars are moved in a continuous flow through pipes to market terminals.

III. REFINING OF PETROLEUM

Crude oil contains a very limited amount of the hydrocarbons which are suitable for immediate use as gasoline components. Therefore refiners must select other types of hydrocarbons from the crude oil and convert them to types which are desirable in gasoline. Tremendous investments in refining equipment are required to separate the types of hydrocarbons needed and to alter their chemical composition. To accomplish this, a wide variety of refining processes have been developed.

Cracking **of** Crude Oil.—The advent of the automobile in the early 1900s and its quick popularity caused a growing demand for gasoline which the refineries were hard put to supply. Petroleum chemists and technologists devised means of improving the refining processes, which enabled them to produce more gasoline from the crude oil, and thus relieved the tension on gasoline supply. They found the answer in 1915–20 in the thermal cracking of crude oil. Crude oil consists of hundreds of differenthydrocarbon compounds. Cracking is the dissociation or breaking down of the molecules and their rearrangement into a more useful form. In effect, the large molecules are literally broken down by high temperatures and pressures, and they are then regrouped to form the desired finished products. By this means the lo -boiling hydrocarbons, formerly useful only as fuel oil, could be converted into gasoline. Moreover, the quality of the cracked gasoline was found to be greatly superior to that produced by the old boiling or distillation (straight-run) method. Engine power was increased by the use of the improved gasoline, and the motorist got more miles per gallon of gas. The result was a tremendous contribution to the conservation of petroleum.

The next advancement was the development of catalytic cracking. In this operation a catalyst (some common catalysts are alumina. silica and certain clays such as bentonite) is introduced into the refining process to promote and expedite the cracking of the molecules.

Polymerization. — There were many other processes which made important contributions to the yield and quality of modern motor fuel. Polymerization came into use in the early 1930s. It catches petroleum refinery gases once largely wasted or used as fuel and converts them into liquid form. This process is the reverse of cracking. Whereas cracking breaks down the heavier molecules of fuel oil into the lighter ones of gasoline, polymerization combines the smaller molecules of certain gaseous by-products of refining into the chemical components of motor fuel. Installations for this purpose were numerous and polymer gasoline began to complement cracked gasoline.

Hydrogenation. — German technicians had developed a process for the conversion of coal into gasoline. called the hydrogenation process. Refiners in the U.S. began experiments to apply to petroleum a similar process brought there in the early 1930s. Before World War II commercial units were successfully using hydrogenation in making high-grade gasoline. diesel fuels and lubricants, special aromatic solvents and special-purpose pure hydrocarbons. In the process, petroleum fractions were subjected to the action of high-pressure hydrogen, at temperatures ranging from 500° to 1,000° F.. in the presence of catalysts.

The characteristics of the charging stock were altered chemically by this method. The refiner controlled the chemical composition of his final products.

Other **Processes.**—Alkylation was another development of the late 1930s and early 1940s. This process converts other gaseous constituents into high-quality gasoline. Involving a reaction between isobutane and various olefins, alkylation was not even considered possible a bare 15 years before; yet during World War II it was the backbone of the United States oil industry's tremendous production of 100-octane gasoline. Hydroforming, thermal reforming, catalytic reforming. aromatization, isomerization and many other additional chemical processes also came out of the oil industry's research laboratories. These processes lent considerable flexibility to refining and made possible an amazing manipulation of molecular groups.

Scientific development of the natural gasoline industry also added to the supply of high-grade motor fuel and aviation fuel. That development brought about efficient and economical means for recovering and stabilizing this volatile gasoline. Weathering could be dispensed with, thereby reducing waste and loss in storing and handling both the natural gasoline and the finished blended motor gasoline. The stabilization process also opened the way for the isolation and recovery of propane, butane, isobutane and other constituents of natural gasoline which formed the basis of a new fuel and chemical resource — liquefied petroleum gases.

Tetraethyl Lead and Octane Rating. — It had been discovered in 1922 that the addition to gasoline of a small quantity of tetraethyl lead would drastically reduce engine knock. Shortly afterward it was noted that a pure hydrocarbon known as isooctane would not knock in the highest compression engine that could then be built, and that another substance, normal heptane, would knock only under certain conditions.

These discoveries led to the formulation of an arbitrary octane-rating standard for motor fuel. A gasoline was called "87-octane," for example, if it produced the same knock as a mixture of 87% isooctane and 13% normal heptane. With standardized antiknock fuels (in 1956 even as high as roo-octane for premium fuel) automotive engineers could develop the high-compression engine which demanded, for satisfactory operation, what are known as high-octane fuels. Tetraethyl lead. therefore. enabled the automobile engineer to build more powerful and more efficient engines, resulting in economy in fuel consumption. Tetraethyl lead ranks along with the cracking process as one of the important factors in the conservation of crude oil.

Additives. — Tetraethyl lead was perhaps the chemical industry's first important direct contribution to the petroleum industry. As better and more powerful engines were developed and the need for better fuels and lubricating oils became more pressing, the chemical industry's contributions multiplied. In the latter 1950s the petroleum industry used millions of pounds of chemicals each year to improve the quality of its products.

These chemicals are used in two ways. First, in refining processes, chemicals are employed as catalysts in cracking up the molecules, or as solvents and acids (*e.g.*, sulphuric acid) for extracting undesirable fractions from lubricating oil stocks. Second, chemicals such as tetraethyl lead are employed as additives to improve highly refined gasoline and oil stocks. Other chemical additives, called oxidation inhibitors have reduced fuel gumming. which is responsible for loss of engine power and for carburettor clogging. Antioxidants and corrosion inhibitors supplied by the chemical industry are added to help motor lubricating oils withstand punishing heat. Detergents put in motor oils help keep engines clean. Pour-point detergents and depressants make oil flow readily in cold climates and help car starting in cold aeather. Viscosity index improver additives keep oil from thinning out when subjected to high temperatures of engine operation. Antiwear additives also are added to motor oils. It has been declared that these additives, plus rust-preventing additives, have doubled the life of automobile engines.

Jet and Rocket Energy From Petroleum Fuel. — The jet-propelled aeroplane, which uses a burning oil rather than gasoline, was a late development of World War II. and refining technologists developed a new fuel for it, as well as for high-speed jet- and rocket-propelled guided missiles. Co-operative fuel research between the petroleum and aviation industries was carried on, similar to that between the petroleum and automobile industries. As well as improving existing jet propellants, petroleum scientists extended their research into the field of rocket propellants made from certain petroleum and petrochemical products. In Feb. 1956 one company announced a potentially inexpensive propellant made of readily available ingredients — synthetic rubber, carbon black and a fertilizer grade of ammonium nitrate which is actually an extremely pure chemical.

The enormous energy output of jet engines made cooling the oil and bearings a major task, but the oil industry found a solution without which the development of supersonic aircraft powered with gas turbines would have been seriously impaired. As larger rockets were built. rnore powerful propellants and new types of motor Lubricating oils mere being developed for aeroplanes in continental and intercontinental travel, as well as for guided missiles and for the space ship of the future.

Automation in Refineries. — The first refineries were controlled by hand, even to hand firing of the stills with coal. Later refineries started using nonautomatic control devices with the controls adjusted manually. By the latter 1950s many refineries were equipped with instruments to continuously determine the composition of process streams and automatically make precise, immediate adjustments to the control devices. formerly reset by hand, mhich then automatically adjust the operating equipment to return the product to correct standards. Technologists identify these instruments by the properties measured, such as refractive index, specific gravity, dielectric constant and infra-red or ultra-violet light absorption.

Products of **Petroleum.**—A barrel of crude oil is generally considered to be composed of five constituent parts, or product groups. The lightest of these groups is made up of gases, and the successively heavier ones consist of the light, middle and heavy distillates and the residues. In the refining process, the lightest groups are distilled or "boiled off" first, and for this reason are referred to as being at the "top of the barrel." By beginning at the top of the symbolic barrel and working down, the order in which the essential petroleum products take form in the refinery can be traced.

A survey conducted by the American Petroleum institute showed a total of 2,347 petroleum products as classified in the following list:

Class of Product	Number of products
Fuel gas	1
Liquefiedgases	13
Gasolines:	40
Motor	19
Aviation	9
Other (tractor, etc.)	12

Gas turbine (jet) fuels	5
Kerosenes	10
Distillates (diesel fuels, light heating oils)	27
Lubricating oils (light and heavy, compounded and uncompounded)	1,156
White oils	100
U.S.P.	78
Technical	22
Rust preventives	65
Transformer and cable oils	12
Greases	271
Waxes (crystalline and microcrystalline)	113
Residual fuel oils	16
Asphalts (including road oils, tars, etc.)	209
Cokes	4
Carbon blacks	5
Chemicals and other (including solvents)	300
Total	2,347

Source: American Petroleum Institute.

The gases that are taken from the ground in association with crude oil are a source not only of gaseous products but of solid and liquid ones as well.

These include gas, used in refineries and factories for heat, light and power; liquefied petroleum gases, used extensively in rural areas for cooking and heating; carbon black, an ingredient of printing inks and synthetic rubber; and raw materials for making chemicals.

One of the most important of these chemicals is synthetic ethyl alcohol. which is valuable both as a solvent and in the manufacture of plastics and explosives. Another is isopropyl alcohol, used primarily as an antifreeze. Oil companies themselves manufacture 300 chemicals, while innumerable others are produced from petroleum intermediates by nonoil companies.

The best-known products of the light distillates are the gasolines. The production of gasolines alone amounts to about 1,250,000,000 bbl. a year, and represents 40 distinct types, each designed to do a specific job. Some are made for automobile engines, some for aeroplanes, some for tractors. Some are designed for summer, some for winter use. Some work best at high altitudes, some at low. Also, gasolines are components of jet fuel. Other light distillate products are the naphthas, from which are derived dry-cleaning fluids, rubber solvents and toluene, used in dyes and explosives.

In the middle distillates are the kerosenes used as fuels; light heating oils for commercial, industrial and home use; and diesel fuels. This group also furnishes a number of important products such as naphthenic acids.

The largest group of products — lubricating oils numbering more than 1,000 — are refined from the heavy distillates. These oils are employed in the moving parts of virtually every machine in existence — from turbines to watches, from the gears in a motorcar to the spindles in a textile mill. There are journal oils and transformer oils. switch oils, hydraulic oils and tempering oils. Each lubricating oil is designed for a clearly defined purpose.

Along with lubricating oils, the heavy distillates provide a wide range of white oils. petrolatums and paraffin waxes. White oils are the base for numerous medicines and cosmetics, for tree sprays and insecticides and the oils used in the manufacture of candy and in the packing of fruits and eggs. Petrolatums are used in preparing salves and creams, and in making rust preventives and rubber softeners. Waxes are important in the manufacture of paper and polishes and as sealers in home preserving.

Asphalts, coke and residual fuel oils are the chief products of the heaviest group, known as the residues. Asphalts provide roofing, paving and waterproofing materials. Coke serves as an industrial fuel and supplies the carbon for carbon electrodes. From the residual fuel oils come boiler fuels and wood preservatives.

The Petrochemical Industry. — In separating the chemical compounds of crude petroleum into their component parts. from light gases to heavy oily liquids, the refining industry supplies many of these parts — or intermediates made from these parts — to the chemical industry for the synthesis of entirely different materials. Because the end products bear no resemblance to petroleum itself. the role of these petroleum derivatives in industry and daily life is less known than that of the more direct products of refinery distillation. Yet petroleum has been the centre of a chemical revolution. Intermediate chemicals derived from petroleum sometimes are called petrochemicals, and products made with their help are referred to as petrochemical products. A whole new synthetic rubber industry grew with the help of the petrochemical butadiene. The array of plastics partly derived from petroleum may run, in finished form, from clocks and combs to nylon socks and acetate rayon neckties — or into the countless uses to which nylon is put in industries and other activities. Crease-resistant fabrics such as Dacron polyester fibre and Orlon acrylic fibre both are made from petroleum intermediates.

Paints, insecticides, detergents, cellophane and photographic film all utilize in their manufacture chemicals derived from petroleum. Polyethylene is another petroleum-derived product that has found many uses. for example. in refrigerator bags, nonbreakable tumblers, squeeze bottles and insulation for electric wires. Petroleum has made possible a revolution in the chemical industry. Some oil companies opened vast new plants, distinct from their refineries, for the manufacture of petrochemicals alone, while, as mentioned, nonoil companies — chemical concerns — made up the other part of the rapidly expanding petrochemical industry.

Petroleum and the Atomic Age. — Oil companies invested millions of dollars in atomic radiation laboratories where, at the beginning of 1956, over 160 atomic refining research projects were being conducted. The oil industry made wide use of radioactivity, especially of radioactive isotopes. Oil drillers gained knowledge of the subsurface by measuring the natural radioactivity of underground strata, or by measuring the reflections of artificial radiation from these rock layers. Flow problems of many kinds, involving both liquids and gases, were studied by means of radioactive tracers.

But in its new radiation laboratories, in the latter 1950s, the petroleum industry was studying applications of radioactivity that extended far beyond these uses of isotopes as tracers. Its major purpose was to explore the possibilities of using radiation to promote chemical reactions essential to oil refining and possibly useful in the production of petrochemicals. Petroleum atomic laboratories also were studying new oil products specifically related to the atomic age — for example, lubricants for atomic engines of the future.

IV. U.S. PETROLEUM INDUSTRY

The recognized birth of the U.S. petroleum industry occurred in the backwoods of western Pennsylvania, near Titusville. There, on Aug. 27, 1859, a former railroad conductor. Edmin L. Drake, struck oil in the first well actually drilled for petroleum. Before that wells were dug by hand or petroleum a-as recovered from seepages.

Investment in the U.S. Petroleum Industry. — By the latter 1950s, the U.S petroleum industry was one of the largest and most important parts of the country's economy. Its operating divisions utilized $37,500,000,000 of gross fixed assets, furnished direct employment to more than 2.000.000 workers and purchased vast quantities of steel, chemicals and other products. With sales of petroleum products. natural gas and chemical products at new levels and with some higher prices, it was calculated that the gross income of the entire industry in the United States, based on consumer prices, reached $19,800,000,000 in 1954. In terms of capital investment. the petroleum business was considered one of the largest in the country. It was estimated that the combined assets employed by the industry as a whole amounted to $47,000,000,000 at the end of 1954. The main components consisted of: gross fixed assets, 79.4%; current assets, 19.4%, other assets, 1.2%. Gross fixed assets amounting to $37,500,000,000 represented the industry's investment in property, plant and equipment. Distribution by departments was as follows. production 59.4%, transportation 11.5%, refining 17.1%, marketing and other facilities 12%. Gross investment of 35 important companies in property, plant and equipment on Dec. 31, 1954, both in domestic and foreign fields, aggregated $30,581,000,000 against which reserves of $14,496,000,000 were accumulated, leaving an indicated net value of $16,085,000,000. See Table I.

U.S. Petroleum Production and Consumption. — In the latter 1950s the U.S. was by far the largest oil-producing country of the world. Annual crude-oil production increased from 209,000,000 bbl. in 1910 to 2,469,600,000 bbl. in 1955 (estimated). *(See* Table II for production figures covering the period 1940–55.)

The U.S. also was the largest oil-consuming nation of the world. and in 1955 over 3,000,000,000bbl. were used. This peacetime consumption represented an estimated 50% of total world consumption. Moreover, the U.S. had provided the bulk of the oil used by the Allied military establishments in World Wars I and II —90% and 69% respectively. Although there were recurring oil shortage scares. no oil famine ever materialized, but in later years the U.S. supplemented home production with imports on a larger scale than ever before. *See* Table III.

Texas was the principal oil-producing state of the U.S. in 1953,

accounting for 43.4% of the total. Following were California with 15.4%; Louisiana, 10.8%; and Oklahoma, 8.5%. *See* Table IV.

There were 501,859 producing oil wells in the U.S. at the end of 1953 and over 57,000 wells were being drilled annually for oil and gas, representing almost double the number drilled in 1945. Of the total drilled in 1955, 21,100 nells or 36% were dry holes.

U.S. Reserves. — After World War II discovery of new oil fields continued in the U.S., with the result that proved reserves rose year after year, despite the mounting production. However, the net yearly increases in proved reserves grew small, and in 1955 were far below those for the immediate postwar years when they exceeded 1,000,000,000 or more barrels on at least six annual occasions. At the end of 1955 proved crude-oil reserves mere 30,012,170,000bbl. and natural gas liquids 5,438,565,000 bbl., making total liquid hydrocarbon reserves of 35,450,735,000 bbl., an increase of only 645,532,000 bbl. over 1954. *See* Table V.

Crude-Oil Prices. — Crude-oil prices were under government control during World War II. When price control was lifted they advanced and were again placed under control after the Korean war started. This control was lifted in April 1953. Oklahoma-Kansas 36 A.P.I. gravity oil sold at $1.02 a barrel in 1939,

advanced to $1.17 in 1941 and remained pegged at that figure during World War II. In 1947 the price advanced to $1.62; in 1948 to $2.57. and in 1954 to $2.82 per barrel.

U.S. Refineries. — To convert crude oil into usable products, United States refineries processed 2,730,200,000 bbl. (estimated) in 1955, a record. This compared with 1,719,534,000 bbl. run in 1941 and 1,237,840,000 bbl. in 1939. Refinery capacity reached a new high, standing at 8,534,900 bbl. per day at the end of 1955, compared with 5,315,856 bbl. at the end of 1945. There were 337 petroleum refineries in 37 states at the beginning of 1954.

Transportation. — To carry the crude oil from field to refinery and refined products from refinery to market there were in the U.S., in 1952, 170,000 mi. of pipelines. The industry operated great fleets of tank trucks. In addition, there was an enormous movement of refined products (and a relatively small shipment of crude oil) by rail in petroleum tank cars which as of Jan. 1, 1953, numbered 121,871, most of them owned by the petroleum industry. A large oil tonnage also was carried by tank barge on inland waterways. And a vast tonnage of both crude oil and petroleum products was transported by tank vessels in coastwise and foreign trade by a world tanker fleet, which at the end of 1955 totalled 2,681 ships of 41,623,100 dead-weight tons, of ahich 490, of 7,989,500 tons, were under U.S. registry and 823, of 13,890,600 tons (all flags), were U.S. owned. *See* Table VI.

Motor Fuel. — Motor-fuel production in the U.S. in 1955 reached a high of 1,343,400,000 bbl. (estimated) compared with 793,431,000 bbl. in 1945. Motor vehicle registration also recorded a new high of 61,300,000 vehicles. compared with 31,000,000 in 1945. **See** Table VII. By 1953 state gasoline taxes ranging from four to seven cents per gallon were imposed by every state and the District of Columbia. In 1932 the federal government also began to tax gasoline.

TABLE VII.—*Motor Fuel Produced and Motor Vehicle Registration, U.S.*

Year	Fuel (000 bbl.)	Motor vehicles (000,000)
1940	616,314	32.5

Of the 56,279,000 motor vehicles registered in 1953, 46,289,000 were passenger cars; 9,162,000, motor trucks; 141,000, buses; and the balance (consisting of publicly owned vehicles) were unclassified. The estimated average annual consumption of motor fuel by passenger cars (calculated by the American Petroleum institute) was 694 gal. in 1953 as against 503 gal. in 1945.

Distillates and Fuel Oil. — The increase in the production and use of distillates and residual fuel oil in the U.S. was no less substantial than that of motor fuels. Refineries had a record output of 602,100,000 bbl. of distillate in 1955, compared with 249,224,000 bbl. in 1945. Residual fuel oil output, however, was still substantially below the 1948 record. *See* Table VIII.

Diesel-Oil Consumption. — Diesel-engine development began after World War I. The diesel engine displaced steam in many passenger vessels and freighters and also began to compete with the steam engine in powering railway locomotives. But, after World War II, U.S. railroads entered into a program of dieselization. which largely relegated the steam locomotive to the past. At the same time, dieselization of motor trucks, tractors and construction equipment occurred on a large scale.

Fuel-Oil Consumption in Homes. — The automatic oil burner for heating homes was introduced in the U.S. in 1917 and came into widespread use in the late 1920s. Its greatest gains, however, came after World War II. There were 6,992,000 automatic oil burners in U.S. homes at the beginning of 1954, more than double the 2,821,000 in use at the beginning of 1947 and more than six times the 1,152,123 in use as of Jan. 1. 1935. In addition there were millions of homes using space heaters which burned fuel oil distillate.

Use of Petroleum Products on the Farm. — By the latter 1950s farmers operated more than one-third of all the motor trucks in the U.S. The use of trucks to carry farm products to the market and manufactured products to the farm had grown into a great transportation system. The gasoline engine, the oil-fuelled diesel engine and the kerosene engine furnished the power for most farm machinery. As of Jan. 1953 there were 4,400,000 tractors in use on farms in the U.S. compared with 2,585,000 at the beginning of 1946 and 1,447,000 at the start of 1939.

Petroleum chemicals played an important role in modern farming practices, being used as fertilizers, soil fumigants and insecticides. Oil companies established agricultural laboratories which included experimental farms serving as proving grounds

for improved and new products.

Liquefied Petroleum Gases.—By the latter 1950s liquefied petroleum gases consisting of propane and butane were widely used in suburban and rural areas for cooking and for heating homes. These bottled gases also supplied motive power on the farms and were used for smoking meat, ripening vegetables. heating incubators and pasteurizing and sterilizing.

Bottled gas also was used to enrich manufactured gas, to heat industrial plants and as a component in synthetic rubber and chemical solvents. Estimated sales in the U.S. during 1955 totalled 6,006,000,000 gal., compared with 1,276,766,000 gal. in 1945 and 76,8 j5,000 gal. in 193 j.

Although house heating was the biggest single factor in the industry's phenomenal growth. by the latter 1950s LPG for motor fuel was one of the fastest growing uses. It was estimated that in 1955, 671,000,000 gal. were used in internal-combustion engines. an increase of 22.6% for the year and representing about 11% of total industry sales. The biggest users were trucks. tractors. buses. irrigation and drilling engines. The largest sales increase in any single category. however. was in the use of LPG in the manufacture of synthetic rubber components. an increase of 56.3% to a total of 481,000,000 gal.

V. WORLD OIL SITUATION

World Production of **Oil.**—Table IX gives the production of the principal oil-producing countries of the world in 1955. However. whereas U.S. production accounted for 71% of world production in 192 j and 63% in 1930, the figure was only 44.56% in 1955. These statistics strikingly revealed (1) the tremendous growth in world production; (2) the gradual recession of the U.S. from its dominant position. though it remained the world's foremost oil-producing country; and (3) a profound change in the traditional flow of oil in the world's markets. Table X reveals the extent of this change.

World Oil Reserves.—Estimated world crude-oil reserves as of mid-year 19 jj reached a total of 154,539,200,000 bbl. compared with 58,026,596,000 bbl. at the end of 1945, as shown in Table XI.

U.S. Operations Abroad.—The picture of world production and reserves as it relates to the position of the U.S., however, needs further explanation. The U.S. industry has become international in scope, operating in the main oil-producing areas which are not under the control of the U.S.S.R. In 1937 U.S. companies. according to private sources, accounted for about a third of the production in areas outside the U.S., exclusive of the U.S.S.R. and the satellites and in 1953 they were credited with close to half of this total.

The Middle East.—With the middle east accounting for 93,265,000,000 bbl. or over 60% of total world reserves (Wallace E. Pratt, U.S. geologist, early in 1956 placed the figure at 121,700,000,000 bbl. or about 70% of his estimated free-world total of 172,100,000,000 bbl.), a reshuffle of world markets occurred. The discovery and tapping of these reserves came only because of pressures related to Europe's relative dependence on foreign oil sources. The British government bought an interest in the Anglo-Persian Oil company (Anglo-Iranian Oil company, British Petroleum company) before World War I as a measure of insurance for a navy whose vessels were being converted to oil burning. Britain saw a middle east supply eventually promoting the end of its dependence on the U.S., which at that time produced about 80% of all world oil and perhaps accounted for as high a percentage of world refining capacity. The Anglo-Persian Oil company met with phenomenal success after World War I. opening up one of the world's greatest oil fields in Iran and building what became the world's largest refinery at Abadan on the Persian gulf. There was also an expansion of home refineries in Europe.

British, Dutch and French interests at the close of World War I took the next significant step in the middle east. With the breakup of the Turkish empire they exercised rights to explore various of the newly set up mandates and protectorates by taking over the Turkish Petroleum company, which had rights throughout the old Turkish sultanate.

Only after the U.S. state department protested the "closed door" policies involved was U.S. participation permitted in the Iraq Petroleum company. formed to supersede the old Turkish Petroleum company. In 1927 a great new field was opened in Iraq. Iraq became the second largest oil-producing country of the middle east. In 1956 Iraq Petroleum ownership was divided 23¾% each between Near Eastern Development (equally owned by the Standard Oil Company [New Jersey] and Socony-Vacuum Oil company), British Petroleum (54% British government owned). Royal Dutch-Shell (60% Dutch and 40% British capital). Compagnie Française des Petroles (35% French government owned), and 5% Participations and Investments Ltd. (formerly C. I. Gulbenkian).

In the 1930s the Standard Oil Company of California and the Texas company jointly with their Bahrein Petroleum company and their Arabian American Oil company (Aramco) made sensational oil strikes on Bahrein Island and in Saudi Arabia. The Gulf Oil corporation and the Anglo-Iranian Oil company with their Kuwait Oil company had as notable results in the tiny sheikhdom of Kuwait. By the beginning of World War II it was evident that the middle east held a fabulous store of oil.

The war vitiated the "red line agreement" which prohibited owners of Iraq Petroleum from operating outside the old Turkish sultanate. This enabled the Standard Oil Company (New Jersey) and the Socony-Vacuum Oil company to share in Aramco's great expansion and in building a pipeline to the Mediterranean.

In June 1951 Premier Mohammed Mossadegh succeeded in ousting the Anglo-Iranian Oil company from Iran and setting up a government-owned company, the National Iranian Oil company. In 1954, after a costly three-year attempt at nationalization during which the oil fields and the great refinery were virtually shut down, a consortium of international oil companies was formed. As the result, from all-British sponsorship Iran's oil development became

the responsibility of a number of nations under a holding company called Iran Oil Participants, Ltd.

Under the agreement, the Anglo-Iranian Oil company, which soon after changed its name to British Petroleum company, was to receive approximately $600,000,000 over a period of years from the other consortium members and, in addition, $70,000,000 from Iran over a ten-year period beginning in 1957 for a portion of its properties excluded from the consortium agreement and the net settlement of claims and counterclaims from the past.

Source: World *Oil*, Aug. 15, 1956.

The agreement, signed only after 11 months of negotiation, was designed to fulfil both the requirements of the consortium for proper business management and the spirit of the Iranian nationalization law. In return for permitting the consortium to operate its nationalized oil development and refining, the government was to receive about $400,000,000 over the first three years in addition to a large and continuous annual income thereafter based upon the volume of business transacted.

The National Iranian Oil company remained as its government's petroleum resources authority. The consortium set up two companies to operate in Iran, one concerned with exploration and production, the other with refining. The national company had two of seven directors on the board of each operating company. Payments to the national company and payment to Iran of income taxes were based on the consortium's participants getting Iranian oil on essentially the same fifty-fifty financial basis as in other middle east producing areas. The national company received a cash payment of 12½% of the price of crude oil, or might elect to take an equivalent of crude oil in kind.

Under the arrangement the national company obtained refined products for consumption in Iran at slightly above their cost and distributed them locally. It was directly responsible for such activities as employee transport, housing, medical services, operation of food supply systems, industrial and technical training. and was to be compensated by the consortium for these services to the extent that they were necessary to the oil operations. With the exception of certain limited rights of the national company as regards exploration and production solely for internal consumption, the consortium operating companies were given exclusive rights to conduct oil exploration and production operations in the area covered by the agreement. The life of the agreement was to be 40 years, including the provisions for three j-year extensions, and the arrangements included reduction of the area covered by the agreement at the end of stated periods. In the event of misunderstandings, procedures for arbitration were specifically stated. The agreement could not be annulled, amended, modified or interfered with through legislative or administrative acts of the Iranian government.

The companies, and the extent of their holdings, in Iran Oil Participants, Ltd., are British Petroleum 40%, Royal Dutch-Shell 14%, the U.S. consortium group of five (Standard Oil Company [New Jersey], Socony-Vacuum Oil company: Gulf Oil corporation, the Texas company and Standard Oil Company of California, 7% each) 35%, Cie. Française des Petroles 6%, and Iricon agency (a second U.S. group comprising Atlantic Refining company, Hancock Oil company, Pacific Western Oil corporation, San Jacinto Petroleum company, Signal Oil and Gas company, American Independent Oil company, Standard Oil Company [Ohio] and Tide Water Associated Oil company) 5%.

Shift to the "Open Door."—In many countries by the latter 1950s. new or amended petroleum laws made it easier for privately owned companies to engage in production operations. This distinct shift from nationalization and a closed-door policy made the path easier for private companies to engage in oil operations outside their own countries.

As a prelude, the pattern of concessions covering oil operations underwent profound change. Concessions by the latter 1950s were hard-bitten contracts indicating economic and social change in underdeveloped countries using, or seeking to employ, a rich natural resource to national advantage. An oil contract adhered not alone to a petroleum law, the passage of which almost invariably preceded the attempted development of the resource, but to existing labour laws.

A concession might cover an entire nation or huge tracts running into millions of acres. On the other hand. it might comprise limited acreage as in Venezuela and Canada. Most, but not all, contracts called for the turning back of a part of the acreage to the government when production was found. Royalties varied in different countries and on different concessions in the same country. The trend in new petroleum legislation was toward a royalty of 12½%—as in Turkey, Libya and Guatemala. Laws in these countries were pointed to as models for nations serious about having foreign capital participate in developing their known or still to be proved oil resources.

A contract usually followed the provisions of the country's petroleum law as to royalty provisions, time limitation. percentage of nationals employed, refinery building obligations and profit participation—and often went further than the law. The contract followed the labour law as to wages, benefits, provision for schools, hospitals, housing, utilities and other services—and again, often went further than the law. For instance. companies voluntarily set up comprehensive employee training courses.

Thus foreign operations, projecting into social spheres of edu-

cation, health, housing and utilities, entailed expenses far beyond operational ones to which the U.S.—and largely the Canadian—operations were confined.

Fifty-Fifty Profit Sharing.— The general idea that government and company should share oil profits equally 'briginated in Venezuela in 1943 and acquired final form there in 1948 by invocation of an income-tax law in addition to the petroleum lam. By the latter 1950s most big producing areas accepted this general idea and wrote it into their contracts.

Implementation varied according to country. As applied to a nation, the basis of the fifty-fifty philosophy is that, in return for its share. the government will open its natural resources to development, provide physical protection to operators and their workers and guarantee the normal protection of its laws. On the part of the companies. it means that. in return for their share, they will provide the initial risk capital, the technical knowledge and access to markets.

Old concessions were modified, or new ones written, to embrace the fifty-fifty principal in Saudi Arabia, Iraq. Kuwait, Qatar and in the consortium agreement with Iran—all profitable oil-producing countries. New legislation of Turkey, Libya, Israel and Guatemala —small-producing or nonproducing countries—while adopting fifty-fifty sharing, recognized that such sharing can only be attained gradually.

Such laws provided that the concessionaire can take home not only what he invests but his earnings. There was recognition that an investing concern must know its financial obligation in advance and also have assurance that such obligation will not be increased during the life of the concession. Another trend was recognition of the incentive value of percentage depletion, this being a part of all the above-mentioned new laws. Then, too. more emphasis has been given to tax and foreign exchange provisions aimed toward nondiscrimination.

"Sowing the Petroleum." — The phrase, "sow the petroleum," refers to the practice of plowing back petroleum revenue into public works and into projects designed to stimulate agriculture and diversification of industry—to equalize the imbalance of an oil economy. In Venezuela. where, by the latter 1950s, 60% of the government's revenue came from oil, a large percentage of the income was used to improve public housing and to build highways, ports, schools and hospitals, and to improve agriculture. In Iraq 70% of all oil revenue received by the government, by law, had to be turned over to the Iraq Development board, which used the money for such purposes as irrigation, drainage projects. road construction, mechanization of agriculture and the extension of electrification. Using revenues from oil royalties, the Saudi Arabian government financed the many projects which were serving to raise the country's standard of living. Similarly, petroleum was being "sowed" in Bahrein and Kuwait with notable results. Employment, vocational training, general education, modern housing and health facilities—all on a substantial scale—have also resulted from oil operations in underdeveloped countries.

In Venezuela, for example, the medical and health programs made possible by oil revenues cut deeply into the incidence of malaria and other diseases which formerly had been widespread. Hospitals and clinics brought modern medical care to great numbers of the Venezuelan people. Children who previously never hoped for even a smattering of formal education came to accept daily schooling as commonplace. Venezuela's highway-building programs in 15 years more than trebled the mileage of all-weather roads linking once-isolated communities.

In the middle east, in a relatively few years, revenue from oil investment brought to a desert people standards of living which normally represent the progress of centuries. Health standards were transformed. Water supplies were created by drilling wells which made it possible for once barren areas to produce more of their own food. Oil-company employees were taught not only the skills essential to their jobs at the drilling rigs or refineries, but also the "three R's," typing, bookkeeping, nursing and other subjects. Particularly promising employees were sent to universities. Doctors, engineers and teachers continued to come from these programs.

Following the consortium agreement of 1954, the government of Iran launched a seven-year plan organization to co-ordinate the development of the country and its resources. This would provide railroad and highway transportation facilities, cement factories, drinking-water supplies, irrigation projects, mining development and general improvement of communications as well as expansion of education and public-health facilities.

The evolution of "sowing the petroleum" showed the oil companies spearheading the movement toward better living in underdeveloped countries and justifies an expressed evaluation of their efforts as a private Point Four program. The capital investments of all the oil companies in the middle east alone amounted to about $1,000,000,000 in the five-year period 1951–55. In 1950 the direct revenues to middle east countries from oil operations were equivalent to about $200,080,000. In 1955, oil provided about $880,000,000 in direct payments to governments, or more than four times the 1950 figure.

In the area of southeast Asia comprising the Malayan peninsula, British Borneo and Indonesia—Asia's principal oil-producing territory—"sowing the petroleum" was actively operative in the latter 1950s. (In Indonesia alone over $1,000,000,000 had been invested by foreign oil companies.) In these countries employment had been provided for tens of thousands, over 90% of whom were nationals. Because oil operations were usually in remote places, the companies created towns and maintained all such necessary facilities as houses, streets, water supply, sanitation, commissaries and power plants. Schools and on-the-job training for employees were established. Roads and harbour facilities were provided and expanded. Aided by petroleum revenues, southeast Asian nations put into operation programs emphasizing the improvement of agriculture, transportation and communications, power supplies and fundamental social services.

Early in 1956 the Venezuelan government indicated it would consider new or modified bids for new oil concessions. The second largest oil-producing country and the world's largest exporter of oil, Venezuela had not granted any new concessions for more than ten years. Venezuelan authorities gave two apparent reasons for the opening of new territory for exploration and development: first, a basic need to increase reserves in ratio to rising production and, second, a prospective plan for more oil revenue to finance an expanded industrial and social development program which Venezuela's government hoped would take the country out of the one-commodity class.

New Oil Areas.—Within practically all the established oil-producing countries, intensive post-World War II exploration resulted in the finding of important new productive areas. While the middle east led in uncovering fresh reserves, the U.S. continued to add to reserves despite heavy annual withdrawals. The same was true of Venezuela. In the western hemisphere, Canada scored outstanding results.

Canada's oil boom dates from the Leduc strike in the prairie province of Alberta in Feb. 1947. At that time Canada produced only 20,000 bbl. daily or less than 10% of its requirements. By the summer of 1949, so intensive and successful had been the search by U.S., Canadian and other companies which joined the rush, an estimated 1,000,000,000 bbl. of reserves justified starting the first pipeline—this to the head of the Great Lakes. Potential daily production had increased from 50,000 bbl. in 1949 to 375,000 bbl. by 1954.

However. during the same period Canadian consumption increased from 314,000 to 560,000 bbl. daily, which meant that, though capable of producing much more than its 1949 consumption, Canada was still able to produce only about 65% of its requirements. In 1955 actual production amounted to about 304,000 bbl. daily and represented 57% of Canadian demand for crude oil.

In the mid-1950s it was estimated that since 1947 the Canadian petroleum industry had spent $1,500,000,000 in developing crude-oil and natural-gas reserves. Over 3,200 mi. of trunk pipelines were built and refinery capacity was more than doubled, at an estimated cost of $1,000,000,000. In 1956 crude-oil and natural-gas pipelines, building and in prospect, represented a further invest-

ment of hundreds of millions of dollars.

Between 1946 and 1954 the use of oil in Canada increased more than twice as fast as in the C.S., the most rapid rise being in distillates chiefly for home heating. which accounted for more than a quarter of Canadian oil requirements. Canadians, per person, were the second highest consumers of petroleum in the world; Canada, as a nation, was the third largest. By the latter 1950s one-third of all homes were heated by oil; there was one motor vehicle for every four Canadians, and there were three tractors for every four occupied farms.

But Canadian production was not confined to domestic markets. It was being piped into the U.S. northwest and middle west. Estimated proven reserves in western Canada approximated 3,000,000,000 bbl. at the end of 1955. Authorities believed that by 1980 the figure would be from 23,000,000,000 to 30,000,000,000 bbl. Oil development improved Canada's balance of payments by reducing the need for imported oil supplies and stimulating diversified investment.

Canada's oil development began as early as that in the U.S. (1859), perhaps earlier. Nevertheless, until the Leduc discovery well in 1947 the country was essentially a have-not nation as far as oil was concerned. Other essentially have-not nations, which for generations starved for want of oil, had begun by the latter 1950s to produce volumes promising to their economies. Among them were west Germany, France: the Netherlands and Italy. The search in other countries such as Great Britain and Australia continued unflaggingly, with promise of ultimately successful results. At the core of the notable discoveries in the middle east, in Canada and in Europe, was not, as it might seem. merely skill and improved techniques. At the root was inexorable social change — the pressure of nations and peoples to improve their economies by developing their own energy resources.

Between 1927 and 1955 Russia doubled its crude-oil production. In 1955 Russia and its satellites were credited with estimated reserves totalling 10,606,000,000 bbl., compared with 8,653,500,000 bbl, in 1945. In 1953 Russia began making barter agreements with other nations using its supposed surplus of oil products. The Soviet's oil development proceeded. with a military purpose primarily, if not solely, in mind, while civilian uses were excluded completely or severely restricted. In 1956 the free world topped Russia and its satellites in oil reserves by 14 to 1. But the U.S.S.R.'s indicated inferior position was more apparent than real. for the petroleum industry was being run by the state on a basis dictated by the needs of the army, navy and air force. Also. the Russians had built up sources of oil in all strategic parts of the country.

PETROLOGY is the branch of geology concerned with the investigation of the composition, structure and history of the rock masses building up the accessible portions of the earth's crust (Gr. *petros*, "rock"). Rocks are usually defined as aggregates of minerals without reference to their state of cohesion. Loose sands, clays, gravels or soils are included among rocks as being mineral masses playing an important role in field geology. On the other hand, the less soluble parts of the skeletons of animals and plants may form a considerable portion of rocks as. for example, in the case of coral limestone, lignite and chalk. Lastly. rocks may be built up almost wholly of noncrystalline material such as obsidian, pitchstone or tachylyte, representing liquids so rapidly chilled that consolidation has occurred in the glassy state. Rocks are the units with which the geologist deals in investigating the structure of the earth's crust, and some varieties cover enormous areas. Granite, sandstone and schist often form whole provinces and build up lofty mountains, while other rock types are of such rare occurrence that they are known only in one or two localities in far-removed parts of the earth's surface.

Broadly speaking, rocks are divided into three great classes, igneous. sedimentary and metamorphic. In this article discussion is confined to the nature, composition, classification and origin of igneous rocks and the methods by which they are examined. For the other groups. *see* SEDIMENTARY ROCKS and METAMORPHISM. *See* also MINERALOGY.

Following are the main subdivisions of this article:

I. Treatment oi the Subject
  1. Composition of Igneous Rocks
  2. Magma
II. Methods of Investigation

    9. Granitization
VII. Geographic Distribution of Igneous Rocks

I. TREATMENT OF THE SUBJECT

Below is a brief survey of that part of the science of petrology which concerns igneous rocks, with the headings under which particular subjects are treated (each italicized item has a separate article).

Igneous rocks occur as intrusions or extrusions. The plutonic or deep-seated intrusive rocks which cooled far below the surface occur as *batholiths, bosses, laccoliths* and *veins (see* ORE DEPOSITS), and include *granite, syenite, diorite, gabbro* and *peridotite:* related to the granites are *aplite, greisen, pegmatite* and *schorl;* to the syenites, *borolanite, nzonzonite, nephelite-syenite* and *ijolite;* to the diorites, *tonalite;* to the gabbros, *napoleonite, pyroxenite* and *theralite,* and to the peridotites, *picrite* and *serpentine.* The hypabyssal intrusive rocks occur as *sills, veins, necks,* etc., and are represented by *porphyry* and porphyrite, *diabase* and *lamprophyre;* to the porphyries belong *felsite* and *quartz-porphyry.* The extrusive rocks are volcanic and found typically as lava flows; they include *obsidian, perlite, pitchstone* and *rhyolite, phonolite* and *traehyte, andesite, dacite* and *basalt* (with the related *spilite, tachylyte* and *variolite*), *nephelinite* and tephrite.

Intermediate between the sedimentary and igneous rocks comes the group of rocks known as pyroclastic or fragmental volcanic rocks. These include *agglomerate,* some types of *breccia* and *tuff (see* also VOLCANO). The agencies which affect igneous (among

other) rocks and modify them are discussed under GEOCHEMISTRY, METAMORPHISM, METASOMATISM and VOLCANISM.

1. Composition of Igneous Rocks. — Though the number of recognized minerals approximates 1,500, comparatively few of these are important as rock formers, more especially if the subdivisions into which the common species are broken up are disregarded. The vast majority of the igneous rocks are built up of less than a dozen groups of minerals. These are: (1) quartz; (2) feldspars; (3) pyroxenes; (4) amphiboles; (5) micas; (6) olivines; (7) nepheline; (8) leucite; (9) iron ores; and (10) apatite. To this list, for sedimentary rocks. may be added chlorite, kaolin, montmorillonite, calcite, dolomite and a few other minerals. Metamorphic rocks are built up largely of the same minerals as igneous rocks but include special species which are foreign to the latter, partly on account of their composition and partly because they appear to require special physical conditions (stress) for their production. The mineralogical nature of a rock is primarily dependent on its chemical composition, but other factors are of first importance in determining the paragenesis of rock-forming minerals. principally the mode of origin of the rock or the physical conditions prevailing during its formation. Two rock masses may have very much the same bulk composition and yet differ fundamentally in their mineralogical assemblages. Thus, certain lamprophyres rich in biotite have much the same composition as certain leucite-basalts, a hornblendite may be similar in composition to a camptonite and so on. Igneous rocks of identical chemical composition but dissimilar mineralogical constitution are said to be heteromorphous. The governing factors are the physical conditions attending consolidation of the rock.

All crystalline rocks have consolidated from solution or from fusion. A granite arises by the consolidation of a liquid at high temperatures and great pressures; a metamorphic rock like mica-schist, on the other hand, represents the recrystallization product of a clay rock under the influence of heat and stress. Throughout this conversion the rock has been essentially solid. recrystallization taking place in the presence of minor amounts of interstitial liquid. Other crystalline rocks, like rock salt, gypsum, anhydrite, etc., have been deposited from solution in water, mostly as a result of evaporation on exposure to the air. The majority of sedimentary rocks, however, consists of a mechanical aggregate of crystalline particles; such are sandstone, clay, etc. The structure of these sedimentary and all pyroclastic rocks is referred to as fragmental.

2. *Magma.* — All igneous rocks have solidified from a state of liquidity, the liquid that finally consolidates as rock being technically referred to as magma (Gr. magma, from *massein*, "to knead"). Rock magma is a complex silicate solution carrying gases; the most important part of the solution is water, which may constitute 5% to 6% of the mass. The greater part of the clouds given off by active volcanoes consists of steam, with which are associated minor amounts of other gases, the chief being carbon dioxide, carbon monoxide, hydrochloric acid, sulfur vapour, oxides of sulfur, hydrogen sulfide, hydrogen fluoride, ammonia, methane, chlorine, fluorine, hydrogen and nitrogen. When the magma consolidates the major part of these volatile constituents usually escapes. With very rapid cooling, however, the magma may solidify without crystallization as a volcanic glass, at the same time retaining much of its water. Analyses of pitchstone show not infrequently a content of 5% to 6% of water, and even higher values are recorded; on the other hand unaltered crystalline igneous rocks seldom show a water content greater than 2%. Here there is almost direct confirmation of the conclusion that the water content of the magma before crystallization is greater than the water content of the rock formed from it.

From what source is igneous magma derived? In the older conception of the earth a volcano was pictured as a safety valve for a molten interior, but a close study of igneous action, past and present, clearly negates any such interpretation. The active vents of Mauna Loa and Kilauea, Hawaii, though only about 20 mi. apart, have the summits of their lava columns at a difference of level of 10,000 ft. Yet liquid lava is erupted more frequently and in greater quantity from the higher column. Clearly these two outlets are not directly connected with a common liquid reservoir. Again, neighbouring vents, as those of the Lipari Islands north of Sicily, erupt widely different products, and each may maintain its independent behaviour regardless of what is happening to its neighbour. The conclusion is enforced that each distinct eruptive centre possesses its own reservoir, and the presence of a number of independent magma chambers underlying an eruptive region is indicated. At greater depth these are no doubt connected with some magmatic reservoir of much larger dimensions. In some such common source the close community of petrographic character revealed in the succession of liquids erupted or intruded throughout any given igneous cycle is to be traced.

II. METHODS OF INVESTIGATION

A. ANALYTICAL

1. Macroscopic Characters. — The macroscopic (Gr. *makros*, "large") characters of rocks, those visible in hand specimens without the aid of the microscope, are extremely varied and difficult to describe accurately and fully. The geologist in the field depends principally on them and on a few rough chemical and physical tests; and to the practical engineer, architect and quarrymaster they are all-important. Although frequently insufficient in themselves to determine the true nature of a rock. they usually serve for a preliminary classification and often give all the information really needed for a particular purpose. With a small bottle of acid to test for carbonate of lime, a knife to ascertain the hardness of rocks and minerals and a pocket lens to magnify their structure, the field geologist is rarely at a loss in deciding to what group a rock belongs. The fine-grained species may be indeterminable by these means, and the minute mineral components of all rocks can usually be ascertained only by microscopic examination; but it is easy to see that a sandstone or grit consists of more or less rounded, natern orn sand grains, and if it contains dull. weathered particles of feldspar, shining scales of mica or small crystals of calcite, these also rarely escape observation. Shales and clay rocks generally are soft, fine-grained. often laminated, and they not infrequently contain minute organisms of fragments of plants. Limestones are easily marked with a knife blade, effervescereadily mith weak cold acid and often contain entire or broken shells or other fossils. The crystalline nature of a granite or basalt is obvious at a glance, and while the former contains white or pink feldspar, clear vitreous quartz and glancing flakes of mica the other will show yellow-green olivine, black augite and grey striated plagioclase.

2. *Microscopic Characters.* — When dealing with unfamiliar types or with rocks so fine-grained that their component minerals cannot be determined with the aid of a lens, the geologist is obliged to have recourse to more delicate and searching methods of investigation. With the aid of the blowpipe (to test the fusibility of detached crystals), the goniometer (to measure crystal angles), the magnet, the magnifying glass and the specific gravity balance the earlier investigators attained surprisingly accurate results. Examples of these may be found in the works of Leopold von Buch, G. P. Scrope, Charles Darwin and many others. About the end of the 18th century D. G. S. de Dolomieu examined crushed rock powders under the microscope and P. L. Cordier in 1815 crushed, levigated and investigated the finer groundmass of igneous rocks. His researches are models of scrupulous accuracy, and he was able to announce that these rocks consisted essentially of such minerals as feldspar, augite, iron ores and volcanic glass and did not differ in nature from the coarser grained rocks. W. Nicol, whose name is associated with the discovery of the Kicol prism, seems to have been the first to prepare thin slices of mineral substances, and his methods were applied by H. Witham (1831) to the study of plant petrifactions.

Petrography. — This method, subsequently of such far-reaching importance in petrology, was not immediately used for the systematic investigation of rocks, and it was not until 1858 that H. C. Sorby pointed out its value. The great work of this investigator was the production of very thin sections of rocks and their systematic examination under the high powers of the microscope. The densest, blackest rock can be made to yield a section of $\frac{1}{1,000}$

in. in thickness, so thin and transparent that fine print can be easily read through it and transmitting light so clearly that the most high-powered objectives of the microscope can be used to discern and study its minutest structures with the same facility that they can be employed upon sections of organic material prepared by the microtome. The introduction of this powerful weapon of research inaugurated a new era in petrology — that of petrography or the descriptive branch of petrology. The optical study of sections of crystals had been advanced by Sir David Brewster, Nicol and other physicists and mineralogists and it only remained to apply their methods to the minerals visible in rock sections. The pioneer workers who brought quantitative methods into the optical side of the problem were A. des Cloiseaux, H. Rosenbusch. F Zirkel, M Schuster, F. Frouqué and A. M. Lévy.

By the second half of the 20th century optical methods for determining minerals with the petrographic microscope were highly developed

Optical *Constants*.—Although rocks at mid-20th century were studied principally in microsections, the investigation of fine crushed rock powders which was the first branch of microscopic petrology to receive attention, was still in use. A mineral whose optical properties are known can be accurately determined by immersing its ponder in liquid media whose indices of refraction are known. and determining the optical constants In the hands of a skilled petrographer the principal optical constants of a single grain of a mineral can be determined in half an hour. The chief fundamental constants measured are the principal indices of refraction, the crystallographic orientation of the directions of light vibration corresponding to those indices and the amount of absorption of light vibrating in these directions, all for one or more standard nave lengths of light. The double refraction, optical character optical axial angle, dispersion of the optic axes and bisectrices and extinction angle are all fixed by the fundamental constants and can be estimated under the microscope.

The immersion media cover a range of optical refraction from that of aater (1.333) to that of a selenium-arsenic selenide melt (3.17). The liquids are chiefly organic substances — acetone. alcohol cinnamon oil. menobrom-naphthalene and methylene iodide. Most minerals have refraction constants ranging in the interval 1.450–1 870, and their refractive indices may therefore be matched by a set of liquids whose refractions cover this range. The modern rotation apparatus whereby thin sections may be tilted irom the horizontal so that the axis of the microscope passes through them at different angles has been of inestimable value in measuring accurately the optical constants of a single grain in a rock slice, and is aidely used for the determination of feldspar and other mineral species of variable composition. A few measurements on a selected section of a mineral permit the determination of its exact chemical composition and the crystallographic orientation of the section itself. The technical methods employed for the determinations referred to above are largely founded on the use of polarized light.

3. Mechanical Separation of Constituents. — The separation of the constituents of a crushed powder in order to obtain pure samples suitable for analysis is also extensively practised. The two principal methods adopted involve either the electromagnet or heavy liquids

By the use of an electromagnet the component minerals of a rock may be separated by varying the strength of the current. A weak magnetic field attracts magnetite, then hematite arid ilmenite. Silicates containing iron will follow in definite order, augite. hornblende. tourmaline, olivine and biotite being successively attracted. The degree of attraction is not, however, proportional to the iron content. The colourless nonmagnetic minerals — quartz, feldspar, muscovite, nepheline. etc.—remain. In the modern laboratory, processes using automatic magnetic separators supplement or replace magnetic separation by hand. Electrostatic and dielectric methods of separation have also been brought into use in the isolation of mineral particles of rocks.

Separation by means of water is not much used in petrographic work. However, a preliminary "panning" as practised by miners is often useful as a means of concentrating rare minerals occurring in very small quantity in the rock before the application of the methods next to be described. Methods of separation of minerals by which they are sorted according to their specific gravities by means of heavy fluids have an extensive application. The fluids used are those which do not attack the majority of the rock-forming minerals.

Of the many liquids used. methylene iodide (sp.gr. 3.32) and bromoform (sp.gr. 2.86) are perhaps the most convenient. For more dense minerals. Clerici's solution — an aqueous solution of thallium formate — is best adopted. By concentration the specific gravity can be raised to 4.32 at 60° C. so that even the heavier rock minerals can be separated without difficulty. By dilution with water, or, in the case of methylene iodide, dilution with bromoform or benzol, successive crops of minerals may be separated in appropriate separating funnels. In this way a granite may be successively fractionated into its component minerals, biotite (sp.gr. 3.1), muscovite (2.85), quartz (2.65), oligoclase (2.64) and othoclase (2.56). All these minerals float in methylene iodide; on dilution with benzol they are precipitated in the order given. Rocks like eclogite containing heavier minerals, such as ilmenite (sp.gr. 4.84), garnet (4.20) and diopside (3.29), may be similarly separated by means of a thallium formate-water solution. Mineral isolation using heavy liquids is commonly carried out with high-speed centrifuges, which greatly hasten settling, especially of the finest particles, and effect a more thorough separation of the minerals.

4. Microchemical Methods. — Chemical methods are frequently of great use. Weak hydrochloric acid will dissolve calcite irom a crushed limestone, leaving dolomite and silicate minerals, and hydrofluoric acid may be used to extract the glassy base of, volcanic and hypabyssal rocks from the pyroxenic minerals. Of much wider use, however, are microchemical methods for distinguishing minerals under the microscope. They are of special value in discriminating alkali minerals like nepheline, haüyne, nosean, analcime and sodalite in the groundmass of igneous rocks. The methods depend on selective attack by acids, the formation of distinctive precipitates and the staining of gelatinous residues. Quartz and ieldspar in fine-grained rocks may be differentiated by etching with hydrofluoric acid; quartz remains clear while the surface of the feldspar grain becomes cloudy, being altered to aluminum fluosilicate. and may be stained by an aniline dye. This method is particularly useful in discriminating quartz and feldspar in fine-grained metamorphic rocks in which the feldspar is without crystal form, is untwinned and shows lack of cleavage.

5. X-ray Methods. — X-ray diffraction methods of identification have also come much into use; they may be applied to single crystals, isolated by the procedures already outlined, or to the finest aggregates. using then the technique of X-ray powder photography. See MINERALOGY: X-ray Diffraction; X-RAYS.

6. Chemical Analysis. — The ultimate chemical composition of a rock is of fundamental importance in determining its nature, and the chemical analysis of rocks is now widely carried out. In rock analysis of the better class as many as 25 constituents are determined and recorded. The most abundant or major constituents are stated as oxides. and any rock analysis of good quality records the content of at least nine or ten of these. They are silica, alumina, ferric and ferrous oxides, magnesia, lime, soda, potash and water. These nine oxides make up about 98% of the igneous rocks. Two other oxides are usually determined, TiO_2 and P_2O_5, as they are represented in the common minor constituents — ilmenite and apatite — titanium being also present in some pyroxenes, amphiboles and micas. Such a chemical analysis is usually sufficient to determine to which of the two great classes, igneous or sedimentary, a rock belongs and, if it is igneous, the position to be assigned to it in any of the conventional classifications. In the case of metamorphic rocks it often establishes whether the original mass was a sediment or of igneous origin.

7. Specific Gravity. — By the balance and the pycnometer the specific gravity of rocks is determined in the usual way. It is greatest in those rocks rich in iron, magnesia and the heavy metals, and least in rocks rich in alkalis, silica and water. Eclogites (sp.gr. 3.5) are among the heaviest of the silicate igneous rocks,

while the vitreous lavas of high silicity like obsidian (sp.gr. 2.35) are among the lightest.

B. Rock Synthesis

The methods of investigation described above may be grouped together as analytical, in contradistinction to the synthetic investigation of rocks, which proceeds by experimental work to reproduce different rock types and thus to elucidate their origin and explain their structures.

1. Pioneer Investigations. — Though the experiments of H. B. de Saussure (1740–99) on the fusion of granites and porphyries may be said to mark the earliest beginnings of experimental petrology, the era of rock synthesis should be dated from the time of the researches of Sir James Hall (1761–1832) on the fusion of dolerites found in the neighbourhood of Edinburg. This investigator shom-ed convincingly that crystalline diabase (British dolerite or whinstone) could be fused and consolidated, according to the rate of cooling, either as black glass resembling natural pitchstone or as crystalline aggregates of minerals much like the diabase from which they came. Hall's most famous experiments, however, were conducted with limestones. Powdered chalk, by being heated in gastight gun barrels, mas converted into a crystalline mass of calcite, thus supporting the contention of James Hutton that heat and pressure had consolidated limestones and converted them into marbles. A lapse of almost 90 years had occurred before the experiments of Hall mere substantiated, when in 1878 the French petrologists F. Fouqué and Michel Lévy began their extensive researches on the synthesis of minerals and rocks by pyrogenetic methods. They succeeded in producing, by the use of a gas furnace and a nitrogen thermometer, such rocks as porphyry, basalt and diabase, at the same time obtaining the characteristic textures — porphyritic. ophitic, etc.—by modifying the conditions under which the melts were cooled. With the more siliceous or acid rocks their experiments were much less successful. They advanced for the first time in a convincing manner the explanation that for the crystallization of these rocks the gases, never absent in natural rock magmas, were indispensable mineralizing agents (mineralizers). Later, it became known that the formation of many minerals is facilitated, or can only be accomplished, in the presence of volatile constituents such as water, borates. chlorides, fluorides, etc. Not only do these assist in promoting the fluidity of the liquid and facilitate crystallization, but they form essential constituents of some of the important minerals occurring in acid igneous rocks (micas, tourmaline, topaz, etc.).

Among the pioneers in synthetic petrology may also be mentioned H. E. Ste.-Clair Deville, H. de Senarmont, P. Berthier, L. Bourgeois, P. G. Hautefeuille, K. Chrustschoff, C. Doelter, J. Morosewicz and J. H. L. Vogt. To Vogt is owed the first comprehensive essay toward bringing the crystallization of igneous rock magmas definitely under the known lams of solution. Beginning a study of a large series of silicate slags, more or less comparable in composition with igneous rocks, he brought together a large body of information throwing light on the order of crystallization, the composition of the eutectics and the lowering of freezing points of the minerals in slag mixtures. these results being directly applied to the elucidation of the crystallization processes in natural magmas.

2. Geophysical Laboratory. — Up to this period the synthetic work, involving as it did the measurement of the melting point of minerals and the succession of crystallization in more or less complex mixtures, though very suggestive, lacked the strictly quantitative element. Experiments were carried out on materials always containing impurities or foreign substances, and the methods adopted for the determination of fixed thermal points such as melting points, inversion points or heat changes were of doubtful precision. In 1904. with the establishment of the Geophysical laboratory at Washington, D.C., synthetic or physicochemical petrology entered upon a new quantitative era. The work of this laboratory was undertaken in order to enter upon a quantitative study of rock formation which should include those minerals and rocks which are geologically important and those which are economically useful, and those formed directly from the magma and those formed by subsequent alteration. The individual problems are in reality problems for physics and physical chemistry; but the delay in attacking them resulted from the fact that the measured relations established by the exact sciences were scarcely of adequate scope to meet the needs of large petrological questions. The great body of physical and physicochemical measurements was confined to a temperature region below 100° C. while processes operating in rocks may have occurred at temperatures up to 1,400° C., an enormous range over which to stretch the application of ordinary methods and one in which the common forms of apparatus not only fail but are themselves threatened with destruction. The initial work of the Geophysical laboratory was primarily to extend the methods of accurate temperature measurement to include the entire field of rock formation from 0° to 1,600" C. The electric pyrometer reached such precision that an error of one or two degrees is all that need be expected in measuring temperatures up to 1,600' C.; moreover. these temperatures can be maintained quite steady for days or weeks at a time. Calorimetric measurements were improved; specific heats can be determined with great accuracy even at the highest temperatures. At the same time petrographic methods were advanced so that the crystallographic and optical constants of the very minute crystals obtained in silicate melts could be accurately measured. The investigation of mineral substances under high pressures and high temperatures combined, and in the presence of volatile constituents, also became a subject of study.

With these methods of precision available for the study of rock materials, examination of simple mineralogical systems was prosecuted. An understanding of the chemistry of the common oxides of rocks and of their combinations is essential to the progress of petrology. Experimental work was conducted on the combinations of the oxides lime, magnesia. alumina, silica; the six possible binary systems were fully n-orked out and the four possible ternary systems thoroughly studied, while portions of the quaternary system were successfully explored. These equilibrium studies were further extended by investigations on silicate systems containing ferric and ferrous oxide, soda and potash and by exploration of some important systems containing water. Much light was thereby thrown on the processes taking place during the consolidation of igneous magmas which, though much more complex in their constitution, yet clearly show by petrographic examination closely similar phenomena, such as are revealed in the crystallization behaviour of these simpler systems. The application of these laboratory investigations to the elucidation of the origin and evolution of igneous rock types will be considered hereafter (see *Plutonic Cornplexes,* below). *See* also Mineralogy: *Experimental Mineralogy.*

III. CLASSIFICATION OF IGNEOUS ROCKS

Igneous rocks are subdivided into many groups according to their composition, chemical and mineralogical, their structures and textures and their mode of occurrence. Between allied rocks there are, however. no hard and fast boundaries, for by increase or decrease in the proportions of their constituent minerals, they pass by every gradation one into the other. Similarly the distinctive textures of one kind of rock may often be traced gradually merging into those of another. Hence the definitions adopted in establishing rock nomenclature merely correspond to more or less arbitrarily selected points in a continuously graduated series. This is frequently urged as a reason for reducing rock classification to its simplest possible terms and using only a few generalized rock designations.

The earliest attempts at the classification of rocks on modern lines are to be found in the works of K. C. von Leonhard (1823) and Alexandre Brongniart (1827). These and other efforts, principally by K. F. Naumann (1850), Bernhard von Cotta (1855) and Justus Roth (1861), while being built on the criteria of composition and structure of rocks, were largely developed from purely macroscopic investigation or ultimate chemical analysis. The pioneer work of H. C. Sorby (1858) in preparing transparent microsections of rocks opened the way for the discovery of the mineral constituents and textures of the finer grained igneous rocks, and

rapid advances in the knowledge of the constitution of igneous rocks followed. The classifications of F. Zirkel (1873) and H. Rosenbusch (1877) were the first products of the application of the new method of petrographic research, and in these mineral constitution was accorded first place as a basis of subdivision. The effect of microscopic study was to stress the importance of mineralogical and textural characters of rocks to the neglect of other characteristics. Rosenbusch in particular, influenced by the contention principally of K. A. Lossen (who urged the significance of the geological relations of igneous rocks, their occurrence and manner of formation). further developed his classification to express the relationship of geological occurrence and texture, and introduced in the second edition of his *Mikroskopische Physiographie* a fundamental change.

This classification is based first on geological position, then on texture and finally on mineral and chemical composition. Igneous rocks are divided thus into three great groups: (1) deep-seated rocks; (2) dike rocks; and (3) effusive rocks. Like others before it, this classification is still essentially qualitative, and at mid-20th century was the one most commonly adopted by petrographers. An exposition of Rosenbusch's classification is set forth in his *Elemente der Gesteinslehre,* revised by A. Osann (1923).

IV. HABIT OF IGNEOUS ROCKS

Igneous rocks occur essentially in two different ways; *i.e.,* either as lavas or as intrusions.

1. Lavas or Effusive Types.—The lavas have been poured out at the surface and have consolidated after ejection, under conditions which are fairly well understood, seeing that they may be examined at active volcanoes in many parts of the world; the intrusive rocks. on the other hand, have been injected from below into cracks and fissures in the strata and have cooled there beneath masses which conceal them from view until exposed by denudation at a subsequent period. The members of these two groups differ from one another in many respects, so that it is often possible to assign a rock to the one group or to the other on mere superficial inspection. The lavas (or effusive rocks), having cooled rapidly in contact with the air, are as a rule finely crystalline or have at least a fine-grained groundmass representing that part of the viscous semicrystalline lava flow which was still liquid at the moment of eruption. At this time they were exposed only to atmospheric pressure, and the steam and other gases, nhich they contained in great quantity, were free to escape. Many important modifications arise from this, the most striking being the frequent presence of numerous steam cavities (vesicular structure) often drawn out to elongated shapes subsequently filled up with minerals by infiltration (amygdaloidal structure). As crystallization was going on while the mass was still creeping forward over the surface of the earth, the latest formed minerals (in the groundmass) are commonly arranged in subparallel ainding lines following the direction of movement, and the larger early minerals which had previously crystallized may show the same arrangement. The first generation of crystals generally forms before the lava has emerged to the surface, that is to say, during the ascent from the subterranean depths to the crater of the volcano. It has frequently been verified by observation that freshly emitted lavas contain large crystals borne along in a molten, liquid mass. The large. well-formed. early crystals are generally admitted to be porphyritic; the smaller crystals of the surrounding matrix or groundmass belong to the posteffusion stage. More rarely lavas are completely fused at the moment of ejection; they may then cool to form a nonporphyritic, finely crystalline rock, or if more rapidly chilled may in large part be noncrystalline rock, or glassy (vitreous rocks such as obsidian, tachylyte, pitchstone). A common and easily recognized feature of glassy rocks is the presence of rounded bodies (spherulites: Gr. *sphaira,* "ball") consisting of fine divergent fibres radiating from a centre; these divergent fibres consist of imperfect crystals of feldspar, mixed with quartz or tridymite; similar bodies are often produced artificially in glasses which are allowed to cool slowly. Rarely these spherulites are hollow or consist of concentric shells with spaces between (lithophysae: Gr, *lithos,* .'stone"; *physa,* "bellows"). Perlitic structure, which is also found to be common in glasses. consists in the presence of concentric rounded cracks as a result of contraction on cooling *(see* PERLITE ; SPHERULITE).

The phenocrysts (Gr. *phainein,* "to shon"; *krystallon,* "a crystal") or porphyritic minerals are not only larger than those of the groundmass; as the matrix was still liquid when they formed they were free to take perfect crystalline shapes, not being interfered with by the pressure of adjacent crystals. They seem to have grown rapidly. as they are often filled with inclusions of glassy or finely crystalline material like the material of the groundmass. Microscopic examination of the phenocrysts often reveals that they have had a complex history. Very frequently they show successive layers of different composition, indicated by variations in colour or other optical properties; thus augite may be green at the centre and various shades of brown outside this; or it may be pale green centrally and darker green with strong pleochroism (aegirine) at the periphery. In the feldspars the centre is usually more basic and richer in lime than the surrounding faces, and successive zones may often be noted, each less basic than those nhich lie within it. Phenocrysts of quartz (and of other minerals), instead of sharp, perfect crystalline faces, may show rounded corroded surfaces, aith the points of the crystals blunted, and irregular tonguelike projections of the matrix into the substance of the crystal; it is clear that after the mineral had crystallized it was partly again dissolved or corroded at some period before the matrix solidified. Corroded phenocrysts of biotite and hornblende are very common in some lavas; they are surrounded by black rims of magnetite mixed with pale green augite. The hornblende or biotite substance has proved unstable at a certain stage of consolidation and has been replaced by a pseudomorph of augite and magnetite nhich may be partially or completely substituted for the original crystal but still retains its characteristic outlines.

2. Plutonic or Abyssal Types.—The characteristics of a typical deep-seated rock similar to granite or diorite will now be considered. That these are clearly igneous is proved by the manner in nhich they have burst through the superincumbent strata, filling the cracks with ramifying veins; that they were at a very high temperature is equally clear from the changes which they have induced in the rocks in contact nith them. But as their heat could dissipate only very slowly, because of the masses which covered them, complete crystallization has taken place and no vitreous, rapidly chilled matter is present. As they have had time to come to rest before crystallizing they are not fluidal. Their contained gases have not been able to escape through the thick layer of strata beneath which they were injected, and may often be observed occupying cavities in the minerals; they have also occasioned many important modifications in the crystallization of the rocks. Because their crystals are of approximately equal size, these rocks are said to be granular; there is typically no distinction between a first generation of large \\ell-shaped crystals and a fine-grained groundmass. Their minerals have formed, however, in a definite order, and each has had a period of crystallization which may be very distinct or may have coincided nith or overlapped the period of formation of some of the other ingredients. The earlier have originated at a time when most of the rock was still liquid and are more or less perfect; the later are less regular in shape because they were compelled to occupy the interspaces left betneen the already formed crystals which pressed on them. The former are said to be idiomorphic (*i.e.,* having their own characteristic form, Gr. *idios,* meaning belonging to one's self), the latter are allotriomorphic (Gr. *hallotrios,* meaning belonging to another). There are also many other characteristics nhich serve to distinguish the members of these tno groups. Orthoclase. or microline, for example, is the typical feldspar of granite. while its modification, sanidine, occurs in lavas of similar composition; leucite is common in lavas, very rare in plutonic rocks; muscovite is confined to the intrusives. These differences shon the influence of the physical conditions under which consolidation takes place. Fundamental studies on the thermal behaviour and polymorphism of the group of minerals and on the

variable inversion temperature of rock-forming quartz shed new light on the long-known mineralogical differences between feldspars and quartz found in acid volcanic rocks and the same minerals found in plutonic rocks. The differences were interpreted as due to changes brought about in these constituents of the plutonic rocks during cooling by processes of inversion, unmixing and recrystallization from an initial character similar to that of the feldspars and quartz of the corresponding volcanic rocks. These conclusions necessitate some revision of ideas of "order of crystallization" and of the origin of mineral textures in deep-seated igneous rocks of this mineralogical character (*J. Geol.*, vol. 58. pp. 489–511 [1950]; vol. 60, pp. 107–124 [1952]). See FELDSPAR.

3. Intrusive or Hypabyssal Types.—There is a certain class of intrusive rocks which have risen upward toward the surface but have failed to reach it, and have solidified in fissures as dikes and intrusive sills at no great depth. To this type the name hypabyssal is often given in distinction from the plutonic (or abyssal) which formed at greater depths. As might be expected, the hypabyssals show structures intermediate between those of the effusive and the plutonic rocks. They are very commonly porphyritic, not rarely vitreous and sometimes even vesicular. In fact many of them are indistinguishable petrologically from lavas of similar composition. The attempt to form a special group of hypabyssal (intrusive and dike) rocks has met with much criticism and opposition. Such a group certainly cannot rank as equally important and equally well characterized with the plutonic and the effusive. But there are many kinds of rock which are not found to occur normally in any other manner. As examples the lamprophyres, the aplites and the porphyries might be cited. These never occur as lava flows or as great plutonic bosses: if magmas of the same composition as these rocks occur in either of these ways they consolidate with different assemblages of minerals or different structures.

In subdividing the plutonic, the hypabyssal and the effusive rocks, the principle is followed of grouping those together which resemble one another in mineral constitution and in chemical composition. In a broad sense these two properties are interdependent.

V. CHEMICAL CHARACTERS

1. Rock Elements.—Twelve elements (oxygen, silicon, aluminum, iron, calcium, sodium, potassium, magnesium, titanium, phosphorus, hydrogen and manganese) constitute about 99.6% of the earth's crust. Of these oxygen is the most abundant and constitutes 46.59% of the igneous rocks of the crust, the elements given above being placed in their order of abundance. These petrogenic or rock elements occur typically as oxides, simple silicates, aluminates. fluorides, chlorides and sulfides. In rock analyses they are stated as oxides. From a computation based on 5,159 analyses. H. S. Washington and F. W. Clarke arrived at the following as the average percentage composition of all igneous rocks: silica, 59.12; alumina. 15.34; ferric oxide, 3.05; ferrous oxide. 3.80; magnesia, 3.49; lime, 5.08; soda. 3.84; potash, 3.13; water, 1.15; titanic oxide, 1.05; phosphorus pentoxide. 0.3; manganous oxide. 0.12; inclusive 0.5. (See GEOCHEMISTRY: *Chemistry of the Earth: Abundance and Origin of Elements.*)

2. Range of Composition.—The known igneous rocks show a vide but limited range of composition. As the most abundant and essential rock minerals are either silica or silicates, silica shows the highest maximum and the widest range of these oxides. In some magmatic ores its content falls to zero but it rises to 78% in some acid granites; alumina varies normally between 10% and 20%, and some corundum-bearing rocks contain much more, being probably not of pure magmatic origin; iron oxides have a general range from 15% to less than 1% and magnesia from 25% to less than 1%. In some olivine rocks (dunite) it reaches a value of 48%. Lime is highest in some pyroxenites and anorthosites (20%–22%), but its general range is from 15% to zero. Soda reaches a maximum of 18%–20% in almost pure nepheline rocks (urtite) but has a general range frorn 15% to nearly zero. Potash usually varies from 10% to zero. Water in fresh crystalline igneous rocks seldom reaches more than 2%, but pitchstones may contain up to 10%.

3. Common Minerals and Associations.—The commonest minerals of igneous rocks are the feldspars, pyroxenes and amphiboles, quartz and the micas. From a statistical examination of 700 igneous rocks an average composition has been calculated as follows: feldspars 59.5%, pyroxenes and amphiboles 16.8%, quartz 12.0%. micas 3.8%, other minerals 7.9% (apatite 0.6%, titanium minerals 1.5%). This estimate however is clearly only an approximation. Rock minerals have been classified empirically into two groups. according as they are capable or incapable of existing in the presence of free silica; *i.e.*, into saturated and unsaturated minerals. The former group includes such minerals as the feldspars, pyroxenes, amphiboles and micas; and the latter olivine, nepheline, leucite and other feldspathoid minerals.

Certain minerals are as a matter of common observation not found together in igneous rocks. Olivine (except fayalite) and quartz do not occur in association, but are represented by rhombic pyroxene. The associations nepheline and quartz, leucite and quartz, pyroxenes or amphiboles and muscovite are almost unknown among magmatic crystallizations; on the other hand, certain mineral associations or parageneses occur frequently; thus aegirine and arfvedsonite, nepheline and nosean, common hornblende and titanite are well known as faithful companions in igneous rocks. Again some minerals are restricted to particular magmas; melanite, melilite and certain rare zirconium-titanium minerals are almost entirely confined to the alkali igneous rocks. By inspection of a rock analysis it is frequently possible to state approximately what minerals the rock will contain, but there are numerous exceptions to any rule which can be laid down. The minerals which crystallize from an igneous magma may depend largely on the physical conditions under which the liquid consolidates; accordingly. rocks of almost identical chemical composition with widely different mineralogical constitution are found. Such rocks, as already noted, are referred to as heteromorphous. Some familiar examples of assemblages of this character are mica syenite and leucite basalt, minette and leucite basalt, hornblendite and websterite.

Certain minerals are practically confined to deep-seated rocks, *e.g.*, microcline, muscovite, diallage and almandine garnet; on the other hand, leucite is very rare in plutonic rocks, as is also anorthoclase and the variety of potash feldspar known as sanidine. Some of these peculiarities are readily explicable, as they depend on the pressure, temperature or concentration of volatile constituents in the crystallizing magma. Others still represent a problem for solution. The subject will be referred to again in a later part of this article.

4. Acid, Basic and Alkali Rocks.—In the classification generally adopted by petrographers, the silica content of the magma forms a basis of further subdivision of igneous rocks. The division of volcanic rocks into acid, intermediate and basic was devised in the first place by W. H. Abich (1841). When this division is applied to igneous rocks in general, those which contain most silica and which if crystallized yield free silica as quartz are erected into a group designated the acid rocks in allusion to the assumed role of silica in the mineral kingdom. Those which have low silica percentages and are rich in magnesia, lime and iron—so that quartz is absent while olivine, pyroxene or calcic feldspar are usually abundant—form the basic group. The intermediate rocks include those characterized by the general absence of both quartz and olivine.

An important subdivision of the intermediate as well as the basic group contains a very high percentage of alkalis (soda or potash or both), and consequently has minerals such as nepheline, nosean, analcime or leucite, minerals not common in other rocks. This group is often referred to as the alkali rocks. Lastly, members of a small subgroup rich in olivine (peridotite, dunite), pyroxene (pyroxenite) or calcic feldspar (anorthosite) have been called the ultrabasic rocks. They have low percentages of silica but much iron, magnesia or lime. With the exception of the last group, including also such ultrabasic lavas as augitite and limburgite and a few related rocks such as monchiquite, melitite

basalt and alnoite, practically all igneous rocks contain feldspar or feldspathoid minerals. In the acid rocks the common feldspars are orthoclase, with perthite, microcline and oligoclase, all having much silica and alkalis. In the basic rocks labradorite, bytownite and anorthite prevail, being rich in lime and poor in silica, potash and soda. Augite and olivine are the common ferromagnesian minerals of the basic rocks, but hornblende and biotite are on the whole more frequent in the acid rocks.

5. Mineralogical Constitution. — The classification in the two tables below is based essentially on the mineralogical constitution of the three great groups of igneous rocks. The alkali rocks containing nepheline and leucite are treated separately, for, though they show transitions into the corresponding intermediate and basic rocks (syenites, diorites, gabbros, etc.), they contain many minerals which are unknown in other rocks. In a purely formal classification such as is outlined here they are more conveniently considered as a distinct series. Their genetic relations among themselves and with the other rock types are considered later.

The lamprophyres form a peculiar group of hypabyssal rocks not included in the tables. They usually occur as dikes in association with granites, syenites. diorites and gabbros, and are basic differentiates of these parent rocks. Thus the minettes, vogesites and kersanites *(see* LAMPROPHYRE) occur in association with granitic or quartz diorite masses, while camptonites, monchiquites and alnoites may be found commonly as satellites of alkali plutonic masses like nepheline-syenite or essexite.

TABLE I.—Alkali Rocks Containing Nepheline and Leucite

Commonest minerals	Alkali feldspar Nepheline or leucite Augite Hornblende Biotite	Plagioclase (limesoda) Nepheline or leucite Augite Hornblende (Olivine)	Nepheline or leucite Augite Hornblende (Olivine)
Plutonic . . .	Sepheline syenite Leucite syenite	Essexite Theralite	Ijolite Urtite Missourite
Hypabyssal . .	Nepheline syenite —porphyry Tinguaite	Essexite and Theralite } Diabase	Nepheline dolerite
Volcanic . . .	Phonolite Leucitophyre	Tephrite Basanite	Nepheline basalt Nephelinite Leucite basalt

The classificatory scheme here adopted is admittedly artificial, for it subdivides rocks aithout particular reference to their genetic relationships. Even regarded as a classification for a utilitarian end it has many imperfections; the subdivisions are of unequal value and transitional types are not included. The latter, however, can be accommodated by further subdivision. Many of them have received special names. The quartz syenites may be interposed between granite and syenite, the tonalites between granite and diorite and so on.

The question may be asked: When is a rock entitled to be recognized as belonging to a distinct species or variety and deserving a name for itself? It must, first of all, be proved to occur in considerable quantity at some locality or, better still, at a series of localities, or to have been produced from different magmas at more than one period of the earth's history. In other words, it must not be a mere anomaly. Moreover, it should have a distinctive mineral constitution. differing from that of other rocks, or something individual in the characters of its minerals or of its structures. It is often surprising how peculiar types of rock, believed at first to be unique. turn up with identical features in widely scattered regions; alnoite, for example, occurs in Norway, Scotland, Montreal. British Columbia, New York and Brazil, tinguaite in Scotland, Norway, Brazil, Montana, Portugal, etc. This indicates that underlying all the variations in mineralogical, structural and chemical properties there are definite relationships which tend to repeat themselves, producing the same types whenever the same conditions are present.

6. Quantitative Classifications. — Various attempts have been made to introduce a quantitative element into igneous rock classification. These have followed either chemical or mineralogical lines. The principal of these is the quantitative chemical classification introduced by a group of U.S. petrographers. The chemical composition of an igneous rock is here regarded as its fundamental characteristic and a series of subdivisions is erected on this basis. Other criteria are relegated to the background. The completed rock analysis is first interpreted in terms of an ideal set of minerals which constitutes the norm, but which in reality seldom corresponds to the actual composition (mode). The rocks are then divided into groups strictly according to the relative proportions of these ideal minerals to one another. The details of the classification need not be described here as they are fully set forth in a treatise specially devoted to this classification (W. Cross *et al., Quantitative Classification of Igneous Rocks* [1903]; see *Bibliography).*

A quantitative element is introduced in other systems by subdividing rocks into groups by arbitrary lines based on mineral percentages: a complicated system framed on these lines was devised by A. Johannsen (J. *Geol.*, 1917, 1919). In another the prime divisions are erected on so-called "principle of silica-saturation" *(S.* J. Shand, *Eruptive Rocks* [1947]), while a third combines some of the features of both the quantitative chemical classification and the Johannsen system with the larger groups of the Rosenbusch system (P. Niggli. *Schweiz. Min. Petr. Mitt.* [1931]). In all, the effect of the introduction of the quantitative element has been to increase the artificiality of the system and by this means to obscure the genetic relations existing between rock types. For this reason these systems are unlikely to supplant the qualitative classification in general use. It is indeed largely to the influence of "quantitative classifications" that the bewildering and unnecessary multiplicity of igneous rock names must be ascribed.

VI. PETROGRAPHICAL PROVINCES

As long ago as 1872 H. Vogelsang had noted that the igneous rocks of certain districts possessed textural or mineral characters in common, serving to distinguish them from the rocks of other districts. The researches of J. W. Judd (1886) and J. P. Iddings (1892) further substantiated this observation and showed that this community of petrographic character applied to the igneous rocks erupted or intruded during a particular period of igneous activity within the region. To such regions Judd gave the name petrographical provinces and Iddings employed the term consanguinity to express the genetic relationship irnplied in these resemblances among associated rocks. Excellent examples of such petrographical provinces or comagmatic regions, as they were termed by H. S. Washington, are the Oslo region of southern Norway, characterized by Permian alkali intrusions and extrusions;

TABLE 11.—Acid and Basic Rocks

Commonest minerals	Acid	Intermediate		Basic	Ultrabasic
	Quartz Orthoclase (and oligoclase) Mica Hornblende Augite	Little or no quartz		No quartz	Augite Hornblende Olivine (Basic plagioclase)
		Orthoclase Hornblende Augite Biotite	Plagioclase Hornblende Augite Biotite	Plagioclase Augite Hypersthene Olivine	
Plutonic	Granite	Syenite	Diorite	Gabbro Norite	Prridotite Pyroxenite Hornblendite (Anorthosite)
Hypabyssal	Quartz-Porphyry	Orthoclase Porphyry Orthophyre	Porphyrite	Diabase	Picrite
Volcanic	Rhyolite Obsidian	Trachyte	Andesite Dacite	Basalt Tachylyte	Limburgite Augitite

the Roman region, characterized by rocks rich in potash; the alkali province of central Montana; and the Tertiary calc-alkali province of Hungary. On a larger scale the volcanoes which girdle the Pacific (Andes, Cordillera, Japan, Philippines, etc.) and those which occur on the volcanic islands of the Atlantic illustrate the same phenomena. The consanguinity in the igneous series of a petrographical province implies that the whole assemblage is derived from some common deep-seated magma, during a period which, while necessarily prolonged, was not of vast duration in a geological sense. The assemblages of a province may and often do show a wide diversity of rock type embracing intrusions and extrusions. Prolonged eruption have in a few cases a somewhat monotonous character as a result of the predominance of one kind of rock. Thus the lavas of the Hawaiian Islands are mostly basaltic, as are those of Oregon, Washington and the Deccan, India, all of which form geological masses of enormous magnitude. In the Oslo district, on the other hand, the assemblages comprise (among the intrusive rocks) a wide range of type—hornblendite, essexite, larvikite, lardalite, nordmarkite, soda, and potash granites.

A. Differentiation

The process by which a magma is split into a variety of partial products is known as differentiation. Its importance from the standpoint of theoretical petrology is very great; it is, in point of fact, the fundamental problem of petrogenesis. The differentiation may appear as a variation either in a single rock body or in an associated series of separate intrusions or extrusions. In the first case a single intrusion shows variation in different parts of its mass, the extreme varieties being usually connected by gradual transition. The contrasted parts are frequently arranged symmetrically with reference to the borders of the mass forming concentric zones in bosses or laccoliths suggestive of a differentiation *in situ* connected with the cooling of the mass. Excellent examples of variation of this kind are provided by the laccolithic intrusions of the Highwood mountains of Montana. The best-known of these—the Shonkin Sag laccolith—has a chilled edge phase, a leucite basalt porphyry (or mafic phonolite) representing a quenched sample of the intruded magma. followed inward by a thick zone of shonkinite which forms an envelope to a central horizontal layer of alkali syenite.

Variation in an associated series is exemplified by the succession of lavas emitted from a volcanic focus. These may differ considerably from one another. Thus in the Berkeley hills near San Francisco, Calif., the volcanic succession is a repeated series of andesites, basalts and rhyolites. In other cases the lavas emitted are much more varied and, while no significant relations in the succession can be discerned, it is to be remembered that a significant order may be obscured by the overlapping of the flows from nearby volcanoes. In the simpler cases the order of eruption is one of increasing divergence from an initial type.

B. Plutonic Complexes

A series of plutonic rocks intimately associated and localized at a centre constitutes a plutonic complex. Such complexes often contain a great diversity of petrographical types ranging from peridotite and gabbro through diorite to acid granite. The succession of these intrusions follows an order of decreasing basicity, the later and more acid rocks usually occupying the greater part of the complex. the earlier and more basic being subordinate in amount and restricted to the borders of the mass. Excellent examples of such plutonic complexes are provided by the early Devonian intrusions of newer granites of the Scottish Highlands (*e.g.*, Garabal hill, Loch Lomond). What then are the operative factors which led to differentiation?

1. Unmixing.—The possible processes leading to heterogeneity in a magma may be considered under (1) those occurring in the liquid prior to crystallization (liquid $\leftrightarrows$ liquid equilibrium); and (2) those incident on crystallization (crystal $\rightleftarrows$ liquid equilibrium). In the first group comes the process known as liquation or unmixing. Many liquids, homogeneous at high temperatures. separate with falling temperature into two or more nonconsolute fractions, and the hypothesis that igneous magmas form such immiscible fractions has been favoured by some petrologists, notably Rosenbusch. H. Backstrom and R. A. Daly. From his own studies Vogt concluded that the rock-forming silicates are freely miscible. The only known case among magmas for which immiscibility can be claimed is that of sulfide-containing silicate melts. Such a magma unmixes at a temperature above the region of crystallization of the usual sulfides, and liquid sulfides, especially those of iron, are separated as liquid drops. These, because of their greater density, sink to the floor of the magma, collecting as a distinct sulfide layer or. in some cases, the liquid layer may be injected into the surrounding rocks. These sulfide aggregates form important ore deposits (*q.v.*). It is among lavas which as a group show the various stages of quenching of liquid magmas that the evidence for immiscibility might be expected; the absence of lavas containing glassy globules of composition distinct from that of the main mass of lava goes far to show that immiscibility is not an operating factor in petrogenesis.

Experimental evidence of immiscibility in silicate liquids was indeed obtained, but the composition range of liquids which show it is unlike that exemplified by rock magmas. This limited miscibility is found in mixtures of silica with any of the oxides (lime, magnesia. ferrous oxide, alumina), but in a region of very high silica content. The minimum temperature for the existence of two liquids is in each case only a little below the melting point of silica. or in the vicinity of 1,700" C. The oxides (soda, potash, alumina) show no such immiscible region in their silica mixtures, and moreover it requires only a small proportion of any of these miscible oxides to render miscible with silica the oxides which are themselves immiscible with silica. No natural magmas are known which approximate in composition to the region of immiscibility in these melts. It is true that natural magmas contain, in addition, water, but accumulating experimental studies in hydrothermal systems had up to 1960 given no reason to believe that fields of immiscibility extend into the composition region of natural magmatic systems.

2. Fractional Crystallization.— The second group of processes referred to above involves a crystal $\rightleftarrows$ liquid equilibrium and comprises crystallization and its converse. the assimilation of crystalline material. Knowledge of the crystallization of silicate magmas is derived from long-sustained observations of igneous rocks themselves and mas greatly augmented by high-temperature experimental research on silicate melts. The great body of evidence thus accruing leads to the belief that fractional crystallization is to be recognized as a fundamental process in igneous rock differentiation—the derivation of igneous rocks of diverse but related character. Either the localization of crystallization or the localized aggregation of crystals is sufficient to produce heterogeneity in a rock magma. The first phenomenon, the localization of crystallization, was at one time thought competent to explain those cases of differentiation *in situ* exemplified by the basic marginal phases of intrusive masses. Examination of igneous rocks early showed that minerals crystallize in a more or less definite order. In general, olivine, hypersthene and other minerals prominent in ultrabasic rocks are among the earliest minerals to separate; then follow augite, calcic plagioclase, hornblende, biotite, potash feldspar and quartz. plagioclase continuing to separate and becoming at the same time more sodic. This is the so-called normal order of crystallization, the validity of which, despite exceptions, has long been recognized. When the rule is expressed in this way the more basic minerals precede the less basic: in a somewhat modified form it was early known as Rosenbusch's law of decreasing basicity. Accordingly. it was supposed that at a cooling boundary there is a precipitation of minerals of early crystallization (basic minerals), the continued growth of many crystals being maintained by diffusion. The completion of this process results in a crystalline mass with a border phase enriched in the minerals of early crystallization.

The rate of diffusion in silicate melts has been the subject of laboratory study and the results obtained show that the possible effects are incompetent to account for the formation of border phases about large intrusions. The marginal phase indeed appears

to represent rather a chilled phase having a composition close to that of the original magma, the more acid phase which it enclosed representing a differentiate formed by much slower cooling of the remainder of the magma. The relative movement of crystals with respect to the liquid from which they separated may be of two kinds: (1) movement under the influence of gravity — sinking or floating of crystals; and (2) movement by straining off or squeezing out of residual liquid by earth movement. Both of these processes can be invoked to explain the more important case of differentiation exemplified by an associated series of intrusions or extrusions. In a crystallizing magma (provided viscosity does not inhibit the free movement of crystalline material) as the first formed crystals are denser than the molten material in which they form. they should sink under the influence of gravity in the liquid. The lower regions of the rock mass into which the crystals sink become enriched, the upper regions impoverished, in the constituents of which they are formed. The sinking of crystals in silicate melts has been both experimentally verified in the laboratory and observed in nature. Darwin (1844) suggested that this process was a potent factor in producing diverse rock types. If the evidence of consolidated rock masses themselves be taken, intrusions are found in which such gravitational segregation is indubitably exemplified. Thus the concentration of early formed olivine crystals near the base of sheet- or sill-like intrusions has been observed in the case of the quartz-dolerite sill of the Palisades (Hudson river) and of the picrite-crinanite sill of the Shiant Isles (western Scotland). The Permian picrite-teschenite sills of central Scotland, while exhibiting similar phenomena of settling of olivine in place, provide, in the main, evidence of injection of crystal-charged magma of picrite following closely upon intrusion of a more liquid teschenite which now margins the sills. The role of fractional crystallization in the production of a series of related rock types within a great magma chamber is spectacularly illustrated in some of the largest intrusive complexes laid bare by erosion. These complexes occur at widely scattered localities in the world in the form of sheets of basic igneous rock of great thickness, showing a layered (banded) structure with systematic types of variation within them. Such are the intrusions of the Bushveld. Transvaal; Duluth, Minn.; Sierra Leone, west Africa; Stillwater, Mont.; and Skaergaard. east Greenland — stratiform structures often several miles thick which, despite much diversity in detail, show broad features of similarity in that systematic variation observed within them.

The interpretation of the petrologic structure of these sheets usually assumed either (1) that the complex is the result of successive sheet intrusions varying in composition; or (2) that they represent the product of crystallization of a single body of magma nith gravitative sorting. Detailed examination of the Skaergaard mass made clear that this layered structure arose from fractional crystallization of a magma occupying a deep inverted cone chamber, solidification proceeding from the base upward, the solid phases accumulating like a sediment on the floor. The intrusion consists of basic rocks and comprises a marginal rock group and a central layered group. The marginal rocks show fluxion structures and banding parallel to the steeply dipping contacts. The layered group is exposed to a thickness of three kilometres, the whole of this consisting essentially of plagioclase, olivine and pyroxene, their composition as solid solution series changing gradually from the lower to the upper horizons. At the lower horizons the plagioclase is bytownite, in the upper it is an andesine-oligoclase. Olivine in the lower horizons is poor in iron, but at the top of the series is fayalite, and the pyroxenes show similar enrichment in iron in their phases as they are traced upward.

The separation of the rocks of the intrusion into marginal and layered groups and the differentiation of the latter may be explained by the fact that the liquid magma was sufficiently mobile to allow a convective circulation and equilibrium, the temperature gradient attained. however. being much less than the downward increase in the average crystallizing temperature, because of the increasing hydrostatic pressure (freezing-point gradient). Data which are available for the silicates give the approximate magnitude of these effects as ½° C. per kilometre for the convective gradient and 3° C. for the freezing-point gradient. Accordingly, although cooling would take place from the top and flanks of the intrusion and the temperature at these points would be cooler, the solid phases would separate near or at the bottom and would gradually accumulate on the floor.

In the Skaergaard mass only the upper portions of the intrusion are laid bare, the rock types ranging from hypersthene olivine gabbros to ferrogabbros and fayalite ferrogabbros with a final residual granophyric differentiate close to the roof. The remarkable correlation in detail of the composition of crystals of solid solution series with their position in the layered mass and the ordered sequence of rock product so yielded, present in all a convincing picture of the results of fractional crystallization of a once homogeneous magma. It is not unlikely that the mechanism thus clearly made manifest for the Skaergaard intrusion characterizes other layered sheets (*e.g.,* Stillwater), although the history of some of these may be further complicated and its tracing blurred by the intervention of intimately associated intrusions.

3. Application of Laboratory Investigations. — The trend in mineral composition revealed in layered series of rocks such as that already described is illuminated by experimental laboratory study of phase equilibriums in silicate systems of related composition. The main contributions in such synthetic studies have come from the Geophysical laboratory at Washington, D.C. (see Rock Synthesis, above). Systems which approach in their complexity some of the simpler types of igneous rocks were explored, and the results obtained justify the conclusion that the fusion and solidification phenomena of igneous rocks are capable of systematic treatment. Starting with pure chemical substances, the melting points, dissociation temperatures and inversion points of numerous rock-forming minerals were determined and the equilibrium phenomena of two- and three-component systems involving the commoner oxides of igneous rocks were quantitatively elucidated.

This study embraced the binary and some of the ternary systems of the oxides lime, magnesia, ferrous oxide. alumina, soda. potash and corundum with silica, and was extended to the exploration of certain plane sections of four- and five-component systems. The investigation of mineral inversions provided data throwing light on the temperature of igneous magma. Such of these inversions as are enantiotropic. or reversible, and take place without appreciable lag can be appropriately used as geological thermometers.

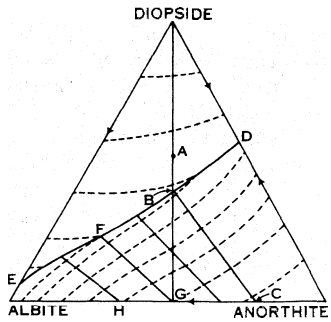
The study of binary and more complex systems has shown that the eutectic relation — for so long given a pre-eminent role in discussions of the crystallization of igneous rocks — is but one of several relations that may obtain between two or more components. Crystallization processes are normally complicated by solid solution and incongruent melting. The former phenomenon is widespread, for most of the major constituents of igneous rocks — feldspars, pyroxenes, olivines, amphiboles and micas — are members of complex solid solution series. (See MINERALOGY: *Nature of Minerals: Solid* Solution.)

In systems of three components the crystallization phenomena are often complex: occurrence of inversion points in one or more of the components, the formation of binary or ternary compounds with congruent or incongruent melting, and the formation of isomorphous mixtures, limited or unlimited, among the phases, are some of the many complications met with in the silicate systems investigated. Ternary systems that have been studied include those mixtures from which the phases plagioclase, pyroxene, olivine, silica and the alkali alumina silicates, potash-soda feldspars, leucite and nepheline, are precipitated.

The crystallization phenomena in a system involving the first two of the phases indicated above — diopside-albite-anorthite — may be taken as an example. The equilibrium diagram is shown in the accompanying figure. The crystallizing phases are diopside and plagioclase. These mixtures are therefore comparable with simple basaltic or gabbroic magmas on the one hand and simple dioritic (augitediorite) magmas on the other, according to the nature of the plagioclase.

Consider the crystallization of a liquid whose composition is represented by the point A (50% diopside, 50% plagioclase—Ab_1An_1).

Crystallization begins with a separation of diopside (supposed to be a simple mineral and not an isomorphous mixture, as it would usually be in rocks) at about 1,275" C. At 1,235° C. the excess of diopside (B) has separated out, and feldspar begins to crystallize. It has about 80% anorthite (C). Thereafter diopside and feldspar both crystallize, but as the composition of the liquid travels along the line DBE from B to F the composition of the feldspar changes from C to G (if it is supposed that all the early feldspar which is unduly rich in anorthite is stage by stage resorbed). The resulting rock has the mineral composition above stated; but if resorption of feldspar is incomplete the last-formed feldspar is richer in albite and has a composition H. The feldspar crystals in that case are zonal with basic centres. If at any time crystallization is suddenly brought to an end a glassy groundmass will be formed, which is richer in soda and silica than the original magma and contains zoned feldspar crystals. This is exceedingly like what takes place in many basaltic lavas. Again, if the original mixture had been richer in feldspar, so that the composition point lay below the line DE, feldspar would have crystallized out first. Original compositions near B then yield early both diopside and plagioclase phases and quenching at this stage would show both enveloped in a glassy base. This is in keeping with observations on glassy basalts which exhibit plagioclase and pyroxene of early crystallization set in preponderant glass.



EQUILIBRIUM DIAGRAM OF CRYSTALLIZATION PHENOMENA

The separation of liquid from crystals can be accomplished not only by zoning but also by the sinking of crystals from the upper layers of the liquid. The resulting liquid is enriched in albite and, under favourable circumstances, the final liquid may approach the albite-diopside eutectic of composition 97% Ab, 33% diopside. The analogy with the differentiation course of gabbroic magma is clear. A mixture rich in diopside and anorthite-rich plagioclase, corresponding to an anorthite-rich gabbro or eucrite, may pass to an assemblage rich in more acid plagioclase with subordinate diopside, corresponding to an augite-diorite.

4. **Discontinuous-Reaction** Series.—The continuous-reaction relation between crystals and liquid in the systems just studied is of fundamental importance in the crystallization history of magmas. This reaction is common to all solid solution series, and such solid solutions are called continuous-reaction series. Very similar effects, however, are produced by another type of crystallization phenomenon revealed in synthetic melts. In this case an early precipitated phase reacts at a certain temperature with the surrounding liquid and a new phase is precipitated, a reaction process of a discontinuous kind. This reaction is illustrated in the system forsterite (olivine)-silica. Here there are three solid phases, forsterite, protoenstatite ($MgSiO_3$) and cristobalite (SiO_2). The orthorhombic pyroxene, protoenstatite, has an incongruent melting point and dissociates at 1,557° C. into forsterite and liquid. From all melts of composition between Mg_2SiO_4 and $MgSiO_3$, the first phase to crystallize is forsterite, which continues to separate until the temperature of 1,557° C. is reached, when the olivine reacts with the liquid to form protoenstatite. When equilibrium is established the resulting crystalline mass consists wholly of olivine and pyroxene. If, however, the opportunity for reaction is inhibited, either by the sinking of olivine crystals or by their enclosure in the reaction product, the course of crystallization is extended and the third phase, silica, is precipitated giving a mass composed of residual olivine, pyroxene and silica.

A reaction relation of this type may effect a series of compounds in a crystallizing melt. These, arranged in their order of succession, constitute a discontinuous-reaction series. The combined effects of discontinuous and continuous reaction are revealed in the related ternary systems diopside-forsterite-silica. Here the magnesia pyroxene forms a complete series of solid solutions (monoclinic pyroxenes) with diopside; they form a continuous-reaction series, the crystals in equilibrium with the liquid being relatively enriched in the magnesian end member ($MgSiO_3$). The effect of hindering the reaction relations is now twofold, the residual liquid (or upper layers of the liquid if sinking of crystals prevails) is enriched in silica and the diopsidic pyroxene, 2s a result of the offset in composition.

The lowest point of formation of liquid in the system (there is no ternary eutectic) is the binary eutectic diopside-silica. In ternary silicate systems containing ferrous oxide, *e.g.,* in the system MgO-FeO-SiO_2, fractional crystallization effects a concentration of iron in the residual liquid which for some initial compositions may yield, according to the degree of fractionation, crystalline aggregates of ferriferous pyroxene and silica or ultimately iron-rich olivines and silica.

5. Natural Magmas.—That reaction processes of these kinds operate in natural magmas is clearly demonstrated. They are seen among minerals in zoned crystals of solid solutions like the plagioclase feldspar and the complex pyroxene phases, or in the resorbed borders of magnesian olivines with their pyroxenic mantles; their cumulative effects may be revealed in the graded sequences in mineral compositions in a layered intrusion, such as that of Skaergaard, crystallizing upward from its base, or in the association of related but contrasted rock types, whether these be the contrasted parts of gravitationally differentiated sills or the contrasted separate intrusions of a plutonic complex.

The normal calc-alkali magma, more complex in composition than the synthetic melts investigated, contains other components, including water, and from these natural melts mineral phases such as amphiboles and micas with constitutional hydroxyl are precipitated. Petrographic data make it clear that these too take part in the reaction process.

The principal minerals of these igneous rocks can in fact be arranged as reaction series, such that any member is produced from the preceding member by reaction with liquid magma, as already instanced by the reaction pair, olivine-pyroxene. The plagioclase feldspars together with potash feldspar form one series and the olivines, pyroxenes, amphiboles, micas and quartz constitute another. Inspection of this order will reveal that it is in essence the "normal order" already recognized in the rule formulated long ago by Rosenbusch.

A basic magma quickly cooled may give rise simply to basic plagioclase and pyroxene or yield by fractional crystallization a differentiation chain embracing all the minerals enumerated above, the continual offset in composition of the residual liquid in which water accumulates being accomplished by appropriate removal of crystals through gravitative settling, squeezing out or filtering off of interstitial liquid by earth movement during crystallization.

6. Hydrothermal Systems.—The extrapolation of experimental equilibrium studies based on data obtained from anhydrous silicate systems, such as the foregoing, to natural rocks, led to great advances; nevertheless the evidence that many igneous rocks have crystallized in the presence of water vapour and in fact contain hydrous mineral phases made clear the limited applicability of the experimental results, directly to the interpretation of the crystallization history of the more siliceous and alkaline rock assemblages. Experimental attack on hydrothermal systems followed later and an outline of the scope of these researches is now presented.

Before World War II quantitative phase equilibrium studies in silicate systems containing volatiles, particularly water, had been few. G. W. Morey and C. N. Fenner had worked out the system H_2O-K_2SiO_3-SiO_2 (report, 1917) and at a later date R. W. Goranson had demonstrated the solubility of water in a liquid of granite composition (report, 1931). During and immediately after the war the great interest in certain crystalline phases, especially quartz, had stimulated a great deal of hydrothermal work and radically new equipment was developed. The first systematic study of a silicate system comparable with a natural assemblage—the system MgO-SiO_2-H_2O—was completed in 1949. This study opened a new era of conquest of the wet mineral silicate and in

many respects laid the ground work for much of the later investigations in the hydrothermal field. This work demonstrated that no liquid appeared in the ternary system even at 1,000° C. and at a water vapour pressure of 40.000 lb./in.², thus throwing new light on the problem of emplacement of peridotites and serpentines in the upper crust. Most of the postwar hydrothermal studies were in fact carried out under PT conditions below that at which a liquid (melt) phase appears and above the critical temperature of water. These studies are therefore largely concerned with crystal ⇄ vapour equilibrium. Examples of such subsolidus studies were those of SiO_2-H_2O, CaO-SiO_2-H_2O, MgO-Al_2O_3-SiO_2-H_2O, and numerous researches dealing with the synthesis and stability of individual mineral groups — feldspars, garnets, micas, amphiboles. nepheline-kalsilite, analcime and several carbonate systems. These investigations proved of particular importance in the study of rock metamorphism (*q.v.*) and some had their application also in the interpretation of phase relations in the cooling history of the igneous rocks.

The most significant liquidus studies related to the petrographically important system of the alkali feldspars ($NaAlSi_3O_8$-$KAlSi_3O_8$) and of these with SiO_2—*see* especially O. F. Tuttle and N. L. Bowen, "Origin of Granite in the Light of Experimental Studies in the system $NaAlSi_3O_8$-$KAlSi_3O_8$-SiO_2," *Geol. Soc.* Amer. Mem. 74 (1958). These are the systems which approach in composition the great group of natural rocks, the syenites and granites. The outstanding feature of the researches was the evidence found to support the indications that a complete series of solid solutions existed betneen potash and soda feldspars at elevated temperatures. but that in the subsolidus region a solvus existed with two feldspars existing side by side. Homogeneous synthetic feldspars thus exsolved at lower temperatures in confirmation of the accepted theory of most natural perthites. In the ternary system with silica at high water-vapour pressures the liquidus has a thermal trough near the centre toward which all liquids moved on crystallization.

This minimum had a composition in the range common for granites, a result in harmony with a long-held view of the magmatic origin of this rock type. The investigation of more basic assemblages of simple gabbroic or eucritic composition, *e.g.*, the system diopside-anorthite, under high water pressure revealed a marked lowering of the liquidus and a change in the composition of the binary eutectic, with the implication that water is markedly soluble in gabbroic magma, as had been shown earlier for the granitic liquid system.

7. Magmatic Assimilation. — Heterogeneity in a magma may derive through a crystal liquid equilibrium not only by the spontaneous process of fractional crystallization and reaction but also by reaction of liquid magma with its wall rock or with what foreign inclusions it may incorporate. This process. known as assimilation, may lead to the development of a diversity of rock type and is to be recognized as an important factor in petrogenesis.

It seems probable that the heat effect connected with the solution of solid rock by a liquid magma is always negative, solution being accompanied by absorption of heat, usually of the order of the latent heat of melting. Simple solution would then demand large amounts of heat. which are only available if the liquid possesses great superheat. Intruding magmas, however, can scarcely be at a temperature much above their crystallization range. Such effects of magma upon its enclosures as are observed must therefore be attributed to processes of reaction and precipitation.

The concept of the reaction series finds fruitful application in the study of this problem. Enclosures of rock fragments in a magma may be divided broadly into two classes, those of igneous and those of sedimentary origin. The first class is built normally of minerals which are members of the reaction series. The magma itself, saturated with a given member of such a series, is effectively supersaturated with all earlier members of that series. If the inclusion is built of these earlier members the magma cannot in consequence dissolve them. It can, however, react with them and transform them into the member with which it is saturated, often by passing through other members of the series as intervening

These changes effected by subtraction of material from the magma induce withdrawal precipitation of the phase with which the magma is saturated. In the course of the reaction the inclusion itself is often disintegrated and may come to be completely incorporated in the liquid.

With an inclusion built up of members of the reaction series later than that with which the magma itself is saturated, the process is one of reactive solution — the inclusion becoming part of the liquid at the expense of precipitation of the magma saturated phase. On the liquid, the resultant effect is a pushing onward along the normal course which fractional crystallization in the process of cooling might accomplish. In these reactions no phase foreign to the reaction series is normally precipitated, and there may result locally rock types scarcely distinguishable from types derivable by fractional crystallization. Plutonic complexes with their range of associated intrusions — basic to acid — often show clear evidence of extensive hybridization by reaction of a later (more acid) magma upon an earlier (more basic) consolidated product, the rock types found near the border approximating in composition and structure to a range of igneous rocks of a normal differentiation series while being in fact the result of hybridization brought about by action of liquid (acid) magma upon a basic (gabbroic) rock.

The monzonitic and tonalitic margins of granitic masses of some igneous complexes may be traced to the hybridizing influence of acid magma on an earlier plutonic rock of basic or ultrabasic composition of which all superficial traces may have disappeared. The newer granite complexes of Scotland provide convincing demonstration of hybridizing processes of this nature. The effects of reaction of igneous magmas upon sediments set a more difficult problem, since sedimentary material may not belong to the reaction series

In many cases the incorporation of sediments in a magma, mhile yielding adjustments in the composition and reiative proportions of existing phases, may effect but little modification in the general course of fractional crystallization. On the other hand, extended incorporation of certain types of sedimentary material may lead to the precipitation of new mineral phases not normally met with in igneous rocks.

Gabbro magma assimilating shales or slates may pass first into norite by precipitation of rhombic pyroxene and basic plagioclase, at the expense clinopyroxene, and eventually yield cordierite norites. Rocks of this character are well developed in Aberdeenshire and elsewhere. Basaltic magma, through assimilation of limestone, may give products rich in melilite and wollastonite and yield, at least locally, an alkali fraction from which nepheline is precipitated. Whether basic magma through this mechanism can generate alkali rocks on a large scale is a question yet to be determined. That their production is not limited to this mechanism. however. is clearly attested by the geological environment and petrographical relations of many examples of this group of rocks.

Assimilation processes clearly play a significant role in the development of some rock assemblages, and among these are to be expected rock types which exhibit in both composition and structure the characteristics of normal igneous rocks. The full contribution of these processes has yet to be evaluated though a limit to their action is prescribed if magmas in general possess little superheat.

8. Palingenesis. — The apparent dominance of granodiorites and granites in orogenic belts led some petrologists to entertain the view that these particular rocks have been derived by remelting of the granitic layer and the intrusion of the resulting liquid to higher levels. This possibility cannot be denied; yet it is to be remembered that a granitic differentiate as a late residual liquid subject to filter pressing during mountain building might well come to dominate in volume the upper regions of a magmatic tract laid bare by erosion. It is conceivable, however, that some granites may have their immediate origin in such refusion and perhaps also that a process of partial refusion may affect siliceous sediments subject to deep burial in the cores of geosynclines. As distinct from the juvenile granites derived by fractional crystal-

lization, granites supposedly originating in this way have been referred to as palingenetic and the process of refusion as palingenesis. The genetic link between granitic and basic (basaltic) material remains, for the dominantly mafic character of the crust makes it evident that the sial or granitic layer must ultimately have been derived from such basic material.

9. Granitization.—The aqueous and alkali-bearing residual liquids emanating from granitic magma during its later consolidation stages are known to penetrate into the surrounding rocks. Where these rocks are argillaceous, metasomatism by the alkali solutions acting upon the micaceous minerals of the sediment may result in the feldspathization of such pelitic rocks, transforming them into assemblages analogous in composition to the parent rock from nhich these solutions came. This is the process of granitization. With such processes there is frequently a merging of the parent intrusive with an igneous-looking rock which is metasonlatic in origin

In the more speculative accounts of the process the parent intrusive itself has been regarded as formed in the same manner and the existence of a genuine igneous intrusive denied, but such an extreme view seems unlikely to be correct. A survey of the problems of granite emplacement with special reference to North America was made by A F. Buddington (Bull. Geol. *Soc. Amer*, vol. 60. pp. 671–747 [1959]).

VII. GEOGRAPHIC DISTRIBUTION OF IGNEOUS ROCKS

A study of the geographical distribution of igneous rocks has shown that the earth's surface may be mapped out into more or less definite petrographical provinces, each with its own community of petrographical characters. Strongly contrasted provinces may exist almost side by side, as is seen in the Tertiary Bohemian and Hungarian provinces standing on either side of the Carpathian range, the one characterized by a suite of igneous rocks rich in alkali, the other comprising an assemblage relatively rich in lime, magnesia and iron oxide. The chain of volcanoes that fringes the shores of the Pacific from Tierra del Fuego to Alaska and thence by Japan and the Philippines to Java and Sumatra represents a province of a larger order, characterized by rocks which have so much similarity in many important features that they are certainly of allied origin. These rocks are all of Tertiary and Recent age; their eruptions began in Eocene or Miocene times and have continued with more or less frequent intermissions up to the present day. The igneous rocks of the Atlantic islands from the Azores to Tristan da Cunha comprise an assemblage of types strikingly different from the igneous rocks of the eastern Pacific borderland. Each of these magmas has been taken as a type, and they are referred to as the Pacific and Atlantic magmas. Chemically the Atlantic (or alkali) rocks are characterized by high percentages of alkalis (potash and soda) in relation to silica and alumina, and mineralogically by the presence of alkali minerals, especially feldspathoids (nepheline. sodalite, analcime. etc.). The Pacific (subalkali or calcic) rocks, on the other hand, show relatively more abundant lime, magnesia and iron oxides.

Certain suites of rocks characterized by high potash content and mineralogically, by the presence of leucite or abundant potash feldspar and micas, have been separated from the Atlantic suite, though they are perhaps not of co-ordinate importance. Rocks of this character are illustrated by the Quaternary province of the Roman region: Vesuvius belongs to a line of volcanoes (extending from Lake Bolsena to the Phlegraean fields) that have poured out lavas of this character. They are sometimes known as the Mediterranean suite.

When one turns to the igneous rocks of older geological periods the same contrasted suites can be recognized. The midland valley of Scotland has been the theatre of igneous action both in Lower Devonian and Carboniferous times. The igneous assemblages of the two periods show. however, a striking contrast. The earlier lavas are distinctly of the Pacific type, including andesites, basalts and rhyolites. while the Carboniferous extrusions and dike rocks include trachytes teschenites, picrites and monchiquites—an Atlantic assemblage. Petrographical provinces are therefore clearly not permanent.

Study of the geological relations of igneous rocks clearly reveals that there is a general correspondence in both time and space between igneous action and movements of the earth's crust, whether these be simply vertical movements of elevation and depression or tangential movements of folding and overthrusting which build up great mountain chains. As in crustal movements so in igneous action, periods of activity have alternated with periods of quiescence. The movements of compression which led to the folded mountain chains fringing the Pacific were accompanied and followed by widespread volcanism, and the movements of depression which in Tertiary times led to the formation of the Great Rift valley of east Africa were attended and followed by a great suite of volcanic eruptions. The interdependence of igneous action and crust movement is even of a still more intimate kind, for not only the distribution of igneous rocks, but the distribution of different kinds of igneous rock is seen to stand in unmistakable relation to the great tectonic structures of the earth. The examples referred to above are illustrative of this conclusion. The volcanoes of the Pacific cordillera erupted calcic andesites and basalts, and are associated with granodiorite and quartz-diorite intrusions; the eruptions associated with the African Rift valley are in contrast, being of alkali type and including soda trachytes, phonolites and related alkali lavas. Whether attention is confined to Tertiary igneous rocks or extended to those of earlier date, the conclusion is enforced that rocks of the Pacific suite are closely associated with folded mountain chains and appear in regions subject to movements of compression and lateral thrust, and that the Atlantic or alkali suites are associated with regions of subsidence, subject to tension and faulting. The volcanic rocks of oceanic islands are dominantly olivine basalts and with these, though in minor development, are associated typical Atlantic differentiates—trachyte and phonolite. More siliceous lavas have not been frequently reported, but their occurrence with basalts and trachytes in an oceanic environment attests an intimate genetic relationship and adds support to the theory that granitic differentiate can derive from parental basaltic magma. Quartz trachyte or alkali rhyolite have been thus recorded in the inner Pacific at Easter Island and in Tutuila (Samoa), in the south Atlantic (Bouvet Island) and in the Indian ocean (Kerguelen archipelago).

The tectonic environment of rocks of the Mediterranean suite is less clearly defined. In general their spatial arrangement in relation to the Pacific and Atlantic suites reflects their intermediate position. They are characteristic of the region lying between the orogenic zones and the forelands or regions of subsidence. The position of the potassic Roman province in relation to the Alpine orogenic zone and the alkali (Atlantic) basin of the west Mediterranean illustrates this association clearly.

Between many calcic, sodic and potassic suites no sharp line of division is to be recognized, and in their relative distribution upon the face of the globe may be seen the influence of tectonic processes as an external factor exerting a profound influence on the trend of differentiation. See also Index references under "Petrology" in the Index volume.

BIBLIOGRAPHY.—Most textbooks of geology treat petrology in more or less detail *(see* GEOLOGY: *Bibliography)*.

Elementary books on petrology include: *A.* Harker, *Petrology for Students,* 8th ed. rev. by C. E. Tilley, S. R. Nockolds and M. Black *(1954,* rep. *1956)*; F. H. Hatch, **A.** K. and M. K. Wells, *The Petrology of the Igneous Rocks, 10th* ed. rev. *(1950);* S. J. Shand, *Eruptive Rocks,* 4th ed. rev. *(1950)*; H. Williams, **F.** J. Turner and C. M. Gilbert, *Petrography (1954)*; E. *E.* Wahlstrom, *Petrographic Mineralogy (1955)*; E. W. Heinrich, *Microscopic Petrography (1956)*; *A.* Sawarizki, *Einfiihring in die Petrochemie der Eruptivgesteine,* 2nd ed. rev. (Russian trans., *1954)*; W. W. Moorhouse, *The Study of Rocks in Thin Section (1959)*.

More advanced works include: N. L. Bowen, *The Evolution of the Igneous Rocks (1928,* reprinted *1956)*; F. *J.* Turner and J. Verhoogen, *Igneous and Metamorphic Petrology,* 2nd ed. *(1960)*; T. *F.* W. Barth, *Theoretical Petrology (1952)*; *E. E.* Wahlstrom, *Introduction to Theoretical Igneous Petrology (1950)*; *H.* Rosenbusch, *Mikroskopische Physiogmphie,* 4th ed., vol. 2 (1907), *Elemente der Gesteinslehre,* 4th ed. rev. by A. Osann *(1923)*; A. Harker, *The Natural History of Igneous Rocks (1909)*; *J. P.* Xddings, *Igneous Rocks . . .*, 2 vol. *(1909–13)*; R. *A.* Daly, *Igneous Rocks and the Depths of the Earth (1933)*; *K.*

For experimental work on silicate mixtures *see* especially the papers published by the workers of the Geophysical Laboratory, Carnegie Institution, Washington, D.C., principally in *American Journal of Science* and *Journal of Geology* (1905 *et seq.*). (C. E. T.)

PETRONIUS ARBITER (GAIUS or ? TITUS PETRONIUS) (d. A.D. 66). Roman voluptuary, poet and the reputed author of the first western European novel. Tacitus gives a graphic account (*Annals*, xvi, 18–19) of his character and the manner of his death. He was an able man, who distinguished himself as governor of Bithynia and consul; but his chief talent lay in the pursuit of pleasure, in which he displayed such exquisite refinement as to earn the unofficial title of the emperor Nero's "arbiter of elegance" *(arbiter elegantiae)*

Being suspected of conspiring against the emperor, he was ordered to commit suicide; his last hours were passed in amusements, social pleasures and the composition of a scurrilous catalogue of Nero's debaucheries. The identification of this Petronius with the author of the *Satyricon* is, notwithstanding all that has been urged to the contrary, reasonably certain. The atmosphere of the work and the internal evidence point to the Neronian period, and it seems unlikely that two different men of the same name and so similar in character and outlook can have existed at the same time.

The *Satyricon* (properly perhaps *Satyrikon liber*, "Book of Satyrlike Adventures") is a "picaresque" romance. It relates the wanderings and escapades of a disreputable trio of adventurers, the narrator Encolpius ("Embracer"), his friend Ascyltos ("Scot-free") and the boy Giton ("Neighbour"—a euphemism). The surviving portions probably represent about one-tenth of the complete work. Some semblance of unity is imparted to the episodic narrative by a wrath motif recalling the *Odyssey* and the *Aeneid:* the narrator is pursued by the enmity of Priapus, whose divinity he apparently offended in a lost portion of the work. The *Satyricon* has obvious affinities with the later Greek prose romances, particularly in the rhetorical flavour which pervades it, but its immorality, or rather amorality, sets it in a class apart from them. Its tone recalls the notorious predilection of Nero and his court for low life and suggests that it may have been composed specially for their amusement. Its literary ancestry is complex and can only be guessed at. The loose narrative framework encloses a number of detached tales of the so-called "Milesian" type, the ancestor of the smoking-room story, a classic instance being the famous "Widow of Ephesus" *(Satyricon*, ch. 111–112); in this the *Satyricon* resembles the later *Metamorphoses* of Apuleius. Other features, however, recall the "Menippean" satire (represented in Latin by M. Terentius Varro): namely, the mixture of prose and verse in which it is composed; and the digressions in which the author airs his own views on various topics having no connection with the plot.

The most remarkable of these digressions, which are the only parts of the work which may properly be called satire, is the passage relating to contemporary epic poetry (ch. 118); it is followed by a hexameter poem of 295 lines on the civil war between Caesar and Pompey, apparently intended as a criticism (not a parody) of Lucan. Whether Petronius had a Greek model or whether the fusion of genres represented by the *Satyricon* was his own invention must, in the present state of the evidence, remain uncertain.

The longest and the best episode is the so-called *Cena Trimalchionis* or "Banquet of Trimalchio" (ch. 26–78), a description of a dinner party given by Trimalchio, an immensely rich and vulgar freedman (former slave) of oriental origin, to a group of friends and hangers-on. Its length appears disproportionate even to the presumed original size of the *Satyricon* (though the story of Cupid and Psyche in Apuleius offers a partial analogy), and it has little or no apparent connection with the plot. The scene is a Greco-Roman town in Campania, possibly Puteoli (Pozzuoli), and the guests, mostly freedmen like their host, are drawn from what corresponded to the *petit bourgeois* class. Trimalchio is the quintessence of the parvenu, a figure familiar enough in ancient satirical literature, but especially so in the 1st century A.D., when freedmen as a class were at their most influential. The setting exemplifies a literary form stemming from Plato's *Symposium* and already employed for satirical purposes by Horace *(Satires*, ii, 8).

Two features distinguish Petronius' *Cena* from other ancient examples: its extraordinary particularity and realism and the figure of Trimalchio. It is obvious that the table talk of the guests in the *Cenu* is based on personal observation of provincial societies. The speakers are beautifully and exactly characterized and their dialogue, quite apart from the invaluable evidence for colloquial Latin afforded by the vulgarisms and solecisms in which it abounds, is a humorous masterpiece. Trimalchio himself, with his vast wealth, his tasteless ostentation, his affectation of culture, his superstition and his maudlin lapses into his natural vulgarity, is more than a typical satirist's figure. That some of his idiosyncrasies are taken from life is proved by Seneca's description of Calvisius Sabinus *(Epistles*, xxvii, 5); and, if due allowance is made for comic exaggeration, little about him is actually incredible. As depicted by Petronius, however, he is one of the great originals of literature, fit company for Shakespeare's Falstaff or R. S. Surtees' Jorrocks. Development of character for its own sake was hardly known in ancient literature: the emphasis was always on the typical, and the classical rules as expounded by, for instance, Aristotle and Cicero, laid down that character was secondary to more important considerations such as plot. Petronius, in his treatment of Trimalchio, transcended this almost universal limitation in a way that irresistibly recalls Dickens, and much else in the *Cenu* is Dickensian—its exuberance, its boisterous humour (rare in ancient literature, where wit predominates) and its loving profusion of detail.

The rest of the *Satyricon* is hardly to be compared with the *Cenu.* It offends not so much by its indecency as by the selfish and flippant hedonism which colours it throughout (a debased Epicureanism: *see* the poem at the end of ch. 132). This, allied to a Latin of unmatched grace and elegance, earned for Petronius (from Justus Lipsius) the title *auctor purissimae impuritatis*, "writer of the purest impurity." The few poems transmitted separately from the *Satyricon* under Petronius' name do nothing to

enhance his reputation. To the middle ages he was known as the author of moral maxims, preserved in fragmentary excerpts; his popularity in modern times dates from the publication in 1664 of the previously unknown *Cena Trimalchionis,* discovered in a manuscript at Trau (Trogir) in Dalmatia.

BIBLIOGRAPHY.—The standard edition of the text is by F. Biicheler, 6th ed. rev. by G. Heraeus (1922); there are also editions by M. Heseltine with Eng. trans. (1913), by A. Ernout, 3rd ed., with Fr. trans. (1950) and, of the *Cena Trimalchionis* only, by W. B. Sedgwick, with introduction and commentary (1950). Translations abound; the best-known English version is by W. Burnaby (1694). For a general introduction *see A.* Collignon, *Étude sur Pttrone* (1892); *E.* Thomas, *Pttrone* (1912); G. Bagnani, *Arbiter of Elegance* (1954). *See* further Sir S. Gaselee, "The Bibliography of Petronius," *Trans. Bibl. Soc.,* vol. x (1910); W. Kroll, "Petronius," in Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft,* vol. xix (1937); R. Helm, "Römische Satiriker," *Jahresbericht uber die Fortschritte der klassischen Altertumswissenschaft,* vol. 282 (1943); R. Muth, "Petronius," in *Anzeiger der Altertumswissenschaft,* vol. ix (1956); H. C. Schnur, "Recent Petronian Scholarship," *Classical Weekly,* vol. 1 (1956). (E. J. KY.)

PETROPAVLOVSK, (1) a town in the Kazakh *oblast* of the Kazakh Soviet Socialist Republic, U.S.S.R., in 55° N. and 69° E., on the left bank of the Ishim river, where the Trans-Siberian railway crosses it. Pop. (1959) 35,000. The town is a centre for caravan trade from the Kirghiz steppe in corn, cattle, furs, tea, wool and cotton and has an Asiatic appearance.

(2) A port on the eastern shores of Avacha bay in the Kamchatka *oblast,* of the Russian Soviet Federated Socialist Republic, U.S.S.R., in 53° 16' N., 159° E. Pop. (1959) 86,000. The inhabitants are mainly Russians, Japanese, Chinese, Koreans and natives. and the town, which has been growing rapidly, is a centre for the fur trade.

There are summer sailings to Vladivostok and Japan, but the harbour is frozen from November to May. There is a wireless station, linking it with Vladivostok and with the fish canneries in the north of Kamchatka.

The Russian Pacific fleet was stationed there for a time and defeated a combined attack by the French and English during the Crimean War. It was transferred in 1854 to Nikolayevsk-on-Amur and, ultimately to Vladivostok.

PETROPOLIS, a city of the state of Rio de Janeiro, Brazil, in an elevated valley of the Serra de Estrêla or dos Orgãos mountains, 2,634 ft. above sea level, is 27 mi. N. of Rio de Janeiro, with which it is connected by railway and highway. It was founded in 1845 by Julius Frederick Knoeller, and was sponsored by Dom Pedro II, the Brazilian emperor for whom it was named. The emperor was attracted to the city's relatively cool climate—9° F. lower than Rio de Janeiro during the summer—and held court there during the warmer months, attended by public officials and members of the diplomatic corps.

The ornate royal palace, surrounded by luxuriant gardens, houses the Museu do Imperio (Museum of the Empire) that contains many of the possessions of João VI of Portugal, who resided in Brazil for several years, and of the two Brazilian emperors, Dom Pedro I and Dom Pedro II. The cathedral of the town is of 13th-century French Gothic design. There is a variety of manufacturing industries in the city and a short distance away are rich farm lands. Pop. (1950) 61,011 (city); 108,307 (mun.). Quitandinha palace, a leading resort centre, is about 3 mi. S. of Petrópolis on the highway to Rio de Janeiro. (J. J. J.)

PETROVARADIN (German **PETERWARDEIN**), a former town and fortress of Croatia-Slovenia, Yugos., situated on a promontory formed by a loop of the Danube; occupied by the axis in 1941. After the return to Yugoslavia it was annexed to the city of Novi Sad.

The fortifications consist of the upper fortress, on a lofty serpentine rock rising abruptly from the plain on three sides, and of the lower fortress, rising from the river on the northern base of the rock.

The fortress is believed to represent the Roman Acumincum, and received its present name from Peter the Hermit, who in 1096 marshaled the levies of the first crusade there. It was captured by the Turks in 1526 and was retained by them for a period of 160 years.

PETROZAVODSK, the chief town in the Karelian Autonomous Soviet Socialist Republic of the Russian Soviet Federated Socialist Republic, U.S.S.R., in 61° 41' N., 34° 20' E., on the west shore of Lake Onega, and on the Leningrad-Murmansk railway. Pop. (1959) 135,000.

PETRUS AUREOLI (*c.* 1280–1322), otherwise PIERRE AURIOL (or ORIOL. D'ORIOL), French Franciscan, theologian and philosopher known honorifically as *Doctor facundus,* "the eloquent teacher," was born near Gourdon in Quercy. Having studied in Paris and taught in Bologna and Paris, he became provincial of his order for Aquitaine (*c.* 1320) and archbishop of Aix-en-Provence (1321). Criticizing both Thomas Aquinas and Duns Scotus, he promoted an individualistic empiricism, supported by a nominalistic-conceptualistic doctrine of universals which in some ways anticipates William of Occam.

His *Commentary on the Sentence:* was first printed in Rome, 2 vol. (1596–1605).

See A. Teetaert, "Pierre Auriol," in *A.* Vacant (ed.), *Dictionnaire de théologie catholique,* xii (1934). (L. M.-Po.)

PETTENKOFER, MAX JOSEPH VON (1818–1901), German chemist and hygienist whose name is most familiar in connection with his work in practical hygiene and nutrition, which he put on a scientific basis, was born on Dec. 3, 1818, at Lichtenheim, near Neuburg.

He studied pharmacy and medicine at Munich (Ph.D., 1843), and after working under Justus von Liebig at Giessen was appointed chemist to the Munich mint in 1845. Two years later he was chosen professor of chemistry in the medical faculty at Munich, and in 1865 he became professor of hygiene. He was ennobled in 1883. In 1894 he retired from active work, and on Feb. 10, 1901, he committed suicide at Munich.

The reaction known by his name for the detection of bile acids was published in 1844.

PETTIE, JOHN (1839–1893), Scottish painter, was born in Edinburgh on March 17, 1839. At 16 he entered the Trustees' Academy in Edinburgh, working under Robert Scott Lauder. His first exhibits at the Royal Scottish Academy were "A Scene From the Fortunes of Nigel"—one of the many subjects for which he sought inspiration in the novels of Sir Walter Scott—and two portraits in 1858. To the Royal Academy in 1860 he sent "The Armourers"; and in 1862 he settled in London, where he joined W. Q. Orchardson. In 1866 he was elected A.R.A., and in 1874 R.A.

Pettie died at Hastings on Feb. 21, 1893.

John Pettie, R.A. (1908), by his nephew Martin Hardie, gives the story of his life, a catalogue of his pictures and 50 reproductions.

PETTIGREW, RICHARD FRANKLIN (1848–1926), U.S. senator, whose amendment to the Timber Culture act of 1891 established the right of the president to reserve public forest lands by proclamation. He was born on July 23, 1848, in Ludlow, Vt. In 1854 the family moved to Wisconsin, first to Dane county and shortly thereafter to Evansville, where he attended the public school and academy. He entered Beloit college in 1864, taught school a year, and in 1867 entered the University of Wisconsin (Madison), where he studied law. In 1869 he went to the Dakota territory as a U.S. deputy surveyor and settled in Sioux Falls (later South Dakota). He was admitted to the bar in 1871 but continued his surveying and dealt in real estate until 1875.

He was elected to the house of representatives of the territorial legislature in 1872 and to the territorial council in 1877, 1879 and 1885. He served as delegate to the 47th U.S. congress from the territory, 1881–83, being elected as a Republican, and in 1889 when South Dakota and North Dakota were admitted to the union, he was chosen a senator for South Dakota. He was re-elected in 1895. Politically independent, he was a single taxer, opposed to the private ownership of land, and believed railroads and telegraph systems should be public utilities. He broke with his party when, as a delegate to the national convention of 1896, he walked out after the defeat of a free silver resolution. He supported the Democratic candidate, William Jennings Bryan, in the following campaign. He was defeated for re-election to the senate in 1900.

He practiced law in New York city before returning to Sioux Falls, where he died on Oct. 5, 1926. His house and his collections of Indian and frontier relics and of specimens of birds, snakes and animals native to South Dakota were bequeathed to the city as the Pettigrew museum.

PETTY, SIR WILLIAM (1623–1687), English political economist and statistician, one of the founders of economic thought and demographic and economic statistics, was born at Romsey, Hampshire, May 26, 1623. Having studied medicine at the universities of Leyden, Paris and Oxford, he was in turn seaman, medical student, physician, professor of anatomy at Oxford, professor of music in London, inventor, surveyor and landowner in Ireland and a member of parliament. He died in London on Dec. 16, 1687.

A protagonist of the empirical scientific doctrines of the newly founded Royal society, of which he was a founder-member, Petty was one of the leading pioneers of political arithmetic; *i.e.*, "the art of reasoning by figures upon things relating to government." His various *Essays on Political Arithmetick* and *Political Survey or Anatomy of Ireland* (1672) presented population estimates and rough calculations of social income. His methods seem crude and audacious by modern standards, but Petty was not unaware of their limitations. His ideas on monetary theory and policy, including the quantity theory, were developed in *Verbum Sapienti* (1665) and *Quantulumcunque concerning Money, 1682* (1691). But his main contribution to political economy was *Treatise of Taxes and Contributions* (1662), in which he expounded what should be the main economic functions of the state. In doing so he touched on the fundamental problem of the theory of value, treating the labour necessary for production as the main determinant of exchange value and seeking a standard of value in the necessary sustenance of a man for a day. Petty—an advocate of religious toleration—favoured allowing scope to the natural forces of individual self-interest and "rather complying with the motions of nature than contradicting it with vehement administratives." But unlike liberals after Adam Smith he considered the maintenance of a high level of employment by monetary and fiscal policies and by public works to be a duty of the state.

See Economic Writings of Sir William Petty, ed. by C. H. Hull, 2 vol. (1899). (T. W. H.)

PETUNIA, a genus of popular garden plants of the nightshade family (Solanaceae), comprising perhaps 15 species, mostly from Brazil and Argentina. The group has been much hybridized and the origin of the common garden sorts is doubtful. Petunias are divided into three main divisions: (1) erect types, 7–15 in high, used for bedding; (2) sprawling or weak-stemmed types, often called balcony petunias, useful for window boxes; and (3) dwarf types. 4–6 in. high, also used for bedding. Modern petunia varieties have typically funnel-shaped flowers, only slightly unsymmetrical, and variously crisped, fringed or ruffled; double varieties have also been developed.

All the petunias are annuals and are not frost-hardy. They may be started from seed sown indoors and just barely covered with fine-grained soil eight to ten weeks before outdoor planting is safe. When warm weather has arrived the seedlings can be planted outdoors in almost any ordinary garden soil. They do particularly well along the seaboard of the Atlantic, and especially so along the coast of Oregon, Washington and northern California, but may be grown in almost any temperate locale. They can be started outdoors directly from seed in the warmer parts of the United States and in southern England.

Amply watered and in a sunny location, these showy plants will bloom profusely all summer, yielding blossoms of pure white through various shades of red violet to deep violet. Some of the large-flowered types are easily beaten down by rain and so should be staked. (N. TR.)

PETWORTH, a town of West Sussex, Eng., 14 mi. N.E. of Chichester by road. Pop. (1951) 2,729. Petworth (Peteorde in Domesday Book, Puetewurth in 1181) is named in a grant by Eardwulf, king of Northumbria (d. 810) to St. Peter's church. Under Edward the Confessor it was an alodial manor, held by his queen, Edith, and in 1086 Robert Fitz-Tetbald held it of Roger de Montgomery, earl of Shrewsbury. Standing in a large park is Petworth house (National trust) with a 13th-century chapel; the manor house was almost wholly rebuilt between 1688 and 1696 by the duke of Somerset. The south front was rebuilt in 1869–72. It is remarkable for its magnificent collection of pictures and its wood carvings by Grinling Gibbons and Jonathan Ritson (1776?–1846).

PEUTINGER, KONRAD (1465–1547), German humanist and antiquarian, was born at Augsburg. In 1497 he was town clerk of Augsburg, and was on intimate terms with the emperor Maximilian. He was one of the first to publish Roman inscriptions, and his name remains associated with the famous *Tabula peutingeriana*, a map of the military roads of the western Roman empire, discovered by Konrad Celtes. Peutinger also edited the *Historia Gothorum* of Jordanes and the *Historia gentis Langobardorum* of Paulus Diaconus.

The *Tabula peutingeriana* was first published as a whole by F. de Scheyb (1753); later editions by E. Desjardins (1869–74) and C. Miller (1888); *see* also *E.* Paulus, *Erklärung der Peutinger Tafel* (1867); Teuffel-Schwabe, *Hist. of Roman Literature* (Eng. trans., 1900).

PEVENSEY, a village in the Hailsham rural district of East Sussex, Eng., 38 mi. E.N.E. of Brighton by road. Pop. (1951) 1,686. It was the landing place of William the Conqueror and became the head of the rape (*q.v.*) of Pevensey, granted by William to the earl of Mortain. It subsequently became the honour of the Eagle. Some time before the reign of Edward I the town of Pevensey was made a limb of the Cinque Port of Hastings and shared the liberties of the Cinque Ports. By an act of 1883 it ceased to exist as a borough. The decline of Pevensey was caused by the silting up of the Pevensey levels, once a shallow bay but by 1700 almost completely reclaimed, leaving Pevensey about 1 mi. inland. Pevensey castle's outer wall. with towers, is Roman, the remains of the powerful fortress of Anderida. Within are the ruins, principally of the 13th century but in part Norman, of the castle proper, with a keep.

PEW, a term, in its most usual meaning, for a fixed seat in a church, usually enclosed, slightly raised from the floors and composed of wood framing. mostly with ornamented ends. Some bench ends are certainly of Decorated character, and some have been considered to be of the Early English period. They are sometimes of plain oak board, 2½ to 3 in. thick, chamfered and with a necking and finial generally called a poppy head; others are plainly panelled with bold cappings; in others the panels are ornamented with tracery or with the linen pattern, and sometimes with running foliages. The large pews with high enclosures, known familiarly as "horse boxes" and common in English churches during the 18th and early part of the 19th centuries, have nearly all been cleared away. The church of Whitby, in Yorkshire, is perhaps the best surviving example of an unaltered interior.

At common law all seats in a parish church are for the common use of all the parishioners, and every parishioner has a right to a seat without paying for it. As against the assignment and disposition of seats by the ordinary, acting through the church wardens, two kinds of appropriation can be set up: (1) by the grant of a faculty by the ordinary; and (2) by prescription, based on the presumption of a lost faculty. Such faculties are rarely granted now, they were formerly common; the grant was to a man and his family "so long as they remain inhabitants of a certain house in the parish." The letting of pews in parish churches became common in the 16th century, but there are some earlier instances of the use, for example at St. Ewens, Bristol, in 1455.

See A. Heales, *History and Law of Church Seats and Pews* (1872); Phillimore, *Eccles. Law*, ii, 1424 *sq.* (1896).

PEWTER, an alloy, the basis of which is tin. Modern pewter is a tarnish-resistant alloy composed of approximately 91% tin, 7.5% antimony and 1.5% copper; the best grades contain no lead. The copper adds ductility and desirable working properties while antimony serves to whiten the alloy and to impart a hardness unknown to old pewter. Old pewter, first used nearly 2.000 years ago by the ancient orientals and Romans contained sufficient lead to cause the surface to darken with age. There are two schools of thought among pewter collectors: some prefer the dark satin-

like sheen of old pewter while others prefer modern pewter which retains its brightness indefinitely and lends itself to a whole gamut of finishes from a crisp bright finish to a soft satin sheen.

Pewter played an important part in the development of civilization as a medium for artistic expression and as a material from which domestic utensils were fashioned. Pewter exceeds most other metals in ductility and ease of working. It may be stretched, compressed and bent into almost any desired shape; and it does not harden or stiffen sufficiently on coldworking with tools for annealing to be necessary. Modern methods of manufacture differ considerably from those of the early craftsmen, which involved casting, turning and hammering. Much of the flat and hollow ware is spun on a lathe instead of being cast; the stamping press is used frequently to produce unique shapes such as oval trays and gravy boats. Casting methods are still essential for making handles, feet, knobs, hinges and for heavy ornamental pieces. Pewter articles can be hammered into shape, the surface can be raised or stretched, surface lines can be emphasized by chasing and embossing and decorative effects can be achieved by etching. Machine methods for polishing have added interesting possibilities in new and artistic finishes.

Modern Pewter.--Modern pewter is somewhat softer than brass or bronze. In spite of its softness, it must be classed as one of the most durable metals and as one which will resist oxidation almost indefinitely. Utensils made from pewter have a high resistance to almost all weak acids: food and drink may be served in them without fear of chemical action.

Modern pewterware falls into two types: antique and modern. For the person who prefers antique pewterware, there are reproductions of early masterpieces of the American colonial period. For instance, a complete line of Williamsburg reproductions are available, some of which are actually cast from original molds. For those who desire modern pewterware, there is a wide variety of articles such as coffee and tea services, plates, trays, water jugs. tankards, candelabras, serviette rings, bowls, flasks, cigarette and jewelry boxes, spoons, trophies, ship models, pepper and salt shakers. ashtrays and communion cups. Most modern manufacturers in adapting original designs or producing new designs, have kept the bold simple lines which are the chief charm of pewter.

The revival of interest in pewter can be attributed to several factors. For example, the public has become educated to the charm and beauty of nontarnishing pewter; contemporary craftsmen are using pewter in new ways and in striking designs. Pewter has been introduced as an important activity in industrial arts courses in the schools and the home workshop.

Historical Background.— The historical background of old pemter is extensive and many historical collections can be seen in museums throughout the world. Famous collections are on display in the Victoria and Albert museum in London, the Smithsonian institute in Washington, D.C., and the University of Copenhagen, Den. There are more than a dozen large pemter collections in the United States. (*See* list of museums, B. N. Osburn and G. O. Wilber, *Pewter,* 1947.)

England.--Specimens of Roman pewter excavated in England leave no doubt that pewterware was made in England by the Roman legions. From the Renaissance, the use of pewter in England had been firmly established in the church and for domestic purposes. Pewter chalices had replaced wooden vessels before the end of the 11th century; until the 15th century it was customary to bury a pewter chalice with the priest. After the Reformation and throughout the 17th and 18th centuries, a large number of pewter vessels were found, especially flagons, alms dishes and collection plates. It was customary for every pewterer to strike his '(touch" or mark: these marks were made with a steel die into which some ornamental design with the initials of the maker had been cut. The mark indicated membership in a guild called the Worshipful Company of Pewterers, chartered by the crown in 1503. Records of touch-plates were destroyed in the great fire of 1666. The activities of the company prospered and pewterware became an important household item. Plates, saucers, tankards, mugs, candlesticks and mustard pots are excellent examples of some commonly used articles in English homes until the period when china and porcelain appeared. During World War I and II many valuable pieces of pewter relegated to the attic were sold for scrap and lost forever. It is surprising that so much pewter has survived and that it is possible to form a representative collection of pewter items from at least the late 17th century to the middle of the Victorian era.

Holland.— Much fine pewterware was made in other parts of continental Europe. The earliest known date on a pewter article made in Holland is 1331. In the 17th century, pewter played an important part in middle-class homes and in the inns.

The modern pewter industry continues the old tradition. Century-old, well-tried models are still being made but craftsmen have given new shapes to the classic material by harmoniously combining usefulness and beauty. Dutch pewterware is plentifully available and is exported to all countries into which importation is allowed.

Sweden.— The manufacture of pewterware began in Sweden before the end of the 13th century. Guild rules existed as early as 1485 when pewterers were required to stamp their wares. A rose-and-crown mark, much in evidence in the 17th century, denoted the highest quality. The artistically brilliant period of pewter in Sweden was the 18th century when it served widely for table wares and candlesticks. The decline occurred as in other countries but manufacture was revived in 1924.

Germany.--Germany had established a pewter industry at Augsburg and Nuremberg in the 14th century. During the next four centuries, pewter was the most versatile metal available and wares of every kind were made. The treatment of pewter in relief was quite common as, for example, the plates with portraits of emperors or medallions of Biblical scenes. German hostels afforded much in the way of tankards and drinking vessels. After World War II, the pewter industry in Germany had revived strongly in the towns of Regensburg, Wurttemburg, Diessen and Nabburg.

France and Belgium.— The rise of pewter in France and Belgium was contemporary with that in other European countries. In France the most interesting period was the 16th century. Highly ornamented pieces have been found which were associated with the name of François Briot, the greatest of French pewterers. His well-known Temperantia salver and ewer are covered with ornament in relief. On the ewer are figures of the cardinal virtues, while on the dish are figures of Minerva and the seven arts, with the four elements and Temperance in the centre. Fine examples of his work are preserved in the Cluny museum, Paris. Little of the ancient pewter remains in Belgium because so much has disappeared during the repeated wars and invasions.

Colonial America.—Pewter was used much in the households of colonial America. The earliest pewterers came from England, bringing their traditional styles with them. The period which marked its greatest production was the 150 years between 1700 and 1850. Boston, New York and Philadelphia were the main centres of manufacture. Every kind of utensil mas made which was in any way requisite for domestic purposes: plates, bowls, spoons, tankards, candlesticks and lamps were made in enormous quantities. With the advent of cheap pottery, particularly plates, the pewterers turned their efforts to the manufacture of coffee pots and these became the mainstays. In the 20th century, there came a revival of interest in colonial period pewter; several firms took up the manufacture of antique reproductions and then branched into new designs which found favour. It is apparent that in spite of other available materials, pewter retained its hold and popularity upon American taste long after it had ceased to interest the European public. During World War II and for a number of years thereafter, the manufacture of pewter was not allowed because tin was reserved for essential purposes. Restrictions were removed in 1953 and manufacturers made up lost ground by leaps and bounds. Since then, the world production of modern pewterware has exceeded the amount of pewter produced in any similar period in the history of the industry. *See* also ANTIMONY; *TIN*.

(R. M. MacI.)

PEYOTISM is the use by American Indians of peyote (*Lophophora williamsii*), a spineless cactus which grows in northern Mexico and in Texas. The word "peyote" seems to be a Spanish version of the Nahuatl term *peyotl*.

The properties of the cactus are such that, when eaten, it produces extraordinary physiological and psychological effects. These effects seem to vary with the social and psychological conditions under which peyote is taken. Scientific observations have been made upon white persons only under laboratory conditions; the effects reported are distinctly different from those observed upon Indians taking peyote under ritual conditions.

There are two major forms of peyotism, the old peyote complex and the peyote religion.

The old peyote complex is the earlier form of peyotism, which flourished prior to the 20th century. Peyote was used by persons primarily as a medicine and to obtain visions for purposes of supernatural revelation. The plant was used collectively as an auxiliary in tribal dancing rites, the purpose of the peyote evidently being to induce a trance state during the dance. Little is known about the preconquest (1521) origin and distribution of the old peyote complex; all that can be stated is that peyote is depicted on pre-Columbian archaeological remains in Mexico. Documents from the 16th century to the 18th report the distribution of the old peyote complex in Mexico and the United States within the area between 18° and 36° N. lat. and between 92° and 114° W. long. In the 20th century the old peyote complex exists in Mexico, with diminished importance.

The peyote religion is a syncretistic form of peyotism which developed during the second half of the 19th century. The peyote religion is practised by a voluntary religious organization, whose rite is one of prayer and quiet contemplation, centred on peyote both as a symbol of the spirits being worshipped and as a sacrament.

The fully developed peyote religion probably originated among the Kiowa and Comanche on their reservation in Oklahoma, about 1885, out of an earlier Apache peyote rite. From 1891 on the religion spread rapidly and became the most widespread indigenous Indian religion, extending from the Great Lakes to the Rocky mountains in both the United States and Canada. Groups practising the peyote religion were incorporated in 1918 as the Native American Church.

Peyotism has the basic traits found in all religions: a doctrine, ethics and ritual. Most peyotists consider themselves to be Christians, for they conceive peyotism to be the Indian version of Christianity. Their proof of this is that they accept the Christian Trinity and Christian ethics.

Doctrine of the Peyote Religion.—Peyotist doctrine, or religious theory, consists of a belief in the existence of power, spirits and incarnations of power.

Power.—"Power" is the Indian equivalent of what the Greek New Testament calls *pneuma* (Holy Spirit, Holy Ghost) and anthropologists mana. It is an immaterial and invisible supernatural force, which produces characteristic effects in things influenced by it and can be transferred from one thing to another under the proper ritual conditions. Man needs power to be successful and healthy; without it he becomes unsuccessful and ill.

Spirits.—Spirits are immaterial personifications of power. The peyotist pantheon consists of what may be called white and Indian spirits.

White Spirits: the Trinity.—God is equated with the Great Spirit. He is universally acknowledged to be the supreme being and the ultimate source of all power; therefore He controls the destiny of everything in the universe, including man. Whether He is the creator spirit as well depends upon the tribe. Jesus plays various roles. In some tribes He is the culture hero (often equated with the traditional culture hero) who gave the white version of Christianity to the whites and peyotism to the Indians. In other tribes He is a guardian spirit who, rejected by the whites who murdered him, now looks after the equally rejected Indians. Another of Jesus' roles is that of intercessor spirit between God and man. The Holy Ghost has been adopted as part of the Trinity.

Indian Spirits.—Waterbird is usually identified as the water turkey (Anhinga nnhinga). Some equate Waterbird with the traditional Indian Thunderbird, others with the white Christian dove. Most often it has the role of a messenger spirit that carries man's prayers to God.

In many tribes peyote itself is personified as Peyote spirit. In general, the role of Peyote spirit is similar to that of the guardian spirit aspect of Jesus in white Christianity; he is a compassionate being, always benevolent, sympathetic and helpful.

Incarnations.—Incarnations are material embodiments of power, and peyote is the prime incarnation. It was given to the Indians by God because he took pity on them for being a subject people—poor, weak, helpless and ignorant. God made the peyote and put some of his power into it in order to help the Indians. Therefore when one eats peyote he absorbs the power inherent in it, which he can then utilize. Thus it is a sacrament like the bread and wine of white Christians, which are consumed in order to absorb the Holy Spirit inherent in them.

The characteristics of the plant are such that when taken internally it produces remarkable physiological and psychological effects. From the supernaturalistic viewpoint of Indian peyotists, these properties consist of the power within the peyote; when the sacramental plant is taken internally, this power is absorbed and affects the individual's spiritual and physical state. From the viewpoint of scientists, these properties consist of alkaloids; when the alkaloids are taken internally they affect the central nervous system.

The next most important incarnation of power is the water drunk during the rite at midnight and in the morning. Water is needed by all living things, and therefore all water is sacred. In addition, the water used in the rite is prayed over and "blessed" so that it acquires additional power. The morning water is particularly sacred because it is brought in and prayed over by the wife or other close female relative of the leader. She represents womanhood as the source of human life (she symbolizes "the mother of us all") and in some tribes also Peyote Woman to whom the rite was revealed.

The foods used in the morning communion breakfast (usually corn, game and fruit) also contain power, for they represent the important classes of foods man needs for life.

Ethics and Eschatology.—The peyotist ethical code constitutes a way of life called the Peyote Road, and conforming to the ethic is "following the Peyote Road." This ethic has four main parts.

Brotherly Love.—Members should be honest, truthful, friendly and helpful to one another. This is conceived as a spelling out of the Golden Rule (Matthew vii, 12; Luke vi, 31).

Care of Family.—Married persons should not engage in extramarital affairs and should cherish and care for one another and their children. Money should be spent on the family as a whole, rather than selfishly.

Self-Reliance.—Members should work steadily and reliably at their jobs and earn their own living.

Avoidance of Alcohol.—There is a maxim, "Peyote and alcohol don't mix."

Ritual.—Characteristically, but not always, the rite (called a meeting) is held in a Plains-type tepee. It is an all-night ceremony, usually lasting from about 8 P.M. on Saturday to 8 A.M. on Sunday. Essentially the rite has four major components: prayer, singing, eating the sacramental peyote and contemplation.

The reasons for choosing peyote as a sacrament can best be explained in terms of the fourth component of the rite; namely, contemplation. After eating peyote each worshipper spends most of his time in contemplation; any given person spends relatively little

time in solo singing. What does he contemplate about, and why does he need peyote to help him do so?

As in the case of any other sacrament, the worshipper eats peyote under the proper ritual conditions in order to obtain power to commune effectively with God and the other spirits. Perhaps the most important element in contemplation is concentration on such communion. For in all religions the purpose of communion is to lift the worshipper from the commonplace level of mundane existence to the exalted level of spiritual sublimity. In the culture areas under consideration, the traditional Indian means of obtaining the power needed for a successful and healthy life was through the vision quest. The individual went off in isolation. subjected himself to ordeals so that he would be pitied, and prayed for assistance until some spirit appeared in a vision and gave him personal power. Peyotism changes the traditional pattern somewhat. The individual participates in a collective rite, but he spends most of the time in contemplation—he is in a collective isolation. as it were. Two features exist which are peyotist equivalents of the traditional ordeal. Most persons do not find peyote pleasant to take: "It is hard to eat peyote." In addition, they find it difficult to sit on the ground all night in one position: "It is hard to sit through a meeting." The prayer for assistance is important; one prays that God and the other spirits will take pity on him and help him, through peyote. But this is elaborated in peyotism, so that it becomes necessary to be in the proper spiritual and psychological state when eating peyote. Spiritually, one must put away all evil thoughts. Psychologically, one must be conscious of his personal inadequacy. humble, sincere in wanting to obtain the benefits of peyote, and concentrate on it.

When taken under the proper conditions, peyote causes the worshipper to experience a revelation that in most cases takes the form of a vision, in uhich he sees or hears a spirit. In some cases the revelation takes the form of a mystical state, the unification of all immediate experience with God. In either circumstance the individual has a vividly direct experience of what has been revealed, qualitatively different from inference or hearsay. which is so characteristic of revelation in all societies. Therefore the peyotist is an individualist and an empiricist; he believes only what he himself has experienced: "The only way to find out about peyote is to take it and learn from peyote yourself." It may be interesting to know what others have to say; but all that really matters is what one has directly experienced—what has been revealed to him personally by peyote.

The traditional visions brought personal power; by contrast, peyotist revelations afford insight. This should be obvious for mystical states, but some explanation may be in order in the case of peyote visions. Usually the visions consist of God, Jesus or some other spirit presenting a revelation depending upon the personality and problems of the individual. The following are typical: He may be comforted by seeing or hearing some previously unexperienced item in the peyote doctrine or departed loved ones now in a happy existence. He may be guided on the one hand by being shown the way to solve some problem in daily life; on the other hand, he may be reproved for evil thoughts and deeds and warned to repent.

Peyote is also eaten as an aid to contemplation; through it one obtains increased powers of concentration and introspection. (1) The worshipper concentrates on communion and revelation in order to obtain the maximum from them. (2) On behalf of himself and others, he prays silently or aloud, concentrating as hard as he can in order to procure the attention and acquiescence of the spirits to whom the prayer is directed.. (3) Peyote heightens introspection and sensitizes the conscience. The worshipper examines his life meticulously to see where he has strayed from the Peyote Road because of evil thoughts and deeds. He then confesses his sins and promises to repent and discipline himself.

Peyotists express these results of contemplation as "learning from peyote." Used properly in this way, peyote is an inexhaustible teacher. A stock statement is, "You can use peyote all your life, but you'll never learn all there is to know about peyote. Peyote is alnays teaching you something new."

Another important use of peyote is as a medicine. It is believed to be a catholicon, or universal panacea. Other medicines, both Indian and white, are good for particular diseases, but peyote is good for all ills, spiritual as well as bodily. The peyotist etiology is based upon traditional Indian beliefs. Disease is produced either by insufficient power or by a foreign object. Sickness can therefore be cured in three ways. First. the sick person eats enough peyote to absorb the amount of power needed to restore health. Second, in more serious cases one prays to God and other spirits to give the patient added power, over and above that which is obtained from eating the peyote; the invalid may do this for himself, but in the most serious illnesses a doctoring meeting is held so that others can help pray for the required power. Third. the sick person may vomit as a result of eating peyote. In this way the foreign object which caused the disease is ejected from the body; the patient then eats more peyote in order to obtain the power necessary to restore health. (Vomiting also purges one of spiritual uncleanness.)

PFAFF, JOHANN FRIEDRICH (1765–1825), German mathematician, was born on Dec. 22, 1765, at Stuttgart. He studied at Gottingen and Berlin.

From 1788 to 1810 Pfaff was professor of mathematics in Helmstedt; from 1810 till his death, April 21, 1825, he held the chair of mathematics at Halle. His researches bore chiefly on the theory of series, to which he applied the methods of the so-called combinatorial school of German mathematicians. and on the solution of differential equations. His two principal works are *Disquisitiones analyticae maxime ad calculum integralem et doctrinam serierum pertinentes* (vol. i. Helmstedt. 1797) and a memoir on partial differential equations in *Abh. d. Berl. Acad.* (1814–15). His method of integrating partial differential equations of the first order with any number of variables led Jacobi to introduce the term "Pfaffian problem."

PFALZBURG: *see* PHALSBOURG.

PFEFFER. WILHELM (FRIEDRICH PHILIPP) (1845–1920), German physiological botanist whose work on osmosis marked an epoch in investigations on the properties of semipermeable membranes and water solutions *(see* SOLUTIONS: *Osmotic Pressure)*. He was born in Grebenstein near Kassel on March 9, 1845. After earning a degree in botany and chemistry from Gottingen university in 1865, he spent the next several years studying botany and pharmacy at Marburg university. He continued his botanical studies as a private assistant to Nathanael Pringsheim at Berlin (1869–70) and to Julius von Sachs at Würzburg university (1870–71). In 1871 he returned to lecture at Marburg as a *Privatdozent* ("official but unpaid lecturer") and in 1873 was appointed *Extraordinarius* at Bonn university. In 1877 he accepted a professorial appointment at Basel university and later similar positions at the universities of Tiibingen (1878) and Leipzig (1887).

He also made significant contributions in the following areas of plant physiology: respiration, photosynthesis, protein metabolism, tropic and nastic movements. In 1881 he published the first part of his *Handbuch der Pflanzenphysiologie* (Eng. trans. by A. J. Ewart, *Physiology of Plants*, 3 vol., 1906) which prevailed for many years as an important text. He died, Jan. 31, 1920, in Leipzig. He published more than 100 papers and books. (W. J. McI.)

PFEIFFER, IDA LAURA (1797–1858), Austrian traveler, daughter of a merchant named Reyer, was born at Vienna on Oct. 14, 1797. In 1820 she married Pfeiffer, a lawyer of Lemberg, who subsequently incurred official persecution and was reduced to poverty. In her later life Mme. Pfeiffer devoted her limited means to extensive travel. Her last journey was in 1846 to Madagascar. Becoming involved in a plot to overthrow the government, she was expelled from the country. She died at Vienna, Oct. 27, 1858.

Her travels are described in *Reise einer Wienerin in das Heilige Land* (Vienna, 1843); *Reise nach dem Skandinavischen Norden und der Insel*

Island (Pest. 1846); *Eine Frauenfahrt um die Welt* (Vienna, 1850); *Meine Zweite Weltreise* (Vienna, 1856); *Reise nach Madagascar* (Vienna, 1861, with a biography by her son).

PFLANZER-BALTIN, KARL, FREIHERR VON (1855–1923), Austro-Hungarian general, was born at Pecs in Hungary in 1855. On the outbreak of World War I he mas charged with the defense of Transylvania, but when the Russians crossed the Carpathians, Pflanzer-Baltin, with an improvised division, attacked this enemy. After fighting with varying success in the southern part of eastern Galicia and in the Bukovina, the 7th army under his command was driven back by Brussilov's offensive in June 1916, whereupon he was relieved of his command. In the summer of 1918. entrusted with the command on the Albanian front which was yielding before the attack of the entente army, Pflanzer-Baltin won back, after a brief and powerful attack, the old positions southward of Fjeri and Berat.

PFLEIDERER, OTTO (1839–1908), German Protestant theologian, was born at Stetten near Cannstadt in Württemberg on Sept. 1, 1839. From 1857 to 1861 he studied at Tübingen under F. C. Baur; and afterward in England and Scotland. He then entered the ministry, became a tutor at Tiibingen and for a short time held a pastorate at Heilbronn (1868). In 1870 he became chief pastor and superintendent at Jena and soon afterward professor ordinarius of theology, but in 1875 he was called to the chair of systematic theology at Berlin, having made his name by his *Der Paulinismus,* published in 1873 (2nd ed., 1890; Eng. trans., *Paulinism,* 2 vol.. 1873, etc.).

Other important works are: *Das Urchristentum, seine Schriften und Lehren, in geschichtlichem Zusammenhang beschrieben* (1878; enl. ed., 1902; Eng. trans., 1906); *The Development of Theology Since Kant, and Its Progress in Great Britain Since 1825* (1890), written for publication in England; *Religionsphilosophie auf geschichtlicher Grundlage* (1878; Eng. trans., *The Philosophy of Religion on the Basis of Its History,* 1886–88); *Die Entstehung des Christentums* (1905; Eng. trans., 1906); *Religion und Religionen* (1906; Eng. trans., 1907); and *Die Entwicklung des Christentums* (1907). Pfleiderer was Hibbert lecturer in London in 188j and Gifford lecturer at Edinburgh in 1894. He died on July 18, 1908. In New Testament criticism Pfleiderer belonged to the school of F. C. Baur, but showed a greater disposition to compromise than the early Baur school.

PFLÜGER, EDUARD (1829–1910), German physiologist, was born in Hanau and studied under J. P. Müller and Du Bois Reymond at Bonn. In 1868 he founded the *Archiv fur die gesamte Physiologie,* and ten years later opened the new Institute of Physiology at Bonn. His *Untersuchungen uber die Physiologie des Electrotonus* (1859) marked the beginning of his lifelong researches on metabolism, embryology and respiration. He experimented with cross-fertilization of the eggs of different species of frogs and became interested in the cleavage in the development of the eggs. He was able to show that the seat of respiration is not in the blood or lungs, but in the tissue.

PFORTA or SCHULPFORTA, formerly a Cistercian monastery dating from 1140, afterward a German public school. It is in the Prussian province of Saxony, on the Saale, 2 mi. S.W. of Naumburg. The remains of the monastery include the 13th-century Gothic church, restored, the Romanesque chapel (12th century) and other buildings later used as dormitories, lecture rooms, etc. There is also the Fiirstenhaus, built in 1573. Schulpforta was one of the three *Fürstenschulen* founded in 1543 by Maurice, duke and later elector of Saxony, the others being at Grimma and at Meissen. Pforta passed to Prussia in 1815.

PFORZHEIM, a town of Germany, formerly in the *Land* of Baden, after 1945 in Baden-Württemberg, at the confluence of the Nagold and the Enz, on the margin of the Black forest, 19 mi. S.E. of Karlsruhe by rail. Pop. (1950) 54,143. Pforzheim is of Roman origin. From about 1300 to 1565 it was the seat of the margraves of Baden. It was taken by the troops of the Catholic league in 1624, and was destroyed by the French in 1689. It has the old palace of the margraves of Baden, and the Schlosskirche, the latter an edifice of the 12th–13th centuries. Pforzheim became the chief centre in Germany for the manufacture of gold and silver ornaments and jewelry.

PHAEDO, Greek philosopher, founder of the Elian school, was a native of Elis, born in the last years of the 5th century B.C. In the war of 401–400 between Sparta and Elis he was enslaved in Athens. He became a pupil of Socrates, who conceived a warm affection for him. It appears that he was intimate with Cebes and Plato, and he gave his name to one of Plato's dialogues. Athenaeus relates, however, that he resolutely declined responsibility for any of the views with which Plato credits him, and that the relations between him and Plato were the reverse of friendly. Aeschines also wrote a dialogue called *Phaedo.* Shortly after the death of Socrates Phaedo returned to Elis, where his disciples included Anchipylus, Moschus and Pleistanus, who succeeded him. Subsequently Menedemus and Asclepiades transferred the school to Eretria, where it was known as the Eretrian school and is frequently identified (*e.g.,* by Cicero) with the Megarians. The doctrines of Phaedo are not known, nor is it possible to infer them from the Platonic dialogue. His writings, none of which are preserved, were in the form of dialogues.

See Wilamowitz, *Hermes,* xiv, 189 *seq.*

PHAEDRA, in Greek legend, daughter of Minos and Pasiphae. With her sister Ariadne she was carried off by Theseus to Athens, and became his wife. On the way to Eleusis she met Hippolytus (*q.v.* for the rest of the legend).

PHAEDRUS (fl. 1st century A.D.), Roman fabulist of uncertain date. whose work, though ignored by classical Roman writers, was apparently the first of its kind in Latin and attained great popularity in the middle ages. It seems probable that he was born *c.* 15 B.C. and lived at least until the reign of Claudius. His birthplace was Thrace, whence he went early to Italy and received the customary training in Greek and Latin, studying among other authors, Euripides. Simonides, Ennius and Virgil. A slave by birth, he became a freedman in Augustus' household, but, as the prologue to book iii of his *Fabulae Aesopiae* states, later fell foul of Tiberius' minister Sejanus and was prosecuted and punished. "The fable," wrote Seneca *c.* A.D. 43, "has not been tackled by the Roman genius." If one presses the word "Roman" and recollects Phaedrus' foreign extraction, this statement need not imply ignorance of Phaedrus. The Phaedrus mentioned by Martial (iii, 20, j) has been identified, but on uncertain grounds, as the fabulist. Fables are placed by Quintilian (i, 9, 2) on the curriculum of the young, but. though "Aesop" is named, Phaedrus is not. Unless Martial's Phaedrus is the same man, the earliest reference to him is in the works of Avianus, who about the end of the 4th century composed 42 fables in undistinguished elegiacs.

Though Ennius, Lucilius and Horace had introduced fables into their poems, Phaedrus was the first writer to latinize whole books of fables. His contribution consists of free versions in iambic metre of Greek prose fables then circulating under the name of "Aesop." His iambic senarius, or six-foot line, conceivably influenced by that of Publilius Syrus, is nearer the rough vigour of Plautus than the monotonous artificiality of Seneca: spondees frequently replace iambs in the second and in the fourth feet. Phaedrus' latinity, apart from a few instances of slipshod syntax and vulgar speech, is close to the Augustan norm. Abstract expressions (*e.g., majestas ducis* = "the emperor") smack of the Latin of the silver age. Original poetic imagery is wanting, and epithets are mainly conventional. Phaedrus plumes himself on his brevity; for this as for his simplicity he merits praise.

The popularity, both in Europe and in the east, of the literary beast fable needs no emphasis. (*See* FABLE.) Even the ubiquitous moral tag subtracts little from enjoyment of such favourites in the Phaedrian corpus as "The Fox and the Sour Grapes," "The Wolf and the Lamb," "The Lion's Share," "The Two Wallets" and "The Pearl in the Dung-heap." Phaedrus considers himself a genuine artist, the pioneer of a genre unattempted by his Roman predecessors, whose poems, combining charm with a serious didactic purpose (*utilitas),* are assured of immortality. His stories are enlivened by various references to contemporary Roman society, and some could be interpreted, especially if the cap fitted, not merely as social but as political satire.

The Recovery of the Text.—Avianus states that Phaedrus

wrote five books of fables only; and the first printed edition of Phaedrus, published by Pierre and François Pithou at Troyes in 1596, in fact had its contents divided into five books. At the beginning of the 18th century, however, there was discovered at Parma a manuscript of Nicolaus Perottus (Niccolò Perotto or Perotti; d. 1480), the humanist archbishop of Siponto, containing 64 fables of Phaedrus, of which 30 were new. These new fables were published by G. A. Cassitto in 1808 and next, more correctly, by C. Jannelli in 1809; but these editions were superseded by the discovery of a much better preserved manuscript of Perottus in the Vatican, published by Angelo Mai in 1831. The authenticity of these new Phaedrian fables was for some time disputed. but is now generally accepted, though it is impossible to assign them to their original places in the five books. They are usually printed as an appendix.

Knowledge of Phaedrus' works, meanwhile, can be further extended by a careful investigation of the prose versions of his fables current in the middle ages. Of these the oldest collection existing seems to be that known as the *Anonymus Nilanti*, so-called because first edited by J. F. Nilant (at Leiden in 1709). For his edition Nilant used a manuscript of the 13th century, but the collection itself is associated with a little-known writer called Romulus and may have been made in the Carolingian period or even earlier. Later such collections are the Adhemarian, made by Adhémar de Chabannes; and the Weissenburg, from the monastery of SS. Peter and Paul at Wissembourg in Alsace. After a detailed examination of these three medieval collections, Carl Magnus Zander *(see* bibliography) restored 30 more fables to the iambics of Phaedrus.

BIBLIOGRAPHY.—There are editions of the *Fabulae Aesopiae* by J. P. Postgate (1920), by L. Havet (1895; annotated ed. 1923) and by A. Brenot (with Fr. trans., 1924). *See* further C. M. Zander, *Phaedrus solutus* (1921). (H. H. HY.)

PHAER (PHAYER), **THOMAS** (1510?–1560), English writer, best known for a translation of Vergil's *Aeneid* (1558) which is less medieval in tone than those of Gavin Douglas (1553), and the earl of Surrey (1557). Educated at Oxford and at Lincoln's Inn. London, Phaer was a doctor (M.D. 1559) and lawyer as well as a writer and describes himself as "solicitor to the king and queen in the marches of Wales." He translated. with original additions, a medical text by Jehan Goeurot under the title *The Regiment of Lyfe* (1544). He also contributed to *A Myrroure for Magistrates* (1559) and has been credited with *Ratura Brevium Newly Corrected in Englisshe* (1532) and *A Newe Book of Presidentes* (1543). *Seven First Bookes of the Eneidos of Virgill Concerted in Englishe meter* appeared in 1558; it was extended to nine books in 1562. The task, left unfinished at his death (Aug. 1560 at Kilgerran. Pembrokeshire) was completed by Thomas Twyne (1584).

(H. H. Ds.)

PHAETHON, in Greek mythology. was the son of Helios, the sun-god, and the nymph Clymene (Gr. *phaethon,* "shining." ('radiant"). He persuaded his father to let him drive the chariot of the sun across the sky, but he lost control of the horses and, driving too near the earth, scorched it. To save the world from utter destruction Zeus killed Phaethon with a thunderbolt. He fell to earth at the mouth of the Eridanus, a river of northern Europe (identified in later times nith the Po), on the banks of which his weeping sisters. the Heliades, were transformed into poplars and their tears into amber.

The story is most fully told in the *Metamorphoses* of Ovid (i. 750, ii, 366, and Nonnus, *Dionysiaca,* xxxviii). The fall of Phaethon is a favourite subject, especially on sarcophagi. as indicating the transitoriness of human life

See G. Knaack, "Quaestiones phaethonteae" in *Philologische Untersuchungen* (1885); Wilamowitz-Möllendorff and C. Robert in *Hermes,* xviii (1883); Frazer's *Pausanias,* ii, 59, which gives interesting parallels; S. Reinach. *Revue de l'hist. des religions,* lviii (1908).

PHAGOCYTOSIS is the orocess bv which living cells ingest or engulf other cells or particles. The phagocytic cell may be a free-living. unicellular organism, such as an amoeba, or one of the body cells such as a leucocyte (white blood cell). The particles commonly phagocytized include bacteria tissue cells (usually dead). protozoa. various dust particles pigments and other minute foreign bodies. In the simpler forms of animal life, such as amoebae and sponges. phagocytosis is a means of feeding; in higher animals phagocytosis is chiefly a defensive reaction against infection.

To Elie Metchnikoff is due the chief credit for recognizing the importance of phagocytosis in protecting the body against infectious agents. In man and in vertebrates generally, the most effective phagocytic cells are the macrophages (large phagocytic cells) and the granular leucocvtes (small phagocytic cells). The macrophages occur especially in the liver, spleen and lymph nodes, where their function is to free the blood and lymph of bacteria and other particles. Macrophapes are also found in all tissues as wandering amoeboid cells. and a cell related to the macrophage is found in the blood (*q.v.*). The smaller type of phagocyte (granular leucocyte) is carried along by the circulating blood until it reaches an area of infection, where it crawls through the blood vessel wall, being directed toward the invading bacteria by means of substances given off by the bacteria.

FROM "JOURNAL OF IMMUNOLOGY" 24:455 (1933); REPRODUCED BY PERMISSION OF AMERICAN ASSOCIATION OF IMMUNOLOGISTS

PHAGOCYTOSIS OF TUBERCLE BACILLI BY A MACROPHAGE

This directed movement is known as chemotaxis.

Before phagocytosis is accomplished, the phagocyte and particle must adhere to each other, and whether this is possible depends largely on the chemical nature of the surface of the particle. On less virulent bacteria ordinary proteins from the blood form a surface film to which leucocytes adhere, and phagocytosis follows. But virulent bacteria are ingested with more difficulty. Leucocytes. instead of adhering to them, succeed only in pushing them away. If, however, the leucocytes succeed in pushing them against a firm surface. such as the lining of a blood vessel. the bacteria may not be able to slip away and are ingested. This process is known as "surface phagocytosis." Other virulent bacteria may not be phagocytized until their surfaces are coated with peculiar globulins (proteins) formed by the body in response to the presence of that kind of bacterium. Such globulins are called antibodies. and antibodies are of great importance in establishing immunity (*q.v.*) of the body to diseases. In the treatment of infections by penicillin, phagocytosis may be an important auxiliary in stopping the growth of bacteria.

The manner in which a phagocytic cell ingests a particle varies somewhat with the size of the particle. Small particles. such as bacteria or minute grains of charcoal. seem to be ingested in an instant. At one moment they appear through the microscope to be adherent to the surface of the phagocyte: at another moment they are inside it. Larger objects such as clumps of bacteria or tissue cells are phagocytized by a more prolonged response of the leucocyte. The cell flows around the object until it has been completely engulfed.

The results of phagocytosis are digestion and destruction of the particle by means of ferments inside the phagocyte. This is the chief means by which the body gets rid of bacteria and other microorganisms. If the particle is indigestible. however, as is a grain of carbon, it eventually may be ejected by the phagocyte. Also, ingested living organisms. such as tubercle bacilli, may be resistant to the intracellular digestive ferments and not only survive but multiply within the phagocyte. In moving about. the phagocyte may then carry such bacteria into other parts of the body and therefore actually assist in the spread of disease instead, as is more usual, of defending the body against infection.

It is possible to mimic phagocytosis by means of a demonstration of nonliving models. A drop of chloroform is suspended in water and a bit of clean thread of glass is placed in contact with the chloroform. Under these conditions, the glass is not taken up by the chloroform. Then the glass thread is coated uith shellac and,

since the chloroform is able to spread on the shellacked surface, the drop of chloroform phagocytizes the glass thread. Finally the chloroform dissolves the shellac and then ejects the uncoated glass thread.

See also BACTERIAL AND INFECTIOUS DISEASES; INFLAMMATION.

See Stuart Mudd, Morton McCutcheon and Balduin Lucké, "Phagocytosis," Physiol. Rev., 14:210–275 (1934); J. Berry and T. T. Spies, Medicine, Baltimore 28:239 (1949); M. R. Smith and W. B. Wood, Jr., *J. Exp.* Med. 103:509 (1956). (M. McC.)

PHAGOTUS, a curious reed instrument, developed by Afranio Albanesi of Pavia (16th century) from the ancient Serbian bagpipe or piva. It was shaped like the letter H, the upper part of each side pillar containing the sound-producing tubes, pierced with finger holes, and the wind supply being provided by an attached air reservoir in the form of a bag, and bellows.

REDRAWN FROM a PHOTOGRAPH, N.Y. ZOOLOGICAL SOCIETY

VULPINE PHALANGER (TRICHOSURUS VULPECULA)

PHALANGER, a name applied to the members of the diprotodont marsupial family Phalangeridae (see MARSUPIALIA).

Phalangers are small or medium-sized woolly coated animals, with long, often prehensile tails, large claws and opposable, nailless, first hind toes. They are nocturnal in habit and feed on fruit, leaves and blossoms, though a few are insect eaters. Several possess gliding membranes between the fore and hind limbs.

The ring-tailed phalangers (Pseudocheirus) of Australia and New Guinea are the most generalized forms. Allied to them is the Australian "flying squirrel" (Petauroides volans), ranging from Queensland to Victoria. Another flying genus is Petaurus, with several species on the Australian continent, Aru Islands and New Guinea. A third parachuting form is the minute Acrobates *pygmaeus* of eastern Australiz.

The cuscuses (Phalanger) are arboreal animals, the size of cats. They inhabit the Solomon Islands, ranging thence to Timor and Celebes, being the only old world marsupials found west of New Guinea. The fur is woolly and the tail prehensile. Nearly allied to these are the Australian forms of which the brush-tailed phalanger (Trichosurus *vulpecula*), about the size of a small fox, is the best known. Other species are T. *fuliginosus* of Tasmania and T. canina of South Queensland and New South Wales. These animals are locally known as "opossums."

PHALANX, the name, in Greek history, of the arrangement of heavy-armed infantry in a single close mass of spearmen (Gr. phalanx, of unknown origin) (see ARMY).

PHALARIS, tyrant of Acragas (Agrigentum) in Sicily, c. 571–555 B.C., was responsible for the building of the temple of Zeus Atabyrius in the citadel. and took advantage of his position to make himself despot (Aristotle, Politics, v, 10). Under his rule Agrigentum seems to have attained considerable prosperity; its splendid planning, with a row of temples along the line of the wall and spacious quarters within the walls. belongs probably to his time. He fought wars against the Sicans, and the people of Himera on the north coast of the island entrusted themselves to him in spite of the warnings of the poet Stesichorus (Aristotle, Rhetoric, ii, 20). Late authors call him master of the whole island. He was overthrown in a general rising headed by Telemachus, the ancestor of Theron (tyrant c. 488–472), and, it is said, burned in his brazen bull.

Later ages have held up Phalaris to infamy for his cruelty. In his brazen bull, devised by Perilaus (Perillus) of Athens, the tyrant's victims were roasted alive, their shrieks representing the bellowing of the bull. Perilaus himself is said to have been the first victim. The bull is referred to briefly by Pindar (Pythians, i, 95–96). No doubt the bull is derived from Rhodes, the mother city of Agrigentum, together with the worship of Zeus Atabyrius; connection with the human sacrifices of the Phoenicians has been suspected. but is problematical. The Carthaginians carried away a brazen bull from Agrigentum, which was restored by Scipio.

The sophists represented Phalaris as a naturally humane man and a patron of philosophy and literature; and the famous letters bearing his name (148 in number) no doubt have their origin as a rhetorical exercise. They are now chiefly remembered for the crushing exposure they received at the hands of Richard Bentley (*q.v.*) in his controversy with Charles Boyle (later earl of Orrery), who had published an edition of them in 1695. The first edition of Bentley's Dissertation on *Phalaris* appeared in 169; in W. Wotton's Reflections on Ancient and Modern Learning, and the second edition, replying to the answer which Boyle published in 1698, came out in 1699. Bentley proved that the letters were written by a sophist or rhetorician (possibly Adrianus of Tyre. died c. A.D. 192) hundreds of years after the death of Phalaris. Suidas admired the letters and before their exposure by Bentley they were highly thought of, *e.g.,* by Sir William Temple in his Essay on Ancient and Modern Learning (1692), though others, as Politianus and Erasmus, perceived that they were not by Phalaris. An edition of the Epistles by R. Hercher appeared in *Epistolographi* Graeci (Paris, 1873), and Bentley's Dissertation was edited by W. Wagner (with introduction and notes, London, 1883).

See R. C. Jebb. *Bentley* (London, 1882).

PHALAROPE, the name given to a family of shore birds with three genera, *Phalaropus, Steganopus* and Lobipes. The phalaropes are allied to the sandpipers (*q.v.*), from which they differ in their swimming habits and the lobed membranes that fringe their feet and by the close nature of the lower plumage. They are aquatic birds, spending the winter on the open sea. The male is less brightly coloured than the female and performs the duties of incubation.

The red-necked phalarope (*Lobipes lobatus*) breeds in the Hebrides and Ireland. and the group as a whole is arctic. *Steganopus* tricolor is exclusively American. (K. P. S.)

PHALLICISM or PHALLISM, an anthropological term applied to that form of worship in which adoration is paid to the generative function symbolized by the phallus, the male organ (from Gr. *phallos*). The same principle is at the root of the nature worship of Asia Minor, whose chief deity. the Great Mother of the Gods (*q.v.*), is the personification of the earth's fertility. Similarly in India worship is paid to divine mothers; the phallus is called *linga* or *lingam,* with the female counterpart called *yoni;* the *linga* symbolizes the generative power of Siva, and is a charm against sterility. The rites classed together as *Sakti* puja represent the adoration of the female principle.

Phallic emblems are found in many parts of the world. The tendency, however, to identify all obelisklike stones and tree trunks. together with rites like circumcision. as remains of phallic worship has met with much criticism, and the best modern view is that phallicism never developed into an organized cult; *e.g.,* Robertson Smith, Religion of the *Semites,* 3rd ed., pp. 456 and 688.

PHALSBOURG, a town of France, in the *département* of Moselle: stands on a plateau (1,080 ft.) above the main road from Saverne to Nancy and Metz, 25 mi. N.W. of Strasbourg by rail. Pop. (1954) 1,798.

The principality of Phalsbourg, of which this town was the capital, originally a part of Luxembourg, afterward belonged in turn to the bishop of Metz, the bishop of Strasbourg and the duke of Lorraine, and passed to France in 1661.

The town commands the passes of the Vosges, and was strongly fortified by Vauban in 1680. Of these fortifications only the Porte de France and the Porte d'Alsace remain.

PHALTAN, a town and taluka (subdivision) of Satara North district. Bombay state! India. The town (pop. [1951] 12,142) is about 50 mi. S.E. of Poona.

PHALTAN TALUKA (pop. [1951] 99,781) corresponds with the former princely state of that name (area 391 sq.mi.; pop. [1941] 71,437), controlled in British days through the Deccan and Kolhapur agency and merged with Bombay on March 8, 1948. Area of modern taluka is 456 sq.mi.

PHANARIOTES, a name derived from Phanar, the chief Greek quarter at Stamboul, where the ecumenical patriarchate

is situated. and applied to those members of families resident in the Phanar quarter who bet een the years 1711 and 1821 were appointed hospodars of the Danubian principalities; that period of Moldo-Wallachian history is also usually termed the Phanariote epoch. The active part taken by the Greek princes in the revolt of 1820–21 induced the Porte to revert to the appointment of native princes.

PHANGNGA, a small Thai *changwat,* borders the Andaman sea on the west side of peninsular Thailand. It is sparsely populated. Area 1,530 sq.mi.; pop. (1947) 60,335. The *changwat* is forested, hilly and mountainous with shallow and poor soils. There is more fertile soil in the southern part of the *ckangwat,* between the rough terrain and the sea, but that area is comparatively inaccessible. Phangnga is noted for tin production.

Phangnga, the capital, is about 45 mi. N.E. of Phuket. The population of the city of Phangnga was 14,250 in 1947.

(T. F. B.)

PHANIAS (PHAINIAS) (*fl. c.* 300 B.C.), Greek philosopher, of Eresus on the island of Lesbos, was a pupil of Aristotle and a friend of Theophrastus, whom he joined in the Peripatetic school. He is mentioned as the author of works on logic, in which he probably followed Aristotle's doctrine; he also wrote, as Theophrastus did, on botany; and there are remains of works by him on poets, on the Socratic philosophers and on history. His *Prytaneis* of *Eresus* was a history in which events in the Greek world in general were included, the chronology being determined by the series of the successive magistrates of his native place. In his *Tyrants of Sicily* he seems to have dealt with western history against a Panhellenic background.

See the texts ed. by Carl Müller, *Fragrnenta historicorurn graecorum,* vol. ii (1848); also R. Laqueur, article *s.v.* "Phainias," in Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft,* vol. xix (1938). (F. Wi.)

PHANTASMAGORIA, a name invented by a certain Philipstal in 1802 (from Gr. *phantasma,* "phantasm," "apparition"; and *agora,* "assembly") for a show or exhibition of optical illusions produced by means of the projecting lantern. The word was later applied to any rapidly or strikingly changing scene, or disordered phantasy.

PHARAOH, the Hebraized title of the king of Egypt (*q.v.*), in Egyptian Per-'o; Pheron in Herodotus represents the same. Its combination with the name of the king, as in Pharaoh Necho, Pharaoh Hophra, is in accordance with contemporary native usage; the name of the earlier Pharaoh Shishak (Sheshonk) is rightly given without the title. In hieroglyphic a king bears several names preceded by distinctive titles. In the 4th dynasty there might be four of the latter: (1) identifying him with the royal god Horus: the name is commonly written in a frame representing the façade of a building, perhaps a palace or tomb, on which the falcon stands; (2) connecting him with the vulture and uraeus goddesses, Nekhabi and Buto of the south and north; (3) a hawk on the symbol of gold, signifying the victorious Horus; (4) the old titles of the rulers of the separate kingdoms of upper and lower Egypt, to be read *stni,* "butcher(?)" and *byti,* "beekeeper(?)." The personal name of the king followed (4), and was enclosed in a cartouche apparently symbolizing the circuit of the sun which alone bounded the king's rule. Before the 4th dynasty the cartouche is seldom found: the usual title is (1), and (3) does not occur. In the jth dynasty the custom began of giving the king at his accession a special name connecting him with the sun; this was placed in the cartouche after (4), and a fifth title was added: (j) Si-re, "son of the sun-god," to precede a cartouche containing the personal name. The king was briefly spoken of by his title *stni* (see 4). or *hnm-f,* "his service," or *Ity,* "liege lord." These titles were preserved in the sacred writing down to the latest age. An old term for the royal palace establishment and estate was Per-'o, "the Great House," and this gradually became the personal designation of Pharaoh. (F. Ll. G.)

PHARISEES, a Jewish sect of the second commonwealth. Its origins and the etymology of its name are obscure. According to rabbinic tradition, the Pharisees were in the direct line of transmitters of the oral law from Ezra and the Men of the Great Synagogue. Modern scholars too detected some antecedents in the Old Testament, especially in Malachi iii, 16. Their more immediate ancestors a-ere the pietistic group of Hasidim who, in the middle of the 2nd century B.C., helped spearhead the Maccabaean revolt (I Macc. ii, 42) (*see* MACCABEES). They gradually disappeared as a distinct movement after the fall of Jerusalem in A.D. 70, only because virtually the whole Jewish people accepted their ideology. Many hypotheses have been advanced for their name. Later suggestions that it stemmed from *Parsaah* (Persian) because of their acceptance of Parsee angelology (Thomas Walter Manson), or that they had been called "heretics" by their opponents and subsequently adopted that designation (Louis Finkelstein), seem less likely than their ancient equation with "separatists" because of their self-imposed separation from the nations and, in some respects, also from the masses of less observant Jews.

Religious Teachings. — In his extensive descriptions of the Jewish sectarian conflicts, Flavius Josephus (A.D. 37–9j?) stressed particularly dogmatic differences. Addressing himself to a Graeco-Roman audience, the Jewish historian undoubtedly exaggerated the importance of these theoretical controversies, and gave them an excessively Greek philosophic colouring. But he was undoubtedly right that, in contrast to the Sadducees, the Pharisees believed in retribution after death and personal resurrection, and also espoused a combination of free will and predestination. "Everything is foreseen, but nevertheless freedom of [individual decision] is given," although recorded only in the name of R. Aqiba (Mishnah Abot iii, 1j), represents the long-accepted doctrine of the Pharisees. Far more important, however, was the Pharisees' insistence on the binding nature of oral law which, in their opinion, had been revealed to Moses simultaneously with the written Torah and had co-ordinate authority with it. In that law were reflected traditions and practices which had developed in the preceding centuries, often without direct scriptural backing. To supply such scriptural links the Pharisees developed a ramified system of hermeneutics, seven major rules of which were formulated by their great leader Hillel (*q.v.*).

Political Struggles. — In the overheated religious atmosphere of the second commonwealth, political controversies were immediately translated into sectarian differences and vice versa. The Pharisees as such were nonpolitical. In fact, for them religious values towered so high above all other concerns that they were ready to submit to foreign domination rather than to an impious government of their own. On one occasion, three successive Pharisaic delegations appeared at great personal danger before Mark Antony, pleading for the removal of Herod. During the great war with the Romans both their leader. Johanan ben Zakkai, and another prominent member, Josephus, made peace with Vespasian. But because of the deep interlocking of politics and religion, their leaders became constantly embroiled in the struggle with the Maccabaean kings John Hyrcanus and Alexander Jannaeus (135–78 B.C.) and later with the Herodian dynasty and the predominately priestly and landowning Sadducees. Only during the short reign of Salome Alexandra (78–69 B.C.) did they control the government, In these struggles, the Pharisees enjoyed increasing backing by the masses. Although their leaders sometimes looked askance at the religious laxity oi many "people of the land" and, for the sake of greater ritualistic strictness, organized themselves in special fraternities (*haburot;* hence their members were called *haberim),* they enjoyed wide popular following. In Josephus and the New Testament they appear as the spokesmen of the overwhelming majority of the population. For this reason religious reformers wishing to overthrow the existing religious order attacked them severely. The polemical utterances in the Gospels (for instance, Matthew xxiii, 15; Mark vii. 6), apparently aimed at the more rigid faction of the house of Shammai, created the image of the Pharisees as religious hypocrites — an image from which only modern research was able to free them.

PHARMACOLOGY. In the broadest sense, pharmacology is the study of the changes produced in living animals by chemical substances (except foods); the animals may include any species from a microorganism to man.

The term pharmacology is used sometimes, in a more restricted sense, to refer to the study of the action of drugs, that is, agents used to treat diseases. This represents the most important application of pharmacology and explains its place among the medical sciences. It is clearly distinguished from pharmacy, the art of preparing drugs for use, but is closely related to therapeutics, the application of drugs to the treatment of disease, and to toxicology, the study of poisons and poisonings; both of these may be considered to be specialized applications of pharmacology. In a practical sense, pharmacology is the experimental science on which therapeutics is based, since the safe and effective use of drugs in the treatment of diseased patients is possible pnly after careful observations of their effects in the laboratory.

Origins of Pharmacology. — Attempts to use drugs to alleviate disease are as old as the history of man, but until the last century they were based mainly on superstition, magic, religion or at best on trial and error. European medicine before A.D. 1500 was characterized by rigid adherence to the medical doctrines of the ancient Greeks — principally those of Galen (A.D. 131–201), whose prolific writings, about a hundred volumes in all, represented some original observations, many elaborate recipes for prescriptions and a great many dogmatic "explanations." The writings of Galen were accepted as absolute authority for more than a thousand years, to such an extent that original observations and experimentation were not only discouraged but often actually forbidden. The first among many successful rebels against Galenism was Paracelsus (Aureolas Theophrastus Bombastus von Hohenheim, A.D. 1493–1541), a truly bombastic iconoclast who wandered through northern Europe, always in trouble with the local authorities, but overcoming the objections of his contemporaries by his therapeutic successes. He was an original thinker and daring innovator who introduced many new remedies and advocated simple prescriptions with one or a few ingredients rather than the dozens handed down from Galen.

In the next 300 years. there was a steady accumulation of information on the structure and functions of the body both in health and disease. However, therapeutics remained an "art" rather than a science, and, although the term "Pharmakologie" was used in 1692 by S. Dale in London, it meant merely the description of substances used in medicine. The *pharmacopoeias* (official volumes containing descriptions and outlining standards for drugs) included such remedies as dried vipers, foxes' lungs, and moss from the heads of criminals who had been hanged in chains, along with some herbs of real value. The concept of systematic laboratory investigation of drug action did not arise until about 1850; it was not until then that the public was made aware of the necessity for animal experimentation (by François Magendie. the French physiologist). Observations of the action of chemicals on the animal body became possible only after the new physiologists developed sensitive methods for the measurement and recording of changes in the function of the body, An equally important contribution was the striking development of chemistry. It was difficult to experiment with the crude drugs and extracts available because their potency varied from one batch to another. The situation began to change during the first half of the 19th century, when the new chemists in France and Germany isolated many active substances — morphine, strychnine, atropine, quinine and many others — from their crude plant sources.

As these pure chemicals became available (and later, as thousands of new chemical compounds were synthesized in the rapidly expanding German dye industry). more and more studies of drug action were made. The first students of pharmacology were physiologists who became curious about the effects of the substances on heart rate, respiration or other of the physiological functions they were studying — or who used the compounds as tools to study physiological problems. The first laboratory devoted exclusively to experimental pharmacology was that of Rudolph Buchheim at Dorpat in 1846–47; he contributed the idea that the effects of drugs on the body should be explained as well as described.

Pharmacology as an independent experimental science was really founded and firmly established by the German Oswald Schmiederberg (1838–1921). He defined its purpose — the study of the damage brought about in living organisms by chemically acting substances (except foods, whether used for therapeutic purposes or not). He wrote a textbook of pharmacology, helped to found the first journal devoted to reports of pharmacological experiments, and, most important, headed a school at Strasbourg which attracted students from all over the world. His school was the nucleus from which independent departments of pharmacology were established in universities all over the world.

Methods and Purposes of Pharmacology. — The work of pharmacologists is closely related to that of other biological scientists. In order to understand the changes produced in living animals. pharmacologists must understand, and be able to measure. the normal operations of the animal body — physiology. They must also understand pathology, the study of changes in structure and function resulting from injury or disease. The recognition and description of such changes may require not only gross observations on living animals, but also microscopic examination of tissues or cells, or chemical determinations on body fluids or excretions. If pharmacologists study the effectiveness of such drugs as antiseptics or antibiotics, they must use the concepts and methods of bacteriology. If they are attempting to find the ingredients responsible for the actions of crude plant drugs, they may find themselves involved both in chemistry and botany. Their work is often related to biochemistry (chemistry of living things), since they study effects of foreign substances on cells or chemical systems of the body.

During the earlier years of the new science, its workers became aware that a relation exists between the chemical structure of a compound and the effects it produces in the body. Since that time, increasing emphasis has been placed on this phase of pharmacology and many studies describe the changes in action resulting from small changes in the chemical structure of the drug. Since most agents of medical interest are organic chemicals (complex structures containing carbon atomsj, pharmacologists who engage in such studies must have a considerable understanding of organic chemistry.

The development of atomic resources for peacetime uses after World War II brought pharmacologists into a new area of investigation. One of the major problems of pharmacology has always been the difficulty of determining the fate of foreign compounds in the body. The doses of most potent drugs and poisons are small, and when they are distributed in large volumes of body fluids. they become almost impossible to detect or measure by ordinary chemical means. However, it is highly desirable to trace minute amounts of the compounds in the bloodstream or in the organs of the body in order to determine whether they are concentrated in any organs or cells and to establish how long they remain and how they are excreted. This was made possible by the availability for scientific investigation of radioactive isotopes (chemical elements having almost exactly the same chemical properties as the normal, but capable of being detected by Geiger counters or similar instruments). Since 1945, pharmacologists have been tracing the passage of some compounds through the body by incorporating radioactive atoms into the compounds they wish to study. The small amounts of radioactivity are not harmful to the animals; in fact, in some carefully controlled studies such determinations have been made on human volunteers. The tracer compounds are usually synthesized chemically, but where this is difficult or impossible, they have been prepared by exposing plant

or animal sources to radioactive materials in such a way that radioactive atoms are incorporated into the desired compounds as the living plant or animal manufactures them; the radioactive substances are then isolated and purified to be used in experiments.

In general. pharmacologic investigations are directed toward describing completely the interaction between the body and the drug. This includes describing fully the sequence of physiological changes that occur and describing what happens to the drug itself. It includes also explanations for the observed changes, at least in terms of physiology, and preferably in terms of chemistry or physics. Chemical explanations of mechanisms of action have been established for a number of chemical substances. These explanations have much more than academic interest; they tend to increase our knowledge of physiology and other biological sciences; they make it possible to use drugs more effectively; and by showing what characteristics are necessary for therapeutic action they stimulate the search for more effective new agents, without the undesirable side effects possessed by many available drugs. Such information is also sought for poisonous compounds used in the home (bleaches, insecticides, etc.), in industry or in agriculture (pesticides) in order to minimize health hazards (see *Pharmacology in Public* Health, below).

Pharmacology in Medical Education and Research.—Since pharmacology is a part of the curriculums of medicine, dentistry, veterinary medicine and pharmacy, departments of pharmacology are usually associated with educational institutions in these fields; the programs usually include training and study at the graduate level as well as the required courses of instruction. Such departments. especially in medical schools, are traditionally devoted to the study of basic problems in pharmacology and to the application of basic principles to the solution of speci'fic medical problems. Research in pharmacology is conducted also in many hospitals and foundations, either publicly or privately supported.

Pharmacology in the Drug Industry.——Important basic research is carried out in the research laboratories of pharmaceutical and chemical companies. After 1930, this area of pharmacological research expanded rapidly. particularly in the United States. The utilization of the financial kesources of industry, together with the contributions of universities, hospitals and foundations, resulted in the solution of many complicated problems in a surprisingly short time. Many new therapeutic agents were developed (*e.g.*, sulfa drugs, antibiotics, cortisone, "tranquilizing" drugs and many others), and a great body of fundamental knowledge was accumulated.

The work of pharmacologists in industry deals also with the exhaustive tests that must be made before promising new drugs can be introduced into medical use. Detailed observations of effects on all systems and organs of experimental animals are necessary before the physician can accurately predict effects of the drug on his patients, but their principal purpose is to disclose any potential toxicity to man. It must be emphasized that, except under unusual circumstances, the pharmacologist does not test the effects of drugs in patients; this is done only after complete tests on animals and is usually conducted by physicians to determine the clinical effectiveness of new drugs.

Constant testing is also required for the routine control and standardization of drug products. Those which contain only pure active ingredients can be tested by chemical means, but a few still remain that consist of relatively crude mixtures of plant or animal products (digitalis and pituitary, for example). These can be standardized (adjusted to standard strength) only after the pharmacological potency of each batch is determined by comparing its effect on some species of animal with the effect of a standard sample of drug. This process of testing is known as bioassay, and the entire process of standardization is known as biological standardization.

Pharmacology in Public Health.—The public welfare is obviously dependent on adequate pharmacological examinations of new products, but the development of new compounds and new processes throughout industry is also associated with potential health hazards for workers. The study of such hazards is termed industrial toxicology and the concepts and experimental methods are those of pharmacology, adapted for special conditions. Another application of pharmacology (or, more specifically, of toxicology) is in the study of the poisons used in agriculture to control plant pests and animal parasites. Here pharmacological or toxicological studies are undertaken to discover how the agents act to destroy pests; this makes it possible to use the agents more efficiently. and to develop more satisfactory new ones. Attention is also focused on the evaluation of potential health hazards and on the development of antidotes and methods of treatment to be used in cases of accidental poisoning. See also PHARMACY; PHARMACOPOEIA. (V. E.)

PHARMACOPOEIA, a book published by a government, or otherwise under official sanction, to provide for a specific political area, standards of identity. quality and strength for those medicinals which represent the best practice and teaching of medicine. The primary function of a pharmacopoeia is to describe each drug of the approved list in such a way that whenever dispensed it meets the standards of quality and strength established for it. The provisions of the pharmacopoeia in force (*i.e.*, the one that is "official") are binding upon all who produce drugs and those who dispense them. The pharmacopoeia is a fundamental safeguard to public health.

The task of compiling most pharmacopoeias is carried out without compensation by experts in the professions of medicine, chemistry and pharmacy at the request of the agency undertaking the compilation, usually that responsible for matters of public welfare. Most programs are financed from government funds, but the British *Pharmacopœia* and the United States *Pharmacopeia* are written by private, nonprofit organizations with the sanction of their respective governments. In the case of these pharmacopoeias, the proceeds of their sale support the work of revision.

The oldest record in the form of a pharmacopoeia is a stone tablet of ancient Babylonia, believed to have been inscribed about 1700 B.C. The first true pharmacopoeia to appear in Europe mas the Florentine Nuovo *Receptaris* (1498). The Danish Pharmacopoeia (established 1772) is the oldest in continued existence. The following countries established pharmacopoeias (the dates indicate the latest edition or [italics] supplement or reprinting): Argentina (1957), Austria (1906), Belgium (1930, *1953*), Brazil (1929, *1947*), Chile (1941), China (1953), Czechoslovakia (1954, *1958*), Denmark (1948, *1954*), Egypt (1953), Finland (1956), France (1949, *1954*), Germany (1926, *1951*), Greece (1924), Hungary (1954), India (1955), Italy (1940), Japan (1951), Mexico (1952), Netherlands (1958), Norway (1939, *1953*), Paraguay (194j), Poland (1954), Portugal (1946), Rumania (1956), Spain (1954), Sweden (1946), Switzerland (1933, *1954*), Turkey (1948), U.S.S.R. (1952, *1952*), United Kingdom (1958), United States (1955, *1958*), Venezuela (1942), Yugoslavia (1951).

Most countries not having a national pharmacopoeia adopted that of one or more other nations or in rare cases adopted the International Pharmacopoeia (see below).

The pharmacopoeial standards form the basis for enforcement of laws on the quality of drugs made available within the country concerned. Thus. the standards established have a vital bearing on the level of public health and the practice both of medicine and pharmacy. Actual enforcement of the standards is generally a function of an agency separate from that which creates them, but there are exceptions to this, notably in Canada, where the same department both establishes and enforces the standards. Enforcement involves collection and analysis of drug samples purporting to be of pharmacopoeial quality; when the analytical findings do not substantiate the label claim, legal action may be taken. This form of control varies greatly from one country to another. Where the central government is strong, the control is generally on a uniform national scale, as in the Americas and most of Europe. Where the local government is strong, as in the case of the cantons of Switzerland, enforcement is mainly on a local scale. These inter- and intra-national differences result in variations in the strength and quality of drugs, which cause confusion for both travelers and medical practitioners and are not in the best interests of public health. Travelers benefit especially from uniform drug standards. For example, a diabetic who travels must depend

largely upon local sources for the insulin that makes the difference for him between good health and dangerous illness. Insulin is prepared from the pancreatic glands of cattle and its potency must be standardized by assays on rabbits or mice. Furthermore, it deteriorates if not kept cold. However, thanks to the acceptance of uniform pharmacopoeial standards, good insulin is available almost everywhere.

International Pharmacopoeia. — Efforts to eliminate international differences in drug standards date to 1865, but the first practical move was made in 1902 by the Belgian government in sponsoring an international conference in Brussels. This resulted in the Brussels agreement of 1906, which proposed uniform nomenclature and standards of strength for many important drugs, particularly those which were being dispensed in the form of tinctures and infusions. A second conference in 1925 went still further toward establishing uniformity in pharmacopoeial standards among nations. These agreements were limited in scope, since they applied to only a few of the drugs in use.

The problem became more acute with the increase in international travel and in international trade in medicinal products after 1925. and received the attention of the Health Organization of the League of Nations, which created a Technical Commission of Pharmacopoeia1 Experts. The original seven-member group undertook to prepare an international pharmacopoeia, but this was interrupted when the League went out of existence. However, the work was resumed almost immediately upon creation of the World Health organization, a specialized agency of the United Nations which is the successor to the Health Organization of the League. The newly formed Expert Committee on the Unification of Pharmacopoeias (which later became the Expert Committee on the International Pharmacopoeia and Pharmaceutical Preparations) succeeded in compiling the first volume of the *Pharmacopoea Internationalis* for publication in 1951. A second, complementary volume appeared in 1955, and a supplement was added in 1958. The WHO published the texts in English, French and Spanish, but translations into German and Japanese were undertaken privately under WHO authority. The WHO planned to revise the standards periodically toward the end of providing model specifications for all of the important drugs.

The *Yharmacopoea Internationalis* was put forward by the WHO only as a recommendation aimed to minimize or eliminate entirely variations among national pharmacopoeial standards. Some nations among those without their own pharmacopoeia, for example, Ethiopia and Israel, made the International Pharmacopoeia official for use within their borders.

The four Scandinavian countries and Iceland provided a notable example of international co-operation toward uniformity in drug standards. Jointly, they formed the Scandinavian Pharmacopoeial council, which laid the foundation for publication of a single pharmacopoeia in four languages (Danish, Finnish, Norwegian and Swedish) to supersede the existing national pharmacopoeias of those countries as the binding authority on the identity, quality and strength of drugs.

PHARMACY is the science and art concerned with the collection, preparation and standardization of drugs. Its scope includes the cultivation of plants that are used as drugs and the synthesis of chemical compounds of medicinal value. It further includes the analysis and standardization of medicinal agents. The pharmacist is responsible for the manufacture of the dosage forms of drugs, such as tablets, capsules and sterile solutions for injection. As a dispensing pharmacist, he compounds physician's prescriptions for drugs. Pharmacology (*q.v.*) is the science that embraces all knowledge of drugs with special reference to their mechanism of action in the treatment of disease. Obviously this broad science has many subdivisions, such as toxicology (the study of poisons) and therapeutics (the use of drugs in the treatment of disease). Pharmacy, according to the foregoing description, is one of the subdivisions or specialties of pharmacology.

Historical Development. — The beginnings of pharmacy are lost in the mists of antiquity. When early man expressed a juice from a succulent leaf to apply to a wound he was practising this ancient art. In the book of Exodus, Moses was directed by the Lord to prepare "an ointment compound after the art of the apothecary." In the Greek legend, Aesculapius, the God of the healing art, delegated to the beautiful Hygeia the duty of compounding his remedies. She was his apothecary or pharmacist. The physician-priests of Egypt were divided into two classes, those who visited the sick and those who remained in the temple and prepared the remedies for the patients.

In ancient Greece the art of healing recognized a separation between the duties of the physician and those of the pharmacist, and this separation prevailed also among the Roman practitioners. During the middle ages in Europe the separation of the two groups became less distinct. Many physicians undertook 'the preparation of their own medicines. The Moorish influence in Europe brought about the practice of separate duties for the pharmacist and physician again. The trend of specialization is exemplified by a law enacted by the city council of Bruges. Belg., in 1683, forbidding physicians to prepare their own remedies.

The distinct role of the pharmacist as separate from that of the physician is evidenced by the establishment of the office of apothecary general in the army of France during the middle of the 18th century. In America, Benjamin Franklin took an important step in keeping the two professions separated when he appointed an apothecary to the Pennsylvania hospital.

Education. — The history of pharmaceutical education has followed in the wake of medical education. As the training of the physician underwent the change from the apprenticeship system to formal educational courses, so did the training of the pharmacist. The first college of pharmacy was founded in the United States in 1821 and is now known as the Philadelphia College of Pharmacy and Science. Other institutes and colleges were established in the U.S., Great Britain and continental Europe. Later many universities organized schools and colleges of pharmacy within their courses of instruction. Colleges of pharmacy as independent organizations or as schools of universities operate in most countries of the world.

The course of instruction leading to the degree in pharmacy (bachelor of science in pharmacy) extends over four academic years. Many institutions, however, offer graduate courses in pharmacy and cognate sciences leading to the degrees of master of science and doctor of philosophy. These advanced courses are especially intended for those who are preparing for careers in research, manufacturing or teaching in the field of pharmacy.

It is clear that since the medication of the sick with drugs encompasses a wide field of knowledge in the biological and physical sciences, an understanding of these sciences is necessary for an adequate pharmaceutical training. The basic four-year curriculum in the colleges of pharmacy of the United States embraces physics, chemistry, biology, bacteriology, physiology, pharmacology and many other specialized courses such as dispensing pharmacy. In addition, subjects of a general educational character such as languages and mathematics are included. As the pharmacist is engaged in a business as well as a profession, special training is provided in merchandising, accountancy and pharmaceutical jurisprudence. After 1960 one year of college work in addition to high school was required for entrance to colleges of pharmacy in the United States.

Legislation. — Before he is permitted to practise pharmacy, an applicant must be qualified by graduation from a recognized college of pharmacy, meet specific requirements for experience and pass an examination conducted by a board of pharmacy appointed by the government. The passing of this board examination confers upon the person the legal right to practise pharmacy. In the United States he is then designated a registered pharmacist.

The pharmacy laws include the regulations for the practice of pharmacy, the sale of poisons, the dispensing of narcotics and the sale and labeling of dangerous drugs. The pharmacist sells and dispenses drugs within the provisions of the food and drug laws of the country in which he practises. These laws recognize the national pharmacopoeia as the standard for drugs *(see* PHARMACOPOEIA). The pharmacopoeias of the different nations are compiled and published according to the respective legal national procedures. For example. the publication of the *British Pharmacopoeia* is regulated by sec. 47 of the Medical act, 1956. Subsection (1) of this section, which reproduced similar provisions in earlier acts, is as follows:

47.—(I) The General Council shall, at such intervals as they may determine, cause to be published under their direction new editions of the *British Pharmacopoeia,* containing such descriptions of and standards for, and such notes and other matter relating to. medicines. preparations, materials and articles used in the practice of medicine, surgery, or midwifery, as the council may direct.

Pharnzacopeia of the United States is prepared and published by the U.S. Pharmacopoeia1 convention. The League of Nations in 1925 proposed an international pharmacopoeia. The World Health organization of the United Nations assumed the task of the League after World War II and published the *Pharmacopoea Internationalis* in 1951. English, Spanish and French editions were later published. The purpose of the *Pharmacopoea Internationalis* is to standardize, as far as possible, the medication with drugs throughout the world.

Furthermore, the *Pharmacopoea Internationalis* provides standards for drugs for smaller nations that have no national pharmacopoeia.

Organizations. — There are numerous national and international organizations of pharmacists. In Britain the Pharmaceutical Society of Great Britain, established in 1841, is typical of the pharmaceutical organizations. In the United States the American Pharmaceutical association, established in 1852, is a society that embraces all pharmaceutical interests. Some of the other organizations in the United States are the American Drug Manufacturers' association. the Federal Wholesale Druggists' association and the National Association of Retail Druggists. Among the international societies is the Fédération Internationale Pharmaceutique, founded in 1912 and supported by 35 national societies, for the advancement of the professional and scientific interests of pharmacy. The Pan American Congress of Biochemistry and Pharmacy includes the pharmaceutical societies in the various countries in the western hemisphere.

There are also other international societies in which history, teaching and the military aspects of pharmacy are given special emphasis.

Ethics of Pharmacy. — The code of ethics of the American Pharmaceutical association sets forth the ethical code under which pharmacy in the United States is to be practised. Since the code is applicable to the profession in all parts of the world, certain excerpts are given here:

The primary obligation of pharmacy is the service it can render to the public in safeguarding the preparation, compounding and dispensing of drugs and the storage and handling of drugs and medical supplies. . . . The pharmacist willingly makes available his expert knowledge of drugs to the other health professions. . . . The pharmacist refuses to prescribe or to diagnose; he refers those needing such service to a properly licensed practitioner. . . . The pharmacist compounds and dispenses prescriptions carefully and accurately, using correct pharmaceutical skill and procedure.

Research. — Pharmaceutical research is conducted mainly in the schools of pharmacy and in the laboratories of the pharmaceutical manufacturing houses. It embraces the organic chemical synthesis of new chemical agents for use as drugs and is also concerned with the isolation and purification of plant constituents that might be useful as drugs. Research in pharmacy also includes methods for assay and standardization of medicinal agents. These phases of research in pharmacy are primarily an application of the science of chemistry to drug products, but the pharmacist also engages in research that is peculiar to the profession. This research involves formulation of dosage forms of medicaments, a study of their palatibility, methods of standardization and their stability. The researches of pharmacy are usually published in journals, such as the *Journal of Pharmacy and Pharmacology* (London), the *Journals* of the American Pharmaceutical association (Scientific Edition and Practical Edition) (Washington), the *American Journal of Pharmacy* (Philadelphia) and the *Pharnzaceutica Acta Helvetiae* (Ziirich). *See* also APOTHECARY: PHARMACOLOGY; PHARMACOPOEIA.

PHARNABAZUS, Persian soldier and statesman, the son of Pharnaces, belonged to a family which from 478 B.C. governed the satrapy of Phrygia on the Hellespont. from its headquarters at Dascylium. Pharnabazus first appears as satrap of this province in 413, when he entered into negotiations with Sparta and began war with Athens. After the war he came into conflict with Lysander *(q.v.; see* also PELOPONNESIAN *WAR),* who tried to keep the Greek cities under his own dominion. A letter sent by Pharnabazus to the ephors at Sparta was one of the causes of Lysander's overthrow.

When in 399 the war with Sparta broke out Pharnabazus again tried to conduct it strenuously. With the help of Conon and Evagoras of Salamis he organized the Persian fleet, and while he was hard pressed on land by Agesilaus he prepared the decisive sea battle which was fought in August 394 at Cnidus under his and Conon's command and completely destroyed the Spartan fleet. He sent support to the allies in Greece, by which the walls of the Piraeus were rebuilt. But in the war on land he struggled in vain against the lethargy and disorganization of the Persian empire; and when at last, in 387, in consequence of the embassy of Antalcidas to Susa. the king decided to conclude peace with Sparta and to enter again into close alliance with her. Pharnabazus, the principal opponent of Sparta, was recalled from his command in high honours to marry Apame, a daughter of the king.

In 38j Pharnabazus was one of the generals sent against Egypt, and in 377 he was ordered to prepare a new expedition against the valley of the Nile. The gathering of the army took years, and when in 373 all was ready, his attempt to force the passage of the Nile failed. A conflict with Iphicrates, the leader of the Greek mercenaries. increased the difficulties; at last Pharnabazus led the army back to Asia.

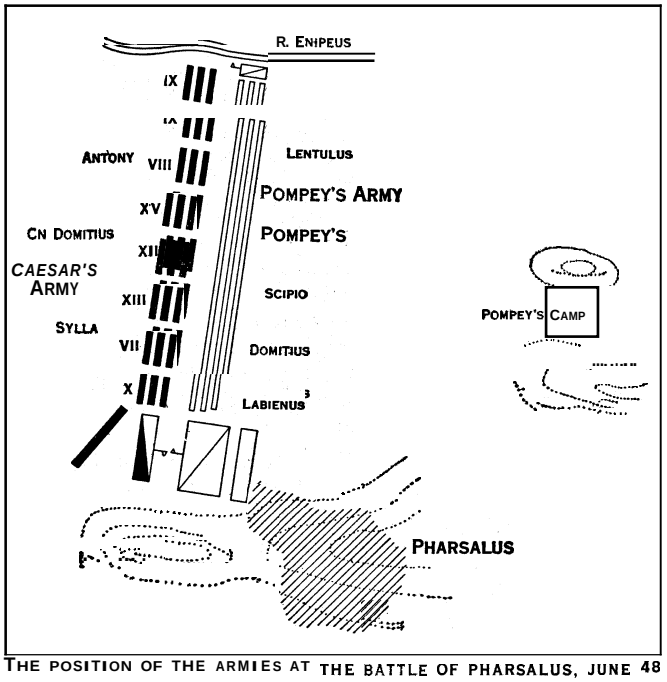
When Pharnabazus died is not known. (ED. M.)

PHARSALUS, BATTLE OF (48 B.C.). The defeat sustained by Julius Caesar at Dyrrachium in May 48 B.C. in no way disheartened him, but it compelled him to change his plan, and that at once. The task before him was a difficult one. namely, to retire before a victorious enemy and cross two bridgeless rivers, the Genusus and Apsus. Leaving 15 cohorts and 300 vessels to guard Dyrrachium, Pompey set out toward Heraclea, while Caesar made his may to Aeginium in Thessaly, where he was joined by Cnaeus Domitius and two legions; this brought his force up to nine ––about 24,000 men. He moved eastward and camped northwest of Pharsalus in the plain on the left bank of the Enipeus. There he awaited his enemy. whose army numbered 50,000 infantry, 7,000 cavalry and a large number of light troops. Pompey felt certain of victory, but he overlooked the personal factor and forgot that Caesar *was* his army and that, as one writer says: "The whole body was instinct with his purpose." The battle was fought on June 7 (Julian calendar).

Pompey planned to hold Caesar's front with his infantry and mass his cavalry. largely outnumbering Caesar's, on his left wing in order to envelop Caesar's right wing and attack it in the rear. Pompey's right wing rested on the river Enipeus and was protected not only by the steep banks but by a force of about 600 horsemen, as Caesar saw. It was under the command of Lentulus, and was composed of Cilician and Spanish troops—good soldiers. His left wing numbered the I and III legions and was accompanied by Pompey in person. Scipio held the centre with two Syrian legions and the bulk of the cavalry. slingers and archers, under Labienus were massed on the outer flank of the

left wing.

Caesar drew up his legions in three lines of cohorts, four in the first, three in the second and three in the third; his men stood eight deep. On the right he placed the X. legion and on the left the



THE POSITION OF THE ARMIES AT THE BATTLE OF PHARSALUS, JUNE 48 B.C. WHEN JULIUS CAESAR DEFEATED THE ARMY OF POMPEY

IX. Antony commanded the left, Sylla the right and Cn. Domitius the centre; he himself took up his position opposite Pompey. Thus far his order of battle was normal, but he had noticed the large force of cavalry massed on his enemy's left. Recognising that this mass was intended to outflank him, he drew up a fourth line of chosen cohorts, taken from the third line, and placed six of these cohorts and his small force of horse on his right, telling them that on their courage would depend the results of the battle. The third line he proposed to hold in reserve, and the first and second he ordered not to charge until he required it to. The trumpets were then sounded, and the battle cry of "Venus Victrix" raised, to which the Pompeians answered: "Hercules Invictus."

Pompey had ordered his men to await the enemy's assault, for he considered that when the two forces clinched his troops would be the fresher; but Caesar realising that this was a sign of weakness ordered his legions forward, trusting as he did to the impetus of the charge inspiring them with courage. Mid-way his men paused to regain breath, then advanced again, and when within range the front rank men hurled their javelins and drawing their swords rushed forward, and the two lines clinched. Immediately Pompey launched his cavalry and archers against his enemy's right flank, driving Caesar's cavalry from the field. Then the fourth line came into play, and in place of casting their javelins they closed on the horsemen with the sword "striking at the horses' breasts, and the men's legs and faces." In spite of their numbers the horsemen turned and fled, and the fourth line falling upon the archers and slingers drove them back, then, wheeling to the left, they struck Pompey's front, now locked in battle, on its flank and rear. At once Caesar galloped to his third line and ordered it to advance. This it did, breaking through Pompey's front. When Pompey saw his cavalry routed, despairing of success, he fled to his camp, possibly to rally the fugitives. The camp was eventually assaulted and taken, whereupon Pompey and 30 horse fled to Larissa and embarked for Egypt, where later on he was assassinated by Ptolemy Auletes, or rather by his tutor the eunuch Photinus, for Ptolemy was but a boy of ten. In this battle Caesar lost 30 centurions and 200 men killed, and Pompey 15,000 killed and 24,000 prisoners.

Caesar for political reasons showed great clemency by proclaiming a general pardon. He then organised his prisoners into two new legions and sent them to Asia.

PHARYNGITIS, [illegible] sillar areas. The causes are those of inflammations in other regions. and the sequels are also analogous. There may be local pain and discomfort with fever in the more acute cases.

(*See* INFLAMMATION; THROAT. DISEASES OF; RESPIRATORY SYSTEM, DISEASES OF.) (F. L. A.)

PHARYNX, in anatomy, the cavity into which the nose and mouth lead and which serves as a passage for both food and air. *See* THROAT.

PHASES. The different luminous appearances presented by the moon (*q.v.*) and several of the planets, the variety of the amount of surface visible from the earth being termed phases.

PHATTHALUNG is one of two small landlocked *changwats* of peninsular Thailand. Most of Phatthalung's surface water and products move eastward to Thale Sap, Songkhla and the South China Sea on the east side of the [illegible] for navigation. Rice, coconuts, betel nuts! oilseeds and rubber are grown on Phatthalung's fertile plain. Area (1956 survey) 1,262 sq.mi.; pop. (1960 census) 228,863. Phatthalung, the capital (1947 census, 75,838), on the west shore of Thale Sap and 45 mi. N.E. of Songkhla. is on the peninsular trunk railroad and the transpeninsular highway connecting Songkhla and Phuket. (T. F. B.)

PHEASANT, the bird, according to legend, introduced by the Argonauts into Europe from the banks of the Phasis (now Rion) in Colchis, and later supposedly first introduced into England by the' Romans. This bird. *Phasianus colchicus,* is the type of the family *Phasianidae,* and is reared in England for shooting. Ring-necked pheasants were first successfully introduced in America in 1881, when birds from eastern China (*P. c. torquatus*) were liberated in Oregon; later, hybrid birds from England (*P. c. colchicus* × *P. c. torquatus*) were released in New England. They are now well established in extreme southern Canada and throughout the northern United States, where they breed in late April and early May, lay 7 to 13 olive-buff eggs in a nest, on the ground hidden by a tussock of grass or small bush. The male is a handsome bird with brilliant plumage and red wattles; the female protectively coloured in mottled brown. The wings are short; the tail is long. The birds are polygamous; they feed on grain. seeds, shoots and insects, and both fly and run well. Pheasants will cross with numerous other gallinaceous birds. including the common fowl; the offspring in this case is called a *pero.* The true fowl-like game birds, family Phasianidae, include turkeys of North America. guinea fowl of Africa, the grouse and prairie chickens, the quail and partridges of the northern hemisphere, and the chicken-like birds of the subfamily Phasianinae. Among the latter are some 48 genera and 149 species: which include the peafowl of southeastern Asia, francolins of Africa and southern Asia, old world quail, and particularly the Asiatic jungle fowl or wild chickens and their close relatives the pheasants, likewise natives of Asia. The pheasants number 20 genera and 48 species, some represented by several geographical races, as many as 42 being recognized in *Phasianus colchicus,* which ranges across central Asia from the Black sea to Japan and Formosa. Reeves' pheasant (*Syrmaticus reevesii*) from northern China has a very long tail. The golden pheasant (*Chrysolophus pictus*), Amherst's pheasant (C. *amherstiae*) and the silver pheasants (*Gennaeus* spp.) are even more beautiful. They are all Chinese birds and are well known in aviaries. The lovely Argus pheasants (*Argusianus*) of Malacca and Siam may measure 6 ft. from the beak to the tail in the male; the secondaries of the wings (which are longer than the primaries) have metallic spots resembling

PAINTED FOR THE ENCYCLOPÆDIA BRITANNICA BY HELEN DAMROSCH TEE-VAN

PHEASANTS AND THEIR ALLIES

This family contains, besides the Pheasants, the Peacock, most magnificent of birds, and the Jungle Fowl, whose domesticated descendants are very useful to mankind. Most of the males are brilliantly coloured, while many are adorned with magnificent tails. Their original homes are in Asia, from the Caucasus to Japan and the East Indian Islands

1. Reeves' Pheasant (*Syrmaticus reevesii*). 2. Lady Amherst Pheasant (*Chrysolophus amherstiae*). 3. Golden Pheasant (*Chrysolophus pictus*). 4. Indian Peacock (*Pavo cristatus*). 5. Silver Pheasant (*Gennaeus nycthemerus*). 6. Red Jungle Fowl (*Gallus gallus*). 7. Germain's Peacock Pheasant (*Polyplectron germaini*). 8. Impeyan Pheasant (*Lophophorus impejanus*). 9. Satyr Tragopan (*Tragopan satyra*). 10. Malayan Crested Fireback Pheasant (*Lophura rufa*). 11. Eastern Chinese Ring-necked Pheasant (*Phasianus colchicus torquatus*)

eyes. The monals (*Lophophorus*) inhabit the Himalayas. The peacock pheasants (*Chalcurus* and *Polyplectron*) inhabit Burma, Siam, Indochina, and the Malay region; the plumage is ornamented with metallic eyespots. The adornments of male pheasants are strikingly displayed in courtship. *(See* COURTSHIP OF ANIMALS.)

See Tegetmeier, *Pheasants; their Natural History and Practical Management;* Beebc, *Monograph of the Phasianidae* (1918–22).

PMEIDIAS: *see* PHIDIAS.

PHEIDON (8th or 7th century B.C.), king of Argos. According to tradition he flourished during the first half of the 8th century B.C. He was a vigorous and energetic ruler and greatly increased the power of Argos. He gradually regained sway over the various cities of the Argive confederacy, the members of which had become practically independent, and (in the words of Ephorus) "reunited the broken fragments of the inheritance of Temenus." His object was to secure predominance for Argos in the north of Peloponnesus. Pheidon assisted the Pisatans to expel the Elean superintendents of the Olympian games and presided at the festival himself. The Eleans, however, refused to recognize the Olympiad or to include it in the register, and shortly afterwards, with the aid of the Spartans, who are said to have looked upon Pheidon as having ousted them from the headship of Greece, defeated Pheidon and were reinstated in the possession of Pisatis and their former privileges. Pheidon is said to have lost his life in a faction fight at Corinth, where the monarchy had recently been overthrown. He made changes in the existing system of weights and measures in the Peloponnese, and his system was in use at Athens before Solon (Arist. *Ath. Pol.* x, 2), but Ephorus' statement that he first coined silver money seems unlikely.

His date is disputed. Pausanias assigns the Olympiad at which he presided to 748, but the balance of modern authority is in favour of the first half of the 7th century.

See Hcrodotus vi, 127; Ephorus in Strabo viii, 358, 376; Plutarch, *Amatoriae narrationes,* 2; Marmor parium, *ep.* 30; Pollux ix, 83; Nicolaus Damascenus, frag. 41 (in C. W. Muller's *Frag. hist. graecorum,* iii); G. Grote, *History of Greece,* pt. ii, ch. 4; B. V. Head, *Historia Numorum* (1887); F. Hultsch, *Griechische und römische Metrologie* (1882); G. Rawlinson's *Herodotus,* appendix, bk. i, note 8. On the question of Pheidon's date, *see* J. B. Bury, *History of Greece,* ii, 468 (1902); J. P. Mahaffy, *Problems in Greek History,* ch. 3 (1892); J. G. Frazer's note on Pausanias vi, 22, 2; and especially G. Busolt, *Griechische Geschichte* (2nd ed., 1893), ch. iii, 12. C. Trieber, *Pheidon von Argos* (Hanover, 1880), and J. Beloch, in *Rheinisches Museum,* xlv, 595 (1890), favour a later date, about 580.

PHELPS, EDWARD JOHN (1822–1900), American lawyer and diplomat, was born on July 11, 1822, at Middlebury, Vt. He graduated from Middlebury college in 1840, was a schoolmaster for a year in Virginia and was admitted to the bar in 1843. From 1851 to 1853 he was second controller of the U.S. treasury, and then practised law in New York city until 1857, when he returned to Burlington. He was one of the founders of the American Bar association, and was its president in 1880–81. From 1881 until his death he was Kent professor of law in Yale university. He was minister to Great Britain from 1885 to 1889, and in 1893 served as senior counsel for the Cnited States before the international tribunal at Paris to adjust the Bering sea controversy. His closing argument, requiring 11 days for its delivery. was an exhaustive review of the case.

Phelps lectured on medical jurisprudence at the University of Vermont in 1881–83, and on constitutional law at Boston university in 1882–83, and delivered numerous addresses. among them that on "The United States Supreme Court and the Sovereignty of the People" at the centennial celebration of the federal judiciary in 1890 and an oration at the dedication of the Bennington Battle monument. unveiled in 1891 at the centennial of Vermont's admission to the union.

In politics Phelps was always conservative, apposing the anti-slavery movement before 1860, the free-silver movement in 1896, when he supported the Republican presidential ticket, and after 1898 becoming an ardent "antiexpansionist."

He died at New Haven. Conn., on March 9. 1900.

See his *Orations and Essays,* edited by J. G. McCullough, with a "Memoir" by J. W. Stewart (1901); and the memorial address by M. H. Buckham, in *Proceedings of the Vermont Historical Society* (Burlington, Vt., 1901).

PHELPS, OLIVER (1749–1809), U.S. public official and merchant. who is remembered chiefly for his land speculations after the American Revolution, was born near Poquonock. Conn.. on Oct. 21, 1749. He entered the mercantile business at an early age and soon became a prosperous trader. During the Revolution. he was in charge of army purchases in Massachusetts and he served in the lower house of the state legislature, 1778–80, and later in the senate. 178j.

Phelps also served at the constitutional convention, 1779–80, and was a member of the governor's council in 1786.

In April 1788 Phelps and Nathaniel Gorham, who was also a merchant and was president of the Continental congress in 1786, purchased pre-emptive rights—the right of first purchase from the Indians—to about 6,000,000 ac. of land in western New York. Massachusetts had received those rights under the treaty of Hartford with New York in 1786. The partners, however, soon encountered financial difficulties. They failed to sell sufficient shares in the speculative enterprise to meet their obligations to Massachusetts and the original cost, moreover. was increased by a rise in the value of Massachusetts currency. with which the debt was to be paid. They thus were unable to make their first payment and in 1790 returned most of the land, known as the Genesee country, to the state.

Phelps's later speculations in lands on the lower Mississippi river and elsewhere, based chiefly on credit, also eventually led to financial disaster. He retired to the Genesee, where he retained minor holdings. and died on Feh, 21, 1809.

PHELPS, SAMUEL (1804–1878), English actor and manager, was born at Devonport on Feb. 13. 1804.

He was early thrown upon his own resources, and worked in various newspaper offices. Shortly after his marriage in 1826 to Sarah Cooper (d. 1867), he accepted a theatrical engagement in the York circuit at 18s. a week. and afterward appeared in south of England towns in prominent tragic roles. attracting sufficient attention to be spoken of as a rival to Edmund Kean.

He made his first London appearance on Aug. 28, 1837, as Shylock at the Haymarket. After a short season there. he was with William Macready for about six years at Covent Garden, the Haymarket and Drury Lane successively.

In 1844 he became colessee of Sadler's Wells theatre with Thomas L. Greenwood and Mary Amelia Warner (1804–54). Greenwood supplied the business capacity. Phelps was the theatrical manager and Mary Warner was the leading lady. Phelps spent 20 years at Sadler's Wells theatre, during which time he raised the Sadler's Wells house to an important position and himself appeared in an extensive and varied repertory.

Thirty-four of Shakespeare's plays were presented there under his direction. In 1861 Greenwood retired from the partnership, and Phelps, unable to cope with the business of management, retired from it in the following year.

For the next 15 years he acted under various managements, achieving considerable success in some of Andrew Halliday's dramatic versions of Sir Walter Scott's novels. such as *The Fortunes* of *Nigel* and *Ivanhoe.* His last appearance was in 1878 as Cardinal Wolsey in *Henry VIII.* He died on Nov. 6. 1878.

He was a sound and capable actor rather than one of any marked genius; and. in spite of his predilection for tragedy, was most successful in such characters of comedy as called for dry humour. Perhaps Sir Pertinax Macsycophant in Charles Macklin's *The* Man *of the World* was his finest impersonation. He published an annotated edition of Shakespeare's plays (2 vols., 1852–54).

BHELPS, THOMAS STOWELL (1822–1901), U.S. naval ofiicer and surveyor, was born at Buckfield, Me., on Nov. 2, 1822. At the age of 17 he entered the U.S. navy and as part of his training as a midshipman served with the Mediterranean and Brazil squadrons. He was made passed midshipman in 1846 and promoted through the grades to rear admiral by the time of his retirement in 1884.

Phelps was on duty with the U.S. coast survey for a number of

years before he served on the sloop-of-war "Decatur," which defended the northwest coast against Indians, 1855–56. He later participated in the successful Paraguay expedition, 1858–59, which the U.S. sent to gain redress for a military Paraguayan action in 1855 against a U.S. ship.

During the Civil War Phelps surveyed the Potomac river and conducted other surveys in preparation for federal military actions. At the second naval attack on Fort Fisher (near Wilmington, N.C.), Jan. 13–15, 1865. he commanded the sloop "Juanita."

Phelps commanded the South Atlantic station. 1883–84. He published *Sailing Directions for the Straits of Magellan, Reminiscences of Seattle . . .* (1881). dealing with his service on the "Decatur." and various articles on historical topics. He died in New York city on Jan. 10, 1901.

PHELPS, WILLIAM LYON (1865–1943), U.S. teacher and author, did much to popularize the teaching of contemporary literature. Born on Jan. 2. 1865, in New Haven, Conn., he attended Yale university (B.A. 1887, M.A. 1891) and Harvard university (Ph.D., 1891). He taught at Harvard for a year. and then returned to Yale where he was for 41 years a member of the English department and Lampson professor from 1901 until his retirement in 1933. For years his students voted him Yale's most inspiring professor and thronged to his classes on contemporary drama, in the teaching of which he was a pioneer, and on Tennyson and Browning. In 1895 he taught the first U.S. college course in the modern novel, doing much to introduce Russian novelists to U.S. readers. A popular lecturer and critic, his literary essays in *Scribner's Magazine* and other periodicals and his syndicated newspaper column. "A Daily Thought," brought him an audience estimated in the millions.

As a critic he helped make the popular reputation of Thornton Wilder. An object of the scorn of H. L. Mencken, he endorsed Mencken's *Prejudices*. He died on Aug. 21, 1943, in New Haven.

His numerous books were devoted chiefly to English literature. His *Autobiography with Letters* was published in 1939.

See also F. *H*. Barber's *Fellow of Infinite Jest* (1949).

PHELPS, WILLIAM WOODWARD (1869–1938), U.S. naval officer, was born on Nov. 26, 1869, in Baltimore. Md. Graduated from the U.S. Naval academy in 1889, he was commissioned an ensign in 1891 and promoted through grades to rear admiral on Dec. 31, 1921. During World War I he commanded the fast transports "Great Northern" (1917–18) and "Leviathan" (1918–19). He commanded the "Arizona" (1920–21) after service as chief of staff at the Naval War college (1919–20).

He became commander of the Yangtze river patrol and of the U.S. Asiatic fleet from July 1922 to Nov. 1923. He also served as a member of the general board of the navy (1924–26), commander of the fleet base force, U.S. fleet (1926–28), commandant of the Portsmouth, N.H., navy yard (1928–31) and from 1931 until his retirement in 1933 commandant of the Brooklyn navy yard.

He died in New York city on May 11, 1938.

PHELYPEAUX, a French family of Blésois. Its two principal branches were those of the seigneurs of Herbault, La Vrillière and St. Florentin, and of the comtes of Pontchartrain and Maurepas.

RAIMOND PHELYPEAUX, seigneur of Herbault and La Vrillière (d. 1629), was treasurer of the *Épargne* in 1599, and became secretary of state in 1621. His son LOUIS succeeded him in this latter office and died in 1681.

BALTHAZAR PHELYPEAUX, marquis de Châteauneuf (d. 1700), and LOUIS, marquis de La Vrillibre (d. 1725), respectively son and grandson of Louis, were also secretaries of state.

LOUIS PHELYPEAUX (1705–77), comte de St. Florentin and afterward duc de La Vrillibre (1770), succeeded his father as secretary of state; became minister of the king's household in 1749, a minister of state in 1751, and discharged the functions of minister of foreign affairs on the disgrace of Étienne François duc de Choiseul (1770). He incurred great unpopularity by his abuse of *lettres de cachet*, and had to resign in 177j.

RAIMOND BALTHAZAR PHELYPEAUX, seigneur du Verger, a member of the La Vrillière branch, was sent as ambassador to Savoy in 1700, where he discovered the intrigues of the duke of Savoy, Victor Amadeus II, against France; and when war was declared he was kept a close prisoner by the duke (1703–04). At the time of his death (1713) he was governor general in the West Indies.

The branch of Pontchartrain-Maurepas was founded by PAUL PHELYPEAUX (1569–1621), brother of the first-mentioned Raimond, he became secretary of state in 1610.

PHEMISTER, DALLAS BURTON (1882–1951), **U.S.** surgeon, was one of the first to show that surgical shock was due to loss of blood and was also noted for devising a procedure to equalize bone growth in children. Born on July 15, 1882, in Carbondale, Ill., he took his M.D. degree from Rush Medical college, Chicago. Ill., in 1904 and established his practice in Chicago in the same year. From 1917 to 1919 he served with the American expeditionary forces as a major in the medical corps.

Phemister established the department of surgery at The University of Chicago medical centre, and was chief of surgery at the centre from 1925 until his retirement in 1945.

He served as president of the American College of Surgeons from 1948–49 and of the American Surgical association. He was a member of the Society of Clinical Surgery and of the Chicago Surgical society. He died on Dec. 28, 1951, in Chicago.

PHENACETIN, a drug contained in both the U.S. and British pharmacopoeias, in the former under the name of acetophenetidin. It is also a common ingredient of patent headache and "pain-killing" remedies. Phenacetin is a useful analgesic and antipyretic for headaches, colds, muscular pains and rheumatic conditions.

The drug crystallizes from water in colourless plates, melting at 135° C. It is soluble in about 70 parts of hot and in about 1,400 parts of cold water. It is prepared by acetylating paraphenetidine, or by heating paraacetylaminophenol and potassium ethyl sulphate with alcoholic soda to 150° C. Paraphenetidine is prepared by treating the sodium salt of paranitrophenol with ethyl iodide, and reducing the nitrophenetole to paraphenetidine or aminophenetole.

The yield may be doubled by diazotizing paraphenetidine, coupling with phenol, ethylating and reducing.

PHENACITE, a rare mineral consisting of beryllium orthosilicate, occasionally used as a gem stone. In general appearance it is not unlike quartz, for which indeed it had been mistaken, and was for this reason named from the Greek meaning a deceiver.

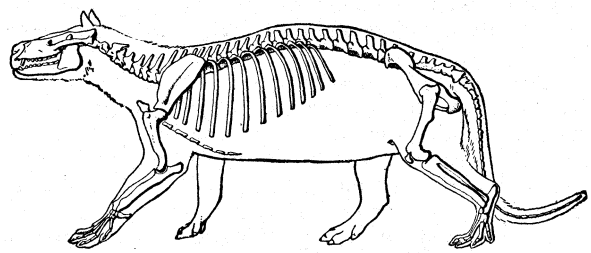
For gem purposes the stone is cut in the brilliant form but it is not in general use; fine examples are seldom seen outside of private or museum gem collections. The indices of refraction are higher than those of quartz, beryl or topaz; a faceted phenacite is consequently rather brilliant and may sometimes be mistaken for diamond.

Phenacite has long been known from the emerald and chrysoberyl mine on the Takovaya stream, near Sverdlovsk in the Urals, where large crystals occur in mica schist. It is also found with topaz and microline in the granite of the Ilmen mountains in the southern Urals and of the Pikes peak region in Colorado. Large crystals of prismatic habit have been found in a feldspar quarry at Kragero, Nor., and clear lenticular crystals are abundant at San Miguel de Piricicaba in Minas Gerais, Braz.

The formula of phenacite is Be_2SiO_4. It occurs as isolated crystals, which are rhombohedra1 with parallel-faced hemihedrism and are either lenticular or prismatic in habit. There is no cleavage, the fracture is conchoidal, and the crystals are sometimes perfectly colourless and transparent, but more often grayish or yellowish and only translucent. The hardness is high, being 7.5–8; the specific gravity is 2.98. (CL. F.)

PHENACODUS, a primitive and generalized hoofed mammal of the Lower Eocene, now extinct. The two best-known species are represented by complete skeletons found in the Bighorn basin of Wyoming in 1881. They are of the size respectively of a pig and of a fox, and typically of the family Phenacodontidae of the order Condylarthra. The teeth of *Phenacodus* are very short-crowned, uith low rounded cusps, the dentition unreduced, the premolars smaller than the molars and of simple pattern. The feet are five-toed but the first and fifth digits are considerably re-

duced; the small flattened hoofs resemble those of the tapir. The arrangement of the wrist bones is serial, the upper row directly overlying the lower ones, as in *Hyrax* and the elephant, instead of alternating as with other hoofed animals.



FROM SCOTT. "LAND MAMMALS OF THE WESTERN HEMISPHERE" (MACMILLAN)

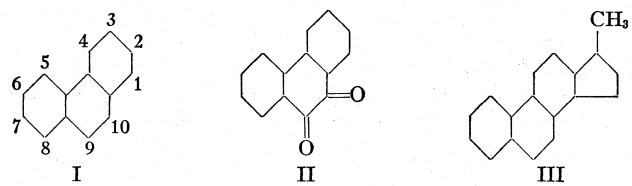
SKELETON OF PHENACODUS, IN THE AMERICAN MUSEUM OF NATURAL HISTORY. NEW YORK CITY

The astragalus in the hind foot is like that of Carnivora with distinct neck and convex rounded head. This character distinguishes the Condylarthra from the higher ungulates as the primitive construction of their teeth distinguishes them from the variously specialized ungulate tooth patterns. The brain was small and of inferior structure. (W. D. M.)

PHENANTHRENE, an aromatic hydrocarbon (first discovered in 1872) having the same composition, $C_{14}H_{10}$, as anthracene (*q.v.*) and found with the latter in coal-tar distillates boiling between 270° C. and 400° C. Pure phenanthrene, I, melting point 100° C.–101° C. and boiling point 340° C., is obtained from this mixture by fractional crystallization by virtue of its greater solubility than anthracene, the chief other component. Final traces of anthracene are removed by oxidative treatment, taking advantage of the greater ease of oxidation of anthracene. Phenanthrene is readily oxidized to the orange phenanthraquinone, II, a typical orthoquinone (*see* QUINONES).

Degradation of this quinone eventually yields diphenic acid and ultimately biphenyl. compounds which serve to establish the structure of phenanthrene.

The completely or partly hydrogenated phenanthrene nucleus is present in a wide variety of important natural products including certain alkaloids (notably morphine), resin acids (*see* ABIETIC



I II III

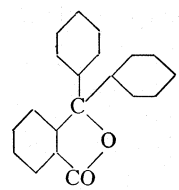
ACID), sterols, bile acids, sex hormones, heart poisons and saponins. The structures for many of the sterols, bile acids and sex hormones were established readily after the correct formulation of Diel's hydrocarbon, III, a product obtained from these substances by selenium dehydrogenation. as 3'-methylcyclopentenophenanthrene, III, was proved by synthesis (1934). Many cancer-producing hydrocarbons contain the phenanthrene nucleus. Many methods for the synthesis of phenanthrene and related substances were developed.

See L. F. Fieser, *The Chenzistry of Natural Products Related to Phenanthrene,* 2nd ed. (1937). (M. S. N.)

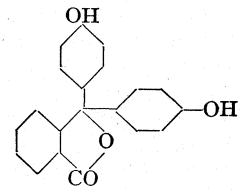
PHENIX CITY, a city of eastern Alabama, U.S., in Russell county, on the Chattahoochee river, is opposite Columbus. Ga., of which it is a residential and industrial suburb. Manufactured products include lumber. caskets and embalming supplies.

In 1923 the legislature extended the corporate limits of Phenix City to include the town of Girard but it did not alter the county boundaries. In 1927, a branch courthouse was established, in that part of Phenix City which had formerly been Girard, to maintain jurisdiction over the northern division of Russell county. The county boundaries were finally altered in 1932, to include all of Phenix City in Russell. The legislature in 1943 provided for the transfer of all records from the old county seat, at Seale, to Phenix City. For comparative population figures *see* table in ALABAMA: *Population.* (P. A. B.)

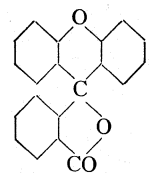
PHENOLPHTHALEIN, an organic compound of the aromatic series which has two uses: (1) as an indicator for acids and bases in volumetric analysis; (2) as a purgative drug. The



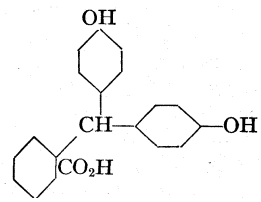
Diphenylphthalide



Phenolphthalein



Fluorane



Phenolphthaline

phthaleins are prepared by condensing phenols with phthalic anhydride, phenol itself giving rise to phenolphthalein together with a small quantity of fluorane, while resorcinol under similar conditions yields fluorescein (q v.).

Phenolphthalein is obtained when phenol and phthalic anhydride are heated with concentrated sulfuric acid. It crystallizes in colourless crusts (m.p. 250°–253° C.) and is nearly insoluble in water, but dissolves in dilute alkaline solutions with a fine red colour, because of the formation of the red disodium salt. It may be reprecipitated from these solutions by the addition of an acid. It is to this remarkable colour change that its use as an indicator is due. It dissolves in concentrated caustic alkalies to a colourless solution which contains the colourless trisodium salt.

Phenolphthalein has extended use as a purgative under such synonyms as purgen, laxoin, laxans, etc. Phenolphthalein is dissolved in the bile and intestinal fluid, which are slightly alkaline, and being irritant to the intestine it causes intestinal peristalsis and evacuation.

PHENOLS, a large class of organic substances of which phenol is the parent compound. They are characterized by the presence of at least one hydroxyl group attached to the benzene ring.

Phenol or carbolic acid was discovered in 1834 by F. F. Runge, who separated it in crude form from coal tar and called it *Karbolsäure.* In 1841 *A.* Laurent produced the pure substance, again from coal tar, and named it *hydrate* de *phényle* or *acide phénique.* The term "phenol." which was later used, was introduced by C. F. Gerhardt. He prepared the substance in 1843 by the dry distillation of salicylic acid in the presence of lime. In 1867 A. Wurtz and A. Kekulé discovered the synthesis from benzene, a process still of commercial importance involving the fusion of a strong alkali with the alkali salt of benzene sulfonic acid.

Phenol is found in coal tar, in wood tar and in many other products derived from the pyrolysis of animal and vegetable matter. In small quantities it is also present in Galician and Caucasian petroleum. It is a product of animal metabolism and, bound to other substances, it occurs in the urine of many mammals.

The commercial manufacture of phenol began in 1860. Originally this substance was obtained solely from coal tar. In the early years of the 20th century, and particularly during World War I, the demand exceeded the supplies available from coal tar, and production was augmented by the commercial synthesis of phenol from benzene.

As a result of the rapid rise of the plastics industry, which absorbed increasing amounts of phenol in the making of Bakelite and epoxide resins, production by synthesis outgrew the volume recovered from coal tar, and by the mid-1950s less than 5% of

the total annual U.S. production of about 500,000,000 lb. came from coal tar and more than 90% was made synthetically.

Uses.—Although in the 19th century phenol was used extensively because of its antiseptic properties, its use in the operating room was discontinued because of its irritating action. It also lost its important position among disinfectants where it was largely supplanted by its higher-molecular-weight homologues, by its derivatives and by other chemicals. But it is still used as a standard in the evaluation of disinfectants.

The great demand for phenol during World War I can be attributed to the extensive use of its trinitro derivative (see PICRIC ACID) as an explosive. Although made by some of the Allies during World War II, it did not compare in importance with explosives such as trinitrotoluene.

The increasing demand for phenol at mid-20th century was caused principally by the expanding plastics industry. which absorbed about two-thirds of the total production. There phenol is treated with formaldehyde to make the infinite variety of Bakelite-type resins used for molding purposes, for laminating of paper, cloth and wood, for adhesives, protective coatings, paints and many other uses. For the epoxide-type resins, phenol is reacted with acetone to form bisphenol [2,2-bis (4-hydroxyphenyl) propane] uhich in turn is condensed with epichlorohydrin. Roughly one-fourth of the output went to the chemical and pharmaceutical industries for conversion into such derivatives as salicylates, chlorophenols, alkyl phenols, phenyl phosphates, nitrophenols and phenolsulfonic acids. The production of salicylic acid was one of the best-known outlets for phenol. From it many medicinals (*e.g.*, aspirin), flavours and dyes were prepared. The chlorophenols are important as bactericides, fungicides, selective herbicides (2,4-dichlorophenoxyacetic acid) and starting materials in the production of pharmaceuticals and photographic chemicals. The alkyl phenols are useful as oxidation inhibitors (di-tert butylphenol). starting materials for drying-oil-soluble varnish resins (paratertiary butylphenol) and as reagents in the manufacture of synthetic detergents. Triphenyl phosphate is a plasticizer used in cellulose acetate film and phenolsulfonic acids find application principally in the production of synthetic tanning agents. The remaining production was used as selective solvent in the refining of lubricating oils, the extraction of aromatic fractions (toluene) from petroleum distillates and for many other purposes.

Properties.—Phenol is closely related to benzene, having, in place of one of the six hydrogen atoms present in the benzene ring, a hydroxyl group which is the combination of one oxygen and one hydrogen atom. Its formula is $C_6H_5.OH$. Thus it stands in the same relation to benzene as methyl alcohol, $CH_3.OH$, does to methane. CH_4.

Although it has some properties which resemble those of the aliphatic alcohols, in particular of the tertiary alcohols, phenol cannot be classified as an alcohol. It is characterized by its acidic nature and its readiness to form salts with strong bases. Phenol is the prototype of the hydroxylated members of the benzene series.

Phenol has a molecular weight of 94.11. At atmospheric pressure it boils at 182° C. It solidifies at 41° C. into colourless needles. At 25° C. its density is 1.072 and its refractive index at 41° C. is 1.5425. It has a characteristic pungent odour and in dilute water solution a sweetish taste. In more concentrated form it is poisonous and produces burns on the skin. At room temperature phenol is sparingly soluble in water. If more than 8% by weight of phenol is present, two phases appear in the solution, a bottom layer consisting of phenol with some dissolved water and a top layer of water containing about 8% phenol. As the temperature is elevated. the mutual solubility increases, until above 66° C. phenol and water become soluble in all proportions. Phenol is readily soluble in alcohol, ether. chloroform, carbon disulfide, glacial acetic acid and the hydrocarbons of the aromatic series. It is less soluble in the liquid hydrocarbons of the aliphatic series. Because of its acidic nature, it dissolves readily in solutions of alkalies with the formation of alkali-metal salts. These salts are readily decomposed by the addition of acids. Similarly to ordinary alcohols, phenol can be esterified with carboxylic acids, although the reaction does not proceed with the same ease and often requires the action of the chloride or anhydride of the carboxylic acid or an alkali-metal salt of phenol. It can be converted into an ether by treating its sodium or potassium salt with an alkyl halide. such as methyl iodide, or by treating it under elevated temperature and pressure with acetylenes in the presence of alkaline catalysts.

As a derivative of benzene, phenol can be sulfonated, nitrated and halogenated. The presence of the hydroxyl group enhances the reactivity of the benzene ring, so that milder conditions are indicated to control the reactions. Halogenations proceed quantitatively to the trihalide stage, a fact that is useful in the analysis for phenol. Substitutions take place principally in positions ortho and para to the hydroxyl group. Hydrogen, in the presence of active catalysts. will add to phenol to form cyclohexanol or. under more drastic conditions, cyclohexane. Of great commercial importance is the readiness nith which phenol reacts with aldehydes, in particular formaldehyde, to form condensation products of high molecular weight.

Preparation.—Natural phenol is recovered at coal-tar-distillation plants from a distillate fraction boiling between 160° C. and 230° C. To extract the phenol together with its homologues—the various cresol (methyl phenols) and xylenol (dimethyl phenols) isomers—from this fraction, it is washed with dilute aqueous sodium hydroxide solution. To "spring" the acids out of the aqueous solution the extract is purified and treated with an acidic material, such as carbonic acid which is often available in stack or kiln gases. The thus liberated acids are withdrawn. purified, and finally fractionally distilled under vacuum to yield phenol in various grades of purity followed by the cresol and xylenol cuts.

Synthetic phenol is produced from benzene mainly by three general procedures which may be classified according to the main process steps as follows:

1. Sulfonation process, which consists in the treatment of benzene with sulfuric acid and subsequent fusion of the resulting benzenesulfonic acid with sodium hydroxide to form sodium phenoxide, which is dissolved in acids to liberate phenol.
2. Chlorination process, which consists in the treatment of benzene with chlorine and subsequent hydrolysis of the resulting chlorobenzene with steam or with aqueous alkaline solutions to form phenol or alkali phenoxide solutions, the latter being treated with acids to liberate phenol.
3. Cumene process, which consists in the reaction of benzene with propylene to form cumene, (monoisopropylbenzene); oxidation of the cumene with air to make cumene hydroperoxide; and, finally, cleavage of this hydroperoxide to produce phenol and acetone.

In the sulfonation process benzene is caused to react with an equivalent amount of concentrated sulfuric acid to form monobenzene sulfonic acid according to the equation

$$C_6H_6 + H_2SO_4 \longrightarrow C_6H_5SO_3H + H_2O$$

Since the reaction slows down as the reactant sulfuric acid becomes diluted with the water of reaction, the process is often carried out by passing benzene vapour through a sulfuric acid bath, maintained at a temperature above 100° C.. in such a way that only a portion of the benzene reacts while the rest escapes as vapour together with the water formed in the reaction. The vapours are condensed, the water is separated and the benzene is returned to the sulfonation bath. At the end of the cycle there is obtained in the bath benzene sulfonic acid which is essentially free of sulfuric acid and which can be used directly in the fusion step without the laborious intermediate steps necessary if appreciable quantities of free sulfuric acid remain dissolved in the sulfonation product. The second. so-called fusion step in the process, proceeds according to the reaction

$$C_6H_5.SO_3H + 3NaOH \longrightarrow C_6H_5.ONa + Na_2SO_3 + 2H_2O$$

In practice this operation is carried out in cast-iron vessels. Caustic soda in excess of the theoretical requirement is first charged and heated to about 300° C. Then the benzene-sulfonic acid or its sodium salt is pumped into the molten mass. After about six hours the reaction mixture is plunged into aqueous-process liquors in which sodium sulfite crystallizes out because of its low solubility in strongly alkaline solutions. The solution is filtered, and the fil-

trate, containing sodium phenoxide and residual free caustic soda. is treated with sulfuric acid to liberate the phenol and to convert the soda into sodium sulfate. A final distillation of the phenol removes water and furnishes the marketable product.

In the chlorination process, benzene is treated with chlorine to form monochlorobenzene according to the equation

$$C_6H_6 + Cl_2 \rightarrow C_6H_5.Cl + HCl$$

The reaction is carried out in cylindrical vessels. Iron is added to the charge as a catalyst. To repress the formation of the more highly substituted polychlorobenzenes. an excess of benzene is maintained in the reaction zone. The resulting crude chlorination product is treated with a dilute caustic-soda solution to free it of by-product hydrogen chloride.

After settling, the product is subjected to fractional distillation to separate from it the nonconverted benzene and to purify the monochlorobenzene. The more highly chlorinated products remain in the still bottoms. The conversion of monochlorobenzene into phenol is commercially accomplished by any one of fhe following reactions:

(1) $C_6H_5Cl + H_2O \rightarrow C_6H_5.OH + HCl$
(2) $C_6H_5.Cl + 2NaOH \rightarrow C_6H_5.ONa + NaCl + Hz0$
(3) $C_6H_5.Cl + Na_2CO_3 + H_2O \rightarrow C_6H_5OH + NaCl + NaHCO_3$

Reaction 1, in the presence of a catalyst, proceeds in the vapour phase at about 500° C. and atmospheric pressure. Reaction 2 is carried out in the liquid phase at high pressure and temperature in corrosion-resistant autoclaves. The resulting sodium-phenoxide solution is treated with the by-product hydrogen chloride from the chlorination step to liberate the phenol. Reaction 3 is utilized in the Dow Chemical Co. process in which chlorobenzene and soda-ash solution are pumped through long copper coils at a pressure of 3,000 lb. per square inch and at about 320° C. After cooling the mixture, the pressure is released and free phenol separates from the bicarbonate solution. Diphenyl ether appears as the product of a side reaction. Fortunately, its formation can be suppressed by returning some of it to the mixture entering the hydrolysis step. For final purification the phenol is subjected to a fractional distillation under vacuum.

Since the vapour-phase hydrolysis (reaction 1) furnishes hydrogen chloride, economies could be realized if this by-product were utilized as a source of chlorine in the chlorination of benzene. This has been accomplished by the Raschig process, which combines the principle of the Deacon process—the preparation of chlorine from hydrogen chloride and oxygen—with the chlorination of benzene and the subsequent vapour-phase hydrolysis of chlorobenzene. The process uses air as the source for oxygen and is operated on a large scale. The individual reactions can be summarized by the equation

$$C_6H_6 + \tfrac{1}{2}O_2 \rightarrow C_6H_5.OH$$

In the cumene process (used commercially since 1950), benzene is treated with gaseous propylene in the presence of an acidic catalyst such as aluminum chloride or phosphoric acid on a clay support. After neutralization the resulting reaction mixture is distilled to separate monoisopropylbcnzene (called cumene) from polyisopropplbenzene and unconverted benzene. The cumene is then subjected to air oxidation until about one-third is converted to cumene hydroperoxide. The excess cumene is removed from the oxidation mixture by distillation at reduced pressure and recycled. The residue contains the concentrated cumene hydroperoxide and is contacted with a strong acid whereupon it decomposes into phenol and acetone. These reactions are shown by the equations:

$$C_6H_6 + C_3H_6 \rightarrow C_6H_5\text{-}CH(CH_3)_2$$
$$C_6H_5\text{-}CH(CH_3)_2 + O_2 \rightarrow C_6H_5C(CH_3)_2OOH$$
$$C_6H_5C(CH_3)_2OOH \rightarrow C_6H_5OH + (CH_3)_2CO$$

The final products, phenol and acetone, are separated by fractional distillation. (E. W. V.)

PHENOMENALISM (from the Greek *phainomenon*, "appearance": see PHENOMENON), a philosophical theory of perception and the external world. Its essential tenet is that propositions about material objects are reducible to propositions about actual and possible sensations. or sense data, or appearances. According to the phenomenalists. a material object is not a mysterious something "behind" the appearances which we experience in sensation. If it were. the material world would be unknowable; indeed, the term "matter" itself would be unintelligible unless it could somehow be defined by reference to sense experiences. In a phenomenalistic analysis of material-object propositions, it is of course essential to mention possible sensations and not merely actual ones. The wall which someone sees just in front of him is hard and rough. though he is not at the moment touching it. But it is still true that, if he were to stretch out his hand. he would experience tactual sensations of hardness and roughness. These tactual sensations are possible, though not at the moment actual. Moreover. material objects continue to exist at times when they are not being observed at all. For instance, there is a fire burning in the next room: though no one at present sees or feels it. But it is still true that. if there were an observer in the next room. he would experience bright. flickery, yellowish colour-patches. and he would feel warmth. Moreover. the precise character of the visual sensations which he would experience and. likewise, the degree of warmth which he would feel would vary with the point of view which he occupied in the room. In speaking about a material object, then. we must be referring to a very large group or system of many different possibilities of sensation. Whether actualized or not. these possibilities continue during a certain period of time. When the object is observed. some of these possibilities are actualized, though not all of them. So long as it is unobserved, none of them are actualized. In this way. the phenomenalist claims! we can give an "empirical cash-value" to the concept of matter, by analyzing it in terms of sensations.

It must be emphasized that the term "possible sensation," as phenomenalists use it. is a kind of shorthand for a hypothetical ("if . . . , then . . .") proposition. When it is said that a visual sensation of such and such a kind is possible. though not actual, the meaning is that a colour sensation of that kind would occur if there were an observer at such and such a place where there is in fact no observer.

Some of the classical difficulties of phenomenalism arise directly from the central part which these hypothetical propositions play in the phenomenalist analysis. The phenomenalist claims to analyze all material-object expressions in terms of actual and possible sense experiences. But it is difficult for him to avoid using material-object expressions in his if-clauses, and this would make his analysis circular. In the example just given, "an observer" (*i.e.*, an animate human organism) is a material-object expression, and so is "in the next room." No doubt we might attempt to analyze each of these material-object expressions in terms of other possible sense experiences. "The next room." for instance, might be resolved into the visual and other sensations which an observer would have if he opened the door or looked through the window. Expressions referring to an observer might be analyzed in terms of the sensations which another observer would have if he were to look in a certain direction. But now the same difficulty arises again about these new if-clauses. A second and even more important objection is this: it is very difficult to believe that categorical propositions about material objects (*e.g.*, "there is a fire in the next room") can be analyzed without remainder into sets of hypotheticals; *i.e.*, that a statement about what there actually is can be reduced to a set of statements about what there would be if certain (nonexistent) conditions were to be fulfilled.

PHENOMENOLOGY, a term used in philosophy and psychology to denote a study of the varying forms in which something appears or is manifested. as opposed to studies of causal origins, real constitution, significance, etc., which go beyond what is apparent. The word was used by Hegel in his Phenomenology of *Spirit* (1807) to stand for a study of the forms assumed by mind

or spirit in its development toward complete self-consciousness. It is also much used in contemporary psychology to cover descriptions of direct, personal experience, as opposed to accounts based on an observation of behaviour. Thus a typical modern phenomenological study is David Katz's *Der Aufbau der Farbwelt* (1930; original ed., *Die Erscheinungsweisen der Farben,* 1911; Eng. trans,, *The World of Colour,* 1935), which deals with the varying ways in which colours appear to the percipient; *e.g.,* as spread over surfaces, as filling space, as lustrous, as a property of the lighting, etc. The term was also used by Edmund Husserl (*q.v.*), professor of philosophy at Gottingen and Freiburg, who made it stand for an a priori psychological discipline which, in studying the ways in which objects appear to the mind, should provide a foundation for all empirical psychologies. Husserl's methods were subsequently widened so as to apply to other scientific disciplines and so as to develop into a universal phenomenological philosophy. The present article will confine itself to the phenomenological teaching of Husserl.

The phenomenology of Husserl is a lineal descendant of the "psychognosy" of Franz Brentano (*q.v.*), under whom Husserl studied in Vienna in 1884–86. This psychognosy was an attempt to delimit the subject matter of psychology, by laying down certain basic features which entitle us to call a phenomenon psychical (or mental) and by classifying psychical phenomena into certain fundamental types. The most important result of these psychognostic investigations is that mental states are all characterized by intentionality or direction to objects (the term was borrowed by Brentano from the schoolmen): "In a presentation something is presented, in a judgment something is acknowledged or rejected, in love something is loved, in hate hated, in desire desired, etc." *(Psychologie vom empirischen Standpunkte,* 1874). Brentano maintained that the intentional inexistence of objects in experience was the peculiar feature of the psychical (mental): no physical phenomenon showed anything comparable. Further. he divided "psychical phenomena" into the basic class of presentations, in which an object is simply set before consciousness, and the more complex classes of the judgment and of the phenomena of love and hate, which are built upon and presuppose the former. He held, further, that every mental state reveals its existence and character to an attendant state of inner observation or perception, which is part of itself: it is by exercise of this inner perception that our psychognostic studies must proceed.

The term phenomenology first becomes prominent in Husserl's early masterpiece, *Logische Untersuchungen* ("Logical Investigations"; 1900–01). In this work Husserl is concerned to refute psychologism, a view which makes the subject matter of logic and mathematics psychological, which regards them as dealing with our mental acts of judging, counting, adding, inferring, calculating, etc., and which also makes their validity depend on the contingent make-up of the human mind. As opposed to such psychological interpretations, Husserl proposes to build up a phenomenological account of our mental approaches. both in the logico-mathematical and in other fields. This phenomenological account will not concern itself with the actual states of mind of men and animals of which there is empirical evidence; it will deal abstractly and generally with the sorts or kinds of experience in which certain sorts of object are set before us. It will seek to analyze such directed experiences and to discover the relations to objects (and to other experiences) that are implied by their being the sort of experiences that they are. Such an investigation will be intuitive, in that one will not be able to give reasons for the particular analyses that one adopts; one may also call it descriptive, since it will be in many ways like the description of objects given in sense perception. But though intuitive and descriptive, it will also be non-sensuous and a priori: the kinds examined and analyzed will be "there" only for abstraction and for reflection, and whatever is laid down about them will be true of necessity or "grounded in their essence," and not merely found to go with them in experience. Such phenomenological analyses of our mental approaches will also involve a treatment of the various sorts of object that are set before our minds: though such objects are distinct from our mental approaches, it is nonetheless part of the description of the latter that they should "terminate on" or "be directed toward" certain objects. The phenomenologist is concerned, however, not with the actual existence or real character of such objects, but only with their status as objects, as phenomena for consciousness. Hence an abstract, incomplete, merely possible or even impossible object will be as important for his researches as one that is actual. The phenomenologist will, in fact, consider objects (like experiences) only as abstract types or kinds: this abstraction will reach a peak in the logicomathematical sciences where he will only deal with them as "somethings-or-other" or as objects in general. Logic and mathematics together constitute for Husserl a *mathesis universalis* or study of things-in-general. Though not themselves psychological or phenomenological studies, they have a foundation in the latter, insomuch as their objects enter into reality only as part of the description of certain abstract and generalizing intentions.

Apart from its first volume of antipsychologistic *Prolegomena* (which, read in isolation, gives a wholly misleading impression of Husserl's philosophy), the *Logische Untersuchungen* comprises six important studies. The first, *Ausdruck und Bedeutung* ("Expression and Meaning"), deals with the "meaning-conferring" acts which lie behind the significant use of linguistic expressions. The second, *Die ideale Einheit der Spezies und die neueren Abstraktionstheorien* ("The Ideal Unity of Species and Modern Theories of Abstraction"). deals penetratingly with the accounts of abstraction given by Locke, Berkeley, Hume. Mill and others and distinguishes the pure contemplation of abstract kinds or essences from selective attention to the "moments" or abstract aspects of objects. The third study, *Zur Lehre von den Ganzen und Teilen* ("Toward a Doctrine of Wholes and Parts") deals with this very problem of the "moment" or abstract aspect of an object, which is incapable of existing apart from its whole. The fourth study, *Der Unterschied der selbstandigen und unselbstandigen Bedeutungen* ("The Distinction Between Independent and Dependent Meanings"), deals with the intentional background of the distinction betueen categorematic and syncategorematic expressions. In the fifth study, *Über intentionale Erlebnisse und ihre "Inhalte"* ("On Intentional Experiences and Their 'Content' "), Husserl criticizes and develops Brentano's notion of intentionality as the distinguishing feature of the mental. He puts forward his own notion of the conscious "act," (which he explicitly disassociates from connotations of activity and agency) and draws elaborate distinctions between what he calls the quality of acts, the manner in which they approach their objects. and their matter (*Materie*), the side of them that determines what object they deal mith. It may be noted that Husserl, like Brentano, does not make the object of a mental act an actual part of it: to be concerned in thought with the god Jupiter is not to have that god as an actual element in one's concern. Nor does concern mith an object entail its extramental existence anywhere: its status may be merely intentional, it may be merely the case that we have ideas of it. Intentionality is no relation between a mental act and something lying outside of it: concern with an object is something self-sufficient and complete, to live through it is to have its object before one, whether that object has any further real status or not. It will be observed how Husserl, by the radical originality of these concepts, avoids many of the pitfalls into which his Cambridge contemporaries fell. The last study in the book, *Elemente einer phanomenologischen Aufklarung der Erkenntnis* ("Elements of a Phenomenological Elucidation of Knowledge"), is probably the most characteristic and valuable of all Husserl's writing. He here develops the distinction between the act of mere meaning (*Bedeutungsintention*), the object of which is not actually present, and the experience of fulfillment of meaning (*Bedeutungserfüllung*), in which what is referred to is also itself directly given. Obviously it is basic to thoughts, whether in the theoretical or in the practical sphere, that they should be capable of existing empty or unfulfilled and that they should also be capable of being realized carried out, executed, fulfilled in one manner or another. In the theoretical field it is in our passage from an unfulfilled to a fulfilled reference that all that is called knowledge arises; *e.g.,* when I expect something to be black and

also find it to be black. In this connection Husserl's thought comes near to adopting something like the modern verification principle. a meaning for him is always correlative to some fulfilling intuition. Only he is willing to widen the notion of intuition to cover the case of abstract and even of synsemantic meanings; we can be brought face to face with the meaning of an "and," an "or" or a "but" or other syntactical connectives. There is a categorial intuition of ideal objects and of their a priori relationships. which is quite distinct from sensuous intuition.

Husserl's more mature views of the task of phenomenology, together with an actual attempt to carry out his phenomenological program, are to be found in his later work *Ideen zu einer reinen Phänomenologie und phanomenologischen Philosophie* (bk. i, 1913, bk. ii and iii in the posthumous *Husserliana*, 4 and 5, 1950–52; Eng, trans. of bk. i by W. R. Boyce Gibson. *Ideas: General Introduction to Pure Phenomenology*, 1952). Phenomenology is here ranged among a large body of eidetic disciplines, each of which works out an ontology for a peculiar region of objects and sets forth the types and the axioms applying to objects of that kind. There is one such eidetic science dealing with colours, sounds and the sensible qualities generally, another with spatiality, another with temporality, another with material thinghood, and so forth. Logic and mathematics together constitute an eidetic science the categories and axioms of which apply in all regions and which is consequently without a proper region of its own; it may, however, with due reserve, be said to govern a formal or analytic region. These regional sciences are arrived at by abstraction and by an examination of essence, but phenomenology (which is the eidetic science of the region of experiences) is not arrived at merely in this manner; it requires, in addition, that one should practise a sort of Cartesian doubt in regard to all common-sense beliefs, that one should put them all in brackets, subject them all to a transcendental suspension or *epoche*. Without ceasing to believe in them. one should put one's belief in them out of action. In this suspension of conviction, consciousness itself will become highlighted, the mere appearance of houses, trees, men, etc., being tantamount to the existence of one's awareness of them. Consciousness itself is thus immune from the *epoche* which dissolves its objects. In connecting our suspension of conviction in regard to the natural-empirical world with our inner perception of our own conscious dealings with it, Husserl is adding depth to Brentano's notion of inner perception: it no longer merely means a sort of secondary empirical perception of our own mental acts, which is tacked on to those mental acts themselves. And once consciousness has thus been made manifest to our inner perception, it can be subjected to the same generalizing abstraction and examination of essence that have been applied to its objects. In this way one supplements one's regional ontologies with a pure phenomenology which explains how their objects appear or are given.

Husserl, however, passes on to certain theses which would seem to involve the abandonment of his original *epoche* and a complete surrender to metaphysical idealism. For he holds that, while appearances and acts of consciousness exist absolutely, their natural-empirical objects can be said to exist only for consciousness: their being is by its nature intentional. Even the transcendent objects of physics enjoy a transcendence which is only constituted in and by consciousness, their whole function being to provide a satisfactory account of experienced things. Husserl goes further and maintains that the existence of a pure self or ego, the point of unity of our mental acts. is guaranteed by our inner perception: those acts then become its spontaneous activities. Husserl is here going back on the teaching of the *Logische Untersuchungen*, which refused to see in the self anything more than the systematic unity of our mental acts and which disjoined its notion of act from suggestions of activity. The act of perceiving X means no more for the *Logische Untersuchungen* than that *X* appears or is given: in his later work it involves a transcendental subject and its activities. It would appear, then. that the *Logische Untersuchungen* is more strictly phenomenological, more chary of going beyond the appearances, than are the works in which Husserl's phenomenological program is most loudly proclaimed.

Husserl's actual carrying out of his program is to be found in the latter portions of the *Ideen* (and elsewhere). Here only a few points can be mentioned. While accepting Brentano's general position that concern with objects is the distinguishing mark of the mental. Husserl accepts into his mental realm factors which, though not themselves intentional, nonetheless serve as the stuff for our sense-making, interpretative references. The data of sense as well as certain primitive feelings are such hyletic constituents of experience. Husserl also draws a distinction between the noetic and the noematic aspects of our conscious experiences. We consider an experience noetically when we study the way in which it approaches its objects, whether attentively or inattentively, believingly or unbelievingly, approvingly or disapprovingly, and so on; whereas we consider the same experience noematically when we consider the intentional objects that come to light in it. Hardly, however, has Husserl drawn this distinction than he puts forward a principle which does much to obliterate it. he holds that to every noetic aspect of experience there is always a corresponding noema. that to every mode of our conscious approach there is an answering feature in the object approached. All consciousness is, in short, implicitly presentative. The noematic correlate of an approach need not, however, come to light in that approach itself: it may require another subsequent act to elicit it. Thus, when I deny something of an object, I am concerned simply with that object and not with its lack of an attribute: its lack of a given attribute is, however, the noematic correlate of my act and can itself become the object of a subsequent act. In the same way, if I surmise or desire a state of affairs, I am concerned with that state of affairs and not with its probability or its desirability; the latter are, however, the ideal noemata corresponding to my act, which can be made the objects of a subsequent awareness. Phenomenologically, Husserl holds, there is all the difference in the world between experiencing a denial, a surmise or a wish and contemplating the absence, the likelihood or the desirability which are their respective objective correlates. Husserl gives interesting phenomenological analyses of outer and inner perception. of attention. of our consciousness of time, of belief, surmise and supposal: he also deals with the experiences (classified under the heading of *Vernunft* or reason) which provide justifying evidence for our other attitudes. He then goes on, in later books of the *Ideen*, to give phenomenological accounts of external nature; of the space and time nhich are its structure; of the sense-qualities which qualify its objects; of its various lifeless, living and conscious inhabitants; and of the personal and social arrangements and cultural activities of these last. Though phenomenology suspends belief in the natural empirical order, it can nonetheless deal with that order in bracketed fashion. No thing or feature in that order need escape its net of essence: it can always deal with it as an object of consciousness or as an instance of certain ideal possibilities. Husserl's followers Max Scheler, Martin Heidegger (*qq.v.*), Fritz Kaufmann, Oskar Becker and Gerhart Husserl developed a concrete phenomenology of the emotional, aesthetic, ethical, religious, social and juridical spheres.

By the middle of the 20th century it was still not possible to pass a balanced judgment on Husserl's contributions to philosophy: a thinker of such originality and such difficulty would obviously take a long time to make his full impact on philosophical thought and to engender a comprehending and comprehensive reaction. Part of the difficulty is linguistic: Husserl's idiom, though entirely sober and suited to its material, is by no means easy to master. It becomes even harder in translation. It may, however, be suggested that Husserl's fundamental contributions are much simpler than they at first sight appear to be; thus there is little more to his transcendental *epoche* and examination of essence than a determination to examine the meaning of common concepts and ordinary beliefs rather than to add factual detail to our knowledge. His program is, in fact, not very different from that of modern British and U S. analytic philosophy. We may note, further, that his analyses of mental states do little more than bring out what is involved in their "intentionality" or direction to obiects But since this property is as much characteristic of outward action as of inward experience — for our actions can be shown to be oriented to things and to situations — there is much in his

analyses that could be given a behaviouristic interpretation. It has already been suggested that his best work is to be found in the *Logische Untersuchungen.*

BIBLIOGRAPHY.—The periodical *Jahrbuch für Philosophie und phänomrnologische Forschung* (1913–30) published Husserl's *Ideen,* bk. i (see text above, 1913), *Phanomenoloaie des inneren Zeitbewusstseins* (1928) and *Formale und transzendentale Logik* (1929), also, among other important contributions, Max Scbeler's *Formalismus in der Ethik* (1916) and Martin Heidegger's *Sein und Zeit (1927).* (These works were also published separately.) The periodical *Philosophy and Phenomenological Research,* ed. by M. Farber (1940–), is a continuation of the *Jahrbuch. See* further the *Husserliana,* ed. by H. L. van Breda (1950–), and works cited in the bibliography of the article HUSSERL, EDMUND, especially M. Farber, *The Foundation of Phenomenology* (1943), which contains summaries of the *Logische Untersuchungen.* (J. N. F.)

PHENOMENON (Greek *phainomenon,* from *phainesthai,* "to be shown," "to seem," "to appear"), any object, fact or occurrence perceived or observed. The Greek verb *phainesthai* can be used with or without the implication that the thing perceived is other than what it appears to be. Thus in Aristotle's ethics "the apparent good" is what seems good to a man, whether or not it really is good. In general, phenomena are the objects of the senses, sights and sounds, contrasted with the real objects apprehended by the intellect. In later Greek philosophy phenomena are the observed facts contrasted with the theories devised to explain them. A theory is said to "save the phenomena" if it is consistent with the facts.

This last use became common in the early part of the 17th century when scientists used phenomena for the observed facts that they sought to explain (*e.g.,* astronomical phenomena, the phenomena of gravitation, phenomena of magnetism), a use still current. In modern philosophy the word is sometimes used for what is immediately apprehended by the senses before any judgment takes place; but it has never become a technical term, most philosophers preferring more artificial words such as sense-datum (hence such terms as phenomenalism and phenomenology, *qq.v.*). In English versions of Kant the word is often used to translate *Erscheinung* ("appearance"), Kant's word for the immediate object of sensory intuition, the bare datum which becomes an object only when interpreted through the categories of substance and cause. Kant himself uses it for the object interpreted through the categories as opposed to the noumenon (*q.v.*), or thing-in-itself, to which the categories do not apply. (P. H. N.-S.)

PHERECRATES, Greek poet of the old Attic comedy. was a contemporary of Cratlnus, Crates and Aristophanes. At first an actor, he seems to have gained a prize for a play in 438 B.C. The only other ascertained date in his life is 420, when he produced his play *The Wild Men.* As Crates, whom he imitated, he abandoned personal satire for more general themes, although in some of the fragments of his plays one finds him attacking Alcibiades and others. He invented a metre, called after him Pherecratean, which occurs in the choruses of Greek tragedies and in Horace.

A number of fragments from his 16 (or 13) plays have been preserved in T. Kock, *Comicorum Atticorum Fragmenta,* i (1880) and A. Meineke, *Poetarum Comicorurn Graecorum Fragrnenta* (1855).

PHERECYDES OF LEROS, Greek mythographer (fl. *c.* 454 B.C.). He is probably identical with Pherecydes of Athens, although the two are distinguished by Suidas (also by I. Lipsius, *Quaestiones logographicae,* 1886). Numerous fragments of his genealogies of the gods and heroes have been preserved.

PHERECYDES OF SYROS (fl. *c.* 550 B.C.), Greek mythographer and cosmogonist, who is traditionally associated with the Seven Wise Men, especially with Thales. He was the son of Babys and is to be distinguished from the genealogist Pherecydes of Athens, who lived about a century later. The earliest known reference to Pherecydes of Syros is in the 5th-century poet Ion of Chios. The belief that he was responsible for a *heliotropion* (a means of marking the "turning-point" of the sun at the solstice) on the island of Syros made some connect him with a line in the *Odyssey* (xv, 404) and place him earlier than Homer; but tradition made him the teacher of Pythagoras. The same miracles were ascribed to both, and this may be the reason why Cicero (*Tusculan Disputations* i, 16, 38) and Augustine (*Contra Academicos* iii, 17; *Epistle* cxxxvii. 12) say that he first taught the immortality of the soul. He was also credited with the doctrine of metempsychosis.

Aristotle (*Metaphysics* 1091 b 8) characterized Pherecydes' work as a mixture of myth and philosophy. His book the *Heptamychos* (L. Preller's correction *Pentemychos* is probably unnecessary), of which only a few fragments remain. described the origin of the world and the loves and battles of the gods. Despite its mythical form, it has features reminiscent of 6th-century Ionian speculation; for instance, the god Time creates three elements, fire, air and water, which Zeus-Eros unites to form a cosmic system. Allegory is prominent, as in the names of the gods and in a fragment describing a robe embroidered by Zas (Zeus) for his bride Chthonie (Earth) with representations of earth and ocean. Its philosophical tendency and its prose form distinguish the work from most of the rich cosmogonical literature of the 7th and 6th centuries B.C. (*e.g.,* the theogonies of Hesiod and of the pseudo-Orpheus); some critics have seen the influence of Anaximander in both features.

See O. Kern, *De Orphei, Epimenidis Pherecydis theogoniis* (1888); H. Diels and W. Kranz, *Die Fragmente der Yorsokratiker,* 3 vol., 7th ed. (1954). (W. K. C. G.)

PHET BURI (PHETBURI), a province of peninsular Thailand lying between the Gulf of Thailand and southern Burma. The eastern part, especially astride the middle course of the Phet Buri river, contains areas of productive alluvial soils which produce rice, coconuts and palm sugar. Irrigation, however, is necessary. The topography of the western part is mountainous and heavily forested. Pop. (1956 est.) 225,761; area 2,454 sq.mi.

Phet Buri (pop. [1947] 53,448), the capital, is near the mouth of the Phet Buri river 93 mi. by rail southwest of Bangkok.

In ancient times before the sea route through the Straits of Malacca and around the Malay peninsula was developed, Phet Buri was the eastern terminus of an overland trade route from India and Europe to continental southeastern Asia. Ruins of ancient Brahman and Buddhist temples and caves are found in the environs; also an old palace built by King Mongkut and a modern palace built by his son King Chulalongkorn. (T. F. B.)

PHIDIAS (PHEIDIAS; active from about 475 to 430 B.C., or later), an Athenian, the son of Charmides and pupil of Hegias, may be regarded as the greatest of Greek sculptors. Among his early works, the most important were a bronze group at Delphi (perhaps *c.* 465), erected as a memorial after the battle of Marathon; a gold and ivory statue of Athena in Achaia; and the famous bronze Athena on the Athenian Acropolis, also a thank offering after Marathon, but not set up until *c.* 456 (*cf., Hesperia,* xv, pp. 106 ff.; 1946).

When Pericles rose to power (449) and initiated a great building program in Athens, Phidias was put in charge of all artistic undertakings (*see* Plutarch, *Perikles).* Phidias himself made the gold and ivory statue of Athena, about 40 ft. high including its base, that stood inside the Parthenon and was dedicated in 438.

According to Pausanias' *Description of Greece* (I, 24, 6), the goddess stood erect, wearing a tunic, aegis and helmet, a winged victory on her extended right hand, a spear in her lowered left; by her side were a shield and a serpent; base, shield and helmet were adorned with figures. From this description a number of copies have been identified. notably the Varvakeion and Lenormant statuettes in Athens, the Strangford shield in London and the reliefs found in the sea off the Piraeus.

Though Phidias himself could not have executed the sculptures of the Parthenon—the 92 metopes, the frieze about 170 yards long and the two pediments—it seems probable that he was responsible for their design. Much of the sculptural decoration has survived (now mostly in London, Athens and Paris; a few pieces in the Vatican). Since they are Greek originals, these remains show the style of Phidias better than a host of Roman copies. (*See* PARTHENON.)

Phidias' foremost work, in the estimation of the ancients, was the gold and ivory statue of Zeus, about seven times life-size. that he made for the temple at Olympia. It was considered the greatest religious statue of Greece, and Quintilian (*Institutionum*

Oratoriarum, XII, 10, 9) says that "its beauty can be said to have added something to traditional religion." All that now remain are the description by Pausanias, small reproductions on Roman coins and terra-cotta moulds used for the drapery. Zeus was shown seated on a throne, holding a Nike in his right hand and a sceptre in his left. All parts of the statue, even the sandals, were richly decorated.

After long discussion among modern archaeologists, it is now agreed that Phidias made the Athena Parthenos earlier than the Olympian Zeus; for the moulds from Olympia, which were found in a dump adjoining what was described by Pausanias as Phidias' workshop, and which had evidently been used for hammering into them the gold for the draperies of Zeus and Nike, indicate a style in the 430s rather than the 450s.

Besides his two masterpieces, ancient writers mention a number of other statues by Phidias, all now lost. The most credible identifications are: The Lemnian Athena, set up on the Acropolis and famous for its beauty, which is perhaps reproduced in a head in Bologna and a statue in Dresden; the Apollo Parnopius, also erected on the Acropolis, perhaps reproduced in the Cassel Apollo; the Anadumenus of Olympia, perhaps reproduced in the Farnese Diadumenus of the British museum; and the Amazon—made in competition with Polyclitus, Cresilas, Cydon and Phradmon (*cf.,* Pliny, N.H., xxxiv, 53)—probably reproduced in a number of copies, all headless, of which the best-preserved is that found in Hadrian's villa, near Rome.

From these works one can gain some idea of Phidias' style. Quiet stances, serene expressions and a certain majesty of conception characterize his single figures; even when movement is represented in some of his reliefs, a monumental quality is imparted. Though the construction of the human body is perfectly understood, its rendering is restrained and harmonized. In other words, Phidias may be called the initiator of the idealistic, classical style that distinguishes Greek art in the later jth and the 4th century B.C., after the experimental epoch of Myron and his associates, and before the advent of the realistic Hellenistic age. And this idealistic quality—expressed in restrained modeling and in elevation of spirit—is still considered typical of Greek art.

Phidias was also a painter, an engraver and a worker in embossed metalware. His chief pupils were Alcamenes, Agoracritus and Colotes.

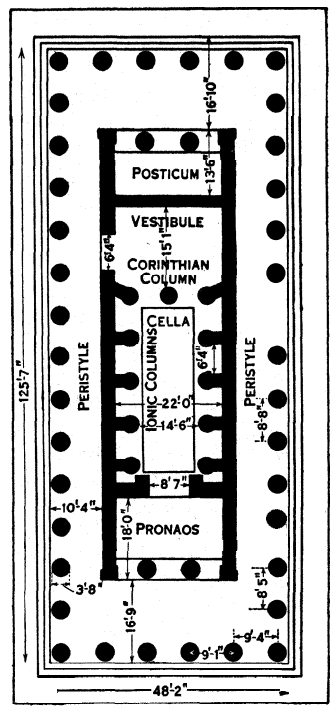
(1956), on the molds from Olympia. Lippold and Becatti give extended bibliographies of the earlier writings. (G. M. A. R.)

PHIGALIA or PHIGALEIA (mod. FIGALIA or PHYGALIA), an ancient Greek city on the Neda river in the southwest angle of Arcadia. among some of the highest mountains in the Peloponnesus, including Mt. Cotylium and Mt. Elasum.

In 659 B.C. Phigalia was taken by the Spartans, but soon after recovered its independence by the help of the Orasthasians. During the struggle between Achaeans and Aetolians in 221 B.C., it was held by Dorimachus, who left it on the approach of Philip V of Macedon. In common with other cities of Arcadia, it appears to have fallen into utter decay under Roman rule. Several curious cults were preserved near Phigalia, including those of the fish-tailed goddess Eurynome and the Black Demeter with a horse's head. whose image was renewed by Onatas. No autonomous coins of Phigalia are known. Nothing remains above ground of the temples of Artemis or Dionysus and the works of art which existed in the time of Pausanias. A great part of the city wall survived in modern times. 2 mi. in circuit, built of fine Hellenic masonry with a large square central fortress with a circular projecting tower.

Not at Phigalia itself, but at Bassae, 5 or 6 mi. away, on the slope of Mt. Cotylium is a well-preserved temple of Apollo Epicurius. It commemorates relief from a plague in the jth century. Pausanias (viii. 41) notes it as (next to that of Tegea) the finest in the Peloponnesus, "from the beauty of its stone and the symmetry of its proportions." It was designed by Ictinus, joint architect with Callicrates of the Parthenon at Athens. The temple was explored and measured in 1811–12 by C. R. Cockerell, the internal sculptured frieze of the cella being found in almost perfect condition. This and other fragments of sculpture are now in the British Museum.

The temple is of the Doric order, but has an internal arrangement of its cella which is unique. Probably to suit the ground, it lies north and south but the vestibule has a door to the east. It is hexastyle with 15 columns on its flanks (see figure). The internal columns of the cella are strangely placed, apparently without symmetry as regards the interior.



PLAN OF THE TEMPLE AT BASSAE

With the exception of one at the south end, which is Corinthian, the internal columns are of the Ionic order and are engaged with the cella wall, forming a series of recesses which may have been designed to contain statues. Another peculiarity of the interior is that these columns reach to the top of the cella in one order, not in two as was Doric fashion. These inner columns carried an Ionic entablature, of which the frieze formed a part. The pediments and external metopes of the peristyle appear to have contained no sculpture, but the metopes within the peristyle on the exterior of the cella had sculptured subjects. The position occupied by the great statue of Apollo is disputed. The main entrance is at the northern end through the pronaos, once defended by a door in the end of the cella and a metal screen, of which traces were found on the two columns of the pronaos. There was no door between the posticum and the cella. The general proportions of the fronts resemble those of the Theseum at Athens. except that the entablature is less massive, the columns thicker and the diminution less. In plan the temple is long in proportion to its width—measuring. on the top of the stylobate, 125 ft. 7 in. by 48 ft. 2 in., while the Theseum (built probably half a century earlier) is about 104 ft. 2 in. by 4j ft. 2 in.

The material is a fine gray limestone (once covered with painted stucco), but the roof tiles, the capitals of the cella columns, the architraves, the ceilings and the sculpture are of white marble. The roof tiles. specially noticed by Pausanias, are remarkable for their size, workmanship, and the beauty of the Parian marble. They measure 2 ft. 1 in. by 3 ft. 6 in., and are fitted together in the most careful and ingenious manner. Unlike those of the Parthenon and the temple of Aegina, the joint tiles are worked out of the same piece of marble as the flat ones, for the sake of more perfect fit.

Traces of painting on various architectural members were found by Cockerell, but they were too much faded for the colours to be distinguished. The designs are the usual Greek patterns—the fret. the honeysuckle. and the egg and dart.

The sculpture is of the greatest interest, having been designed to decorate one of the finest buildings in the Peloponnesus in the latter half of the 5th century B C.

The frieze acquired by the British Museum is complete: it is nearly 101 ft. long by 2 ft. high, carved in relief on 23 slabs of marble $4\frac{1}{2}$ to j in. thick. The subjects are the battle of the Lapithae and the Centaurs; and that between the Amazons and the Greeks, the two favourite subjects in Greek art of the best period. They are designed with wonderful fertility of invention, and lifelike realism and spirit; the composition is arranged so

as to form a series of diagonal lines or zigzags M, thus forming a pleasing contrast to the unbroken horizontal lines of the cornice and architrave. The various groups are skilfully united by some dominant line or action, so that the whole subject forms one unbroken composition.

The relief is very high, more than $3\frac{1}{2}$ in. in the most salient parts, and the whole treatment is quite opposite to that of the Parthenon frieze, which is a very superior work of art to that at Bassae. Many of the limbs are quite detached from the ground; the drill has been largely used to emphasize certain shadows, and in many places, for want of due calculation, the sculptor has had to cut into the flat background behind the figures. From this it would appear that no finished clay-model mas prepared but that the relief was sculptured with only the help of a drawing. The point of sight, more than 20 ft. below the bottom of the frieze, and the direction in which the light fell on it have evidently been carefully considered. Many parts, invisible from below, are left comparatively rough. The workmanship throughout is unequal, and the hands of several sculptors can be detected. On the whole, the execution is not equal to the beauty of the design, and the whole frieze is somewhat marred by an evident desire to produce the maximum of effect with the least possible amount of labour — very different from the almost gem-like finish of the Parthenon frieze. Even the design is inferior to the Athenian one; most of the figures are ungracefully short in their proportions, and there is a great want of refined beauty in many of the female hands and faces. It is in the fire of its varied action and its subtlety of expression that this sculpture most excels. The noble movements of the heroic Greeks form a striking contrast to the feminine weakness of the wounded Amazons, or the struggles with teeth and hoofs of the brutish Centaurs; the group of Apollo and Artemis in their chariot is full of grace and dignified power. The marble in which this frieze is sculptured is somewhat coarse and crystalline; the slabs appear not to have been built into their place but fixed afterwards, with the aid of two bronze bolts driven through the face of each.

Of the metopes, which were 2 ft. 8 in. square, only one exists nearly complete, with eleven fragments; the one almost perfect has a relief of a nude warrior, with floating drapery, overcoming a long-haired bearded man, who sinks vanquished at his feet. The relief of these is rather less than that of the frieze figures, and the work is nobler in character and superior in execution.

PHILADELPHIA, the Greek name of the ancient Rabbath-Ammon, in Eastern Palestine, commemorating Ptolemy Philadelphus (285–246 B.C.), mod. 'Ammân. Alexander Jannaeus (102–76 B.C.) although lord of the rest of the land east of the Iordan never conquered Philadelphia. With the coming of Pompey (63 B.C.) Philadelphia was made a member of the Decapolis. When Trajan set up the *Provincia Arabia* (A.D. 106) he assigned the town to the new province and Philadelphia advanced with Bostra to greater might and prosperity. Its extensive ruins include a Byzantine basilica, baths, theatre, citadel, temple, etc. (E. Ro.)

PHILADELPHIA, the largest city of Pennsylvania, U.S., known primarily. perhaps, for its high place in U.S. history, but also one of the principal cities of the northeastern United States. In the first part of the 20th century it showed one of the most rapid rates of population growth among the major U.S. cities, its industrial growth was proportionately high and it became a leader in devising redevelopment programs to deal with the urban problems characteristic of the 20th century.

The 1950 population of the city proper was 2,071,605, a 14.6% increase over the 1940 population. Like most other large U.S. cities. Philadelphia lost population in the following decade; the 1060 census figure was 2,002,512, a decrease of 3.6%. For comparative figures for certain other years, see table in PENNSYLVANIA: *Population.* The 1960 population of the standard metropolitan statistical area. which includes Bucks. Chester, Delaware, Montgomery and Philadelphia counties in Pennsylvania and Burlington, Camden and Gloucester counties in New Jersey, was 4,348,897, an 18.5% increase over 1950. Within the metropolitan area as defined by the census bureau are the cities of Chester and Norristown (*qq.v.*) in Pennsylvania and Camden (*q.v.*) in New Jersey. The suburbs reach out far to the north and south virtually to meet those of New York city and Baltimore. for Philadelphia is a part of the almost unbroken urbanized region which has come to extend along the Atlantic coast from Maine to Virginia.

Philadelphia's eminence resulted to a large extent from its geography. Its central and oldest section lies on a peninsula between the Delaware and Schuylkill rivers. Although it is 88 nautical miles from the Atlantic ocean, the broad Delaware river and bay ensured ready access to the sea and made the city one of the leading U.S. seaports. Furthermore, Philadelphia occupies the place where the principal roads from New Tork city southward run close to the Delaware just after crossing it; an Indian trail followed this route even before the coming of the white men. Thus the city is important to inland as well as to nautical communication. The valleys of the Schuylkill and of other tributaries to the Delaware, finally, have always given Philadelphia avenues to the rich agricultural, mining and industrial areas of eastern Pennsylvania.

From the peninsula between the Delaware and the Schuylkill, where the centre of the city lies, Philadelphia stretches north and south along the Delaware to a total river frontage of 23.7 mi. Inland its extension varies from 5 mi. to 15 mi. The topography of the city is largely of a sort more characteristic of New Jersey than of the Pennsylvania hills to the west, since much of it occupies the Atlantic coastal plain. The southern extremity, the Tinicum lowland, is protected by dikes, for in places it is more than 5 ft. below high tide. The greatest part of the coastal plain rises gradually from the Delaware to a height of about 150 ft. above sea level at the fall line. There, in the western extremities of the city, communities such as Roxborough and Chestnut Hill climb hills of the Piedmont plateau, reaching an elevation of about 400 ft.

History.—Of the important Atlantic coastal cities, Philadelphia was the last to be established, in part because navigation of Delaware bay and the Delaware river presented severe problems to early mariners. The entrance to the bay was a dangerous open roadstead, which until the building of the immense Delaware breakwater in the early 19th century continued to claim hundreds of ships. The channel of the bay and river were uncommonly intricate, so that even after numerous improvements, Delaware pilots are oiten known as the most skillful on the Atlantic coast.

Giovanni da Verrazano may have seen Delaware bay in 13'24 and Henry Hudson is known to have reached its mouth in 1609. Thereafter various explorers traveled up the bay and the river until sufficient interest was stimulated lo lead to settlement attempts by the Dutch and the English in the 1630s. The first permanent white settlements in what is now Philadelphia were planted in the 1640s by the Swedes, whose interest in the region had been aroused by certain dissidents from the Dutch West India company who believed their company had not been sufficiently energetic in exploiting the Delaware country. In 163'5 New Sweden surrendered to a Dutch expedition from New Amsterdam, but from the brief Swedish colonial effort came a population of about 2,000 Swedes and Finns who inhabited the Delaware area by the 1680s, including the community in what is now South Philadelphia which was later to build Old Swedes' church.

The reign of the Dutch also proved brief. ending when New Netherland surrendered to the English in 1664. Thereafter the early history of the city of Philadelphia is inseparable from that of the state. (*See* also PENNSYLVANIA: *History.*) On March 4, 1681, William Penn received from Charles II, out of friendship with the king and the duke of York and in payment of a debt of L16.000 owed by the king to Penn's father, his charter for a colony to lie north of Maryland and west of the Delaware. As a Quaker leader. I'enn planned in his colony a "Holy Experiment," where men of his own religious sect and of other persuasions might find

freedom of the mind. Soon he sent out surveyors who were to plat a city along the river, which Penn envisioned as the capital and metropolis of his colony. He instructed the surveyors to choose a high, dry and healthy site, one where ships might well ride, and if possible one where a navigable creek flowing into the Delaware would lend further encouragement to commerce. When the surveyors reached Pennsylvania, they found such a site at the peninsula formed by the flow of the Schuylkill into the Delaware. The Lenni-Lenape Indians of the area called this place Kué-quenáku or, as the white men more commonly rendered it, Coaquannock, meaning "grove of tall pines." Penn, however, had already selected his own name, one with both classical and biblical associations and with a meaning appropriate to his purpose: Philadelphia. Passages in the Book of Revelation refer to the city of Philadelphia in Lydia in Asia Minor. That city was worthy of remembrance as the seat of one of the seven early Christian churches, and its name signified brotherly love.

Penn enjoined his surveyors and other agents so to plan Philadelphia that it should be "a greene countrie towne which will never be burnt, and always wholesome." Each house, Penn instructed, ought to be placed in the middle of its plot, with garden, orchards and fields around it. The streets were to be laid out in a straight and regular pattern, reserving spaces for markets and squares — instructions scrupulously obeyed by Thomas Holme, Penn's surveyor-general. Holme's town plan formed a perfect checkerboard, to which the streets of central Philadelphia have generally continued to adhere.

William Penn himself sailed to his colony and city late in 1682, arriving in the ship "Welcome" inside the Delaware capes on Oct. 24 and proceeding thence, probably by barge from Chester, to Philadelphia. He remained only until the political and business problems of his colony called him back to England in Aug. 1684, but during his brief stay he was able to uitness a remarkable gronth of his city and colony. His policy of religious freedom together with his astute advertising of the potential uealth of Pennsylvania began to attract a large and multinational immigration which was to make Pennsylvania the prototype of the American melting pot. Swedes and Finns were already present; Englishmen and Welshmen, especially Quakers, came in large numbers; and the interest awakened by Penn's travels in Holland and Germany brought from those areas German Pietists, religiously akin to the Quakers, who were the vanguard of the great German migration to colonial Pennsylvania. Whatever part of Pennsylvania was their destination, most immigrants landed in Philadelphia and many of them stayed there. By the time Penn departed in 1684 there were 357 houses in Philadelphia, many of them "brave brick houses." By the next year, there were said to be 600 houses, and in that year the population of the colony, centring on Philadelphia, was estimated at more than 7.000. When Penn returned to his colony in 1699, for another two-year stay, he found that population growth already had erased his "greene countrie towne." His governors had felt compelled to divide and subdivide the city lots, and many of the owners had done likewise. The rich continued to enjoy lawns and trees but the middle class was coming to live in row houses facing each other across narrow streets, while the workingmen and their families occupied still more constricted quarters, often pressed into the narrow alleys behind the principal streets. As the 18th century began, Philadelphia was becoming the crowded city of narrow red brick houses which it was to be through the revolutionary period. Remains of this period can still be seen in such places as Elfreth's alley.

The *Metropolis* of Colonial America. — By the time of Penn's second visit the economic pattern of 18th-century Philadelphia was becoming plain. Like all the cities of colonial North America, Philadelphia built its economic life upon a commerce aimed at bringing to the new world the manufactured goods of the old world. Philadelphia was well supplied with commercial resources which. as the 18th century progressed, enabled it to become the wealthiest and most populous city of British North America.

For the export trade Philadelphia could draw upon the produce of the fertile farmlands stretching from the Delaware to the Susquehanna and beyond, a region which through the early 18th century filled up with skillful and industrious German farmers and then, farther west, with Scotch-Irish settlers. Wheat, corn, hemp, flax, beef, pork and timber products reached Philadelphia from the Pennsylvania hinterland. By the second third of the 18th century iron furnaces and forges up the Schuylkill and farther west were adding another product to Philadelphia commerce. From the neighbouring provinces of New Jersey and Maryland, from the Delaware counties and in time even from the Shenandoah valley of Virginia came still more agricultural products.

Much of Philadelphia's export trade sailed to the West Indies, where foodstuffs u-ent to the plantations in exchange for sugar, molasses or rum. Directly or indirectly the sugar trade in turn gave Philadelphia merchants staples which they sold in England and there bought manufactured goods. A brisk wine trade developed with the Madeiras. In time of war with France, *i.e.*, continually through Philadelphia's colonial history, many of the West India traders were not above turning to privateering; even certain Quaker merchants seem to have formed connections with privateers. Whether righteous or not, this activity also brought swift increments of wealth. In 1696 the governor of the province reported that "Philadelphia in fourteen years is become equal to the City of New York in trade and riches." Customs receipts increased from £1,500 in 1699 to £8,000 in 1702. By the middle years of the 18th century, Philadelphia was surpassing even Boston in volume of commerce.

Often overlooked, but of equal importance with Philadelphia's \Vest India commerce and more important than her trade with Europe, was her coastwise commerce. By the 1730s Pennsylvania had become the granary for the tobacco and rice colonies of the south as well as for the West Indies. In addition and more important, Philadelphia had developed an exceedingly profitable business with New England, which produced neither wheat nor bar iron sufficient to its needs; therefore these products sailed from Philadelphia to the colonies to the north in exchange for merchandise, coins and bills of exchange. In 1752, 103 vessels cleared Philadelphia for New England. The favourable balance of this trade in the mid-18th century amounted to over £52,000 annually.

Philadelphia manufactories began to develop both as a result of the city's commercial growth and as a cause of further growth. After 1725 the Delaware valley became a shipbuilding centre; in 1726 the Delaware yards turned out only 7 ships but during the next decade and a half they built 380 vessels. The yards were soon the most extensive in the colonies. The demands of the port stimulated cooperage establishments. Flour mills appeared in the city and in 1690 the first American paper mill began to operate along the Wissahickon creek. By 1718 the cordwainers (workers in leather) were numerous enough to incorporate a craft. Fourteen rum distilleries, three steel furnaces and an anchor forge, four carriage and wagon shops, an establishment for the manufacture of fire engines and a glass works soon appeared. A distinct merchant class developed but there also emerged a growing lower class of mechanics and artisans.

With urban growth came civic improvements. In the mid-18th century Philadelphia ceased to be a wilderness outpost and became a community whose appearance rivaled that of European cities of comparable population. Public street-lighting was instituted in 1752 and in the 1760s the streets began to be paved, while 500 public pumps were set up to supply the citizens with water. Public buildings of substantial size began to appear, many of which had grace as well as size and were among the architectural achievements of colonial America. Most notable was the state house, now known as Independence Hall, the construction of which began in 1732. Attorney General Andrew Hamilton had drawn up plans for a civic centre and shared with master carpenter Edmund Woolley the designing of the building itself; in it they gave Philadelphia an imposing structure of balanced masses in the 18th-century style.

During the 18th century the population of Philadelphia spilled beyond the original northern and southern boundaries, Vine street and South street, to form the suburbs of Southwark, the Northern Liberties, Passyunk and Moyamensing. The total population of

the city and suburbs grew from 13,000 in 1740 to 22.000 in 1760 and to 40.000 by 1775. By that time Philadelphia was the largest city in the colonies (by about 15,000 persons) and in size probably ranked second only to London among empire cities.

By the 1770s Philadelphia was a centre of learning and culture as well as of trade and industry, not only by American standards but by European as well. Its growth in these directions had once been slow; in the beginning, of course, its settlers were too busy wresting a livelihood from the wilderness to bother with things of the mind, and even as late as the 1720s visitors were impressed with the way in which business swallowed up all other concerns. But a new era was coming. Historians often regard 1726 as marking the beginning of the change, for in that year Benjamin Franklin returned to the city from his first visit to England, still an obscure printer but destined to become the civic leader of Philadelphia and to guide his city into new paths of intellectual achievement. Among his contributions to the cultural life of colonial Philadelphia were his organization of certain' alert and ambitious young mechanics of the city into the mutual improvement society which became the Junto; his assistance in the development of the Library Company of Philadelphia, the first subscription library in America, out of the Junto; and his leadership in the foundation of the American Philosophical society and in the establishment and growth of the Philadelphia academy, out of which the University of Pennsylvania was to arise.

But important as he was, Franklin was merely first among equals in a general cultural awakening. The way for Franklin had been prepared (albeit by a man who did not like him) by James Logan, William Penn's secretary, the collector of a private library of more than 2,000 volumes. Among Franklin's Philadelphia contemporaries were the botanist John Bartram, correspondent of Linnaeus; the physician John Morgan, who first discovered that pus is a secretion of the blood vessels; Ebenezer Kinnersley, who rivaled Franklin as a pioneer investigator of electricity; and the astronomer David Rittenhouse. a leader in the observations of the transit of Venus across the sun in 1769 which were of great importance in determining the parallax of the sun. In the arts and letters, Benjamin West ventured his first artistic efforts in Philadelphia; Thomas Godfrey, Jr., wrote the first American tragic drama; and the literary circle which formed around Provost William Smith of the College of Philadelphia is worth mentioning if only to call attention to Smith, a man whose personal efforts did much to make Philadelphia an intellectual centre.

Colonial and Republican Capital. — Its general prominence. together with its central location, led to the selection of Philadelphia as the meeting place of the first continental congress in 1774 and the city embarked on its turbulent revolutionary career. The first continental congress met in Carpenters' hall, and there drew up the continental association and the Declaration of Rights and Grievances, steps which led the colonies almost directly into war against the mother country. In 1775 the second continental congress met in the state house, acknowledged the fighting around Boston by organizing the continental army under the command of George Washington and, by thus embarking on rebellion, took the course which led to the adoption of the Declaration of Independence the following year. The role of Philadelphia as the headquarters of the revolutionary government made it the objective of the British general Sir William Howe's campaign of 1777; after Howe defeated Washington's forces south of the city the congress fled and Philadelphia was occupied by the British through the winter of 1777–78. The continental army camped outside the city at Valley Forge, and fighting occasionally flared up at such places as Germantown and Barren Hill on the outskirts. In the spring of 1778, a change of generals and of war plans led the British army to evacuate the city and to return across New Jersey to New York, opening the way for the reconvening of the congress in Philadelphia.

The British occupation underlined the fact that the American Revolution made Philadelphia a city much divided within itself. Certain leading families were obviously not unhappy to welcome the British, and many Philadelphians participated gladly in the gay social season which the British officers improvised. Many Philadelphians, like many other Americans throughout the colonies, could not easily abandon the loyalty nhich as British subjects they had always felt to the crown. Mixed with their emotions of loyalty, furthermore, was the resentment which many members of the upper classes had come to feel toward a Revolution, which in Philadelphia had become peculiarly the cause of the lower classes, the mechanics and artisans. By the opening of the Revolution, Philadelphia society had become distinctly stratified. The growth of commerce had been highly profitable to some Philadelphians and had opened wide economic divisions nithin the population, so that social and economic leadership was held tightly by a comparatively small group of merchants, professional men and proprietary agents. Political leadership resided in the same hands, since the franchise was limited to men who possessed a freehold estate or personal property to the value of £50. By 1776 only about 1 in 50 of the male inhabitants could cast a ballot. The political power of the upper class further enhanced its economic power, for the city government frustrated competition from below through its regulations of markets, auctioneers and peddlers. When the Revolution broke out, the aristocrats, naturally conservative, hesitated to endorse the movement. But the mechanics, artisans and labourers took advantage of that hesitation to discredit the aristocrats as an unpatriotic class and thus to make the independence movement also a movement for increased democracy. They joined with equally discontented farmers from the back country of Pennsylvania to establish the radical Pennsylvania constitution of 1776, which allowed every adult male taxpayer to vote and hold office in the state government. It was against this background of a rising of the lower classes that much of the Philadelphia aristocracy welcomed the British occupation in 1777.

The end of the occupation brought back to Philadelphia both the continental congress and the ambitious local democratic party, but the withdrawal of the British and the eventual American victory in the Revolution did not open the way for the unmitigated triumph of either group. The continental congress was transformed into the congress of the Articles of Confederation, and during the 1780s that congress, meeting sometimes in Philadelphia but sometimes elsewhere, sank gradually into impotence. The success of the Pennsylvania and Philadelphia democrats in the state constitution of 1776 gradually gave way before a counter-revolution which culminated in the conservative state constitution of 1790. The economic power and social prestige of the Philadelphia aristocracy emerged from the war largely unimpaired, and these elements aimed at a substantial recapture of political power. In 1789 the state assembly passed an act of reincorporation of Philadelphia which was considerably more democratic than the colonial charter but nevertheless favourable to the merchant aristocracy. The vote mas restricted to freeholders, who elected 30 common councilmen for three-year terms and 15 aldermen for seven-year terms. The aldermen chose the mayor from among their own number. Significantly, the first mayor under the new government, Samuel Powel, had also been the last mayor under the colonial charter.

As for national affairs the Constitutional Convention laboured in the Philadelphia state house during the summer of 1787 with the Philadelphians Benjamin Franklin and James Wilson among its most influential members. The congress of the new government first met in New York city, but in 1790 it voted to establish the seat of the new government at Philadelphia for ten years before moving to the permanent capital on the Potomac river.

The decade 1790–1800, when Philadelphia was once again the U.S. capital, constitutes something of a golden age in Philadelphia history. Political, economic and cultural leadership of the new nation were all concentrated in Philadelphia. Congress and the US, supreme court sat in new buildings flanking the state house. Presidents Washington and John Adams maintained a republican court, centring on the president's mansion on Market street near Sixth, whence Washington proceeded through the streets in a cream-coloured French coach, ornamented with cupids and flowers. The leaders of the new nation combined with the aristocracy of the city to give Philadelphia a social life distinguished

for its conversation as well as for its gaiety and glitter.

The Philadelphia economy had by this time readjusted from the dislocations of the Revolution and was growing at least as rapidly as before the war. The shipyards were prospering, building vessels of such quality that even Boston, New York city and Baltimore papers advertised ships "built of the best white oak and finished off in the neatest manner on the Philadelphia plan." The US. navy yard had been established, building during the 1790s the frigate "United States," on the plan provided by the Philadelphia designer Joshua Humphreys for six sister ships, including the "Constitution." The merchant ships built in Philadelphia yards and sent out by Philadelphia merchants ventured into new quarters of the globe. Thomas Willing was instrumental in organizing the Philadelphia, Boston and New York city venture which in 1784 sent the first American trading ship to China, and thereafter until the middle of the 19th century the city uas responsible for one-third of the China trade of the United States. Philadelphia traders, at last outside the British navigation system, found new ports in Europe; coastwise trade also continued to expand. In 1793 the total value of Philadelphia exports was $6,958,736, exceeding those of all New England by $1,717,572 and of New York city by $2,934,370. Behind Philadelphia trade still stood the wealth of the hinterland, which in 1790, for example, sent 150,000 bu. of wheat to the metropolis from the upper Susquehanna country alone.

The Philadelphia golden age of the 1790s was not without a few scars. During the early years of the decade mechanics and artisans aroused by the French Revolution became increasingly noisy in their discontent with the conservative turn of C.S political events, to the point where some alarmed property owners began to fear new violence. Conservatives and democrats alike suspended political agitation. however, in the face of the great yellow fever epidemic of 1793, in which perished between 4.000 and 5,000 people, $\frac{1}{10}$ of the city's total population.

Meanwhile Philadelphia moved to leadership of the new nation in still another area, finance. Prerevolutionary America had possessed no banks in the modern sense of the term, but from the establishment of the first such institution, the Bank of North America, in 1781, the growth of an American banking system was rapid. The Bank of North America nas chartered by the Confederation congress largely at the urging of Robert Morris, its principal purpose being the financing of the Revolution. Its location in the city assured Philadelphia's position as the first financial centre of the United States. State-chartered banks quickly followed in various places and the charter of the Bank of North America was suspended briefly during the 1780s; but the priority of Philadelphia in banking plus its general economic leadership gave the city continued financial pre-eminence. For this reason as well as because Philadelphia was the national capital, the first Bank of the United States was established there in 1791 and remained even after Philadelphia ceased to be the political capital. After the charter of that bank expired in 1811, state-chartered banks reassumed first place in a financial world of which Philadelphia remained the centre. Stephen Girard of Philadelphia emerged as the principal financier of the War of 1812 and nhen congress chartered a second Bank of the United States in 1816 it was located in Philadelphia. Through the second bank and the activities of Girard, Philadelphia retained financial leadership until the 1830s. despite the fact that by that time economic supremacy in other matters had passed to New York city.

The *19th* Century.—By Andrew Jackson's presidency the golden age of Philadelphia had long since ended. The U.S. capital moved to Washington in 1800 and the capital of Pennsylvania already had departed from Philadelphia in 1799. The removal of the federal capital cast something of a shadow upon Philadelphia's cultural leadership. presently superseded by that of Boston and New York city. Philadelphia culture in the 19th century was to be distinguished by the presence of such notables as the Peales, Gilbert Stuart, Thomas Sully, Henry Inman and Thomas Eakins in painting. William Rush in sculpture, William Strickland and Thomas U, Walter in architecture, and Walt Whitman as well as lesser lights such as Bayard Taylor and S. Weir Mitchell in literature. But the relative position of the city was far below what it had been; except possibly in painting, there was no longer in Philadelphia a community of national cultural leaders, but simply a collection of various individual luminaries.

Commercial ascendancy passed from Philadelphia partly because its port could not match New York city harbour. The approach to Philadelphia by water was far more difficult. the space for berthing of ships was limited and the port was on occasion impeded by ice in winter (the Delaware is fresh water at Philadelphia). The riches of the Philadelphia hinterland as compared with the narrow Hudson valley had more than offset the deficiencies of Philadelphia harbour during the colonial and early republican periods. but in the early 19th century there was opened to New York city a hinterland far richer and vaster than Philadelphia's: the old northwest, the Great Lakes and Ohio river country. Between Philadelphia and this region rose the barrier of the Appalachian mountains; between New York city and the northwest stretched the open avenue of the Hudson and Mohawk valleys. The completion of the Erie canal in 1825 added immeasurably to the already great convenience of that avenue. Promptly after the opening of the canal. the census of 1830 revealed that for the first time the population of New York city exceeded that of Philadelphia. Even earlier, in 1820, Philadelphia's exports had been only some $6,000.000 to New York city's $12,000,000, while Philadelphia imports had stood at $9,000,000 as against $23,000,000 for New York city.

Philadelphia did not yield its population and economic leadership without a contest. The city sought an answer to the Erie canal, a route of its own into the great valley beyond the mountains. Its effort to solve the problem was extraordinary, for the city promoted and helped to finance the completion of the amazing state-owned "Pennsylvania system" west to Pittsburgh. Beginning in 1834, passengers could travel from Philadelphia to Pittsburgh in 4 days, freight in 12–14 days, over a 394-mi. route combining railroads, canals and inclined planes.

Extraordinary, even heroic, as it was, the Pennsylvania system did not serve to recapture Philadelphia's advantage over New York city; the Erie canal was a more convenient freight-handling system. But even a westward transportation system equal to New York city's could not compensate for the inferiority of the Philadelphia port. This fact emerged clearly after the Pennsylvania railroad was completed to Pittsburgh in 1854; it became one of the great railroads of the world but New York city continued increasingly to outdistance Philadelphia in population, wealth and general economic importance.

With its national pre-eminence lost. Philadelphia embarked on a less spectacular career as a regional urban centre, but the city did not cease to be a major one; it remained second in size among U.S. cities until Chicago finally surpassed it in 1890. The agricultural wealth of the immediate hinterland remained and as the 19th century proceeded this area increasingly supplied industrial wealth as well. Philadelphia looked relatively less to its harbour and more to its inland resources to sustain itself. It developed its own manufactures. The textile industry was among the first to rise in the Cnited States as in other nations in the early stages of industrialization, and in that industry Philadelphia was a leader. By 1825 there were 33 cotton and woolen factories in the city and its vicinity, 20 of them alone working 28,750 spindles. Iron foundries and glass works also secured an early prominence. After 1831 Baldwin locomotives and, still later, Stetson hats carried the name of Philadelphia through the 19th-century world. Philadelphia shoes. especially women's shoes, won note throughout the United States. The city became the principal distributing centre for the anthracite coal fields of northeastern Pennsylvania. which after about 1820 began their era of prosperity. The relative loss of emphasis upon the sea did not bring the abandonment of the shipbuilding industry; the William Cramp and Sons Ship and Engine company, founded in 1830, became the principal builders of the U.S. naval vessels during the 19th century and the builders of merchant ships, foreign and domestic, as well.

With industrial growth, the city's population increasingly spilled over the political limits, which had not changed since the first

drawing of the town plan. These limits confined the city to an area of two square miles. Beyond that area, much of Philadelphia county was as densely populated as the city itself. There political subdivisions had sprung up haphazardly until the county included 29 such units, variously organized as cities, townships or boroughs; nearly all of them lay immediately adjacent to each other, constituting for all common-sense purposes a single city but frustrating each other through their political independence. In 1854 the Pennsylvania legislature at last acted to remedy this chaos, passing the Consolidation act, which annexed 28 of the 29 subdivisions into Philadelphia.

The city shared in one way or another in most of the principal national events of the 19th century. The influx of Irish and German immigrants to the United States during the mid-19th century called forth in reaction the first major American nativist movement. In Philadelphia, nativism culminated in a series of riots extending through the spring and summer of 1844, during which two Roman Catholic churches were destroyed by fire, seven civilians and two militiamen were killed and many more persons were injured. Earlier the slavery issue had led to antiabolitionist riots, and this issue continued to divide the city during the Civil War. Philadelphia Quakers had a long history of antislavery activity, but on the other hand prewar Philadelphia was a principal banking and mercantile centre for Southern agriculturalists and had many Southern business connections. Some Philadelphians supported the Union war effort only lukewarmly even after Ft. Sumter, but for the most part the city rallied with determination to the Union cause. Philadelphians followed the leadership of Jay Cooke in contributing to war finance, and their Unionism tended to become more pronounced after the Confederate invasion of Pennsylvania in 1863. The Union league was an expression of Philadelphia's support for the Union and membership in the league soon became a mark of status in the city.

Philadelphia was the site of the 1876 Centennial exposition commemorating the adoption of the Declaration of Independence. Financed largely by Philadelphia citizens, the exposition opened 180 buildings along the Schuylkill to more than 8,000,000 visitors. The emphasis of the exposition was upon industrial and commercial technology, in which the United States already ranked as a leading nation of the world.

Journalists remarked during the exposition that the political progress of the Gnited States since independence had not matched material progress; the era was that of "Grantism." The same comment applied to Philadelphia. After the Civil War, the Republican party used its record as a war party, its program of friendship with business interests and an astute cultivation of every city precinct to win a stranglehold on Philadelphia politics. Philadelphia and Pennsylvania were in the hands of the machine led first by Sen. Matthew Stanley Quay and then by Sen. Boies Penrose. In the 20th century a local machine led by the brothers George A., Edwin H. and William S. Vare successfully challenged the statewide Penrose machine for control of Philadelphia, but with no change in the quality of city government. Lincoln Steffens not inaccurately described turn-of-the-century Philadelphia' in a phrase that has become a byword, "corrupt and contented."

The city remained contented in its corruption partly because the old problem which had led to the Consolidation act of 1854 had emerged again: population had spilled beyond the city's political boundaries. Many civic leaders moved into the suburbs and out of city politics. They worked in the city but did not live in it and they found bad government tolerable. At the same time the Philadelphia machine, like its contemporaries elsewhere. drew many of its votes from the new immigrants who came crowding into U.S. cities from southern and eastern Europe unprepared for the responsibilities of democratic citizenship. As in other U.S. cities, the new immigrants sought security by forming neighbourhoods along ethnic lines. The long history of many Philadelphia neighbourhoods as independent political entities made for an unusual degree of neighbourhood parochialism, and the forming of ethnic neighbourhoods intensified that tendency.

The 20th Century —In the 20th century, especially after World War I, the immigrants and their children gradually became leks docile voters. Other factors worked also to undermine the power of the city machine, not the least of which mas the growth in the 1930s of federal social welfare programs under the New Deal. Providing social security of various sorts in return for votes had been one of the bulwarks of all urban political machines; the federal government removed such welfare measures from local politics. For these reasons and others, by the mid-20th century traditional machine dominance had much decayed.

Furthermore, the decline of machine politics was only one of a complex of changes stirring in Philadelphia in the middle of the 20th century. By that time the phrase "corrupt and contented" was no longer so accurate; a new sense of civic responsibility had arisen. The citizens alnays had been proud of their city but that pride was becoming difficult to sustain. Rapid but unplanned industrial and population growth had created slums that were among the worst in the world. A real property survey made in 1934 disclosed that of 506,420 dwellings in the city, 19,035 were unfit for occupancy, while another 28,768 were in need of major repairs. About 19,000 houses were without bathing facilities of any kind. Many of the slum dwellings were of the distinctive "bandbox" type, three stories high but only one room wide and deep. Such were depression conditions in the 1930s, but the years during and after World War II scarcely lightened the housing problem. 4 large influx of Negroes injected racial issues into already serious difficulties and many parts of Philadelphia became overcrowded Negro ghettoes. At the same time Philadelphia suffered from the common problem of all urban centres in the automobile age, an accelerated decay of the central city as population, industry and even commerce moved into the suburbs. The only virtue in all these developments was that they made it impossible for proud citizens to remain contented; they stimulated the new sense of civic responsibility.

Civic Redevelopment. — The Philadelphia Redevelopment authority, established under a state law of 1945, was constituted under a board appointed by the mayor. Its purpose was to eliminate blighted areas and, in co-operation with both public and private enterprise, replace them with socially and economically sound projects. The authority mas to make use of federal, state and city funds. By 1955, 19 areas of the city, comprising about 11.5% of the total area and containing more than 20% of the population, had been scheduled for redevelopment. The activities of the redevelopment authority in such areas included construction of middle- and low-income housing, the rehabilitation of certain old row houses, the development of new industrial sites, the conversion of blighted areas into improved and enlarged campuses for several of the city's universities, the provision of new parks and playgrounds and projects for automobile parking and street widening. In many of its activities the redevelopment authority co-operated with the Philadelphia Housing authority, a similar agency outside the regular structure of city government, whose purpose was to clear slum areas and to build on slum and open sites safe and sanitary dwellings for low-income families. Meanwhile, private enterprise rebuilt part of downtown Philadelphia into a planned commercial area, Penn Center.

Thus Philadelphia sought to renew its blighted areas and to assure its citizens of adequate housing, and it made substantial progress toward those goals. But social problems spawned during several centuries of unplanned growth could not be remedied in a decade or tno; large blighted areas remained and new ones tended to appear as old ones were eliminated. Furthermore, new housing alone could not cope nith the fact that much of the city's housing problem was also a problem in race relations. Viewing the growth of an already large Negro minority (about 25% of the population in 1960), city leaders considered experiments which mould seek to prevent new housing developments from becoming Negro ghettoes.

Government. — Important to the progress of the various redevelopment programs of the mid-20th century was a newly reorganized city government. From its first incorporation under William Penn. Philadelphia was governed under various charters, all drawn up by the Pennsylvania legislature. After the Revolution, the charters tended to model the structure of municipal

government upon the state and federal governments, with a bicameral legislature in the city council, an executive in the major and his elected and appointed assistants and a municipal judiciary. This system brought a multiplicity of offices and a diffusion of responsibilities grossly inappropriate to city government. Under the charter of 1885, for example, the bicameral city council grew to a total membership of 145, the largest municipal legislative body in the United States, so large that it tended to strangle its own usefulness. The charter of 1919 remedied this particular problem by creating a unicameral council whose membership ranged from 20 to 22. But the charter of 1919 still failed to meet the full needs of a modern city, especially in that the mayor remained too weak an executive to assure efficient or even honest administration.

Philadelphians came to conclude that what their city required was a charter drawn up by its own inhabitants, who understood their own needs. A fight for such a charter vent on sporadically after 1922, when an amendment to the state constitution made possible municipal home rule. In 1951 the efforts of a local Committee of Fifteen combined with revelations of embezzlements by city officeholders to bring the movement for reform to a climax. In that year a special Philadelphia commission drew up a hoine rule charter, which was accepted by the voters; it went into effect early in 1952.

Under the 1952 charter, the administration is in the hands of a relatively strong mayor, elected for a four-year term. Executive responsibility is focused upon the mayor, who appoints and removes the principal administrative officers and controls expenditures. Furthermore, the mayor participates in the legislative function by recommending measures to the council, exerting his influence for their passage and exercising a power of veto which can be overridden only by a $\frac{2}{3}$ vote of the membership of council. The mayor formulates the city budget, with the council simply voting lump-sum appropriations to each agency. The council consists of 17 members, 10 of them elected from geographic districts and 7 elected at large. While the council's administrative poners are severely limited in order to assure the responsibility of the mayor, its legislative powers are broad; it can legislate on many matters vhich before 1952 required state legislative action, notably in the fields of public health and municipal salaries.

Most municipal activities are in the hands of 14 departments, which are co-ordinated by the mayor's four principal appointees: (1) the managing director, who supervises the departments of police, fire, streets, water, public health, public welfare, recreation, licenses and inspection, records and public property; (2) the director of finance, who conducts, under the mayor. budgeting, accounting and purchasing, and supervises the departments of collections and procurement; (3) the city representative, who is the city's chief public relations officer and heads the department of commerce, through it holding responsibility for wharf and airport facilities; and (4) the city solicitor, who heads the law department which gives legal advice to city agencies and represents the city in litigation. In addition, there are various independent or semi-independent boards and commissions, such as the civil service commission.

The school district is a governmental unit completely separate from the city government. In addition to the city government and the school board, five "authorities" created for special purposes outside the regular governmental structure operate within the city. These are the Philadelphia Housing authority, the Philadelphia Redevelopment authority. the Philadelphia Parking authority. the Philadelphia Airports Improvement authority and the Delaware River Port authority, the latter an interstate body.

Philadelphia courts are part of the judicial system of Pennsylvania and thus are constitutionally separate from the city government. Their structure is that which is common to all Pennsylvania judicial districts, with the exception that Philadelphia also possesses a municipal court, with limited jurisdiction over specified civil and criminal actions, and 28 magistrates' courts, which have jurisdiction in minor civil and criminal cases and hold preliminary hearings in more serious criminal cases.

An amendment to the state constitution was passed in Nov. 1951, consolidating the Philadelphia city and county governments, with all county agencies becoming city agencies. Subsequently there was a gradual integration of the former county offices into the structure of city government.

The home rule charter and the progress of city-county consolidation did much to give Philadelphia effective government. but they also left many problems unsolved. For example, the problem which the Consolidation act sought to solve in 1854 emerged again in aggravated form. In 1960 there were 625 governmental units in metropolitan Philadelphia on the Pennsylvania side of the Delaware alone. The tendency of this multiplicity of governments was to complicate such issues as police protection, water supply and urban transportation. There was an obvious need for some measure of general metropolitan area government; but there were many obstacles, both constitutional and traditional, in its path.

Industry, Commerce and Transportation. — Theleading industries are metals and metal products, textiles, food products and chemical and petroleum products. During the mid-20th century industrial expansion was especially noteworthy in the metals industry. with the establishment at Morrisville on the Delaware of a new plant of the United States Steel corporation intended for the processing of ore from Labrador-Ungava and Venezuela. In the early 1960s, there were over 1,500,000 persons employed in business establishments. Over 500.000 of them in manufacturing.

Railroads serving Philadelphia and its industries include the Pennsylvania, of which the city is the headquarters, the Reading and the Baltimore and Ohio. Truck and motorcar transportation proceeds from the city over a highway network dominated by the Pennsylvania turnpike to the west and the New Jersey turnpike to the northeast. The Philadelphia International airport brings to the city the services of transcontinental and trans-Atlantic air lines.

Although visitors are likely to remark that in no U.S. seaport is the presence of maritime activity less evident except in the immediate waterfront area. and although the harbour has long since ceased to be the major focus of Philadelphia commerce, the port continues active. The Delaware River Port authority supervises the second largest port in the United States, surpassed only by New Work city, and the largest fresh-water port in the world.

The trend in banking in Philadelphia as elsewhere in the latter part of the 20th century was toward consolidation into larger institutions. In 1950 there were 39 commercial and savings banks in the city; in 1960 there were 27.

Education. — The Quakers who founded Philadelphia were not devoted to education with the ardour of the Puritan fathers of New England. They favoured schooling in the rudiments of learning and in practical subjects but were inclined to regard higher learning as a form of worldly ostentation. Therefore they early founded elementary and some secondary schools but they did not hurry to do more. William Penn and his council hired a schoolmaster in 1683 and in 1689 leading Quakers established the Friends' Public school, now the Penn Charter school, which was intended to be open to students of poor families without fee. Not until the mid-18th century, however, was an institution approaching collegiate rank inaugurated. In 1755 various antecedents coalesced to form the College of Philadelphia. By that time the original emphasis on modesty in learning as in living had lost ground among many Philadelphia Friends and in any case the intellectual leadership of the city had passed largely to Anglicans and disciples of the Enlightenment. Once established, the college rose rapidly to prominence among kindred institutions of British America. It mas noteworthy among colonial colleges especially for the emphasis upon scientific studies and modern languages which its founders, including Provost William Smith, sought to place beside the traditional preoccupation with the classics. But it had to pass through further vicissitudes during the revolutionary era before it emerged as the University of Pennsylvania.

Meanwhile numerous private and church-related elementary schools and academies had made their appearance, with Germantown academy (1780) and Episcopal academy (1785) notable among the latter. During the late 18th century proposals for state-sponsored public education began to arise but it mas not until 1818 that Pennsylvania took a substantial step in that direction

by establishing in Philadelphia a school district where pupils might obtain education at public expense. By 1830 more than 34,000 children had received instruction. with girls between 5 and 13 and boys from 6 to 14 eligible for its free services.

The Philadelphia school district now maintains public schools through senior high school. The Roman Catholic diocese of Philadelphia maintains an extensive educational system, including elementary, special and high schools. There are in addition over 40 other private schools.

The University of Pennsylvania remains the largest educational institution in Philadelphia (see PENNSYLVANIA: *Education*), followed closely by Temple, a private university founded in 1888. Other institutions in the city include the College of Pharmacy and Science (1821); Jefferson Medical college (1825); Hahnemann Medical college (1848); Women's Medical college (1850); St. Joseph's, a Roman Catholic college for men (1851); the Protestant Episcopal Divinity school (1862); Lutheran Theological seminary (1863); La Salle, a Roman Catholic college for men (1863); St. Vincent's Roman Catholic theological seminary (1868); Drexel Institute of Technology, a private coeducational institution (1891); and Dropsie college for Hebrew and Cognate Learning (1907). In the metropolitan area are Haverford (1833), Swarthmore (1869) and Bryn Mawr (1880), colleges Quaker in affiliation or origin, and Villanova, a Roman Catholic university (1842).

Cultural Activities.— During the 18th century, Philadelphia led the British colonies in the establishment of libraries open to the public. In 1731 Benjamin Franklin and his associates founded the Library Company of Philadelphia, the first subscription library in America. Three other such libraries had been founded when the first public library in the colonies, the Loganian library, based on James Logan's collections, was opened in 1760. By 1792 the Library company had absorbed the other collections. Meanwhile the American Philosophical society had also begun a noteworthy library and the Pennsylvania hospital had established the first medical library in the United States. The 19th century witnessed the founding of the Philadelphia Bar Association Law library (1802), the Philadelphia athenaeum (1814), the German society library (1817), the Mercantile library (1821) and the Philadelphia City institute (1852). In 1891 was chartered the Free Library of Philadelphia, the present municipal library. In 1943 this institution received custody of the Library company and the Loganian library, and in the following year of the Philadelphia City institute and the Mercantile library, thus establishing a unified system. Among the approximately 280 private and special libraries in Philadelphia, that of the University of Pennsylvania is outstanding. The libraries of the Historical Society of Pennsylvania and American Philosophical society are especially rich in documents relating to American history.

Philadelphia was also something of a pioneer among U.S. cities in the establishment of museums; soon after the Revolution Charles Willson Peale, the artist, opened his famous museum in Independence Hall, a hodgepodge collection of stuffed animals, a mastodon skeleton, curious gadgets and portraits of American patriots; in assembling it Peale apparently was unable to decide whether his chief purpose was education or entertainment. Most of the portraits remain in Independence Hall.

Philadelphia has attempted to sustain the artistic tradition begun by Charles Willson Peale and. before him, Benjamin West. There are in the city about 40 art associations, schools, museums and collections. public and private. The Pennsylvania Academy of the Fine Arts, oldest art institution in the United States, dates officially from a charter of 1805, but unofficially from Peale's efforts to organize an art school beginning in 1791. Its schools remain among the most distinguished in the United States. Thomas Eakins was long an instructor, and among those he stimulated were the artists of the Henri group, or the Ash Can school (see HENRI, ROBERT). The permanent collection of the academy is rich in examples of the evolution of U.S. art.

The Philadelphia Museum of Art, a huge Greek temple standing on the leveled top of Fairmount, offers collections giving a broad view of the development of art throughout history. It has noteworthy "period" rooms, outstanding special collections such as the Arensburg collection of 20th-century painting and much U.S. and Philadelphia material. Associated with it is the Philadelphia Museum School of Art, founded in 1877–78.

In the promotion of science, the American Philosophical society continues in the path opened by Franklin and his fellow scientific leaders of 18th-century Philadelphia. The Academy of Natural Sciences (1812), the oldest such institution in the United States, has sponsored numerous explorations, including Adm. Robert E. Peary's voyage of 1892 which proved that Greenland is an island. It maintains a museum in its headquarters building. The Franklin institute (1824) emphasizes the promotion of applied science and also maintains a large public museum.

The theatre in colonial Philadelphia, as elsewhere in colonial America, had to surmount obstacles both in public attitudes and in law in order to establish itself. Itinerant performers drew crowds to the outskirts of the city as early as the 1720s, but the usual date given for the establishment of the Philadelphia theatre is 1754, when Lewis Hallam's company arrived from London. Within little more than a decade, in 1766, the Southwark theatre was erected, and the next year occurred the performance of Godfrey's The *Prince* of *Parthia,* the first American tragedy. Thereupon the Philadelphia theatre entered upon a century of imposing development. The completion of the first Chestnut Street theatre in 1793 was an architectural as well as a theatrical event. The Walnut street theatre, opened in 1809, remains as the oldest existing theatre in the United States. The Arch street theatre (1828) became the most famous of all Philadelphia theatres, associated with Joseph Jefferson and the Drews. Late in the 19th century, however, a theatrical decline set in, as the Philadelphia stage became increasingly a satellite of the New York city stage.

Music in Philadelphia began with the German immigrants; the first recorded recital was given by German mystics, the Hermits of the Wissahickon, who in 1703 played the viol, oboe, kettledrum and trumpet at an ordination service in Old Swedes' church. During the heyday of the colonial city a wider musical interest developed. An Italian music master helped encourage the art; the first public concert mas given in 1757; and Francis Hopkinson emerged as the first American composer of any importance. Organized cultivation of music was a product of the 19th century, with the organization of the Harmonic society (1802), the Haydn society (1809), the Cecelia society (1824) and. most important, the Music Fund society (1820), which built its own hall in 1824 and established a school of music there. At this hall the principal performances took place until the opening in 1857 of the Academy of Music, which with its remarkable acoustics still serves as the centre of Philadelphia musical activities. It is the home of the Philadelphia symphony orchestra.

Hospitals.— Philadelphia has been a medical-surgical centre since the 18th century. The Pennsylvania hospital (1751) was the first to be established in the British colonies and it early distinguished itself especially in the study of mental diseases. The medical school of the University of Pennsylvania (1765) is the oldest in the country. A Philadelphia medical society was organized in 1768 and the College of Physicians and Surgeons was established in 1787; by the mid-20th century the latter society had gathered a medical library of about 175,000 volumes. There are more than 40 general hospitals and more than 30 special hospitals and dispensaries within the city.

Parks and Recreation.— The Philadelphia city park system of more than 7,500 ac. includes large and small parks scattered through the city, athletic fields and play areas, maintained by the board of education, and Fairmount park, supervised by a special agency of the city government. It comprises almost 4,000 ac. and extends 10 mi. along the Schuylkill river and Wissahickon creek, including within its boundaries the beautiful Wissahickon and Cresheim valleys, the Philadelphia Zoological gardens, oldest in the United States. Robin Hood Dell for summer concerts, 15 historic mansion houses, 2 surviving buildings of the Centennial exposition, more than 50 sculptural groups and figures and many miles of driveways, avenues, footpaths and bridle paths. Throughout the park system there are varied recreational facilities, including golf; baseball, football, swimming, boating and tennis. A

special board of trustees administers Convention hall, which can be used as an indoor sports arena. Independence Hall is now a part of the Independence National Historic site, 18 ac., administered by the National Park service since 1951. The Old Custom House, a fine example of Greek revival architecture and site of the second Bank of the United States, is also a part of the national park and monument system.

PHILADELPHIANS, a sect of religious mystics, founded in London in the latter part of the 17th century. In 1652 John Pordage (1607–1681), rector of Bradfield, Berkshire, gathered together a few followers of Jakob Boehme, the chief of whom was Jane Lead or Leade (1623–1704). Mrs. Leade had been from girlhood of a mystical temperament, and experienced phantasms which she recorded in a diary entitled *A Fountain of Gardens,* beginning in 1670, in which year the Philadelphian society was definitely organized. In 1693 some of Mrs. Leade's writings were translated into Dutch, and by this means and her acquaintance with Francis Lee (1661–1719), an Oxford scholar who studied medicine at Leyden and became her son-in-law, a connection was opened up with Germany and Holland. In 1703 the Philadelphians drew up their confession. but they made no further progress and soon declined, the Dutch brand withdrawing and the English government forbidding the society to meet.

PHILADELPHUS, a genus of the Saxifragaceae (*q.v.*), with about 70 species and more than 100 horticultural varieties, characteristic of North America, southern Europe and eastern Asia. They are commonly known as mock orange and are often referred to as syringa, which, however, is the proper generic designation of the lilac. The characteristic odour is the chief reason for the selection of the name mock orange to designate these plants. They are all deciduous shrubs with opposite entire or toothed leaves, the pith being solid, the lateral buds hidden in the leaf axils. The often showy flowers are solitary or arranged in terminal or lateral racemes, always 4-merous, the petals mostly white, in some varieties somewhat purplish at the base, and with numerous stamens. The fruit is a capsule with many small seeds.

These shrubs are much planted in temperate regions because of their conspicuous white flowers which are frequently very fragrant. The species can be cross fertilized readily and much hybridizing has been done. Some of the species grow unusually well in dry soils and endure the trying conditions encountered in city gardens. The mock orange is subject to few insect pests and plant diseases and is thus justly popular as an ornamental plant. The growth habit is usually upright with arching branches, most of which originate at the base of the plant.

ROCHE

PHILADELPHUS, COMMONLY KNOWN AS MOCK ORANGE

Some varieties are not more than 2 ft. high, others attain a height of 15 ft.

The size of the flower and degree of fragrance varies. Some, like *Philadelphus hirsutus,* P. *pekinensis* and *P. subcanus,* have flowers only three quarters of an inch in diameter, while the flowers of such varieties as Belle Etoile, Bicolore and Argentine attain a size of two inches or even more. Many of the species have single flowers but in some hybrids such as Glacier, Girandole and Virginal the flowers are double.

Fragrance varies considerably. some species and varieties being odourless and others, like the old-fashioned P. *coronarius,* being very fragrant.

See A. Rehder, *Manual of Cultivated Trees and Shrubs* (1940). (E. D. MI.)

PHILAE, an islet in the Nile above the first cataract, of great beauty and interest, but after the completion of the Aswan dam in 1902 submerged except for a few months yearly, when the water was allowed to run freely through the sluices of the Aswan dam. Philae marks also the end of the cataract region. Ancient graffiti abound in all this district, and on Bigeh, a larger island adjoining Philae, there was a temple as early as the reign of Tethmosis III.

About 350 B.C. Nekhtnebf, the last of the native kings of Egypt, built a temple to Isis, most of which was destroyed by floods. Ptolemy Philadelphus reconstructed some of this work and began a large temple which Ptolemy Euergetes I completed, but the decoration, carried on under later Ptolemies and Caesars, was never finished.

The little island won great favour as a religious resort, not only for the Egyptians and the Ethiopians and others who frequented the border district and the market of Aswan, but also for Greek and Roman visitors. One temple or chapel after another sprang up upon it dedicated to various gods, including the Nubian Mandulis. Ergamenes (Arkamane), king of Ethiopia, shared with the Ptolemies in the building.

Besides the temple of Isis with its birth temple in the first court, there were smaller temples or shrines of Arsenuphis, Mandulis, Imuthes, Hathor, Harendotes (a form of Horus) and Augustus (in the Roman style), besides unnamed ones. There were also monumental gateways, and the island was protected by a stone quay all around with the necessary staircases, etc., and a Nilometer. The most beautiful of all the buildings, an unfinished kiosk inscribed by Trajan, became well known under the name of "Pharaoh's Bed."

The decree of Theodosius (A.D. 378), which suppressed pagan worship in the empire, was of little effect in the extreme south. It was not until the reign of Justinian, A.D. 527–565, that the temple of Philae was finally closed, and the idols taken to Constantinople. Remains of Christian churches were disclosed by the thorough exploration carried out in 1895–96.

The tops of most of the buildings and the whole nucleus of the temple of Isis to the floor remained all the year around above the water level until the dam was raised another 26 ft.—a work begun in 1907—when the temples were entirely submerged except during July–October. But the beauty of the island and its ruins and palm trees, the joy of travelers and artists, almost vanished.

PHILANTHROPY. Philanthropy, which literally means "love of mankind," is a term now often preferred to the older and more homely word "charity." It is a comparative newcomer to the English language and does not seem to have been commonly employed before the 18th century, though Jeremy Taylor used it in one of his sermons about 1650. In modern parlance it is usually, though not always. applied to charitable enterprises on a large scale, aiming at the prevention as well as the cure of human ills.

Charity in the form of personal almsgiving began with the dawn of civilization. The closely integrated primitive tribal community had no need of it, but as soon as human societies were sufficiently differentiated to admit of rich and poor, that need arose and was met by men and women inspired by natural kindliness, by a nascent sense of social justice, or, more usually, by religious belief Practically all religions have stressed the virtues of almsgiving. "She stretcheth out her hand to the poor; yea, she reacheth forth her hands to the needy," says the Book of Proverbs of the virtuous woman; and centuries before that book was written, the Egyptian *Book of the Dead* recorded of a good man that "He gave bread to the hungry, water to the thirsty, raiment to the naked; he gave a boat to a man who had none." "Whoso giveth

to the poor lendeth to the Lord," says an ancient Christian adage; and in every age pagans, Jews, Moslems and Christians alike have been influenced by the sincere belief that he who relieves suffering in this world lays up treasure for himself in the next.

If, as was undoubtedly the case, philanthropy began with direct almsgiving, it soon spread to wider fields. Rome's greatest contribution to medicine, the hospital, developed from a refuge for sick slaves that existed in republican times on an island of the Tiber. By the 1st century A.D. private hospitals or *valetudinaria* for slaves and poor freemen had come into being and these were followed by the public hospitals of the later empire. In Christian Europe, where the care of the sick was considered a primary religious duty, hospitals, lazar houses and refuges for the aged and disabled flourished throughout the middle ages. Among the most famous hospitals of this period were St. Bartholomew's (1123) and St. Thomas's (1215) in London, and the great house built in Rhodes by the knights of St. John of Jerusalem in the early 14th century.

Mediaeval philanthropists built or endowed churches, monasteries, schools, chantries, colleges, almshouses and hostels for pilgrims and travellers. Roads and bridges were also maintained by the gifts of the charitable. In some European countries bridges were the responsibility of the Frères Pontiffes, an order founded in the 12th century, but in England their work was mainly done by lay guilds, or generous individuals like Sir Hugh Clopton who built a stone bridge at Stratford-on-Avon in the 15th century, with "a long causey made of stone, low walled on each side" leading up to it. An inquiry held in 1343 at Wool, Dorset, revealed that "the bridge . . . is and always has been maintained by alms, and nobody is bound to maintain it."

Doles for poor men and wayfarers were a common form of bequest in mediaeval wills. Bells were often endowed for the guidance of benighted travellers, and for many other purposes; in 1344, for instance, Margery Doubleday, a Nottingham washerwoman, left all her small estate to endow a morning bell to awaken her fellow laundresses, and so save them from losing money through oversleeping.

The dissolution of the monasteries and chantries in the 16th century deprived the poor of much customary aid. including those schools which the suppressed chantries and collegiate churches had formerly maintained. The widespread interest in learning so characteristic of the period inspired many rich men to found or endow free schools in their place, such as Christ's hospital (1552), Hugh Sexey's two schools at Bruton, or the small school for poor boys which John Lyon established at Harrow in 1590, little dreaming that it would eventually become one of England's most famous public schools. "There are a great number of Grammar Schools throughout this realm," wrote Harrison in 1577, "and those very liberally endowed for the relief of poor scholars." Bequests for apprenticing boys to various trades or rewarding the faithful service of maidservants were also common at this time.

By the early 18th century, however. the general attitude toward the education of the poor had changed for the worse. Many people sincerely felt that it was unnecessary, and even dangerous, for poor children to learn more than their catechism and such useful arts as knitting, lacemaking or carpentry. Of the existing free schools some had deteriorated and many were poorly attended because the growing custom of employing young children in industry and farm work made parents unwilling to send them to school when they could be earning money. As a result, countless children grew up without teaching of any sort and many more would have done so had it not been for the strenuous efforts of enlightened philanthropists and charitable organizations.

The Society for Promoting Christian Knowledge (formed 1698) founded nearly 2,000 charity schools during the first century of its existence. In 1780 Robert Raikes opened a Sunday school in Gloucester and so started a movement which spread very rapidly throughout the country. In 1789 Hannah and Martha More, shocked by the virtual savagery of children in the Mendip hills, opened schools for reading. handicrafts and religious teaching. Some millonners, like the Gregs of Styal, ran classes for their child apprentices on Sundays, the only day when work did not go on from dawn till dusk. Parish clergymen and landowners in many districts maintained schools for local children at their own cost. In the first years of the 19th century the National Society for Promoting the Education of the Poor in the Principles of the Established Church throughout England and Wales (1811) and the British and Foreign School society (1814) were founded, and upon these two voluntary organizations the main burden of English elementary education rested until the passing of the education act in 1870.

The sweeping economic and social changes of the 18th and 19th centuries brought many new problems for the charitable, not the least of nhich was the question of the destitute and homeless child. Foundling hospitals for unwanted babies existed in some European countries as early as the 17th century, usually in connection with convents and other religious houses. In 1741 a similar institution was opened in London by Capt. Thomas Coram, who had more than once been horrified to see deserted babies lying by the roadside.

The Marine society was founded by Jonas Hanway in 1758 for rescuing vagrant boys and sending them to sea in the royal navy. In 1867 Thomas Barnardo started a children's home in Stepney Causeway, London, the first of many "Barnardo Homes" which have since rescued thousands of destitute boys and girls. Similar work was, and still is, carried on by the Waifs and Strays society (now the Church of England Children's society), organized by Prebendary Rudolf in 1881, and the National Children's home founded by Stephenson in 1869. The Fairbridge society organization began in 1909 when Kingsley Fairbridge conceived the idea of settling English children overseas and training them for healthy and useful lives in farm schools specially founded in Canada and Australia.

The desire to prevent crime and raise moral standards led many philanthropists to concern themselves with prison reform and the cure of prostitution and begging. In Bavaria the U.S.-born Count Rumford established a system of workshops. or "houses of industry," to provide work for beggars between 1785 and 1795. In London Robert Dingley and Jonas Hanway founded the Magdalen hospital (1758), where penitent prostitutes could be trained for a better life in what Dingley insisted was not to be "thought a House of Correction but an happy Asylum." Hanway also attacked the worst features of the English prison system, but it was not until John Howard published The State of the Prisons in 1777 that serious reforms were attempted.

Howard recommended many drastic changes, including hard labour and solitary imprisonment, with better accommodation, food and ventilation, and more frequent jail deliveries (*i.e.*, clearances of the jails in order that prisoners might be brought to trial). Though he was sincerely concerned for the health and welfare of prisoners, his general outlook was harsh and unsympathetic and some of his suggestions were too severe even for the unimaginative government of his day.

A more humane reformer was Elizabeth Fry who, in the early 19th century, began working among the prisoners of Newgate and later induced parliament to remedy some of the worst abuses, both in the prisons themselves and in the arrangements for transporting convicts to Australia. A smaller but very valuable achievement was that of Sarah Martin, a poor seamstress of Great Yarmouth who, by personal work and propaganda, succeeded in establishing a system of paid work for women in jail and opportunities for employment after their release. Her work, and that of Elizabeth Fry, was afterward carried on by voluntary committees.

Philanthropy throughout this period mas many-sided and vigorous. inspired by religion, patriotism and the many new needs created by the Industrial Revolution. In England the Society for Bettering the Condition of the Poor was founded in 1795 by Bishop Barrington; in France the now world-wide organization for the relief of poverty knoun as the Society of St. Vincent de Paul was started by Antoine Oxanam and Jean-Sylvain Bailly in 1833. In the same year Theodor Fliedner established an order of Protestant Deaconesses in Germany, at whose school at Kaiserswerth Florence Nightingale was trained as a nurse. There were

then no English training schools to which she could go, and it was the knowledge gained at Kaiserswerth which enabled her to perform the heroic nork among the wounded in the Crimea for which she is best knoun, and subsequently to devote the rest of her life to the creation of an efficient nursing service in both civil and military hospitals.

The career of Anthony A. Cooper, 7th earl of Shaftesbury was similarly devoted to the relief of suffering. but in his case philanthropy took the form of a long struggle against the many abuses of the contemporary industrial system. He was directly responsible for a series of acts of parliament nhich improved conditions in factories, protected women and children in industry, introduced badly needed reforms in mines and lunatic asylums and forbade the employment of "climbing-boys" by chimney sweeps. In addition, he did much to improve public health and housing.

Among others nho fought against the evils resulting from bad housing were the Baroness Angela Burdett-Coutts, whose modern lodginghouses in London's east end nere begun in 1856; George Peabody, an American living in London, aho created a fund for building uorkingmen's dwellings in 1862; and Octavia Hill, whose remarkable system of house property management, now known all over the uorld, started in 1864 with the experimental purchase, restoration and personal management of three verminous and decaying houses in Marylebone, the capital for which was advanced by John Ruskin.

The first Charity Organization society in the world was formed in 1869 by a group of notable Englishmen, including Lord Shaftesbury, J. H Newman and W E Gladstone. The pioneer university settlement. Toynbee hall, was established in Whitechapel by Canon S. A. Barnett in 1884. The Working Men's college in London came into being in 1854, largely through the efforts of John Frederick Maurice. The work of Elizabeth Gilbert among the blind inspired the foundation of the Society for Promoting the General Welfare of the Blind, and other associations existed to care for the deaf and dumb, cripples and other afflicted people. Jewish philanthropists were naturally concerned to relieve their oppressed coreligionists in various countries; in this sphere the work of Sir Moses Montefiore was specially remarkable, as was that of Baron Maurice de Hirsch, who established the Jewish Colonization association, one of the great philanthropic trusts.

The existence of slavery had begun to trouble the consciences of thinking men as early as 1671, when George Fox, founder of the Society of Friends, urged all Quakers in Barbados to free their own slaves. In 1787 William Wilberforce began his long campaign for the abolition of the slave trade and the emancipation of existing slaves. As a result of his work and that of Thomas Clarkson and others the transport of slaves in British ships was forbidden in 1807 and in 1833 an act of parliament freeing all slaves in British dominions mas passed only a few days before Wilberforce's death. Great Britain's example was followed by other nations and nithin a comparatively short time after the passing of the Emancipation act. slavery had vanished from most civilized lands and their dependencies. Wilberforce thus indirectly achieved a far-reaching reform in many countries besides his own, though he only lived to see the emancipation of British-owned slaves. Another great international achievement of the 19th century mas that of Henri Dunant, the Swiss founder of the Red Cross. Horrified by the suffering which he witnessed at the battle of Solferino (1859), he put forward the hitherto unheard-of idea that there should be an international body for the care of the sick and wounded in war. His proposals, upon which the work of all Red Cross societies is based, were embodied in the famous Geneva convention, which was accepted by the representatives of 16 nations meeting at Geneva in 1864.

The first half of the 20th century saw the rise of several great philanthropic trusts, some of which were international in character. In 1902 the Rhodes trust was founded by Cecil Rhodes to provide scholarships to Oxford university for students from all parts of the British empire, the United States and Germany. In 1910 Andrew Carnegie established the Carnegie Endowment for International Peace. Three years later he founded the Carnegie United Kingdom trust to assist charitable and cultural enterprises in the country from which his family had emigrated to America. Another U.S. foundation of the same nature was the Pilgrim trust, established by E. S. Harkness in 1930, which also helps British philanthropic societies and those concerned nith the preservation of beauty spots and places of historic interest King George's Jubilee trust, which caters for the needs of youth, was formed in 1935 on the occasion of George V's silver jubilee.

The many benefactions of Lord Nuffield cover a very wide field and have been specially notable in the spheres of medicine and education. The Nuffield Trust for the Advancement of Medicine was founded in 1936, the Provincial Hospitals' trust in 1939. In 1943 the Nuffield foundation was established for the advancement of health, the improvement of social \?ell-being and the care and comfort of the aged. Other funds were created for orthopaedic work in Britain and South Africa, for the provision of iron lungs for sufferers from poliomyelitis, and for the Nuffield Institute of Medical Research at Oxford. Among the best-known of Lord Kuffield's educational benefactions are the Dominion Scholarships fund and the erection and endowment of Nuffield college in the University of Oxford.

By the middle of the 20th century the governments of Great Britain, France and several other European countries had taken over a large part of the social relief work that once depended almost wholly upon charitable individuals or organizations. Statutory social services cannot, however, cover every human need and there are many gaps which modern philanthropy is concerned to fill. That the spirit of benevolence had not withered under conditions of state responsibility was clearly shown, not only by the great trusts and benefactions mentioned above, but also by the steady public support of innumerable societies for the betterment of human conditions and the protection of animals, and the unfailingly generous response to such emergency appeals as the Save the Children campaign in 1919 and the Flood Relief appeals in 1953.

Modern philanthropy may be said to have three main aims: the elimination of evils at the source by means of education, reform and pressure for parliamentary action; the protection and assistance of the distressed, especially those for whom the statutory services make no provision, or for whom such services would be unsuitable; and the general enrichment of the quality of life in all its aspects.

Among the many associations working for these varied ends are the National Council of Social Service (1919), a representative and co-ordinating body working through rural community councils and community associations in towns; the National Society for the Prevention of Cruelty to Children (1884), with its counterpart, the Royal Society for the Prevention of Cruelty to Animals (1824); the University Federation for Animal Welfare; the Red Cross, whose peacetime activities include welfare work of all sorts; the Distressed Gentlefolks' Aid association; the Discharged Prisoners' Aid society; the National Association of Boys' Clubs and the National Council of Girls' Clubs; and a wide range of other children's and youth organizations.

Besides these, there are many societies for the care of the aged and the physically handicapped, such as the Heritage Craft schools, the National Institute for the Deaf and the National Library for the Blind, which translates books into Braille. In addition, professions and trade unions often maintain benevolent funds for their onn members, like the Musicians' Benevolent fund, the Actors' Benevolent fund and those maintained by the services.

(C. S. HE.)

UNITED STATES

The most impressive fact about philanthropy in the United States during the first half of the 20th century was the scale at

which it continued in spite of the vast expansion of government funds for education. health, research and welfare. The right to deduct the amount of giving up to 15% of personal income made giving less expensive. but a widespread and growing interest in private financial support of human services. independent of government operations, also played an important part.

As an attitude, philanthropy may be defined as devotion to human welfare. and, as an act of good will. it is a manifestation of freedom of choice in the use of private resources for the benefit of one's fellow men. The total amount of philanthropic giving in a year in the U.S. in the 1950s was not exactly known, but some fairly dependable estimates could be made.

The purposes for which the money is given is in large part a matter of record. The traditional objects of giving are education, fine arts. health. libraries. museums, research. religion and welfare. Huge sums were raised by private persons during and after World Wars I and II to relieve distress and to improve production of goods and services. Government does not contribute directly to religion and in only limited ways to the fine arts and museums. but it became the largest contributor after World War II to broad plans for human betterment in many lands.

Giving by government on a large scale to foreign countries is in a real sense collective philanthropy. The voters approve such giving, or congress would not vote the funds. This was something new. Sporadic gifts, like the remission of the indemnity received from China for damage to persons and property during the Boxer Uprising, had occurred, but nothing on the scale of the aid programs after World War II has ever been known. The U.S. government gave outright billions of dollars to people of other sovereignties on every continent after 1945.

The services to education, health. research and welfare performed by government for its own citizens is sociologically different from the governmental contributions to foreign nations. No reliable national figures for expenditures as far back as 1930 by local, state and federal governments for this kind of services existed in the late 1950s, but the amount in dollars of that year would be a small fraction of the dollars of 1954. In May 1954, about 11.000.000 persons received $774,000,000 in social insurance and veterans' payments. and 5,200,000 persons received $219,901,000 in public assistance payments. This was almost 10% of the total population, and the amount spent was about $6.00 per capita per month for the entire population of the country.

The objects of expenditures by philanthropy and government sometimes overlap. but are usually different. Obviously religion is an exclusive domain of private giving. and in large measure the fine arts and museums depend upon voluntary contributions. Experimentation with new ways of meeting the needs of people is always open to the "venture capital" of philanthropy. and basic research in the physical. biological and social sciences continues to he a favourite use of private gifts.

Giving by Living Donors.—People continually make contributions during their lifetimes. Sometimes they endow specific projects, but most living donors give 'money to pay the costs of ongoing operations of religious institutions, the fine arts, education, research or other enterprises.

Church giving by members is in some degree obligatory. but the amount is not fixed, as it would be in taxation. The Golden Rule foundation estimated that gifts to churches and synagogues in 1952 amount to about $2,196,000,000—about one-half of all gifts by living donors. The amounts spent for charity in both the Catholic and Jewish churches is large, and the Catholic church spends large sums on education., In 1950, F. Emerson Andrews reported that the Catholic church was operating 11,497 schools, colleges and universities in the United States. Alaska and Hawaii, a part of the cost of mhich was paid by current contributions.

Private contributions are made every year to both private and public institutions of higher learning. In its report for 1953–54 the U.S. office of education reported 1,851 institutions of higher learning in the continental U.S. and outlying territories, of which 1,205 were under private control. For the year 1947–48 Andrews estimated that the amount of contributions tciinstitutions of higher learning was $91,000,000. The amount going to private institutions was $77,000,000, which was about equal to the returns on their endowments.

The annual gifts to health and welfare organizations runs to about $1,800,000,000. The Golden Rule foundation estimated the amounts for 1952 as follows: health and hospitals, not counting allocations by community chests. $151,766,650; to American Cancer Society, Inc.. Heart association, Red Cross. CARE. Community Chests and Councils of America, Inc . National Foundation for Infantile Paralysis, United Defense fund, United Jewish Appeal and a few smaller national organizations. $1,632,217.560

Community chests require separate mention. There were in 1954, 1,627 community chests in the U.S which conducted annual campaigns for funds. Most of them are small, but they blanket the country and symbolize organized philanthropic giving outside the churches by living donors. The amount of contributions in 1954 was $273,503,300. (See also COMMUNITY CHEST; FOUNDATIONS, PHILANTHROPIC.)

Philanthropic Accumulations.—The largest amounts of philanthropic funds at any one time are held by foundations, endowed institutions and trusts. Large portions of the assets of such organizations are invested and produce income. Foundations are increasingly interested in new ideas and new programs rather than in construction of buildings for which much of their money was spent. Some funds of this sort receive additions to their capital assets by new gifts by the original donor or other donors. It is the aim of some foundations, such as the Julius Rosenwald fund. to give away both capital and interest in a limited period of time. Others set no time limit for their extinction.

More than 4,000 foundations probably existed in the U.S. in the late 1950s and they had assets of about $3,000,000,000 in 1954. Only five of these—Carnegie trusts, Duke endowment. Ford foundation. Pew Memorial foundation and the Rockefeller foundation—had more than $100,000,000 each in assets, but about 350 foundations had assets of more than $1,000,000 each. The amount of their annual benefactions was unknown. One of the oldest foundations. Rockefeller. made grants of more than $12,00,000 in 1952. The relatively old Russell Sage foundation. with assets of $14,431,514, appropriated $337,374 in 1953. The Field foundation, started in 1941, had assets of $12,435,415 and made awards of $621,023 in 1951. The Ford foundation was established in 1936, and had assets of $520,232,088 in 1953. In that year Ford foundation made gifts of $60,jj5,703. Several large foundations have within the last few years been organized in the southwest and the west.

The community trusts are a distinctly U.S. invention. The first one was organized in Cleveland. O., in 1914 and is called the Cleveland foundation. There were 99 community trusts in 1954, the five largest of mhich were the Permanent Charity fund, Boston, Mass.; the California Community foundation, the Chicago Community trust, the Cleveland foundation and the New York Community trust. These five community trusts had assets of $71,030,945 in 1954, and the combined resources of all community trusts amounted to $127,395,738. Any individual or family may donate a sum of money to a community trust, however small or large. and give a name to the "fund." and it becomes a part of the community trust. Most of the awards of the trusts are made for education. health, research and welfare in their own communities. By 19j4 they were distributing more than S5,000,000 a year.

The endowments for higher education constitute a large amount of philanthropic giving. The oldest such endowment is that of Harvard university, which dates from 1636. This had grown to $271,859,993 in 1954. Chicago, Columbia and Yale universities all have large endowments. By the end of 1951 the private institutions of higher learning in the U.S. had endowments of $2,195,959,543 or $14.57 per capita for the U.S. (1950 census). Many state universities receive private donations. and some, such as California. Michigan and Texas. had large endowments. The endowment of the University of Texas in 1951 was over $131,000,000. The total endowment of state universities amounted to $482,570,573 in 1951, or a per capita amount for the U.S. of $3.20.

Total Annual **Gifts.**—Andrews gave an estimate of total individual contributions each year from 1929 to 1949 inclusive. In terms of adjusted dollars the contributions were $1,206,000,000 in

1929 and $3,961,000,000 in 1949, or about twice as much per capita in 1949 as in 1929. Income tax returns show that corporations in 1950 made contributions of $245,493,000 (adjusted dollars); much of this was given to universities and community chests.

PHILARET [THEODORE NIKITICH ROMANOV] (?1553–1633), patriarch of Moscow, was the eldest son of the boyar Nikita Romanovich. During the reign of his cousin Theodore I (1584–98), he distinguished himself both as a soldier and a diplomatist. On the death of the childless tsar, he was the popular candidate for the vacant throne; but he acquiesced in the election of Boris Godunov, who compelled him, three years later, to take monastic vows under the name of Philaret. Philaret was confined to the Antoniev monastery, but when the pseudo-Demetrius overthrew the Godunovs he released Philaret and made him metropolitan of Rostov (1605). In 1609 Philaret fell into the hands of pseudo-Demetrius II, who named him, apparently against his will, patriarch of all Russia though, in fact, his jurisdiction was limited. In 1610 he was sent by the Muscovite boyars to King Sigismund III of Poland to negotiate for the accession of the latter's son Wladislaus to the throne of Russia. The king's intransigence caused these negotiations to break down, and Philaret was eventually arrested and sent to Poland, where he was kept in confinement (1611–19). After the election of his son Michael Romanov as tsar of Russia (1613), and a long delayed exchange of prisoners, Philaret returned to Moscow, and in June 1619 he was enthroned patriarch of all Russia. Henceforth, until Philaret's death, father and son shared as co-regents the sovereignty of the realm.

Philaret replenished the treasury by a more equable and rational system of assessing and collecting the taxes. His most important domestic measure was the chaining of the peasantry to the soil, a measure directed against the ever-increasing migration of the downtrodden serfs to the steppes, where they became freebooters instead of taxpayers. The taxation of the tsar's *sluzhylye lyudi*, or military tenants, was a first step toward the proportional taxation of the hitherto privileged classes. Philaret formed the nucleus of the subsequently famous Patriarchal library, and commanded that every archbishop should establish a seminary for the clergy, himself setting the example. He also reorganized the Muscovite army with the help of foreign officers. His death in Oct. 1633 put an end to the Russo-Polish war (1632–33), withdrawing the strongest prop from an executive feeble enough even when supported by all the weight of his authority.

PHILATELY (STAMP COLLECTING) is the hobby of collecting and studying postage stamps. The first postage stamps for prepayment of letter postage were issued in England in 1840. Everything connected with them began at that date, including the vocabulary needed for the hobby of stamp collecting and even the name stamp itself. The term philately was coined in 1865 by a Frenchman, M. Herpin, who invented it from the Greek *philos* "love," a "negative," *telein* "to tax." Since the postage stamp was evidence of a letter's coming free of charge to the recipient, the postage stamp rendered it untaxed. The term caught the popular fancy much more than the word timbromania previously used, and has become the accepted word to describe stamp collecting and the study of postage stamps.

I. HISTORY

1. Posts.—Unlike postage stamps, the posts are as old as history. Herodotus speaks with admiration of the postal system of the Persians, and his words, "Neither snow nor rain nor heat nor gloom of night stays these couriers from the swift completion of their appointed rounds," have been carved over the doors of many post offices.

The first posts were the perquisite of the kings. but they were often permitted to carry letters and messages for members of the royal courts and friends of the courtiers, and gradually their accommodations were extended to merchants. As commerce became appreciated, so the posts became more important. Such postal privileges as had been allotted to favourites or corporations were gradually recaptured for the benefit of the state (which was often identical with the crown, of course). By the beginning of the 19th century, the theory of the post as a monopoly of the state was accepted everywhere.

The first postage stamp was not a proof of payment but the impression of a hand stamp (or what came to be known as a postmark). "A stamp is invented," wrote Henry Bishop, postmaster general of Great Britain, in a letter dated Aug. 2, 1661, "that is putt upon every letter shewing the day of the moneth that every letter comes to this office. so that no letter Carryer may dare to detayne a letter from post to post; which before mas usual." These date stamps. known as "Bishop marks," were used in Britain until 1787, after which they were enlarged and expanded until the modern common postmarks developed. A modified form was introduced into the American colonies.

The posts merely carried the letters from town to town, and to put a letter into the posts required delivery at the posting office—usually the point whence the post departed—or to receive one necessitated a visit there. In 1653, de Villayer established a service of collection and delivery of letters within Paris, and issued wrappers that were sold. each wrapper being proof of the prepayment of the charges of the local post. This was the forerunner of prepaid mail, and the wrapper was the first precursor of the postage stamp. The service ceased after a short vogue when the novelty wore off. In 1680 William Dockwra set up a penny post for London and its suburbs, which was suppressed by the government in 1682 as an infringement of its monopoly of post roads. However the entire system was incorporated into the British postal system in 1682, with Dockwra as comptroller from 1697 to 1700.

The use of embossed stamps on documents as evidence of imposts and excise taxes paid, which originated in the Netherlands, was introduced into Britain in *1694*. The famous stamp tax (or excise tax evidenced by stamps) on commodities for the American colonies of Great Britain was passed in *1765* and repealed the following year, but contributed to the unrest in America that led to the Revolution. In *1818* the kingdom of Sardinia taxed letters, certifying each with such an impressed stamp — not, however, a postage stamp.

Although originally supported by the king's private purse, the English postal system was put on a paying basis in *1635*, by fixing rates for letters on a basis of distance and by "single" and "double" letters and "per ounce." Thereafter, the rates were changed from time to time, usually upward. Each rise in charge decreased the total volume of mail, but increased net revenue. The posts were farmed out to the various postmasters general for several years. In *1812* a further increase in rates brought only a slight rise in net revenue, and actually worked a hardship on legitimate business, the rates becoming too high—4*d*. for *15* mi. or less; 5*d*. for *15* to *20* mi. and so up to 18*d*. for *700* to *800* mi., and 1*d*. for each *100* mi. additional.

2. First Postage Stamp. — In *1835* Rowland Hill (*q.v.*) began to study the tax situation in England, there having been a surplus of revenue. He noted that while reduction of tax rate sometimes brought a reduction of net revenue, the reduction of the tax on coffee by one-half had produced a net increase in revenue of one-half. Furthermore, he determined that postal revenues were falling despite increased rates, while a reduction in postal rates in France had increased the net revenue.

Further inquiry revealed that since most letters went through post unpaid, to be collected on delivery, many of these were refused and had to be returned, often to be unclaimed or refused on return, thus necessitating records at every step of the two-way trip, as well as double portage for no revenue. Most illuminating of all was the discovery that the cost of transport per letter was frequently less for a long journey — from London to Glasgow, for example — than for a short one — such as London to Kent — for the long haul went with a greater number of letters than the short local trip. Hill therefore proposed a radical change: that letters be carried any distance within Great Britain and Ireland for a fixed rate, which he suggested be a penny for each one-half ounce, and that all postage be prepaid. Wrappers and envelopes with the stamp denoting prepayment were to be sold at all post offices, and for those who wished to use their own stationery he proposed "a bit of paper just large enough to bear the stamp" (he meant the imprint of the post office hand stamp), "and covered at the back with a glutinous wash, which might, by applying a little moisture, attach to the back of the letter, so as to avoid the necessity for redirecting it."

Hill's pamphlet, Post *Office* Reform, was issued in Jan. *1837* for private circulation. Parliament investigated, and the postmaster general Lord Lichfield reported that of all the wild and visionary schemes he had ever heard or read of, it was the most extraordinary. A second edition of the book, for public circulation, had its effect. The public response was loud and strong, the treasury reduced rates to a uniform *4d*. per ½ oz. basis, and in *1839* reduced it to Hill's proposed *Id*. per ½ oz. regardless of distance, effective Jan. *10, 1840*.

Hill was asked by the treasury to work out the details. In *1839* he entrusted the design of the envelope and wrapper to William Mulready, R.A. To create the "bit of paper," he held a public competition, and more than *2,600* essays were entered. Meanwhile, Hill had heard of a new process of steel engraving, in which he became interested. When the prizes (four of £100 each) were awarded, the "label" with the glutinous wash on the back was finally produced by the new, revolutionary Perkins process for reproducing steel engravings.

Jacob Perkins, a native of Massachusetts, was an inventor of mechanical devices. In *1819*, having invented the D-roller copper-plate press, an engine lathe for engraving copper and steel plates, and the triple transfer process of reproducing steel engravings together with the machines to carry it out, he was persuaded to travel to England to interest the Bank of England in the process for producing its notes. The British minister to the United States extended the invitation, and though the Bank of England finally decided to proceed with a process then being installed, a grant, reported to be £*5,000*, was made to Perkins and his partners. Mean hile, he secured the business of many other banks, for prior to *1844* almost every British bank issued its own notes.

In brief, the essence of the process is: a soft-steel die is engraved with the original intaglio of the proposed finished engraving. This master die is then hardened and a soft-steel roller is pressed against it in a transfer press and rolled back and forth until a transfer in relief is obtained on the roller. A second, third or fourth relief or even more, likewise can be obtained on the transfer roll, each of them in relief; *i.e.*, the lines that are cut into the original die and that will retain the ink to make the print of the engraving are in relief on the transfer roll. The roll is hardened. in turn. The last stage is to impress the transfer roll against the plate from which the printing is to be done, once more in the transfer press. The relief lines become intaglio lines on the printing plate, exact reproductions of the original die, reproduced as often as wished.

To the inventor's firm of Perkins, Bacon and Petch (later Perkins, Bacon and Co.), Sir Henry Cole, on behalf of Hill, suggested in Dec. *1839* the possibility of securing the contract for the proposed labels.

For Hill's label, the background chosen was an engine-turned lathework that had been used often as a background of bank notes. To use this on the stamp, a die block was impressed with the proper amount of the geometric pattern from the transfer roll. (This same transfer roll was later used to make the background for the Cape of Good Hope triangular stamps of *1853*, the St. Vincent one-crown stamps of *1880* and the New Zealand George V series of *1915*. It is now in the possession of the Royal Philatelic society. The over-all size and the space for the portrait of the queen were carefully marked. The pattern was transferred to a roll, and the space for the queen's head and the unused portion were burnished clean. The roll was then entered on a new die block. The portrait chosen was that engraved by W. Wyon of the royal mint for the medal struck commemorating the queen's first visit to the city of London in *1837*. Henry Corbould made the drawing, and the engraving was made directly on the die by Charles and Frederick Heath. The first die was not used and a second was made. Above the head was a panel with the word "Postage," the upper corners were embellished with a cross *pattée;* below was a panel with "One Penny" or "Two Pence"; in the lower corners were initials. Hill was afraid of counterfeiting, and for this reason the initials were used.

Each plate (11 were used for the one-penny value and two for the two-pence the first year) contained *240* stamps; each horizontal row of *12* was therefore valued at as many shillings as the single stamp was worth pence. There were *20* rows, edch full sheet being worth in pounds what each stamp was valued in pence. The lower right-hand corner of the stamps was lettered "A" for the first vertical row, "B" for the second and so up to "L" for the 12th; the lower left corner was similarly lettered "A" for the first horizontal row, "B" for the second and so to "T" for the 20th. It was thought that any counterfeiter would use only one or two combinations, and any very frequent recurrence of these would apprise the postal clerks of the attempt.

Neither the envelopes and wrappers nor the stamps were ready in January. Hand stamps were used to mark the letters "paid" until May *6, 1840*. On May *1*, both stamps and envelopes, including wrappers, were ready — the one-penny black, the two-pence blue — and nere put on sale. They were not valid for postage until May 6. It was Hill's thought that the envelopes and wrappers would be in demand, and adhesive stamps would be merely for the exceptional user. But in fact, it was the stamps that were in demand, and the printers worked night and day to keep the offices supplied, while the original supply of the envelopes and wrappers was never exhausted in the year they were available for postage.

In the latter part of *1885* James Chalmers, whose father had been a printer in Dundee, advanced the proposition that Hill had

stolen the idea for the adhesive postage stamp from the elder Chalmers. Both the principals were dead, but an unpleasant controversy arose that was scotched by Chalmers' own evidence, which gave the date of his father's suggestion as after Hill's (quoted above) had been read into evidence before a parliamentary comtnittee. However, from time to time, copies of Chalmers' vitriolic pamphlets come into the hands of newcomers to philately and provide another tempest in a teapot.

Although Hill's estimate of the loss of revenue was greatly surpassed by the facts, there was never any serious question of reverting to the old system. Prepaid postage, and with it the adhesive label that later became the postage stamp, had become accepted.

3. Usage Spreads. — In 1843 the empire of Brazil issued three values of postage stamps, becoming the second government to use them. These stamps did not contain the portrait of the emperor, but large figures of value on a background of engine-turning, and are popularly known as bull's-eyes. In the same year two Swiss cantons, Zurich and Geneva, issued stamps. That of Geneva was a double stamp: a half paid the postage within one commune, the whole paid it within the canton.

The first adhesive stamp in the United States was issued in 1842 by the semiofficial City Despatch Post of New York city for local carrier delivery. In 1845 several postmasters in the United States issued stamps to facilitate prepayment of letters—New York city issued a 5-cent value; St. Louis issued 5- and 10-cent stamps (later adding 20-cent); and the postmaster at New Haven, Conn., issued a 5-cent envelope.

In the succeeding two years, more postmasters issued similar local labels all with the tacit consent of the postmaster general, since the postmasters were charged with each letter they forwarded "paid" and the issuing of the stamps was merely their own method of bookkeeping.

In 1847 the United States issued stamps of 5- and 10-cent value and the "postmaster's provisionals" were abandoned. Prepayment became obligatory in 1856.

In 1845 the Swiss canton of Basle issued a stamp. In 1847 the British colony of Mauritius issued two values made locally that have become two of the philatelist's most sought-after rarities. In 1848 the Bermuda postmaster issued a provisional similar in purpose to those issued by the U.S. offices between 1845 and 1847. France and Belgium issued their first stamps in 1849, as did Bavaria. In 1850 Austria, Hanover, Prussia, Saxony and Schleswig-Holstein in central Europe, Spain and the three British colonies of New South Wales, Victoria and British Guiana all issued stamps. So did the Swiss federation, replacing the cantonal issue of previous years, for these stamps were valid in all cantons.

The first British stamps bore no country name, being intended only for internal use. Subsequent issues of Great Britain have likewise been content to bear the legend "Postage" without any designation of the country of issue. The first Brazilian issue was also without a name. The Swiss stamps, seeking to avoid giving offense to German-, French- or Italian-speaking Swiss, were likewise without a country name; subsequent' issues avoided argument by carrying the Latin name "Helvetia," or later "Confoederatio Helvetica."

After 1850 the remaining countries of the world began to issue stamps, more being added each year. Some countries began with local issues for the larger cities. Others plunged into national production. Following World Wars I and II numerous new countries and subdivisions issued stamps, while others ceased to exist as stamp-issuing entities. *See* also POSTAL SERVICES.

II. STAMP MANUFACTURE

Although the first stamps, those of Great Britain, were made by intaglio printing, not all stamps are so made. Five basic processes of printing are used in making stamps: (1) the engraved or intaglio process, in which the lines to be reproduced are incised into the surface of the plate and inked, while the surface is wiped clean; (2) typographed or letterpress, in which the lines to be printed are raised above the surface and inked; (3) lithographed or offset, in which the line to be reproduced is drawn on stone (or, more modern, on a metal plate with a surface simulating that of stone) mith an oily ink which attracts the oily ink used to reproduce it, which in turn is repelled by water on the rest of the stone; (4) embossed, in which the paper is raised by an incised die struck against a soft platen or "force"; and (5) photogravure (rotogravure), in nhich lines are photographed through a screen on a sensitive film covering the plate and then etched into it as in engraving. *See* also GRAVURE; LITHOGRAPHY; PHOTO-ENGRAVING; PRINTING.

1. Production. — The first stamps were made by private contractors under governmental supervision. Great Britain still contracts with private companies for supplies of stamps. The United States began by contracting for both postage and revenue stamps but, after the Civil War, the treasury department began printing its own tax stamps at the bureau of printing and engraving. In 1885 this bureau bid on the postage stamps, but lost to a private concern, the American Bank Note company. In 1894, however, the bureau was low bidder; thereafter it produced the postage stamps as well as the revenue stamps, banknotes, currency and bonds.

France also began with a private contractor, but after 28 years transferred the production of stamps to the national mint. Many countries have followed the lead of Great Britain and entrusted their stamps to private concerns — Perkins. Bacon and Co.. which produced the first British stamps, also produced the original issues for many other countries. For Chile, for example, the company printed the first issue in sheets of the same dimension and layout as the first British issue, which made bookkeeping rather difficult for the Chileans, who use a decimal currency. Most countries with decimal coinage use sheets of 100.

2. Paper and Watermarks. — Philatelists are deeply conscious of the kind of paper used for stamps. Chief item in papermaking for stamps is the watermark (*q.v.*), a sign or symbol made in the paper as it is manufactured. On paper to be used in printing stamps, watermarks may be spaced so as to fall on each particular stamp, or to run through the sheet in a recurring pattern or to fall with one quarter on each stamp, a block making a full pattern. Typical watermarks are the small crown that appears on each of the 1840 stamps of Great Britain or the "crown and C **A**" on many colonial stamps; the "USPS" used by the United States between 1895 and 1915, a letter or part of one letter falling on each stamp; or the wavy lines used by Bavaria for early issues, which fell on each stamp and in the margins as well.

Basically, paper (*q.v.*) is wove or laid. Wove paper is made on a moven screen, and either presents no appearance other than general opacity when held to the light, or it dimly resembles a tiny network, as a moven screen greatly reduced. If the screen is strengthened with heavier wires evenly spaced in one direction, it becomes a laid paper, with these lay-lines showing. If these are exceptionally heavy, it is called batonné paper, and if the heavy batons are placed perpendicular to lay-lines it is laid batonné. A thin onion-skin paper sometimes used for stamps is called *pelure* paper.

Paper in which coloured fibres are used, presenting a gray or mottled appearance, is termed granite paper. Silk paper has tiny threads of coloured silk worked into it, and silk-thread paper has one or two very noticeable silk threads laid lengthwise or across it, falling on each stamp.

3. Gum. — The glue applied to the back of the stamp, which is moistened and thereby made to adhere to the envelope, wrapper, etc., is referred to as gum. Different kinds of gum may be distinguished by colour, opacity, streaks, etc. Stamps may be ungummed. Usually gum is applied to the sheet of stamps before the perforation process is performed.

4. Perforation. — The first stamps were printed on a sheet of paper with no provision for separation one from the other. This required use of a knife or scissors to secure individual stamps. Such stamps are known to collectors as imperforate. In 1847 an Irish engineer, Henry Archer, offered a machine to provide stamps with separations. A toothed wheel cut a series of scallops between the stamps, permitting easy tearing of the sheet. Experiments were made by the British post office, and in 1848 the ma-

chine was put in service. However, the wheel used to cut the scallops soon became blunted; it also aamaged the work table. A new set of wheels with lancet-shaped knives fared little better. In 1849 Archer introduced a machine that punched tiny holes between the rows of stamps. Such sheets as were not ruined in experimenting were sold in the regular course of business by the post offices. In 1854 the machine was so far perfected that thereafter all British stamps were perforated.

Philatelists differentiate between these various methods of separating stamps. The first method, which cuts the paper between the stamps but does not remove any of it, is called rouletting; it is further differentiated by the pattern of the cutting: serpentine. scalloped (or en arc), saw-toothed (or en scie), straight-line (or en ligne), etc. When small portions of the paper are removed, it is termed perforated. These, with imperforate, make up the three main classes of separation of stamps.

Philatelists further differentiate stamps by their perforations. To many, though not all collectors a difference in the number of perforations creates a separate, collectible variety. To obviate differences caused by slight variations in the dimensions of stamps, philatelists measure the number of perforations in 20 mm. Thus, "perf. 12" means that there are 12 holes counted in 20 mm., and so on. Roulettes are similarly counted.

III. STAMP COLLECTING

No one can say with certainty when stamp collecting began, but clearly it was subsequent to May 1, 1840, when the first postage stamps were put on sale. The earliest reference to it is in an advertisement in the Times of London in 1841:

A young lady, being desirous of covering her dressing-room with cancelled postage stamps, has been so far encouraged in her wish by private friends as to have succeeded in collecting 16,000. These, however, being insufficient, she will be greatly obliged if any good-natured person who may have these (otherwise useless) little articles at their disposal, would assist her in her whimsical project. Address to E. D., Mr. Butt's, Glover, Leadenhall Street; or Mr. Marshall's, Jeweller, Hackney.

That this mania for accumulating, if not collecting, was rather widespread within the year is evidenced by this paragraph in Punch, 1842:

A new mania has bitten the industriously idle ladies of England. To enable a wager to be gained, they have been indefatigable in their endeavours to collect penny stamps; in fact they betray more anxiety to treasure Queen's heads than Harry the Eighth did to get rid of them!

Accumulation led to collecting, in all probability, though there is no evidence of just how or where it started. From the practically simultaneous outbreak of evidence in 1862, it seems clear that collecting was spontaneous and not confined to any one region. Great Britain. France, Germany, Belgium and the United States apparently had collectors prior to that year.

1. Catalogues. — In the British magazine Notes and Queries of June 23, 1860, appears a letter from a schoolmaster recounting that one of his pupils had a collection of 300 or 400 different stamps, and that "Sir Rowland Hill had told him at that time there might be 500 varieties on the whole." He suggests that a list of stamps would be useful and asks if there is any shop in London where stamps are sold and that has a list available. The identical idea must have been surging in other lands. In 1861 Oscar Berger-Levrault, in Strasbourg, issued his list of stamps, Timbres-Poste, by lithography from manuscript. In Paris, Alfred Potiquet published a *Catalogue* des Timbres-Poste *Crées dans* les Divers Etats *du* Globe. The acceptance of the lists must have been immediate, for Berger-Levrault issued a second edition later in the year. In Jan. 1862, J. B. Moens of Brussels, Belg., issued his *Manuel du Collectionneur*. In England, Frederick Booty, J. E. Gray and Mount Brown all issued catalogues in 1862. A pirated edition of the last, listing 1,200 varieties, was issued by A. C. Kline in Philadelphia. Brown issued two more editions of his catalogue, the third (1866) listing 2,400 varieties, inclusive of what is now termed postal stationery or envelopes, wrappers and letter sheets, as well as many local issues.

The standard modern catalogues exclude this latter material, and yet the total number of listings, including minor varieties, reaches more than 200,000.

E. Stanley Gibbons issued in 1863 a catalogue that continues to be one of the major catalogues of Great Britain. The standard in France is by Yvert and Tellier; in Germany it is Michel's catalogue, in Switzerland Zumstein's. The Scott catalogue (originating in 1863) and the Minkus catalogue (begun in 1954) are standard works for the United States. Each of the above catalogues stresses information about the country in which it is issued, either as part of the main volume or in a separate specialized edition nhich may include postal stationery. Also, because of the sheer bulk of printed matter needed to catalogue over 200,000 philatelic items, the major catalogues tend to be published in two or three volumes; shortened versions for beginners and general collectors are produced by both Gibbons and Scott.

Many stamps are issued for postal charges other than letter carrying (see below), and some of the major catalogues list these also. Revenue and telegraph stamps also are collectible and may be listed in modern catalogues.

2. Albums. — The first stamp albums were issued in 1862. Justin Lallier originated both the French and the English editions, in Paris. He rapidly increased his albums, to accommodate new stamps as they were issued. and for several years held first place among collectors for the completeness and arrangement of his books. In the latter part of the decade (1867) he began to add information about stamp collecting and bibliographies.

3. Special **Stamps.**—Airmail stamps are issued especially for letters to be carried by air. Italy issued the first of these for an experimental flight in 1917; the first regular issue was that of the United States the following year. Almost every country has issued them since. with the exception of Great Britain and its colonies, though in these countries certain values of the regular postal issues are of denominations primarily for airmail use. Special delivery, registry, insured and acknowledgment-of-receipt stamps are for payment of the special fees levied for these services. Late fee stamps are sometimes issued to pay the extra postage for letters mailed after the closing of special mails.

Official stamps are issued for the use of governmental departments. Formerly widely used, they are now largely supplanted by printed franks.

Semipostal stamps are sold at a premium over their letter-carrying value, the overage going to some officially recognized charity. Postage due stamps indicate the amount a letter lacks of full payment of the charges. which is collected on delivery. Newspaper and parcel post stamps are for the special duties indicated.

Commemorative stamps are regular postage stamps issued to honour some event, activity or person of national importance. They are a species of governmental propaganda. The first stamps of this kind were issued by New South Wales in 1888, on the 100th anniversary of the founding of the colony. Argentina (1892) and the United States (1893) issued stamps commemorating the 400th anniversary of the discovery of America. In 1897 Great Britain and Canada signalized the diamond jubilee of Queen Victoria's coronation. Thereafter, the practice became common.

4. **Specialization.**—When Mount Brown's catalogue listed 2,400 stamps (1866), a modest collection of 2,000 varieties would contain more than 80% of all stamps. A similar proportion in the early 1960s would necessitate 150,000 varieties. Because of the sheer bulk of such a general collection, most collectors turn to more or less limited fields. For example. they may collect only the stamps of one country, or of one continent or of one period. Others specialize in collections of certain kinds of stamps; some collect only one issue and study it thoroughly, others may collect only revenue stamps or postal stationery. Those interested purely in stamp designs may collect art or religion on stamps, or flowers, fish, bridges, etc.; this sort of collecting is called topical or thematic.

The collection of postal markings, both on stamped and prestamp covers, is a form of specialization; collecting of precanceled stamps is another. Meters (machines that print a postal frank on the envelope) have given rise to yet another specialized form. Telegraph stamps, issued to prepay telegrams in certain countries, are also collected by specialists.

Plating. — The collecting of one issue or even of one stamp

of an early issue, may necessitate some of the deepest philatelic study. The early stamps, especially the engraved ones, were often retouched after transfer, so that each stamp on each plate has minute identifiable characteristics. For instance, it is possible to identify each of the 2.640 specimens of the Great Britain one-penny of 1840, and this is easy, compared with other issues, because the plate position is located by the check letters in the corners. It is also possible to identify most of the 2,600 varieties of the 3-cent U.S. stamps of 1851. This has led to "plating" or reconstruction of the original sheet, which in turn has led to many interesting discoveries of the ways in which sheets were laid out and manufactured.

Christmas Seals.—Christmas seals were invented by a Danish postal clerk, Einar Holbøll, in 1903, as a source of revenue for an antituberculosis society. They were used on packets and letters sent at Christmas, and sold for a small sum, the money going to the society. The use spread to many other countries, where they are issued each year. While they have no franking power, they are widely used and often collected.

Government Philatelic Agencies.—Specialization in 20th-century stamps has been helped by establishment of governmental philatelic agencies to sell fine-quality stamps to collectors. The United States opened the first of these in 1921, and the success was soon so apparent that similar agencies were established by many European countries. The U.S.S.R. made traffic in stamps a government monopoly and Germany followed suit when the nazi party came into power. In 1942 the U.S. placed revenue stamps on sale at a special agency for collectors.

The forms of specialization are limitless, and the ingenuity of collectors leads to the constant discovery of new and individual methods.

5. Famous Collections.--Many famous collections of the past have been dispersed and absorbed by others. One of the most famous of all times was the collection of Philippe la Renotiere von Ferrari, an Austrian subject resident in Paris. During World War I he fled to Switzerland, where he died in 1917. His property was seized by the French government, and his collection, which he had formed during 40 years, was sold at auction, realizing more than 26,000,000 fr. (£400,000 or $2,000,000 at the rates of exchange of the day).

Arthur Hind's collection, which included the Duveen collection of Mauritius and the Griebert collection of Spain and which was sold in 1933–34 after his death. brought a gross return of nearly $1,000,000. In addition, the unique 1-cent British Guiana magenta of 1856 was sold by private negotiation for a price reputed to be more than $45,000, the highest price ever recorded for a single stamp.

The outstanding collection in Europe in the early 1960s was the private collection of Queen Elizabeth II. Principally formed by King George V, who was a famed philatelist, it is especially rich in British and colonial issues.

Of the several famous collections in the United States, one of the most bizarre was formed by Col. E. H. R. Green; it stressed unusual materials, such as quantities of the "blue paper" issues of the U.S., the only position blocks of the 24-cent airmail with inverted centre (U.S., 1918) and a number of sheets of the imperforate 5-cent carmine error (U.S., 1915). Other noted collections were those of Sol Newbury (Chicago), Alfred Lichtenstein and Theodore Steinway (New York). Alfred H. Caspary's stamps were sold in the late 1950s in New York city for $2,895,146, the largest sum realized by any stamp collection to that time.

The Thomas K. Tapling collection, bequeathed to the British museum, may well be the finest in public hands. The Smithsonian institution collection at Washington, D.C., stresses U.S. stamps. The postal museums of many European capitals have outstanding collections; such as those at Berlin, at The Hague and at Stockholm; the last received the Hans Lagerlof (New York) collection.

IV. PHILATELIC SCHOLARSHIP

1. Societies.—Clubs or societies of collectors are to be found in most cities of the world. with national and international societies tending to bind them together. The American Philatelic society, founded in 1886, had about 13,000 members in the early 1960s; the Society of Philatelic Americans (1894) had about 6,000. The Royal Philatelic society of London was founded in 1869 and became "royal" in 1906. The Junior Philatelic society of London was founded in 1899. The Collectors club of New York stands pre-eminently for philatelic research, as does the Royal Philatelic society. Many countries have national philatelic organizations with research groups.

Because of the quantity of philatelic material, added to each year by the issuance of about 3,000 new stamps, with the resultant tendency to specialization, specialist societies have sprung up, notably since 1945. Many of these issue bulletins. Particularly noteworthy are the specialty clubs dealing with the philately of France and colonies, Germany, Italy and colonies, Korea, Lithuania, Luxembourg, Japan, Switzerland, airmails, postal history, postal stationery, U.S. bureau issues, and others too numerous to list.

2. Congresses.—The Philatelic congress of Great Britain celebrated its 50th anniversary in 1959 and the American Philatelic congress celebrated its 25th the same year. The "congress" idea fosters philatelic research by the publication of articles annually in book form, with annual conventions at which these articles are discussed and the material upon which they are based is studied. The first (Congress Internationale des Timbrophiles) congress was held in Paris, June 26, 1878. After 1945, there was an increase in the number of congresses held in various countries.

3. Exhibitions.—One of the most important activities of stamp clubs is the holding of exhibitions from time to time. The national societies hold annual exhibitions, offering valuable awards in competition. International exhibitions are held in the United States at approximately ten-year intervals. Other countries arrange to honour philatelic or national events at the appropriate date with similar world-wide celebrations.

4. Literature.—Perhaps no hobby has been so prolific of literature as philately. The standard catalogues (see above) issued annually are generally minor encyclopaedias of the hobby, but there are and usually have been journals in every language.

It is difficult to list accurately monthly or weekly publications, since many are short-lived. The first one of record that was specifically devoted to philately was the British Monthly Intelligence; appearing first in Oct. 1862, it lasted only three issues. In Dec. 1862 appeared the British Monthly Advertiser, which appeared in Jan. 1863 as the Stamp Collector's Review; it lasted nearly two years. Moen's (Brussels) published the Timbre-Paste for many years, starting in 1863, in which year the German *Magazin* fur Briefmarken-Sammler began. In 1874 John K. Tiffany published The Philatelical Library, a catalogue of philatelic literature in his extensive private library in St. Louis, Mo. This collection of books he afterward sold to the earl of Crawford, who combined it with his own extensive holdings and bequeathed all to the British museum.

Among the journals founded in the 19th century and still extant are *Mekeel's* Weekly Stamp News (founded 1892) and the *American* Philatelist (published by the American Philatelic society, founded 1887, but with two lapses since), in the U.S.; the London Philatelist (published by the Royal Philatelic society); and Echoes de la Timbrologie, in France.

There have been many books on stamp collecting, especially in specialized fields. Since these appeal to a limited public, they are issued in small editions and few remain long in print.

5. Libraries.—In the United States the library of the Collectors club of New York is outstanding. The Philatelic library of Los Angeles, the Eugene Klein collection in the Philadelphia Free library and that of the Philatelic Research society (Oakland, Calif.) also are noteworthy. Many public libraries have growing sections devoted to philately and are usually expected to have at least the standard catalogues. In England the library of the Royal Philatelic society has been kept up-to-date consistently, and in other European countries where there are postal museums, libraries are apt to be an important adjunct. Probably the best philatelic library in private hands is that of George T. Turner of New York.

6. Some Philatelic Terms.—Philatelists, as other hobbyists,

use words with special meanings pertinent to their collecting. Some have been coined, others are words from current usage twisted to specific connotations. Many words in the philatelic vocabulary have been internationalized from the French.

Bisect.—These are stamps that have been cut in half or into smaller bits to serve as postage; *e.g.*, the 3-cent of the 1869 U.S. issue was bisected (trisected would be a better term, but philatelists continue to use bisect) to permit the mailing of a number of forms that called for only two cents' postage. Such bisects are usually collected only when on the original envelope or mailing piece, and then with a cancellation identifying them with the letter. Some bisects also have been overprinted with the new fractional value; in such case they bear their own proof of bona fide and do not need the supporting evidence of the letter.

Block.—A block consists of four or more stamps with the horizontal and vertical separations untouched. Thus, a block of four stamps can only be arranged two wide by two deep.

Booklets.—These are blocks of stamps, sometimes all of the same denomination, sometimes of different denominations, arranged between covers, usually with interleaving to prevent sticking. Size and value of booklets is determined by the country of issue.

Coil Stamps.—These are stamps issued in long strips—(usually 500) for use in mailing or vending machines. Some countries, notably Sweden, prefer coils for post office sale in place of sheets as they are easier to store. The stamps are usually imperforate on top and bottom (or the two sides) and perforate between the stamps. If imperforate top and bottom, they come from horizontal coils; if imperforate on the two sides, from vertical coils.

Cover.—A cover is the outer wrapping of a piece of mail: the envelope or outer side of a folded sealed letter or the wrapper of a packet. A stamp is "tied to cover" when the cancellation or other postal marking falls partly on the stamp and partly on the cover.

Double Impression.—This occurs where the sheet of paper was put through the press twice, the second imprint shifting slightly from the first one.

Double Transfer.—In engraved stamps this occurs where the impression on the printing plate, either through shifting in the transfer press or an attempt to re-enter and deepen the impression has caused portions of the entry to have double lines.

Grill or Grille.—This is the impression of a knurled roller on a stamp to break the fibres of the paper so the canceling ink will soak in and prevent washing to reuse.

Hinge.—In arranging a collection, stamps are not pasted directly on the album page but secured there by hinges. small rectangles of paper gummed on one side and folded. The gum is a special kind that allows the hinge to be peeled off with minimum damage to the stamp and its original gum. One gummed section is fastened to the stamp, the fold at the top of the stamp; the other is fastened to the page. Thus the stamp may be lifted at will for study of the back.

Inverted Centres.—These occur only when two or more plates are used to make a stamp. Occasionally a sheet will be reversed when passing through the second press, and the centre will be inverted in relation to the frame; actually the centre may have been printed first, in which case, strictly speaking, it is an inverted frame.

Miniature Sheet.—This term has two meanings. (1) A form of collecting in which stamps from the corners, sides, top, bottom and at least one from the centre are put together to show every possible variety the sheet possesses—nine stamps from a U.S. sheet of 100 would give this effect. (2) More commonly the term is applied to little sheets of 25, 10 or fewer stamps issued as souvenirs of an occasion or a national event. These are also known as souvenir sheets.

Mint.—This is the condition of a stamp as it comes from the post office, with its original gum undamaged and without blemish on its face. A stamp that has lost its gum but is otherwise unblemished is spoken of as unused—no gum, save in rare instances when there was originally no gum, in which case it is still mint.

Overprint or Surcharge.—Either of these terms is used to refer to a stamp that has been printed over, to change one or several of the original qualifications. The trend is to use the word overprint, to avoid connotations that have become attached to the word surcharge. Stamps are often overprinted to change the value, usually because there is a shortage of a needed denomination and a surplus of another. Stamps are also overprinted to change the country, as stamps of one nation used in the territory of another in war or after cession. Another overprint is applied to change the use of stamps; a revenue stamp, for example, may be overprinted for postal duty. Stamps that have been withdrawn have been overprinted to make them valid again.

Plate Numbers.—These are often put on the margins of plates, and thus are printed on the sheets, to identify the plate. Sometimes, as with many issues of Great Britain, they are worked into the design and appear on every stamp.

Postal Markings.—These are the cancellations, postmarks and other hand or machine stampings applied by the post office to the letter or piece of mail.

Precancel.—Precanceled stamps are a particular form of overprint, a cancellation applied before sale to the user. Only those with special permits are allowed to use precanceled stamps, and these must be employed according to strict regulations. They are intended to save unnecessary labour by the post office clerks, and are usually used for large mailings of identical pieces or for newspapers or periodicals.

Reissues.—These, not to be confused with reprints, are made by governments. hence are often called government reprints; frequently they are rarer and more valuable than the original issues.

Remainders.—Remainders are stamps left in the hands of governments after they have been demonetized. Sometimes these remainders are sold in bulk and accordingly depress the value of unused stamps.

Reprints.—These are stamps printed from the original plates after the stamps are no longer valid for postage. The only reason for doing this is to sell the stamps to collectors, and reprinted stamps are accordingly generally deprecated by philatelists. A few governments have been guilty of this practice, and some of them have been persuaded to turn the plates over to private parties. The most notable cases mere those of certain Central and South .American governments which, in the last decade of the 19th century, entered contracts with the Hamilton Bank Note company, of New York, by which the company furnished a complete series of stamps each year, and after the stamps had been demonetized. was permitted to sell the remainders and such other stamps as it wished to make from the plates. These issues, called Seebecks after the president of the company, have suffered accordingly. Certain African countries made similar contracts more recently.

Se-tenant *Stamps.*—These are two or more stamps unsevered from each other in which one or more of the stamps differ from the other. Sometimes two denominations of stamps are printed in one sheet; a pair of stamps of the different denominations would be described as a se-tenant pair.

Tete-Beche.—Occasionally plates have been made with one stamp entered upside down. Such a stamp is said to be tete-beche, and can only be identified when se-tenant with one or more of the normal stamps.

BIBLIOGRAPHY.—*General* information and advice: Richard McP. Cabeen, Standard Handbook of Stanzp Collecting (1957); Ernest A. Kehr, Romance of Stamp Collecting, 5th ed. (1956); Barbara R. Mueller, *Common* Sense Philately (1956).

Indexes and handbooks: John Boynton Kaiser, "Bibliography: the Basis of Philatelic Research," 19th American Philatelic Congress Book (1953); John Freehafer and Helen K. Zirkle, "Literature: Philatelic Handbooks, including a List of Libraries in Which They May Be Found," *22nd* American Philatelic Congress Book (1956). American Philatelist, American Philatelic society's monthly prints a quarterly index of current philatelic publications from all over the world. For the specialist, it is recommended that each find out what is available by writing to his nearest philatelic library, and that each study the complete file of publications issued by the specialty group in his chosen field.

SOME FAMOUS STAMPS OF THE WORLD

1. **British Guiana, "One-Penny** Magenta." The most valuable stamp In the world, **issued** in 1856. One **hundred** years later **it** was valued at about $100,000
2. Hawaii, two-cent **"Missionary."** First issue of **Hawaii,** 1851
3. Mauritius, "Post **Office."** An Issue of **1847** where the words "post office" rather than **"post paid"** were **used** by the **local** designer of this limited **issue**
4. Switzerland (canton of Basle), the **Basle "Dove"** tricoloured **stamp** of 1845, a favourite of **collectors**
5. **Cape** of Good Hope. "Triangle." The **first series** of stamps to be **issued** in nonrectanguiar shapes **(1853–64)**
6. Mauritius, 1848. The word "pence" was **misspelled "pence"** by the engraver
7. St. Louis, Mo, "Bear." An example of a postmaster's provisional, issued privately by the postmaster in 1845 before the **U.S.** had a general issue
8. New South Wales, "Sydney View." The first pictorial stamp, **issued** in **1850**
9. Japan, 1871. the first issue of Japan. An example of oriental **design** and a stamp without Roman lettering, **which** is relatively uncommon
10. Confederate States of America, five-cent, **1861.** The first general **issue** of the Confederacy
11. United **States, "$1.00** Trans-Mississippi," an early **commemorative stamp** (1898) regarded as exceptionally beautiful by **collectors**
12. Newfoundland, **"Hawker."** The first stamp issued for an **Atlantic ocean flight,** April 1919. It was made by overprinting a regularly **issued stamp**

U.S. AND FOREIGN STAMPS

1. Lebanon, airmail, 1951, showing Crusader castle, Sidon harbour. 2. Brazil, "Bull's-Eye," 1843, the first stamp issued in the western hemisphere. 3. Italy, special delivery, 1948. 4. United States, 5-cent and 10-cent, 1847, the first general-issue stamps of the country. 5. Egypt, commemorative. 1956, honouring Museum week. 6. Sweden. pair of vertically perforated coil stamps, 1954. 7. United States, airmail, 1918; only one sheet of 100 stamps with the centre inverted (plane upside down) reached the public. 8. Netherlands, postage due stamp, 1947–53. 9. Great Britain, "Penny Black," 1840, the first adhesive postage stamp. 10. India, official or service stamp. 1950, for use on government mail. 11. Mexico, postal tax stamp, 1939, obligatory on ail mail, the revenue to be used to combat malaria. 12. Bulgaria, parcel post, 1931–32. 13. Canada, the "Bluenose," 1929, considered exceptionally beautiful by philatelists. 14. Germany, newspaper stamp, 1939. 15. Korea, airmail, 1954, showing east gate of Seoul. 16. Japan, airmail, 1953, showing Buddha of Kamakura and Mt. Fuji. 17. Finland. semipostal stamp, 1938, surtax for benefit of soldiers of the Union of the Finnish Front

328 he was producing plays in Athens, where he eventually became a citizen; he also worked in Alexandria for a time. Some 60 titles from his 9; comedies are known; they survive in Greek fragments (perhaps including quotations from his son, Philemon the Younger). and in Latin adaptations by Plautus *(Mercator, Mostellaria, Trinummus* and possibly other plays). His characteristics include neatly contrived plots, vivid description and frequent moralizing in a style which lacks Menander's grace.

PHILEMON, EPISTLE TO, a New Testament book. A short personal note by the apostle Paul has been preserved. which owes its origin to a romantic episode in the life of a slave, called Onesimus. For some reason he had run away from his master Philemon, a prosperous Christian citizen; it may be inferred that he had also been guilty of pilfering (ver. 18). For either offence he was liable by law to be crucified. In some unexplained way he had come across Paul and been converted to Christianity. This opened a difficult situation. The apostle boldly solved the problem by sending Onesimus back along with Tychicus, who was going to Colossae with Paul's letter to the local church; "I send him with Onesimus, that faithful and beloved brother. who is one of yourselves" (Col. iv, 9). But, not content with this certificate in favour of the converted and penitent slave, Paul sends also a note to his master, bespeaking his Christian interest in Onesimus. It is a brief letter, tactful and charming, in which the apostle, after greeting Philemon and his wife and the local church that met in his house, rejoices over Philemon's character. which, he says, emboldens him to enter a plea for poor Onesimus, now returning to his duty, a very different man from what he was when he ran away. Paul delicately suggests that he would like to have kept the slave beside him, and offers to be responsible for any debts incurred by Onesimus. He hints that this generous action on the part of Philemon will be a personal kindness to himself as well as to the slave. "You count me a partner? Then receive him as you would receive me, and if he has cheated you of any money or owes you any sum, put that down to my account. This is in my own handwriting. 'I Paul promise to refund it'—not to mention that you owe me, over and above, your very soul. Come, brother, let me have some return from you in the Lord. Refresh my heart in Christ."

Where the letter was written. we do not know. Rome was a natural place of refuge for runaway slaves, who could lose themselves in the huge population easily; if Colossians was written from Rome, so was this note. Where Philemon stayed is also uncertain; he may have been resident at Laodicea or at Ephesus, for though Onesimus accompanied the letter to the Colossian church, it does not follow that Colossae was the seat of his master; indeed, as Philemon was converted by Paul, that cannot have taken place at Colossae, which Paul had never visited. Still, Philemon may have shifted his quarters to Colossae.

The letter appears in two 2nd-century canons: that of Marcion and the Muratorian, though its lack of dogmatic importance as well as its brevity threw it afterward into some disfavour.

BIBLIOGRAPHY.—The letter is edited in most commentaries on Colossians (*q.v.*), and by *M*. R. Vincent in his edition of Philippians, *International Critical Commentary* (1897). Special editions: Rothe, *Pauli ad Philemonem epistolae interpretatio historico-exegetica* (1844); van Oosterzee, Eng. trans. (1868); Oesterley, *Expositor's Greek Testament* (1910). The social problems of the letter are discussed by Lightfoot in his Commentary on Colossians; by J. H. Bernard in Hastings' *Dictionary of the Bible* (iv, 832 ff.), and in Renan's *L'Antéchrist* (pp. 95 ff.). (J. MOF.)

PHILEMON AND BAUCIS, in Ovid's *Metamorphoses,* are a pious Phrygian couple who hospitably received Zeus and Hermes when their richer neighbours turned the gods away, they being disguised as wayfarers. As a reward, they were saved from a flood that drowned the rest of the country; their cottage was turned into a temple, and at their own request they became priest and priestess of it, and long after ended their lives at the same moment, being turned into trees.

The story lingers in the New Testament account (Acts xiv) of Paul's healing of the lame man at Lystra, nhose inhabitants identified Paul and his companion Barnabas with Zeus and Hermes, "come down to us in the likeness of men." Similar stories are given in the *Märchen* (fairy tales) of the Grimm brothers.

PHILES, MANUEL (*c.* 1275–134j), of Ephesus, Byzantine poet At an early age he removed to Constantinople, where he was the pupil of Georgius Pachymeres. in whose honour he composed a memorial poem. Having offended one of the emperors by indiscreet remarks published in a chronography, he was thrown into prison and only released after an abject apology. Philes' character. as shown in his poems. is that of a begging poet, always pleading poverty, and ready to descend to the grossest flattery.

PHILETAS OF Cos (c 330–*c.* 275 B.C.), Greek poet and grammarian, is rightly regarded as the founder of the Alexandrian school of poetry He was tutor to Ptolemy II and taught Zenodotus. Hermesianax and Theocritus. The titles of five of his poems or collections of poems have survived, the most Important being apparently the *Demeter,* an elegy narrating Demeter s wanderings. Though he wrote at least one poem in hexameters Philetas chief fame was as an elegist. His lady love was Bittis (or Battis) and Hermesianax states that the Coans put up a statue of him singing her charms. Among the Romans Propertius and Ovid mention him as their model. Philetas also compiled a lexicon of *Miscellaneous Glosses* (*Miscellanea*) comprising a collection of rare words from Homer, the Greek dialects and other sources.

See A. A. Day, *The Origins of Latin Love-Elegy,* pp. 14–19 (1938). (E. A. B.)

PHILIDOR, FRANÇOIS ANDRE DANICAN (1726–1795), French composer and chess player, was born at Dreux, on Sept. 7, 1726. He was widely regarded as the strongest chess player of the 18th century. After producing several musical works of minor importance, he brought out at Paris, in 1759, his successful light opera, *Blaise le Savetier,* which was followed by a number of others He died in London on Aug. 31. 1795.

PHILIP, one of the 12 apostles. *See* APOSTLE.

PHILIP, "the evangelist," is mentioned in Acts vi, 5, as one of "the seven" chosen to superintend certain secular business of the Jerusalem Church, in consequence of dissension between the Aramaic-speaking and Greek-speaking disciples. Luke by mentioning the common meals wishes his readers to connect these officials with the later diaconate, but they seem to have been originally parallel among the Hellenistic Jews to the Twelve among the Hebraists. Philip's was a ministry of the word. He went to Samaria and preached with much success, Simon Magus being one of his converts. He afterwards instructed and baptized the Ethiopian eunuch on the road from Jerusalem to Gaza. His missionary journey ended at Caesarea (Acts viii). Here he entertained Paul and his companions on their last journey to Jerusalem (xxi. 8). (W. K. L. C.)

PHILIP I (1052–1108), king of France, eldest son of Henry I of France and Anne, daughter of Jaroslav I (d. 1054), grand duke of Kiev, came to the throne, when a child of eight, by the death of his father on Aug. 4, 1060. He had been crowned at Reims. May 23. 1059. His minority came to an end in 1066. In the long reign that followed he showed no great ability or energy, and a looseness of morals which embroiled him with the church. Before he was fifty years of age he became "fond of nothing but good cheer and sleep." But he increased the lands of his house around Paris, maintained order in them, and held his own against William I and William II of England, whose power in France far exceeded his own. This he accomplished for the most part by taking advantage of the quarrels among his vassals. During the years 1070–74 he greatly strengthened his position in Flanders by these means. In the struggle between Fulk Rechin and his brother Geoffrey the Bearded for the inheritance of their uncle, Geoffrey Martel (d. 1060), count of Anjou, Philip received

from Fulk in 1069, as the price of his neutrality, Château Landon and the Gatinais. This acquisition linked the county of Sens, acquired in 1055, with the rest of the domain round Paris, Melun and Orleans. War with William I and William Rufus was chronic but intermittent. In his last years Philip left the duty of repelling the attacks of his Norman and other enemies to his son Louis, associating him with himself, as "king-designate," some time between May 24,1098, and Sept. 25, 1100.

It was his second marriage which was the cause of Philip's greatest difficulties. On May 15, 1092, he carried off Bertrada, daughter of Simon, baron de Montfort, wife of Fulk Rechin, and prepared to marry her, though his wife Bertha was still living. The bishops, headed by Ivo, bishop of Chartres, refused to attend the ceremony of marriage, but one was found to perform it. Philip's open simony had long been a cause of friction with the papacy. When he added bigamy and adultery, Urban II excommunicated him. Philip was reconciled with the Church in 1104, and took an oath not to have any converse or society with Bertrada except in the presence of "nonsuspect" persons. But they seem to have gone on living together, and even visited Fulk Rechin (Bertrada's husband) in company on Oct. 15, 1106. Philip died at the end of July 1108.

His reign is chiefly remarkable for the steady growth of the royal domain. By his first queen he had four children: Louis VI, who succeeded him; Henry, who died young; Charles; and Constance, who married Hugh I, count of Champagne, and later Bohemund I, prince of Antioch. By Bertrada de Montfort he had three children: Philip, count of Montes; Fleury or Florus, who married the heiress of Nangis; and Cecilia, who married, first Tancred, prince of Galilee and Antioch, and secondly Pons de Saint Gilles, count of Tripoli.

PHILIP II (1165–1223), known as PHILIP AUGUSTUS, king of France, son of Louis VII and Alice (or Adela), daughter of Theobald II, count of Champagne, was born on Aug. 21, 1165. On Nov. 1, 1179, he was associated with his father as king by being crowned at Reims; and at once his father's illness threw the responsibility of government on him, the death of Louis on Sept. 19, 1180, leaving him sole king. His long strip of royal domain was hemmed in by the Angevin empire on the west and by the kingdom of Arles on the southeast. Henry II of England was feudal lord of the greater part of France, practically all west of a line which began at Dieppe and ended at the foot of the Pyrenees more than halfway across to the Mediterranean, while at one point it nearly touched the Rhone. Philip's predecessors had consolidated the Capetian power within these narrow limits, but he himself was overshadowed by the power of his uncles, William, archbishop of Reims, Henry I, count of Champagne and Theobald V, count of Blois and Chartres. He secured an ally against them, and an addition to the royal domain, by marrying, on April 28, 1180, Isabella or Elizabeth, daughter of Baldwin V, count of Hainaut, and of Margaret, sister of Philip of Alsace, the reigning count of Flanders, who ceded, as Isabella's dowry, the district afterwards called Artois. On June 28, 1180, Philip made a treaty with Henry II at Gisors; but from 1181 to 1185 he had to struggle against the feudal league of his Champagnard uncles and other great barons, whose most active member was Stephen I, count of Sancerre (1152–91). Having secured his position at home, the king turned against Henry II and, by the truce of Châteauroux in June 1187, gained Issoudun and the seigniory of Fréteval in the Vendômois. Though the truce was for two years, Philip assembled an army in 1188 to invade Normandy, demanding Gisors and the conclusion of the marriage which had been arranged between his sister Alice and Richard I of England, who had meanwhile deserted his father. But Richard took the cross, and Philip seized the county of Berry. Further reconciliations and conferences followed, and Henry II, two days before his death, did homage and surrendered the territories of Graçay and Issoudun (capitulation of Azay). Pledges of mutual good faith and fellowship were exchanged between Philip and Richard of England on Dec. 30, 1189, and they both prepared to go on the crusade.

The Crusade.—Before setting out Philip arranged for the government of France during his absence by the testament of 1190, by which he proposed to rule France as far as possible from Palestine. On the way to Palestine the two kings quarrelled. At the siege of Acre Philip fell ill; and he returned to Paris at Christmas 1191, having concluded on his way an alliance with the emperor Henry VI against Richard, despite his pledges not to molest his lands. Philip did his utmost by offers of money to prolong Richard's captivity and, allied with the English king's brother John, attacked Richard's domains. But upon Richard's return the Normans rallied to him, and Philip was defeated at Fréteval on July 5, 1194. He continued the war, generally with ill success, for the next five years. Again a formidable coalition was formed against him, including Baldwin IX, count of Flanders (also count of Hainaut), Reynald, count of Dammartm and Boulogne. Louis, count of Blois, and Raymund VI, count of Toulouse. In Germany, Otto of Brunswick, afterward the emperor Otto IV, allied himself with Richard, while Philip was supported by Otto's rival. Philip of Swabia. Richard's death in April 1199 removed Philip's archenemy, and Richard's successor, John, concluded the treaty of Le Goulet with him on May 22, 1200, ceding to him the county of Evreux, Graçay and Issoudun and the suzerainty of Berry and Auvergne. John also renounced his suzerainty over Brittany and the guardianship of his nephew, Arthur; pledged not to aid the count of Flanders or Otto IV without Philip's consent; paid him a relief of 20,000 marks; and recognized himself as Philip's vassal for his continental fiefs.

Conquest of Normandy.—But in 1202 the war was renewed. At an interview at Le Goulet on March 25, Philip demanded the cession of Anjou, Poitou and Normandy to his ward, Arthur. John refused; he was summoned to Paris before the royal judges and, failing to appear, was sentenced at the end of April 1202 to lose all his fiefs. Brittany, Aquitaine and Anjou were conferred on Arthur. Philip invaded Normandy, took Lyons-la-Forkt and Eu and, establishing himself in Gournay, besieged Arques. But John, joined by William des Roches and other lords of Maine and Poitou, jealous at the increase of Philip's power, defeated and captured Arthur at Mirebeau. Philip abandoned the siege of Arques in a fit of fury, marched to the Loire, burning everywhere, and then returned to Paris. But John soon alienated the Poitevin barons, and William des Roches signed a treaty with Philip on March 22, 1203. Then Philip continued his great task, the conquest of Normandy, capturing the towns around the fortress of Château Gaillard which Richard had built to command the valley of the Seine. Pope Innocent III tried to bring about peace, but Philip was obdurate; and after murdering Arthur of Brittany, John took refuge in England in Dec. 1203. The fall of Château Gaillard, after a siege which lasted from Sept. 1203 to April 1204, decided the fate of Normandy. Rouen, bound by ties of trade to England, resisted for 40 days but surrendered on June 24, 1204. The conquest of Maine, Touraine, Anjou and Poitou in 1204 and 1205 was little more than a military promenade, though the castles of Loches and Chinon held out for a year. Philip secured his conquest by lavishing privileges on the convents and towns. He left the great lords, such as William des Roches, in full possession of their feudal power. In 1206 he marched through Brittany and divided it among his adherents. A truce for two years was made on Oct. 26, 1206, by which John renounced all claims in Normandy, Maine, Brittany, Touraine and Anjou; but it did not last six months. Then Poitou was thoroughly subdued, and another truce was made in 1208, little more than southern Saintonge and Gascony being left in the hands of John. Philip had reduced to a mere remnant the formidable continental empire of the Angevins, which had threatened the existence of the Capetian monarchy.

Philip then undertook to invade England. He had collected 1,500 vessels and summoned all his barons when John, frightened, made his profession of allegiance to the cardinal-legate Pandulph.

Disappointed of his hopes of England, Philip turned his arms against Ferdinand, count of Flanders. He invaded Flanders and took the chief towns within a week; but he had part of his fleet burned by the English at Damme and had to burn the rest to save it from falling into their hands. He returned to Paris; and Ferdinand retook most of the towns which had been taken by the king. A war of fire and pillage began, in which Philip and his son Louis

burned their way through Flanders, and Ferdinand did the same through Artois.

The Victory of **Bouvines.**—In 1214 came the great crisis of Philip's life. A league including his rebel vassals. Reynald of Dammartin and Boulogne and Ferdinand of Flanders, with the emperor Otto IV and a number of German princes of the Rhine region, had been formed in the northeast, while John of England made one more attempt to recover his heritage at the head of an army of mercenaries, aided by the fickle baronage of Poitou. John landed at La Rochelle on Feb. 10, 1214, and was at first successful. On June 19 he laid siege to La Roche-aux-Moines, the fortress which defended Angers and commanded the Loire valley; but on the approach of a royal army under Prince Louis on July 2 his army was panic-stricken, and he fled hastily to La Rochelle. The Angevin empire in France was lost. Meanwhile Philip himself won his greatest victory at the bridge of Bouvines (*q.v.*), among the morasses of Flanders. At first taken by surprise, he turned the abortive attack into a complete rout. Reynald and Ferdinand were taken prisoner, and Otto IV fled from the battlefield. The army of the allies was utterly destroyed (July 27, 1214). The battle of Bouvines, a decisive battle for the history of Germany as well as for France and England, sealed the work of Philip Augustus. The expedition of his son Louis to conquer England can hardly be considered as an incident of his reign, though he was careful to safeguard the rights of the French crown. More important was the Albigensian crusade, in which he allowed Louis to take part, though he himself, preoccupied with the king of England, had refused time after time to do anything. He treated Simon IV de Montfort as if he were a royal *bailli;* but it was not in virtue of any deep-laid scheme of his that in the end Amaury de Montfort, Simon's son, resigned himself to leave his lands to the crown of France and gave the crown a power such as it had never before possessed in Languedoc.

Organization of France.—Philip II surrounded himself with clerks and legists of more or less humble origin, who gave him counsel and acted as his agents. His *baillis,* who at first rather resembled the itinerant justices of Henry II of England, were sent into the royal domain to supervise the conduct of the *prévôts* and to be responsible for all that concerned order, justice and taxes; while in the south local feudal magnates were given similar powers with the title of *sénéchal (see* BAILIFF AND BAILIE). Feudal service was more and more compounded-for by a money payment, and additional taxes were raised. The extension of the system of *sauvegarde,* by which abbeys, towns or lay vassals put themselves under the special protection of the king, and that of *pariage,* by which the possessor surrendered half the interest in his estate to the king in return for protection or some further grant, increased the royal power. The gentry was completely reduced to bondage. The nobles were ceaselessly watched (their widows could not remarry without the king's consent). The king, moreover, held himself to be supreme suzerain and also sovereign over the whole feudal system.

It has been said with some justice that Philip II was the first king of France to take the bourgeoisie into partnership. He favoured the great merchants, granting them trade privileges and monopolies. The Jews he protected and plundered by turns, after the fashion of mediaeval kings. Among the subject towns administered by *prévôts* a great extension of the "custom of Lorris" took place during his reign. Philip was the ally and protector of the communes. Before him they were resisted and often crushed; after him they were exploited, oppressed and finally destroyed. In the case of Senlis he extended the jurisdiction of the commune to all crimes committed in the district. It is true that he suppressed some communes in the newly conquered fiefs, such as Normandy, where John had been prodigal of privileges, but he erected new communes in his own private domain, quite corftrary to the custom of other kings. He seems to have regarded them as a kind of garrison against feudal unruliness, while the rents that they furnished increased his financial resources. He created no new types of commune, however, except Péronne, which received a maximum of political independence.

Philip's policy of building up a strong monarchy was pursued with a steadiness of aim which excluded both enthusiasm and scruple. He shrank from no trickery in carrying out his ends and had no room for pity. He could not even trust his own son with any power and was brutal in his relations with his queen, Ingeborg. As the result of his steadiness of aim and patient sagacity, at the end of his reign the crown was victorious over the feudal nobility and the royal domain extended to the frontiers along with royal authority. Artois, the Amiénois, Valois, Vermandois, the greater part of the Beauvaisis, Normandy, Maine, Anjou. Touraine and an important part of Poitou and Saintonge, were added to the domain during his reign. The number of *prévôtes* was increased from 38 to 94; and the royal revenue increased from 19,000 livres a month to 1,200 livres a day.

Philip Augustus died on July 14, 1223. He was married three times. His first wife, Isabella, by whom he had one son, Louis, died in 1189 or 1190. After her death he married Ingibjörg or Ingeborg (*q.v.*), daughter of Valdemar I oi Denmark, whom he soon repudiated. In 1196, in defiance of the pope, he married Agnes, daughter of Bertold IV, duke of Meran. This led to his excommunication and brought the interdict upon France, and did more to weaken him than any other act of his. In 1200 he was forced to put away Agnes and to recognize Ingeborg as his lawful wife, but he kept her in prison until 1213. By Agnes (d. 1201) he had a son Philip, called "Hurepel," count of Clermont, and a daughter Mary, who married Philip, count of Namur (d. 1213), and then Henry II, duke of Brabant. Ingeborg lived until 1237 or 1238.

PHILIP III (1245–1285), surnamed THE BOLD *(le Hardi),* king of France, son of Louis IX and Margaret, daughter of Raymund-Berengar IV, count of Provence, was born on April 3, 1245. His funeral monument at St. Denis depicts a man with beardless. square-cut features, but lacking character and animation. The authenticity of this effigy is fairly well borne out by what is known of him from other sources. He had many of the virtues of his father, St. Louis, but neither decision of character nor devotion to duty. He was pious, charitable, of unimpeachable morality, quick-tempered but placable, no great scholar and only energetic as a hunter. The absence in him of the qualities that fit a man to rule made his court the arena of intriguing factions, which in reality ruled France during his reign of 15 years (1270–85). Matthew of Vendôme, abbot of St. Denis, an old servant of Louis IX, acted as Philip's counsellor, so the chroniclers state, throughout the reign; but it was probably with administration, not with policy, that Matthew was chiefly concerned. Philip began his reign in 1270 by falling entirely under the influence of Pierre de la Brosse. formerly surgeon and valet-de-chambre to his father, and made him lord (sieur) of Langeais. Châtillon-sur-Indre and Damville. His influence lasted until Philip's second marriage in 1274 with Mary, daughter of Henry III, duke of Brabant. She supplied a centre for the enemies of the favourite, who, in 1278, was charged with various crimes, including that of poisoning the king's eldest son, and hanged at Montfaucon. His death left the parties of Mary, the queen, and Margaret, the queen-mother, to struggle for the mastery.

Nevertheless, under the reign of this feeble and disparaged king, the royal domain was considerably enlarged, particularly in the years during which Philip followed the advice of his father's old counsellors. As early as 1271, he took hold of the huge inheritance of his uncle Alphonse of Poitiers, that is of almost the whole of the Languedocian south. But after Henry III of England had demanded the settlement of the claims allowed to him by the treaty of Paris (1259), the right of his son Edward I to such territories as Guienne, Agenais and southern Saintonge was recognized by the treaty of Amiens (1279). In May 1284, Philip had married his second son Philip to Joan of Artois, the sole heiress of Navarre and Champagne, thus preparing the annexation of the latter province

to France. However, being more and more under the thumb of his second wife Mary of Brabant and of his uncle Charles of Anjou, Philip was carried away to undertake more and more perilous and costly expeditions. An expedition against Castile in aid of the children of his sister, Blanche, proved abortive. Regardless of this warning. he was induced in 1284 to take up the quarrel of his uncle Charles I of Anjou in Sicily, after the Sicilian Vespers (see VESPERS, SICILIAN) in 1282. TWO assemblies of barons and prelates were held at Bourges in Nov. 1283 and Feb. 1284 to deliberate on the question. This was a mere matter of form. Mary of Brabant and her party had decided the matter beforehand, and the crown of Aragon, which the French pope Martin IV had declared forfeited by Peter III, was accepted for Charles of Valois, Philip's third son. The project was strongly opposed by Matthew of Vendôme, who was in correspondence with the king of England on the subject. It was the first warlike expedition undertaken by the house of Capet outside France and proved a disastrous failure. Philip died during the retreat at Perpignan on Oct. 5, 1285.

Philip was twice married. On May 28, 1262, he married Isabella, daughter of James I, king of Aragon, who died in 1271. By her he had four children: Louis, who died in 1276; Philip, born in 1268; Charles of Valois, born on March 12, 1270; and Robert, who died young. By his second wife, Mary (d. 1322), daughter of Henry III of Brabant, whom he married in 1274, he had three children: Louis, count of Evreux; Margaret, who married in 1299 Edward I, king of England; and Blanche, who married Rudolph 111, duke of Austria.

PHILIP IV (1268–1314), called THE FAIR (le *Bel),* king of France, was the son of Philip III and his wife, Isabella of Aragon. His reign, which began in Oct. 1285, is one of the most momentous in the history of mediaeval Europe, yet it belongs rather to the history of France and to that of the papacy than to the biography of the king (see FRANCE: *History).*

No king has ever been so variously judged as Philip the Fair: some saw a great king in him; others deemed him only a feeble character, not of outstanding merit, interested but little in politics and letting his ministers act as they thought fit. Yet, it must be observed that his counsellors, whom he drew from the legal class (that is, from people willing to see the rights of the monarch and of the state increased), never fell into disgrace: such men as Guillaume de Nogaret, Enguerrand de Marigny (*q.v.*) and Pierre Flote had Philip's support in all circumstances; and this suggests that he was perhaps himself the promoter of the whole policy, or at least that he understood it and approved of it. Tall and handsome, with irreproachable manners, well-read, brave, cold and silent, his ambition was to be the sole master of his kingdom, above any other secular or ecclesiastical power and without any limitation of this authority to the royal domain proper.

In the first place, Philip tried to use peaceful methods and succeeded in establishing his judges' orders and the right of appeal to his courts as applicable to Burgundy and Brittany, provinces which did not belong to the domain. His procedure was the same in financial matters. But in Aquitaine, where he had to encounter the king of England, and in Flanders he was unsuccessful and, resorting to violent means, was not always favoured by fortune. In 1294 he attacked Edward I of England, then busied with the Scottish War, and seized Guienne. Edward won to his side the counts of Bar and of Flanders. but they were defeated. A truce was made in 1297 and renewed until the peace of 1303. Meanwhile the Flemings had utterly defeated the French army at Courtrai in 1302. The reign closed with the French position unimproved in Flanders, except for the transfer to Philip of Douai and Béthune and their dependencies by Count Robert of Lille. However, it was in his reign that the royal administration was definitely constituted, the king's rights as sovereign enabling him to interfere everywhere, against the feudal lords and against the clerics. This expensive policy and his interest in the wealth of the monarchy as a means of augmenting his power caused Philip to be permanently occupied with financial affairs; and it was this preoccupation that brought him into conflict with the papacy and led him to suppress the Templars.

The greatest event of the reign was the struggle with Pope Boniface VIII (*q.v.*). The pope went so far in 1296 as to forbid any lay authority to demand taxes from the clergy without his consent. When Philip retaliated by a decree forbidding the exportation of any coin from France, Boniface gave way to save the papal dues, and the bulls issued by him in 1297 were a decided victory for the French king. There was a truce until 1301. After the arrest, by Philip's orders, of Bernard Saisset (*q.v.*), bishop of Pamiers, in that year, the quarrel flamed up again. To ensure the support of his people the king had called an assembly of the three estates of his kingdom at Paris in April 1302; in the following year Guillaume de Nogaret seized the person of the pope at Anagni. Boniface escaped from his captors only to die (Oct. 11); and the short pontificate of his saintly successor, Benedict XI, was occupied in a vain effort to restore harmony to the church. The issue of the conclave that met at Perugia on his death was ultimately determined by the diplomacy and gold of Philip's agents, and the new pope, Clement V, was the weak-willed creature of the French king. When in 1309 the pope installed himself at Avignon, the new relation of the papacy and the French monarchy was patent. It was the beginning of the "Babylonish captivity" of the popes. The most notable of its first-fruits was the hideous persecution of the Templars (*q.v.*), which began with the sudden arrest of the members of the order in France in 1307 and ended with the suppression of the order by Pope Clement at the council of Vienne in 1312. Philip died on Nov. 29, 1314. In 1284, he had married Joan, queen of Navarre (d. 1305), through whom Navarre passed under the king's rule and who brought Champagne to the royal domain. Three of Philip's sons, Louis X, Philip V and Charles IV, succeeded in turn to the throne of France; his daughter, Isabella, married Edward II of England.

PHILIP V (1294–1322), king of France, called THE TALL, second son of Philip IV and Joan of Navarre, received the county of Poitiers as an apanage. While Philip was watching the conclave in Lyons, on June S, 1316, his elder brother Louis X died, leaving a four-year-old daughter, Joan, by his first (adulterous) wife and a widow with child. Philip returned at once to Paris, where his uncle, Charles of Valois, had occupied the royal palace and the Louvre. Supported by the high officers and the Paris burgesses, Philip succeeded on July 12 in taking hold of the palace; on July 16 an assembly of noblemen gave him an oath of allegiance and decided that he should be regent of France and Navarre till the majority of the unborn king. Charles of Valois and his supporters accepted him. On Nov. 15, Queen Clemence gave birth to a son, John I, who lived only five days. Philip had already prepared for the elimination of his niece Joan, by treating with her uncle, the duke of Burgundy, to whom he gave his daughter in marriage. He proclaimed himself king on Nov. 19, received oaths from his brothers and uncles and on Jan. 9, 1317, was crowned in Reims despite the protest of Agnes of Burgundy, Joan's grandmother. Most of the great barons did not attend the coronation, and there was some armed resistance from the nobility in Champagne, Artois and Burgundy.

Because of this dubious legitimacy, Philip tried to keep in touch with public opinion and summoned a number of assemblies to get their support. In Feb. 1317 he received approbation for his conduct from an assembly of noblemen, bishops, Paris burgesses and university masters, which proclaimed that women could not succeed to the crown. In March of the same year two assemblies were held, one in Paris for delegates from the northern towns, the second in Bourges for the south. A fourth meeting took place in Paris in the following April. During the four succeeding years

new assemblies were held, gathering barons, bishops and townsmen either from a single province or from several. They took no political character, dealing only with coinage and weights (the king tried vainly to achieve uniformity by suppression of the feudal coins) and with money demands from the government. They were poorly attended, and their failure illustrates the general obedience and the power of the monarchy. which came undamaged out of the succession crisis.

Philip did much to restore royal power, which had been weakened by the feudal reaction under his brother: he reorganized the police forces by developing the towns' militias, whose captains were under his authority; he ordered large inquests to redress grievances. In an attempt to settle the Flemish question, he made concessions to the Flemish count by the treaty of Paris (Sept. 1, 1316). But the quarrel about the indemnity due from Flanders by virtue of the treaty of Athis-sur-Orges went on, despite papal arbitration in 1318, and Philip had to send armies to Flanders in 1318 and 1319. Then Robert of Béthune, threatened by internal opposition, accepted the papal arbitration and did homage in Paris (April 1320). After difficult and protracted negotiations and the seizure of the county of Ponthieu, Philip got homage from Edward II (at Amiens on June 20, 1320). Philip died on Jan. 9, 1322, leaving a daughter and a pregnant wife.

PHILIP VI (1293–1350), king of France, was the son of Charles of Valois, third son of Philip III the Bold, and of Margaret of Sicily, and was thus the nephew of Philip IV the Fair, whose sons, Louis X, Philip V and Charles IV, died successively without leaving male heirs (except the posthumous and short-lived John I). He succeeded to the throne on the death of his cousin, Charles IV, in 1328. Before his accession Philip had enjoyed considerable influence, for he was count of Valois, Anjou, Maine, Chartres and Alençon. He had married in, 1313 Joan (d. 1348), daughter of Robert II of Burgundy, a determined woman who was long known as the real ruler of France.

When Charles IV died, in Feb. 1328, his wife was pregnant, and it became necessary to appoint a regency until the birth of the child, who would, if a son, succeed to the throne. At the assembly of barons called to choose a regent, Edward III of England, the nephew and nearest male relation of Charles IV, put in a claim. Edward III, however, descended from the royal house of France by his mother Isabella; and the barons, probably actuated by an objection to the regency of an English king, decided that neither a woman, "nor by consequence her son, could succeed to the kingdom of France." Philip of Valois, then, in spite of his belonging to a junior branch of the family, was elected regent. On the birth of a girl to the queen widow the regency naturally led to the throne of France, and Philip was crowned at Reims on May 29, 1328. Navarre had not accepted the regency, that kingdom being claimed by Philip count of Evreux (who was, like Philip of Valois, a grandson of Philip III of France), for his wife Joan, eldest daughter of Louis X. The new king of France secured the friendship of the count by allouing Joan's claim to Navarre, in return for a renunciation of any right to Champagne. Edward III of England, after more than one citation, reluctantly fulfilled (1329–31) the formalities of homage for part of Guienne. Meanwhile Philip VI had won a victory, which he turned into a massacre, at Cassel (Aug. 23, 1328) over Bruges and the other towns of west Flanders, which under the leadership of Jakob van Artevelde had thrown off the authority of their count, Louis of Nevers. The count of Flanders was reinstated and maintained his authority by a reign of terror.

Philip VI enjoyed powerful alliances. In Italy he was allied with his uncle, Robert of Anjou, king of Sicily, and with his former enemy, Galeazzo Visconti; in the north with the duke of Brabant and the princes of the Netherlands; on the east with the reigning princes of Lorraine and Savoy; with the king of Bohemia and with Pope John XXII at Avignon and his successor Benedict XII. In 1336 it seemed that the crusade, for which Philip VI had been preparing since 1330 would at last start; but the relations with Edward III of England, always strained, became worse, and within a year France was embarked on the struggle of the Hundred Years' War. The causes which led to war, the conflict for commercial supremacy in Flanders, disputed rights in Guienne, the help given by France to the Scots and the unnatural situation of an English king who was also a vassal of the French crown are dealt with elsewhere (see HUNDRED YEARS' WAR, THE). The immediate rupture in Flanders was due chiefly to the tyranny of the count of Flanders, Louis of Nevers, whom Philip had reinstated. Edward III had won over most of Philip's German and Flemish allies, and the English naval victory at Sluys (June 24, 1340), in which the French fleet was annihilated, effectually restored English preponderance in Flanders. A truce followed, but this was disturbed after a short duration by the disputed succession to the duchy of Brittany (*q.v.*).

A truce made at Malestroit in 1343, at the invitation of the pope, was rudely broken by Philip's violence. Olivier de Clisson, who with 14 other Breton gentlemen was suspected of intrigue with Edward III, was invited to a great tournament in Paris. On their arrival they were seized on Philip's orders and, without form of trial, beheaded. Then followed Edward III's invasion of Normandy and the campaign of Créçy (*q.v.*). Philip's army was destroyed; he himself was wounded and fled from the field. He sought in vain to divert Edward from the siege of Calais by supporting the Scots in their invasion of England; but eventually a truce was arranged, which lasted until 1351. Philip died at Nogent-le-Roi on Aug. 12, 1350. Philip VI met his necessities by the imposition of the hated *gabelle* or salt tax and by debasing the coinage; and he obtained heavy subsidies from the various provinces. In 1349 he bought Montpellier from James III of Majorca and the province of Dauphiné (for his grandson Charles) from Humbert II, count of Vienne. Philip married a second wife, Blanche of Navarre. By his first wife he left two sons—his successor, John II, and Philip of Orléans, count of Valois.

PHILIP (c. 1177–1208), German king and duke of Swabia, the rival of the emperor Otto IV, was the fifth and youngest son of the emperor Frederick I and Beatrix, daughter of Renaud III, count of Upper Burgundy. and brother of the emperor Henry VI. He entered the church, was made provost of Aix-la-Chapelle, and in 1190 or 1191 was chosen bishop of Würzburg. Philip forsook his ecclesiastical calling and was made duke of Tuscany in 1195 receiving an extensive grant of lands. In 1196 he became duke of Swabia, on the death of his brother Conrad; and in May 1197 he married Irene, daughter of the eastern emperor, Isaac Angelus, and widow of Roger II, king of Sicily. Philip appears to have been designated as guardian of the young Frederick, afterwards the emperor Frederick II, in case of his father's early death. In 1197 he had set out to fetch Frederick from Sicily for his coronation when he heard of the emperor's death and returned at once to Germany. He found growing hostility to the kingship of a child, and the absence of the two Welf claimants, Otto and Henry, the sons of Henry the Lion, made possible Philip's own election as German king at Miihlhausen on March 8, 1198. He was crowned at Mainz on Sept. 8.

Meanwhile a number of princes hostile to Philip, under the leadership of Adolph, the archbishop of Cologne, had elected an antiking in the person of Otto, second son of Henry the Lion, duke of Saxony. War followed, in which Philip drew his principal support from south Germany. In 1199 he received further accessions to his party and carried the war into his opponent's territory. In March 1201 Innocent III placed Philip and his associates

under the ban, and began to work for Otto. Otto, aided by Ottakar I., king of Bohemia, and Hermann I., landgrave of Thuringia, drove him from north Germany, and compelled him to seek, in vain, reconciliation with Innocent. The submission of Hermann of Thuringia in 1204 marks the turning-point of Philip's fortunes, and he was soon joined by Adolph of Cologne and Henry I, duke of Brabant. On Jan. 6, 1205, he was crowned again by Adolph at Aix-la-Chapelle, though it was not till 1207 that his entry into Cologne practically brought the war to a close. Philip was then loosed from the papal ban. He was preparing to crush the last flicker of the rebellion in Brunswick when he was murdered at Bamberg, on June 21, 1208, by Otto of Wittelsbach, count palatine in Bavaria, to whom he had refused the hand of one of his daughters. He left four daughters, one of whom, Beatrix, afterwards married his rival, the emperor Otto IV. Philip was a brave and handsome man, and contemporary writers, among whom was Walther von der Vogelweide, praise his mildness and generosity.

Ficker (Innsbruck, 1881); R. Schwrmer, *Innocenz ZZZ. und die deutsche Kirche wahrend des Thronstreites von 1198–1208* (Strasbourg, 1882).

PHILIP I., king of Macedonia, a semi-legendary prince, son of Argaeus, was, according to Herodotus (viii. 137–139) and Thucydides (ii. 100), the third of the Macedonian kings. There is, however, no real evidence for his existence.

PHILIP II. (382–336 B.C.), king of Macedonia, the son of Amyntas II. and the Lyncestian Eurydice, reigned 359–336. At his birth the Macedonian kingdom, including the turbulent peoples of the hill country behind, was very imperfectly consolidated. In 370 Amyntas died, and the troubled reign of Philip's eldest brother, Alexander II., was cut short in 368 by his assassination. His murderer, Ptolemy of Alorus, ruled as regent for the young Perdiccas, Amyntas's second son. In 367 Philip was delivered as a hostage to the Thebans, then the leading power of Greece, where he got to know Epameinondas, whom he greatly admired and whose influence may be traced in Philip's military reforms. When he returned to Macedonia (364) Perdiccas had succeeded in getting rid of Ptolemy; but he fell in 360–359 before an onslaught of the hill tribes instigated by the queen-mother Eurydice, leaving only an infant son. Pretenders sprang up and the kingdom fell into confusion. Philip seized the throne and drove back his rivals. He now began the great task of his life—the creation of the Macedonian national army. Cavalry, the famous "companions," he already had; his work was to produce an efficient force of infantry. This new force of his making consisted of the *hupaspistai* who may have been peltasts on Iphicrates's model, and the phalanx, which in its use for shock tactics on the wing in conjunction with the cavalry shows the influence of Epameinondas, but was less densely packed, and was armed, unlike Greek troops, with a long pike. The first experiment he made with this new organism was brilliantly successful. The hill tribes were broken by a single battle in 358, and Philip established his authority inland as far as Lake Ochrida. In the autumn of the same year he took the Athenian colony Amphipolis, which commanded the gold-mines of Mt. Pangaeus. Their possession was all-important for Philip, and he set there a new city, Philippi. Athens was temporarily pacified by assurances that Amphipolis would be handed over to her later on.

He avoided as yet a forward policy, and having taken Pydna and Potidaea soon after Amphipolis, he made them over to the Olynthian confederation (*see* OLYNTHUS). His marriage with the fierce witch-woman, Olympias, daughter of the Epirote king, falls in this period, and in 356 she bore him his greater son, Alexander. In 353 Philip was ready for strong action. He first attacked Abdera and Maroneia, on the Thracian sea-board, and then took Methone, which belonged to Athens. An overt breach with Athens was now inevitable. In the same summer he invaded Thessaly, where the Aleuadae of Larissa ranged themselves on his side against the *tagos* Lycophron, "tyrant" of Pherae. Pherae called in the help of the Phocian mercenaries, who had profaned Delphi, and Philip was twice heavily defeated. But next year the Macedonian army won a complete victory over the Pheraeans and Phocians. This battle made Philip tagos of Thessaly, and he annexed Magnesia, which included Pagasae. But on advancing further he found the Athenian expedition which had failed to secure Pagasae holding Thermopylae, and withdrew. From 352 to 346 Philip did not again come south. He was active in completing the subjugation of the Balkan hill-country to the west and north, and in reducing the Greek cities of the coast as far as the Hebrus (Maritza). Then, in 349, he opened war upon Olynthus. Athens sent no adequate forces, in spite of the upbraidings of Demosthenes (see his Olynthiacs), and in the spring of 347 Olynthus fell. Macedonia and the regions adjoining it having now been securely consolidated, Philip celebrated his "Olympian" games at Dium. In 347 Philip advanced to the conquest of the eastern districts about the Hebrus, and compelled the submission of the Thracian prince Cersobleptes. Meanwhile Athens had made overtures for peace (see the De falsa *legatione* of Demosthenes), and when Philip, in 346, again moved south, peace was sworn in Thessaly.

The Phocians, who still dominated Delphi and held Thermopylae, now furnished a pretext to Philip as the champion of Pan-Hellenism and Apollo. The Phocian mercenaries at Thermopylae were bought off and Philip crossed into central Greece. There he made Thebes his ally and visited the Phocians with crushing vengeance. The Pythian games of 346 were celebrated at the delivered Delphi under Philip's presidency. Pan-Hellenic enthusiasts already saw Philip as the destined captain-general of a national crusade against Persia (Isocrates, *Philippus*, about 345). And such a position Philip had determined to secure; the Macedonian agents continued to work throughout the Greek states and in the Peloponnesus Sparta soon found herself isolated. Euboea, too, submitted to Macedonian influence.

But more work had to be done in the Balkan highlands. In 344, or one of the following years, the Macedonian arms were carried across Epirus to the Adriatic and Thessaly was completely reorganized. In 342 Philip led a great expedition north "comparable to nothing in antiquity since Darius' famous march to Scythia." Meanwhile he continued to foster diplomatic relations with various Greek states, and, by conciliatory measures, to support the efforts of the pro-Macedonian party in Athens. But Demosthenes eventually carried the day, and Philip came more or less openly to blows with Athens over Diopeithes's behaviour in the Chersonese. Athens then supported the revolt of Philip's allies in Propontis, and struck a heavy blow at his prestige when his sieges of Perinthus and Byzantium failed in 339. But before marching south he led another expedition across the Balkans into the country now called Bulgaria, and returned to Pella with much spoil but severely wounded in the thigh.

In 338 he once more crossed into central Greece. The pretext was the contumacy shown by the Locrian town Amphissa to the rulings of the Amphictyonic council. Philip's fortification of Elateia filled Athens with alarm. Thebes was induced to join Athens; so were some of the minor Peloponnesian states, and the allies took the field against Philip. This opposition was crushed by the epoch-making battle of Chaeroneia, which left Greece at Philip's feet. Thebes was occupied by a Macedonian garrison; Athens, which had expected a fight to the death, was treated generously. In the following year (337) Philip was in the Peloponnesus and held a congress of the Greek states at the isthmus (from which, however, Sparta held sullenly aloof). The states attending were organized into an Hellenic league, with a constituent council and a supreme judicial court (the Amphictyonic council), acknowledging the military command of Philip and sending contingents for the expedition against Persia that was next in his plans. Philip returned to Macedonia to complete his preparations; an advance force was sent into Asia in the spring of 336. Philip was murdered that year during the marriage festival of his daughter at Aegae, the old capital of Macedonia. He left, however, in the Macedonian army a splendid instrument which enabled his son within ten years to change the face of the world.

See the authorities under **GREECE**: *History. A* vivid and masterly sketch of Philip's personality and work is given in D. *G.* Hogarth's

Philip and Alexander (1897). For economic policy, A. B. West in *Numism. Chron.* (1923) 169.

PHILIP III (ARRHIDAEUS), king of Macedonia, was the feeble-minded son of Philip II of Macedonia by a Thessalian wife. He was chosen by the Macedonian army at Babylon in 323 to be nominal king conjointly with the infant Alexander, and was killed in Macedonia by order of Olympias (317 B.C.). *(See* MACEDONIAN EMPIRE.)

PHILIP IV, king of Macedonia, was the son of Cassander, king of Macedonia; he reigned only one year (297–296 B.C.).

PHILIP V, king of Macedonia, son of Demetrius II and Chryseïs, was an infant at his father's death in 230–229 B.C. His cousin, Antigonus Doson, administered the kingdom as regent till his death in 221–220 B.C., when Philip was 18 years old. Philip now ascended the throne and reigned till 179 B.C. His reign was occupied in the vain struggle to maintain the old Xfacedonian supremacy in the Balkan peninsula, which became hopeless after the intervention of Rome and the decisive battle of Cynoscephalae (197 B.C.). *See* ROME: *Ancient History.* (E. R. B.)

PHILIP I, the Handsome (1478–1506), king of Spain, son of the emperor Maximilian I, was born at Bruges on July 22, 1478. In 1482 he succeeded to the Burgundian possessions of his mother Mary, daughter of Charles the Bold. In 1496 he married Joanna, daughter of Ferdinand and Isabella. He died suddenly at Burgos on Sept. 25, 1506.

PHILIP II (1527–1598), king of Spain, son of the emperor Charles V and Isabella of Portugal, was born at Valladolid on May 21, 1527. Philip was educated in Spain. The emperor, as he moved from one part of his wide dominions to another and in the camps of his armies, watched his heir's education from afar. The trend of his letters was to impress on the boy a profound sense of the high destinies to which he was born, the wisdom of distrusting counsellors, and the necessity for keeping his nobles apart from all share in the conduct of the internal government of his kingdom. Philip grew up grave, self-possessed and distrustful. He was beloved by his Spanish subjects, but utterly without the power of attracting men of other countries. Though accused of extreme licentiousness, Philip was probably less immoral than most kings of his time, and he was rigidly abstemious. His power of work was unbounded, and he had an absolute love of reading, annotating, and drafting dispatches. Unhappily for Spain, Charles decided to transmit the Netherlands to his son. In 1543 Philip had been married to his cousin Mary of Portugal, who bore him a son, the unhappy Don Carlos, and who died in 1545. In 1554 Charles summoned Philip to Flanders and arranged the marriage with Mary, Queen of England, in order to form a union of Spain, the Netherlands and England against France. The marriage proved barren. The abdication of his father (Jan. 16, 1556) constituted Philip sovereign of Spain with its American possessions, of the Aragonese inheritance in Italy, Naples and Sicily, of the Burgundian inheritance—the Netherlands and Franche Comté—and of the duchy of Milan. It was a legacy of immense responsibilities and perils, for France was bound to endeavour to ruin a power which threatened its independence. France was beaten at St. Quentin and Gravelines, and forced to make the peace of Cateau Cambrésis (April 2, 1559). But the death of Mary of England (Nov. 17, 1558) and the establishment of Elizabeth I on the English throne, put on the flank of Philip's scattered dominions another power, forced no less than France by political necessities to be his enemy. His marriage with Elizabeth of Valois (June 22, 1559), and the approach of the wars of religion, gave him a temporary security from France. Kevertheless. when Philip went back to Spain, in Aug. 1559, he was committed to a life-long struggle, in which he could not prove victorious except by the conquest of France and England.

External and internal influences alike drove Philip into conflict with the Netherlands, France and England. The conflict became one between Protestantism and Roman Catholicism, in which Philip appeared as the champion of the Church. It was a part he rejoiced to play. His persecutions hardened the obstinacy of the Dutch, exasperated the English and provoked a revolt of the Moriscoes. No experience of the failure of his policy could shake his belief in its essential excellence. Philip had a high ideal of his duty as a king, and had no natural preferences for violent courses. His strong measures in Aragon in 1591 were provoked by extreme misconduct on the part of a faction. When he enforced his claim to the crown of Portugal (1579–1581) he preferred to placate his new subjects by guarding their privileges. He even made dangerous political concessions to win over the gentry. In private life he was orderly and affectionate to his family and servants. He was slow to withdraw the confidence he had once given. In the painful episode of the imprisonment and death of Don Carlos, Philip behaved honourably. He died at the Escorial on Sept. 13, 1598.

As an administrator Philip had all the vices of his type, that of the laborious, self-righteous man, who thinks he can supervise everything, is capable of endless toil, and jealous of his authority. He set the example of the unending discussions in committee and boundless minute writing which choked the administration.

PHILIP III (1578–1621), king of Spain, son of Philip II, and Anne, daughter of Maximilian II, was born at Madrid, April 14, 1578. He inherited the beliefs of his father, but no share of his industry. He left the direction of government entirely to his favourite, the duke of Lerma, and, after the latter's overthrow in 1618, to the new favourite, the duke of Uceda, Lerma's son. Philip's own life mas passed amid court festivities, on which enormous sums of money were wasted, or in the practice of childish piety. It was said that he was so virtuous as hardly to have committed a venial sin. He died at Madrid. March 31. 1621.

See R. Watson and W. Thompson, *History of Philip III,* 2 vol. (1876, 1808).

PHILIP IV (1605–1665), king of Spain, eldest son of Philip III and Margaret, sister of the emperor Ferdinand II, was born at Valladolid April 8, 1605. His reign, after a few years of barren successes, was a long story of political and military decay and disaster. A fine horseman, a keen hunter and a patron of art and letters, he indulged in these pastimes, leaving the government to his favourite Gaspare Olivares. When, in 1643, the disasters falling on the monarchy led to the dismissal of Olivares, Philip had lost the power to devote himself to hard work. After a brief attempt at directing the administration of the most extensive and the worst organized monarchy in Europe, he returned to his pleasures and was governed by other favourites. His political opinions were those he had inherited from his father and grandfather. He thought it his duty to support the German Habsburgs and the cause of the Roman Catholic Church against the Protestants. to assert his sovereignty over the Ketherlands. and to extend the dominions of his house. The utter exhaustion of his people in a hopeless struggle with the Netherlands. France and England was seen by him with sympathy, but he considered it unavoidable. His court was grossly vicious. Philip IV died on Sept. 17, 1665.

See A. Cánovas del Castilo, *Estudios del reinado de Felipe IV* (Madrid, 1889), and the introduction by F. Silvela to the *Cartas de Sor Maria de Agreda y del rey Felipe IV* (Madrid, 1885–86).

PHILIP V (1683–1746), king of Spain, founder of the Present Bourbon dynasty, was the son of the dauphin Louis and Maria Anna, daughter of Ferdinand Maria, elector of Bavaria. Born at Versailles, Dec. 19, 1683, he was named heir by the will of Charles II. Carefully educated as duke of Anjou by F. Fénelon, he was all his life strongly adverse to the moral laxity of most of the princes of his time, and greatly under the influence of his two wives, Maria Louisa of Savoy (d. Feb. 1714), whom he married in 1702, and Elizabeth Farnese of Parma, whom he married in Dec. 1714. His strongest passion was to secure his succession to the throne of France, and in this pursuit he indulged in many intrigues against the house of Orleans. even abdicating in 1724. But when his son Louis died a few months later, he resumed the throne.

See Coxe, *Memoirs of the Kings of Spain of the House of Bourbon* (London, 1815).

PHILIP, LANDGRAVE OF HESSE (1504–1567), son of the landgrave William II., was born at Marburg on Nov. *13,* 1504. He became landgrave on his father's death in 1509, and having been declared of age in 1518, was married in 1523 to Christina, daughter of George, duke of Saxony. In *1522* and also in 1523 he assisted to quell the rising of Franz von Sickingen (*q.v.*), who had raided Hesse five years previously, and in 1525 he took a leading part in crushing the rebellion of the peasants in north Germany, being mainly responsible for their defeat at Frankenhausen. About this time Philip adopted the reformed faith. His plans to protect the reformers rested upon two main principles—unity among the Protestants at home and military aid from abroad. The schemes he put forward as one of the heads of the league of Schmalkalden, aimed primarily at overthrowing the house of Habsburg. Envoys were sent to seek aid from France, England and Denmark; Turkey and Venice were looked to for assistance; the jealousy felt towards the Habsburgs by the Bavarian Wittelsbachs was skilfully fomented. Before the formation of the league of Schmalkalden Philip was intimate with Zwingli. In *1526* he had aided John the Constant, elector of Saxony, to form an alliance of reforming princes; and in 1529 he called together the abortive conference at Marburg, hoping thus to close the breach between Lutherans and Zwinglians Deceived by the forgeries of Otto von Pack (*q* o.), he believed in the existence of a conspiracy to crush the reformers, and was only restrained from attacking his enemies, in 1528, by the influence of John of Saxony and Luther. In *1529* Philip signed the "protest" presented to the diet at Spires, being thus one of the original "Protestants"; in 1530 he subscribed the Augsburg confession, and helped to form the league of Schmalkalden.

He next restored Ulrich, duke of Wurttemberg (*q.v.*) to his duchy. Württemberg had passed into the possession of the Habsburgs, and after Philip's brief and victorious campaign in *1534* it was said that the landgrave had done more for Protestantism by this enterprise than a thousand of Luther's books would do. The Concord of Wittenberg, made in *1536,* was preparatory to a general attack on the Habsburgs, but war was prevented by the illness of the landgrave and other circumstances. At this point he took a fatal step His union with Christina was unhappy, and, having fallen in love with Margaret von der Saal (d. 1566), he obtained an opinion from Protestant theologians that bigamy was not forbidden by Holy Writ. Luther and Melancthon at length consented to the marriage, but stipulated that it should be kept secret, and it was celebrated in March 1540. The marriage became known, and Philip's friends deserted him. He objected to Luther's counsel to deny the existence of a second marriage. But the general hostility compelled him to come to terms, in *1541,* with Charles V. at Regensburg; he undertook to break off relations with France and England and loyally to support the emperor.

From *1526* onwards Philip had been forwarding the progress of the Reformation in Hesse. Catholic worship was suppressed, and the secularized church revenues supplied an endowment of the new university of Marburg. Peace between the emperor and the landgrave was soon broken In 1542 Philip persuaded the league of Schmalkalden to attack Henry II., duke of Brunswick-Wolfenbuttel, ostensibly in the interests of the Protestant towns of Brunswick and Goslar. The duchy was quickly overrun, and Hcnry—a Catholic prince—driven out; but the good understanding between the emperor and the landgrave was destroyed, and the relations between Protestants and Catholics became worse than before. Nor was the fissure in the Protestant ranks closed, and Charles took advantage of this disunion to conquer Gelderland and to matcre his preparations for overthrowing the league of Schmalkalden. Unlike John Frederick of Saxony, Philip divined, or partly divined, the emperor's intentions, and urged repeatedly that the forces of the league should be put in order. This advice passed unheeded, and when Charles suddenly showed his hand, and in July 1546 issued the imperial ban against the landgrave and the elector, it was seen that the two princes were almost isolated. Fighting began along the upper Danube, and when indecision and want of funds had ruined the league's chances of success, Philip returned to Hesse and sought help from foreign powers; while in April 1547 John Frederick was captured at Miihlberg. After this defeat the landgrave was induced to surrender to Charles in June by his son-in-law, Maurice, now elector of Saxony, and Joachim II., elector of Brandenburg, who promised Philip that he should be pardoned, and were greatly incensed when the emperor refused to assent to this condition. Philip was sentenced to detention for 15 years, but he was released in 1552, and after the Peace of Passau in this year he returned to Hesse. The landgrave continued the work of reforming and organizing the Church in Hesse. In *1562* he aided the Huguenots with troops, and he was frequently in communication with the insurgents in the Netherlands; but his efforts to form a union of the Protestants were fruitless. Philip, who is sometimes called the *Magnanimous,* died at Cassel on March *31, 1567.*

See *Briefwechsel Landgraf Philipps mit Bucer,* ed. M. Lenz (Leipzig, 1881–90); *Politisches Archiv des Landgrafen Philipp,* ed. F. Küch (Leipzig, 1904); W. W. Rockwell, *Die Doppelehe des Landgrafen Philipp von Hessen* (Marburg, 1904); K. Varrentrapp, *Landgraf Philipp von Hessen und die Universität Marburg* (Cassel, 1904), and *Phzlzpp der Grossmütige, Beiträge zur Geschichte seines Lebens und seiner Zeit,* published by the *Historischer Verezn fur das Grossherzogtum Hessen* (Marburg, 1904).

PHILIP, KING (*c.* 1639–1676), chief sachem of the Wampanoag Indians in America, and the son of Massasoit (d. *1662).* To Massasoit's two sons, Wamsutta and Metacoinet, the English gave the names respectively of Alexander and Philip. Alexander succeeded his father as sachem, and in the same year, while in Marshfield, whither he had gone to explain certain alleged unfriendly acts toward the English, was taken ill; he died on his way home Philip, who succeeded Alexander, suspected the English of poisoning his brother. The English had grown stronger and more numerous, and had begun to meddle in the internal affairs of the Indians. In *1671* the Plymouth authorities demanded that the Wampanoags should surrender their arms; Philip consented, but his followers failed to comply, and measures were taken to enforce the promise. Philip thereupon went before the general court, agreed to pay an annual tribute, and not to sell lands or engage in war with other Indians without the consent of the Plymouth government. In *1674,* when three Wampanoags were executed at Plymouth for the alleged murder of Sassamon, an Indian convert who had played the part of informer to the English, Philip could no longer hold his followers in check. There were outbreaks in the middle of June *1675,* and on June *24,* the massacre of whites began.

The colony of Connecticut took quick measures of defence, guarded its frontier, maintained its alliance with the Mohegans, and suffered little injury. Massachusetts and Plymouth were slower in acting and suffered great loss. Rhode Island raised no troops, and suffered severely. Early in the autumn Philip went nearly as far west as Albany in an unsuccessful attempt to get aid from the French and the Mohawks and supplies from the Dutch traders. At Deerfield on Sept. *18,* about *60* English were killed and the settlement was abandoned. In the spring of 1676 it became evident that the Indian power was waning. The warriors had been unable to plant their crops; they were weaker numerically and more poorly armed than the English, and the latter had also made an alliance with the friendly Naticks and the Niantics. On Aug *1,* 1676 Philip's wife and nine-year old son were captured, and on Aug. 11, an Indian traitor guided the English to the sachem's hiding place in a swamp at the foot of Mount Hope (in what is now the township of Bristol, R.I) where early the next morning he was surprised, and while trying to escape was killed by an Indian The head of Philip was sent to Plymouth and set on a pole in a public place, where it remained for a quarter of a century. The struggle was now over in southern New England, but it continued along the north-eastern frontier till the spring of 1678.

See George *M.* Bodges, *Soldiers in King Philip's War* (Leominster, Mass., 1896); John Gorham Palfrey, *History of New England,* vol. iii. (Boston, 1864); and especially George W. Ellis and John E. Morris, *King Philip's War* (1906). *See* also *Entertaining Passages Relating to King Philip's War* (Boston, 1716; new ed. with notes by H. M. Dexter, Boston, 1865), the account by Col. Benjamin Church (1639–1718).

PHILIP, JOHN (1775–1851), British missionary in South Africa, was born on April *14, 1775,* at Kirkcaldy, Fife. In *1818*

he joined John Campbell in his second journey to South Africa to inspect the stations of the London Missionary Society, and in 1822 the Society appointed him superintendent of their South African stations. His anger was aroused by the barbarities inflicted upon the Hottentots and Kaffirs (by a minority of the colonists), and he set himself to remedy their grievances. His influence was seen in the ordinance of 1828 granting all free coloured persons at the Cape every right to which any other British subjects were entitled. During 1826–1828 he was in England, and in 1828 he published *Researches in South Africa.*

One of Philip's ideals was the curbing of colonial "aggression" by the creation of a belt of native states around Cape Colony. In Sir Benjamin D'Urban, Philip found a governor anxious to promote the interests of the natives. When, however, at the close of the Kaffir War of 1834–35, D'Urban annexed the country up to the Kei River, Philip's hostility was aroused. He came to England in 1836, and agitated against the Cape government. D'Urban was dismissed, and Philip returned to the Cape as unofficial adviser on native matters. He died on Aug. 27, 1851. *See* SOUTH AFRICA, UNION OF: *History.*

PHILIPON, CHARLES (1806–1862), French journalist, caricaturist and lithographer who raised caricature from the level of a print-seller's venture to that of a regular feature in journalism. Born at Lyons, April 19, 1806, he settled in Paris in 1823, took to lithography and began to draw caricatures for a living. He was an excellent draftsman with a fertile and irrepressible sense of satire. Moreover, he had vigorous political opinions, an enterprising spirit and boundless energy. Among the projects that overflowed from his active mind was an ambition to found a paper. This was realized in 1830 when he published a journal of political satire, *La Caricature.* Its career was brief and turbulent; after an avalanche of legal actions, it was suppressed in 1834. Meanwhile, in 1832, Philipon had produced a daily paper (with a new drawing every day) called *Le Charivari* which, ten years later, was to become godfather to *Punch* or *The London Charivari.* In 1838 *La Caricature* made a cautious reappearance under the title of *La Caricature Provisoire* but its success was such that, before long, the adjective *Provisoire* was discarded. His next publication of importance, *Le Journal pour Rire* (later *Le Journal Amusant*) appeared in 1849 in the form of large newspaper sheets filled with woodcuts. Besides these journals, Philipon issued many occasional publications, such as *Le Musée Philipon, Le Robert Macaire, Les Physiologies* and numerous political brochures.

As an artist, his best-known invention was a drawing which depicted the gradual transformation of Louis Philippe into the shape of a pear. *La Poire* became the common symbol of the king and all Philipon's artists used it in their caricatures. They were a notable group: he was able to attract and inspire the best talents in France. Honor6 Daumier and Gustave Doré were the most famous but, there were also Paul Gavarni, Grandville (J. I. I. Gérard), Henri Monnier, Auguste Raffet and Charles Joseph Traviés.

For one man, his achievement was considerable; his effect on caricature in France and other countries mas decisive, as was his influence on the development of lithography as an artistic and commercial medium.

Philipon died in Paris, Jan. 25, 1862.

See Champfleury (Jules Fleury), *Histoire de la Caricature Moderne* (1865); Edwin de Turck Bechtel, *Freedom of the Press and L'Association Mensuelle: Philipon Versus Louis Philippe* (1952). (F. W. W.-S.)

PHILIPPA OF HAINAUT (c. 1314–1369), queen of the English king Edward III, was the daughter of William the Good, count of Holland and Hainaut, and his wife Jeanne de Valois, granddaughter of Philip III of France. By a special dispensation of the pope, Philippa was married to her cousin Edward III by proxy at Valenciennes in October 1327, and landed in England in December. She joined Edward at York, where she was remarried on Jan. 30, 1328. Her marriage dower had been seized by the queen dowager Isabella to pay a body of Hainauters, with whose help she had compassed her husband's deposition. The alliance ensured for Edward in his French wars the support of Philippa's influential kindred; and before starting on his French campaign he secured troops from William the Good, as well as from the count of Gelderland, the count of Julich and the emperor Louis the Bavarian.

Before 1335 Philippa had established a small colony of Flemish weavers at Norwich, and she showed an active interest in the weaving trade by repeated visits to the town. She also encouraged coal-mining on her estates in Tynedale. Her eldest son, Edward the Black Prince, was born in 1330, and she subsequently bore six sons and five daughters. In November 1342 she became guardian of John of Gaunt and her younger children, with their lands. The anecdotes of her piety and generosity prove her popularity. On a famous occasion her prayers saved the citizens of Calais from Edward's vengeance. There is a generally accepted story, based on the chronicles of Jehan le Bel and Froissart, that she summoned the English forces to meet the Scottish invasion of 1346, and harangued the troops before the battle of Neville's Cross.

Philippa was the patron and friend of Froissart, who was her secretary from 1361 to 1366. Queen's College, Oxford, was not, as is stated in Skelton's version of her epitaph, founded by her, but by her chaplain. Robert of Eglesfield. His chief benefactions were made to the hospital of St. Katharine's by the Tower, London. She died on Aug. 15, 1369.

See Agnes Strickland, *Lives of the Queens of England,* vol. i. In addition to the account given in his *Chroniques,* Froissart wrote a formal eulogy of her, which has been lost.

PHILIPPEVILLE, a seaport of Algeria, chief town of an *arrondissement* in the *département* of Constantine, and 54 mi. N. by E. of that city, on the Bay of Stora. Pop. (1954) 48,773. Philippeville is important as the port of Constantine. Philippeville occupies the site of successive Phoenician and Roman cities. By the Romans it was named Rusicada. Some parts of the Roman theatre remain. The modern town was founded by marshal Valée in 1838.

PHILIPPI (Turk. FILIBEJIK), a city of ancient Macedonia, on a steep hill near the river Gangites (mod. Angista), overlooking an extensive coastal plain on the highway between Neapolis (Kavalla) and Thessalonica. Originally called Crenides (Fountains), it was fortified by Philip II of Macedon, to command the neighbouring gold mines. In 42 B.C., after the defeat of Brutus and Cassius there by Octavius and Antony, it became a Roman colony, *Colonia Julia Philippensis,* probably increased after the battle of Actium *(Col. Aug. Julia Phil.),* with the Jus Italicum, and the rank of a "first city." It was twice visited by St. Paul, whose Epistle to the Philippians was addressed to converts here. The site, now uninhabited, is marked by ruins of an amphitheatre and a great temple with inscriptions. To the east is the huge monument of C. Vibius, known to the Turks as Dikelitashlar and to the Greeks as the Manger of Bucephalus.

PHILIPPIANS, EPISTLE TO THE, a book of the New Testament. Though Philippi was the first place in Europe where St. Paul preached the gospel, the letter to the local church was one of the last he wrote. Ever since he founded the church, he kept in touch with it (iv, 15f); indeed he had accepted a gift of money from it. But the present letter is an answer to one written by the Philippian Christians, who had enquired anxiously about his health and prospects, assuring him of their prayers, and wondering nhen he would be able to revisit them (i, 25f). Epaphroditus, who had brought the money, had fallen ill, and the apostle apparently sends him back reluctantly, perhaps with the present letter. It is a friendly missive, which falls into two parts. The first begins by relieving their anxiety about himself, assures them that he hopes to return before very long, and warns them, in the meantime, to preserve their unity (i–ii). At this point there is a sudden change in tone. The letter swerves into a passionate denunciation of some errorists or agitators (iii, 1f), after which the writer resumes (iv, 1–7) his counsels to the community. The closing appeal (iv, 8f) is for harmony.

Modern criticism of the epistle is no longer concerned with supposed traces of gnosticism in ii, 6f. The two engrossing questions are *(a)* the place from which the letter was written, and (b) whether or not it is a literary unity.

The former problem is raised by those who point out that the

Greek term "praetorium" ("palace" in the English version of i, 13) does not necessarily mean the Roman barracks of the praetorian guard at Rome, but might conceivably, for example, refer to the palace of Herod at Caesarea (Acts xxiii, 35) or to judicial authorities at a centre like Ephesus, where we know Timotheus mas living (Acts xix, 22), and where the apostle was once imprisoned. The data indicating Rome as the place of composition cannot be hastily set aside, *i.e.*, the considerations which involve the latter part of the two years confinement at Rome (Acts xxviii, 30) as the period when the letter was written.

The second problem starts from the abrupt change in iii, 2. It is thought by some (*e.g.*, by B. W. Bacon. *The Story of St. Paul*, pp. 367f) that iii, 2f represents an earlier letter, written in reply to the gift of money, and subsequently added to the later i, i–iii, 1, as 2 Corinthians x–xiii has been added to an epistle which chronologically it preceded. The partition theories, of which this is the simplest form, imply that two letters have been mutilated and transposed; otherwise, the hiatus at iii, 2 is inexplicable. But the writer may have been interrupted at iii, 1, or something may have occurred which moved him to turn aside sharply. In iv, 4 he echoes the note sounded in iii, 1, and the intervening outburst may be psychologically explained without recourse to any theory of transposition.

He associates Timotheus with him in the address (i, 1), owing to his local ties with Philippi (ii, 22 and Acts xvi, 3f), but the apostle nrites in the first person throughout, even in iv, 21; indeed he speaks of his companions as distinct from himself, and iii, 17 is no real exception to this. The letter is an affectionate personal message from St. Paul in the evening of his life to a church with which his relations had been exceptionally friendly. Their troubles were not connected with doctrine; the great passage in ii, 5f is introduced as a motive to humility, not as specific instruction on the person of Christ. These Macedonian Christians had a naturally affectionate temperament, which affected their religion; the apostle's chief prayer for them is that their emotional warmth may ripen into insight and understanding (i, 9f), and his concern for them is solely for their Christian principles of conduct.

The earliest definite traces of the letter in 2nd-century literature occur in Polycarp, who had some close interest in the church of Philippi. It passed at once into the early canons of Scripture, and soon was quoted by church fathers such as Irenaeus, Clement of Alexandria and Tertullian.

BIBLIOGRAPHY.—In English the older commentaries by Ellicott (5th ed., 1888) and Lightfoot (6th ed., 1891) may be supplemented by H. A. A. Kennedy's in the *Expositor's Greek Testament* (1903), M. R. Vincent's in *The International Critical Commentary* (1897) and a commentary on the English text by M. Jones, *Westminster Commentaries* (1918). German editions are by Lohmeyer (Gottingen, 1928), P. Ewald in Zahn's *Commentar* (1923) and M. Dibelius in Lietzmann's *Handbuch* (1913), and A. Klopper's (1893), Soden's (1903) and R. A. Lipsius' *Handcommentar* (1892) are by no means superseded. General studies of the epistle will be found in R. R. Smith's *The Epistle of St. Paul's First Trial* (1899), in Sir W. M. Ramsay's *St. Paul the Traveller* (ch. x and xv) and in Weizsacker's *Apostolic Age* (vol. i, pp. 218f, 279f). Weizsacker dealt the deathblow to the older view that the epistle was non-Pauline, the last traces of which are to be found in van Manen's article in the *Encyclopaedia Biblica* (3703f).

(J. MOF.)

PHILIPPICUS, east Roman emperor (711–713), became distinguished as a soldier under Justinian II. His proper name, which indicates his Armenian origin, was Bardanes. He made some pretensions to the throne on the outbreak of the first rebellion against Justinian; these led to his banishment, by order of Justinian, to Cherson. There Bardanes successfully incited the inhabitants to revolt, and on the assassination of Justinian assumed the purple. Among his first acts was the summoning of a *conciliabulum* of eastern bishops, which momentarily restored monotheletism. His domains were attacked at once by Terbelis, king of the Bulgarians in Europe, and the Saracens in Asia. The reign of Philippicus was ended by a military conspiracy.

See Gibbon, *Decline and Fall of the Roman Empire*, ed. by J. B. Bury, vol. v, pp. 195–196 (1911).

PHILIPPINES, REPUBLIC OF THE (REPÚBLICA DE FILIPINAS, REPUBLIKA ÑG PILIPINAS), an archipelago named after Philip II of Spain, of approximately 7,100 islands, about 500 mi. off the southeast coast of Asia, lying between lat. 4° 23' and 21° 25' N. and long. 116° and 126° 30' E. It is bounded on the west and north by the stormy China sea, on the east by the Pacific ocean and on the south by the Sea of Celebes and the coastal waters of Borneo. The islands extend north and south about 1,152 mi. and east and west about 688 mi., their shape, if bounded by straight lines, being about that of an isosceles triangle and their area 115,707 sq.mi. The northernmost island, Y'Ami, is 65 mi. S.E. of Formosa, while the southernmost, Saluag, is 30 mi. E. of Borneo. Only 462 of the islands have an area of 1 sq.mi. or more. Eleven have areas of more than 1.000 sq.mi.—Luzon, the most northerly of the large islands, 40,420 sq.mi.; Mindanao, the most southerly, 36,537 sq.mi.; Samar, 5,050 sq.mi.; Negros, 4,905 sq.mi.; Palawan, 4,550 sq.mi.; Panay, 4,446 sq.mi.; Mindoro, 3.759 sq.mi.; Leyte, 2,785 sq.mi.; Cebu, 1,703 sq.mi.; Bohol, 1,575 sq.mi.; and Masbate, 1,262 sq.mi.

In addition to the large islands and those with distinct names are various groups, among which may be noted the Babuyanes and Batanes, north of Luzon; the Visayas (or Bisayas), between Luzon and Mindanao; the Cagayan and the Calamian groups, respectively east and north of Palauan; and the Sulu archipelago of 448 islands, the chief of which is Jolo.

Additional information on the Philippines can be found in the articles on the individual islands, provinces and major cities.

I. PHYSICAL GEOGRAPHY

1. Physical Features.— The irregular configuration of the archipelago, the coast line of more than 14,400 mi., the great extent of mountainous country with the mountains lying close to the sea in many places, the narrow and interrupted coastal plains, the generally northward trend of the river systems and the lakes comprise the salient physical features of the Philippines. The islands have volcanic. coral and all principal rock formations. The mountain ranges for the most part run in the general direction of the main axes of the islands. The Cordillera Central of Luzon, running north to the Pacific ocean from the northern boundary of the central plain, is the most prominent chain. It consists of two, and in places three, parallel ranges, each of which averages 5,900 ft. in height. The narrow Ilocos or Malaya range, lying close along the narrow west coast, rises in places to more than

5,000 ft. The Sierra Madre, fringing the northeast coast, rises to more than 5,000 ft. and is seldom less than 3,500 ft. high; it is largely volcanic. This range and the Cordillera Central coalesce in Nueva Vizcaya forming the Caraballo mountains. North of the latter and between the two ranges is the fertile Cagayan valley, about 50 mi. wide. In the southwestern part of northern Luzon are the rugged Zambales mountains, which consist of more or less isolated old volcanic stocks.

The central plain of northern Luzon is about 150 by 50 mi. and only about 100 ft. above sea level .except near its centre. The greater part of southern Luzon is occupied by isolated volcanoes and irregular masses of hills and mountains. The highest peak is Mayon (7,949 ft.) near Legaspi in Albay province.

Through Palawan (about 15 mi. wide) extends a range with an average height of 4,000 to 5,000 ft. Each of the Visayan islands, except Samar and Bohol, is traversed longitudinally by a single range with occasional spurs. Several peaks in Panay reach an altitude of 6,000 ft. or more. In Negros is Mt. Canlaon, a volcano of 8.087 ft., and other peaks reach an altitude of more than 6,000 ft.

There are several important ranges in Mindanao, the Diuata range along the eastern coast being the most prominent. West of this lies the fertile Agusan valley. 40 or 50 mi. wide. Farther west and southwest is the valley of the Rio Grande de Mindanao, the largest river system in the island, and between the lower course of this river system and the southern coast lies a range trending northwest and southeast. On the southern border of the basin of Rio Grande de Mindanao river is Mt. Apo (9,610 ft.), the highest peak in the Philippines. Around Lake Lanao are a number of volcanic peaks. A low cordillera extends into Zamboanga province.

Many of the mountains are covered with dense forests in which are many valuable hardwood timbers. In northern Luzon the principal mountain tree is the pine. In many places where the forests have been burned away their place has been taken by cogon or other coarse grasses. The plains lying amid the mountains—*e.g.,* the central plain of Luzon, the Bikol plain of southeastern Luzon, the Cagayan plain of northern Luzon, the central plain of Panay and the Agusan and Cotabato valleys in Mindanao—have the densest populations of the islands except in Cebu, where the people live mostly on the coastal plain, as the interior is high and rugged. The most important rivers are the Cagayan, Agno, Pampanga, Pasig and Bikol in Luzon and the Rio Grande de Mindanao and Agusan in Mindanao. The Cagayan, flowing northward through northern Luzon and draining about one-fourth of the island, is the largest river. This river and the Rio Grande de Mindanao and the Agusan are each more than 200 mi. long. The Pasig, flowing through Manila, is commercially important. The largest lake in the archipelago is Laguna de Bay, located south of Manila.

2. Geology.—Mountain building is still in progress, and evidence of the recent vertical movement of various portions of mountain mass can be measured. The archipelago is the crumpled edge of the Asian continental platform. The structure is a complex one, however, for in addition to faulting and folding, volcanic actions of diverse kinds have taken place. Prior to the Tertiary period there seems to have been a period of intense deformation, when some of the schists were formed. Toward the end of the Miocene period, the Vigo and Batan formations were generally folded, in some places being intensively crumpled and faulted. Another less pronounced period of folding occurred in the Pliocene or early Pleistocene period. The islands were subjected to a great uplift during the Pliocene, Pleistocene and Recent periods. A striking similarity exists between the formation in the Philippines and the western coast of America. Practically all rock types are found in the islands, as well as areas of coral limestone.

3. Volcanoes.—The volcanoes are the most conspicuous feature of the landscape, but there is relatively little volcanic activity. All gradations of volcanoes can be seen, from the almost perfect cone of Mayon to old, worn-down volcanic stocks whose present form gives little indication of their origin. The several distinct volcanic areas are that of southwestern Luzon (the provinces of Rizal, Cavite, Laguna, Batangas and a portion of northwestern Quezon); that of southeastern Luzon; the mountain region in Camarines Norte; Negros; Mindanao; Jolo; and a few others. Seismic disturbances are common.

4. Climate.—The archipelago has a decided variety of climate. The general direction of winds is from north to east, October to January; east to southeast, February to April; and southwest, the rest of the year. Typhoons often strike the islands from the east to the southeast, then curve to the north, sometimes crossing the land to the China sea, sometimes only touching the eastern shores. Eighty-five per cent of them affect the islands from Samar to the north while only 15% are felt south of Samar. Often the greatest loss of life and destruction of property are caused not by high-velocity winds but by the concomitant or subsequent torrential rains, which cause floods.

Temperature differences are slight on the lowlands but altitudinal variations are marked. Rainfall variations are important in dividing the archipelago into climatic regions, and many local rainfall patterns exist. The most common raicfall pattern is that having two pronounced seasons, dry in winter and spring, rainy in summer and autumn, with local variation in the length of the dry season and in the total rainfall. This is found in western Luzon and the western Visayas. A second kind of pattern has a marked winter maximum of rain and irregular but short dry seasons during the summer and aututnn, with local variations. This is found in eastern Luzon, the eastern Visayas and northern and eastern Mindanao. Southern and western Mindanao have no pronounced seasonal maximum of rain but do have short irregular dry seasons, with local variations.

5. Vegetation.—About 10,000 species of flowering plants and ferns have been found. The flora is essentially Malaysian, but continental (Himalayan) elements occur in the mountains of northern Luzon, while a few Australian types are found at various altitudes. There is a small percentage of native genera and a high percentage of native species (about 60%). The dominant forest species are usually native. Among the grasses of the grasslands are lalang (cogon) and other coarse grasses. The vegetation of the coastal regions (including the mangrove swamps) is practically identical with that of similar areas throughout the Malay archipelago. Considerably more than half the land area of the islands is covered with forest. Members of the *Lauan* family, known as Philippine mahogany, often comprise a high percentage of the forest. There are many other valuable hardwoods as well as many softwoods. About 1,000 different woods have a commercial value, among which may be noted apitong, camagon, ipil, lauan, *mayapis,* molave, narra, tangile, tindalo and yacal. Some timber trees attain a huge size which makes them especially adaptable for tables and other large pieces of furniture. There are many useful kinds of palms, including the coconut palm, from which is obtained food, clothing, fibre for export, coconut oil, copra, building material and other products. Useful bamboos and rattans abound. About 900 species of orchids occur, some of them very rare. Several hundred fibres are known, among them the abacá, from which Manila rope is made. The forests also yield gums (including rubber), various fruits, nuts, spices and drugs, oils and other useful substances.

6. Animal Life.—Mammals are scarce, with the exception of shrews, rats, mice and bats. The edentates are represented by the pangolin (*Manis javanica*). Red or brown deer (Rusa) are found in Basilan, Mindanao, Leyte, Samar and the Calamian Islands. The mouse deer or chevrotain (*Tragulus nigricans*) is found in Balabac and Palawan. The timarau (Bubalus mindorensis), a small buffalo. is peculiar to Mindoro. Carnivores are represented by mongooses (*Mungos palawanus* and *M.* parvus), the binturong (*Arctictis* binturong), an otter (Aonyx cinerea), civet cats (Viverra and Paradoxurzts) and a small wildcat (Felix *minuta*) which is also found in Java. At least 56 species of bats are known, many being peculiar to the Philippines. The flying lemur (*Cynocephalus volans*) and tarsier (Tarsius) range from Basilan to southern Luzon. Large fruit bats live in colonies and are sometimes hunted for their flesh and fur. Only one genus of monkey (Pithecus) has been found, but it is represented by five species. Five new genera of small mammals (Celaenomys, Chrotomys, *Rhynchomys,* Batomys and *Carpomys*) representing 15 species

have been discovered on a small plateau on the top of Mt. Data in northern Luzon, at an altitude of more than 8,000 ft. There are about 760 species of birds which show rather strong relationship to those of Borneo. Reptiles and batrachians also abound.

The marine fauna is one of the most abundant known, more than 1,000 species having been found, at least three-fourths of which are used as food. Sharks and rays are caught for their fins. The fresh-water fish fauna is relatively unimportant. Terrestrial and marine molluscs are abundant, the Philippines having the richest molluscan fauna of any equal area in the world, and many of the shells are of great beauty. Many of the molluscs are edible and of considerable local importance. Pearl oysters abound and the pearls of the Sulu archipelago have an international reputation. The shells of *Placuna* placenta have been used as a substitute for window glass. Land molluscs are found in great variety and are remarkable for their beauty. The best sponges of the southern islands are equal to those of the Mediterranean. Coral beds are numerous. (R. E. HE.)

II. THE PEOPLE

The population of the Philippines is composed of a considerable number of cultural and linguistic groups, the result of varied historical relationships and of local specialization. Ancestors of the present-day population came from southeast Asia, either by way of the island chains to the south or directly across the China sea. Chinese from the coastal cities of south China came to trade and remained in Luzon and the Bisayas; Arab and Indian traders added their blood to the Moslem population in the southern islands; later came rulers from Spain and the U.S. At the time of Magellan (1521) the estimated population of the Philippines was about 500.000; since then it has increased over fortyfold. During this period there has been a blending of diverse racial strains, though linguistic differentiation continued until well into the 20th century. Increased mobility and the long period of Spanish and U.S. control, however, brought about considerable cultural uniformity except in the Moslem and pagan areas.

1. Racial Types.—The peoples of the Philippines belong to the Malay race which is a subdivision of the great Mongoloid stock of eastern Asia (see RACES OF MANKIND). They were preceded in the archipelago by the Negritos (*q.v.*), small Negroes related to those of the Andaman Islands and Malaya, who entered via land bridges at the height of the last glaciation, and survive today in the Bataan peninsula and other marginal areas. Discovery in 1958 of extinct fauna in apparent association with hand axes in the Cagayan valley make it probable that earlier types of man related to the Java series may have inhabited the area.

The Malay race is sometimes divided into an earlier Indonesian or proto-Malay element, with a more Caucasoid appearance, and a later, more Mongoloid Malay type characteristic of the coastal regions; but these distinctions are not clear-cut in the Philippines. The composition of the "Filipino blend", as it was called by archaeologist H. Otley Beyer, shows a number of earlier migrations, but the origins of the bulk of the population are to be sought in southeast Asia and Indonesia, where there are obvious resemblances in physical type.

2. Languages.—All of the Philippine populations, including the Negritos, speak languages belonging to the widespread Malayo-Polynesian stock which includes most of the peoples of Oceania. Language offers an important clue to the history of Philippine groups, and according to Paul Benedict, the region of Hainan island is the probable "jumping-off" place for Malayo-Polynesian peoples for their journeys into Oceania.

About 75 linguistic groups are found in the Philippines, and today language is an important identifying feature of Filipino ethnic groups. Three or four of these groups are major languages which are gradually absorbing their smaller neighbours. Tagalog (*q.v.*), the most important of these linguistic groups, is second in size, but its strategic position in central Luzon led to its adoption in 1946 as the basis for the national language. Bisayan or Visayan, the largest major language group, occupies the central islands but is split into three subdivisions. In northern Luzon, Ilokano has become the dominant language.

Spanish was never widely used among the masses and declined sharply after World War II. English was the most widely used language at mid-20th century, being spoken by about 40% of the population, but Tagalog was also being taught in the schools and was increasing at a faster rate.

3. Religion.—The great bulk of the Philippine population is Roman Catholic, reflecting the long period of Spanish control. Islam was introduced prior to the Spanish conquest by Moslem traders from the south, but its spread was checked by the advent of the Spaniards until its resurgence in the 20th century. The aboriginal pagan religions are still to be found in the Mountain Province and Mindanao, though many of these groups have come under Christian or Moslem influence.

During the revolt against Spain the Philippine Independent church split off from Roman Catholicism under the leadership of Gregorio Aglipay. The Aglipayans, less than 10% of the population, have kept many aspects of Roman Catholic ritual but have modified doctrine, introduced the vernacular, and added national heroes to the roster of saints. The Aglipayans later divided into two groups, one of which affiliated with the Episcopal Church.

Protestantism entered the Philippines with the U.S. occupation. In 1925 there were about 22 independent national churches, and by the second half of the 20th century the number had more than doubled. With 2% to 3% of the population as members, most of these Protestant denominations are affiliated uith the Philippine Federation of Christian Churches. An independent group, the Iglesia ni Kristo, grew rapidly in the post-World War II period.

4. Customs and Culture.—Filipino culture has roots far back in the past of the Malayan world, and has been profoundly influenced by Spanish culture and by U.S. training for independence. The major ethno-linguistic regional groups show a general cultural uniformity. Outside of the cities rice (or corn) agriculture and fishing furnish the basic subsistence; the family and the "kinship circle" are the centre of social life, and the annual cycle of ceremonies and fiestas of folk catholicism give colour and meaning to daily life.

In the Moslem areas in the south, there is a stronger development of political authority and territorial units, and the religious customs follow the Islamic pattern, but the other bases of life are similar to those in the Christian areas. Aboriginal cultures surviving in marginal regions show greater variability and retain some aspects of the pre-Spanish period. (F. R. E.)

III. HISTORY

The Philippine archipelago first became known to Europeans on March 16, 1521, through Ferdinand Magellan (*q.v.*). But there are authentic Chinese accounts of trading voyages as early as the 10th and 13th centuries, and the contact probably went back much further. A Hindu influence undoubtedly came by way of the Malay peninsula, Java and other islands nearby, and probably reached back to the early centuries of the Christian era. The Hindus influenced the life of the people intimately. Many Sanskrit words in the languages and dialects of the people of the Philippines and the forms of the letters used at the time of their discovery by the Spanish indicate this.

A. THE PHILIPPINES UNDER SPAIN

The second, third and fourth Spanish expeditions were those of Garcia Jofre de Loaisa, Alvaro de Saavedra and Ruy Lopez de Villalobos. The next expedition, that of Miguel López de Legazpi (1564–72), was dispatched, like its predecessor, from New Spain, but it was far more carefully planned. Leaving Puerto de Navidad in New Spain on Nov. 20, 1564, Legazpi reached Cebu in April 1565, where the first permanent settlement was made early in May. But Legazpi, with inadequate forces and resources, meeting prolonged hostility from the Portuguese who also were present in the region, at last (1569) moved his main forces to the island of Panay, hoping thereby to have better protection. In 1571 Legazpi made Manila the administrative centre. Thereafter the conquest of Luzon proceeded rapidly, at first principally under Juan de Salcedo, the precocious young grandson of Legazpi. All the archi-

pelago except the Moro islands of Mindanao, the Sulu archipelago and Palawan were in fairly peaceful possession of the Spaniards before 1600. In June 1572 the city of Manila was formally established. In 1574 Manila was attacked by the Chinese Limahong, but he was forced to retire from the island and from the entire group. Several of the provisional governors were churchmen who played into the hands of the ecclesiastics or catered to their own order.

1. Conquest. — The Spaniards were accepted easily, even hospitably in many cases, and the native populations coming into closest contact with them began almost immediately to take on a veneer of European culture. The conquest was especially easy along the coast and in the low interiors where the Spaniards first went. The principal opposition at Manila in 1570 came from Moslems, but that faith was not yet strongly entrenched in Luzon. The situation was quite different in Mindanao and at various other points in the south. The Spaniards were instinctive enemies of Islam, and it was they who gave the Philippine Moslems the name Moro (*q.v.*) by which they are still known. In 1574 the Moros of the Rio Grande de Mindanao offered submission. In 1578–79 Francisco de Sande (governor, 1575–80) conducted a fairly successful expedition against the Moros, but the Spaniards were unable to gain any lasting advantage. Until 1837 piratical raids were almost continuous. The Moros ravaged the coasts far and wide, even threatening Manila itself. They often joined the Dutch after the latter began to be interested in oriental waters. In 1848 on Balanguingui Island, Gov. Narciso Claveria y Zaldua won the most decisive victory ever gained over the Moros. In 1850 Gov. Antonio de Urbiztondo y Eguia destroyed the strongholds on Tonkil Island and the next year stormed and captured the town of Jolo. This ended the real power of the Moros.

During the interim between Magellan's discovery and the settlement of Manila, the Portuguese actively contested Spanish right to the archipelago. Their hostility ceased only with the union of Spain and Portugal (1580–1640). In 1577 Sir Francis Drake started on the voyage which brought him to the Philippines at Mindanao. Again, in 1587, Thomas Cavendish sailed to the Moluccas and thence back to California to intercept the rich galleon "Santa Ana." He then went to the Philippines, where he tried in vain to capture the shipyard at Iloilo.

The Dutch came next. Their primary object was trade rather than colonies. In 1596–97 Adm. Cornelius Houtman opened trade with the Netherlands, and during the years 1598–1600 the expedition under J. C. van Neck and W. van Warwijck traded in the Moluccas. In 1600 Oliver van Noordt reached Philippine waters, where he committed various depredations. Dutch vessels now traded for spices and other oriental wares in the Moluccas, harried the coasts and waters of the Philippines and attacked Portuguese, Spanish, Japanese and Chinese shipping. In 1610 Gov. Juan de Silva defeated and killed the Dutch admiral Francis de Wittert at Playa Hondo, near Manila, and captured part of his fleet. In 1640 the Dutch captured Malacca and in 1662 they permanently occupied the Moluccas. Their attacks in the Philippines gradually ceased.

On Sept. 22, 1762, a British expedition reached Manila, found the Spanish but ill prepared and on Oct. 5 captured the city. By the treaty of Paris in 1763 Manila was restored to Spain.

With Legazpi had come five Augustinians; in 1577 came the Franciscans, in 1580 the Jesuits, in 1587 the Dominicans and in 1605 the Augustinian Recollects. It was the intention of Spain to replace the friars by secular parish priests whenever any mission assumed the character of a parish. But the friars, desirous of retaining their holdings and power, fought secularization and it was never carried out in its entirety. The friars became the storm centre of the gradually increasing Filipino demand for change; the insurrection of 1896 was directed principally against them, and during the later insurrection against the United States they suffered many indignities.

The last Manila galleon left the Philippines in 1811 and returned in 1815. Thereupon the trade was taken over by private persons, exports to the value of 750,000 pesos were allowed and three other ports besides Acapulco were opened to it, namely San Blas, Guayaquil and Callao. In 1766, however, the crown had allowed direct trade between Spain and Manila by one national vessel annually. In 1785 the Royal Company of the Philippines began to trade between Manila and Cádiz; the company ceased to exist in 1830.

In 1809 an English commercial house was permitted to establish itself in Manila, and in 1814 a like privilege was extended to all foreigners. As a rule, however, Spaniards were still jealous of foreigners, and reactionary decrees in 1828 and 1840 forbade them to sell goods at retail or to do any business in the provinces. The vacillating Spanish policy is seen again in the opening of seven ports to foreign trade in 1830 and their closing the next year. In 1837 Manila was reopened to foreign trade, and Iloilo and Cebu were reopened in 1855 and 1863. In 1842 there were 39 Spanish shipping and commercial concerns in Manila and about a dozen foreign houses. Various governments maintained consuls, among them Great Britain and the United States.

2. Philippine Nationalism. — During the first half of the 19th century, there were only from 2,000 to 5.000 Spaniards in the archipelago. Spanish was spoken by some of the natives, principally in Manila and a few other important centres, but the friars had made comparatively little effort to inculcate a knowledge of Castilian. There was no homogeneity among the several native peoples, very largely because of the different languages. Partly because of these conditions, insular representation in the Spanish *Cortes* carried little meaning or a mistaken one to the mass of the population. After the building of the Suez canal, in 1869, ambitious Filipino youths went to Spain and other countries for study. The first daily newspaper was *La Esperanza* (1847). *La Solidaridad* was founded in 1888 in Barcelona by Graciano López Jaena in the interest of Filipino propaganda, and throughout its course it urged reforms in both religion and government. One of its foremost contributors was the precocious Chinese mestizo, José Rizal y Mercado. The Filipinos had ample grounds for complaint, especially after 1872. That year about 200 native soldiers at the Cavite arsenal revolted, killed their officers and shouted for independence. Plans for a similar demonstration in Manila failed. The insurrection was quickly suppressed. and led to wholesale arrests, life imprisonment and the execution, among others, of three Filipino secular priests, whose connection with the uprising was not satisfactorily explained.

Meanwhile the gradually expanding idea of Filipino nationality began to manifest itself. The campaign of Rizal, Marcelo del Pilar, López Jaena and Apolinario Mabini, leaders in the Young Filipino party, was a protest against both the domination of the friars and economic and administrative caciquism. These aspirations met a sympathetic reception from several governors, but other Spaniards, especially the friars, were diametrically opposed; and much of the old easy and cordial intercourse between the two peoples was changed. Rizal threw himself into the propaganda with eagerness. In 1891 he founded at Hong Kong an organization called the Liga Filipina, and in 1892 formed a branch at Manila. He was arrested in 1896 at Barcelona, returned to the Philippines, given a farcical trial and executed on Dec. 30, 1896. At about the time of Rizal's establishment of the Liga Filipina there was also founded an organization called the Supreme Worshipful Association of the Sons of the People, which is generally called the Katipunan. The organization was altogether Tagalog and is said to have numbered anywhere from 100,000 to 400,000 members. On Aug. 26, 1896, the actual insurrection broke out. "The cry of Balintawak" is the name given to the first hostilities by the Filipinos. The centre of the revolt was in Cavite province, where Emilio Aguinaldo first came into prominence. Spain sent over reinforcements until there was an army of 28,000 besides a few loyal regiments of native soldiers. A stiff campaign of 52 days brought the defeat of the insurgents, but upon the execution of Rizal the insurrection broke out again and spread to the provinces of Pangasinan, Zambales and Ilocos. Fernando Primo de Rivera opened negotiations with Xguinaldo and concluded with the insurgents the pact of Biac-na-Bató. Accordingly, Aguinaldo left for Hong Kong on Dec. 27, 1897. With the blowing up of the "Maine" on Feb. 15, 1898, actual hostilities broke out between

Spain and the United States. (See SPANISH-AMERICAN WAR OF 1898.) Aguinaldo returned to the Philippines May 19. 1898, and announced renewal of the struggle with Spain. The Filipinos, who declared their independence of Spain on June 12, 1898, proclaimed a provisional republic with Aguinaldo as president, and on Sept. 9, 1898, moved their capital to Malolos, with Apolinario Mabini, the "mouthpiece of the revolution," as Aguinaldo's chief adviser. A revolutionary assembly met on Sept. 15 and on Sept. 29 ratified Filipino independence. In November and December revolutionary tribunals were organized in the Visayas. The Philippines were ceded by Spain to the U.S. along with Puerto Rico and Guam by the Treaty of Paris, Dec. 10, 1898.

B. THE PHILIPPINES UNDER THE UNITED STATES

1. The Insurrection. — Relations between the Americans and the Filipinos were unfriendly and grew steadily worse. On Jan. 23, 1899, the Malolos constitution, by virtue of which the Philippines were declared a republic and which had been approved by the assembly on Nov. 29 and by Aguinaldo on Dec. 23, was proclaimed. Aguinaldo, who had been president of the provisional government, was elected president.

On the night of Feb. 4 the inevitable conflict between the Americans and Filipinos surrounding Manila was precipitated. Morning found the Filipinos, who had fought bravely, even recklessly, defeated at all points. While the fighting was in progress, Aguinaldo issued a proclamation of war against the United States. On Feb. 6 the U.S. senate ratified the treaty with Spain, and reinforcements were immediately sent to the Philippines. Antonio Luna, the best-trained military man among the Filipinos, was given charge of military operations, but seems to have been greatly hampered by the jealousy and distrust of Aguinaldo. which he fully returned. Luna was murdered, and on March 31, 1899, Malolos was captured by the U.S. forces. The Filipino government fled northward. In Nov. 1899 the Filipinos resorted to guerrilla warfare, with all its devastating features. The capture of Aguinaldo by Gen. Frederick Funston in March 1901 virtually ended the real insurrection, although the last surrender was that of Gen. Miguel Malvar in Samar on April 16, 1902. The major operations of the insurrection were conducted in Luzon, and throughout the army was assisted materially by the Makabebe scouts, who remained loyal to the U.S. Meanwhile, on April 7, 1900. Pres. William McKinley instructed the second (Taft) commission to "bear in mind that the government which they are establishing is designed not for our satisfaction nor for the expression of our theoretical views, but for the happiness, peace and prosperity of the people of the Philippine Islands." Nothing was said about independence, although the instructions were later often cited in support thereof.

2. Taft.—Gov. William Howard Taft initiated negotiations with Pope Leo XIII for the purchase of friar lands (about 400,000 ac.) which were finally bought Dec 23, 1903, at a price of approximately $7,250,000. Taft pledged the credit of the Philippine government for the amount, and bonds were issued therefor. A considerable portion of the lands, of high agricultural quality, were later sold to Filipinos. The pope also replaced the Spanish archbishop and bishops with U.S. prelates.

In 1904 Taft was called home to become secretary of war, but he continued to govern the Philippines from Washington, D.C. In 1905 he took a party of senators and representatives to the islands, at the expense of the Philippine governinent, and on Oct. 16, 1907, on the eve of his presidential campaign, he opened the first Philippine legislature at Manila, although there was still fighting in the Visayas and the act of 1902 required a state of "complete peace" before convening the legislature. Among other acts, that body voted to continue both Spanish and English as official languages until 1913, when Spanish was to be dropped. That, however, was never accomplished, and it was not until 1940 that Tagalog was added as another official language. On hug. 6, 1909, congress passed the Payne bill, granting important trade concessions to the Philippines, and in 1913 the Underwood act provided for complete free trade between the islands and the United States. This concession continued until Jan. 1, 1941.

3. The Governors **General.**—Taft mas succeeded as governor by Luke E. Wright of Tennessee, who had been a member of the Philippine commission and became the first American to bear the title of governor general. Serving from 1904 to 1906, he was very popular with Americans; but his firm and conservative policy failed to suit the more radical Filipinos and he was transferred to Tokyo as minister. Henry C. Ide of Vermont was the next incumbent of the office. He too was a member of the Philippine commission and had seen service in Samoa during the partition of that group. He was a wise and able administrator but was permitted to remain as governor general for a few months only. He was succeeded by James F. Smith of California, who had come to the islands as a colonel of volunteers and later served on the supreme court and the Philippine commission. It was understood that he was much opposed to accepting the governorship but that Taft insisted on having a Catholic for the office. Smith served from 1906 until 1909. On Nov. 11 of that year, W. C. Forbes of Massachusetts was inaugurated as governor general, serving until Aug. 1913, when he was removed. Some of his acts occasioned bitter controversy (such as his deportation, without trial, of a large and prosperous group of Chinese merchants who had been long established in Manila). and his administration was a stormy one. Francis B. Harrison of New York succeeded and served from 1913 to 1921, the longest term of any U.S. governor general.

The Wood-Forbes mission, sent by Pres. Warren G. Harding in the first year of his administration, reported that the grant of immediate independence would be premature and urged that the U.S. government not be left in a position of responsibility without authority. Leonard Wood, a major general in the regular army and the former military governor of Cuba and later of the Philippine Moro province, seemed unusually well equipped for the governor generalship to which President Harding appointed him, effective Oct. 6, 1921. But by that time the Filipino leaders, having had a taste of power under Wood's predecessor, were in no mood to submit to authority if actually exercised. He administered the government through undersecretaries until 1927, when he died in Boston, Mass. Meanwhile, Pres. Calvin Coolidge had sent Carmi Thompson of Ohio "to investigate and report" on the Philippines. He made the trip with considerable publicity and likewise reported against the grant of independence, but recommended certain reforms.

Henry L. Stimson of New York was the next governor general. As secretary of war in the Taft administration he had acquired considerable familiarity with Philippine affairs, and he had just returned from a successful mission to untangle a difficult situation in a middle American state. Proceeding with tact and caution, he gradually won over the Filipino leaders, obtained some reforms and was about to secure others, when he was called home in 1929 by Pres.-Elect Herbert Hoover to become secretary of state.

In May 1930, Dwight F. Davis of Missouri, who had also been secretary of war, was appointed. His administration was uneventful, as was that of Theodore Roosevelt, Jr., who succeeded him in 1932. Pres. Franklin D. Roosevelt appointed Frank Murphy of Michigan. a strong advocate of independence, who took office as governor general June 15, 1933, and served until Nov. 15, 1935, when he became the first high commissioner in the Philippines. Leaving that post in 1936, Murphy was succeeded by Paul V. McNutt of Indiana, who served until 1939. He realized the value of the islands as a source of supply for tropical products and for their mineral wealth, and evidently felt that the grant of independence was a mistake for both countries. But it was now too late to effect any change in the general policy. Francis B. Sayre of Massachusetts, who was appointed to succeed him, arrived in Manila Oct. 21, 1939. He had been on the faculty of Harvard university and later an assistant secretary of state. His prescribed task was to prepare for independence.

4. Campaign for Independence. — As early as 1929, the campaign of the Filipinos for that goal had been gaining momentum, with new allies, in the United States, among producers of sugar. tobacco, fats and other products and the labour unions which feared the competition of Filipino immigrants. A bill supported by these interests and providing for independence finally passed

both houses of congress, was vetoed by President Hoover, passed again over the veto in Jan. 1933, but failed of ratification by the Philippine legislature because of opposition by Manuel Quezon, who, his opponents declared, wished to divert credit from those who had secured passage of the bill in his absence from Washington. This would have been an opportune time to re-examine the whole question, for the Filipinos had been given their long-sought chance and had rejected it. But the U.S. interests were determined to push the measure through. Quezon hurried to the United States to win President Roosevelt's support for a new bill, differing but little from its predecessor, but omitting the important provision reserving absolutely. as in Cuba, sites for naval bases, etc. (These were later to be the subject of "negotiation" and promised to be a fruitful source of trouble.)

The new bill, known as the Tydings-McDuffie act—public law 127—passed both houses of congress, received presidential approval March 24, 1934, and was ratified by the Philippine legislature on May 1. It established a Philippine commonwealth, provided for independence in 1946 and for a graduated tax on Philippine exports to the United States (to be collected by said government for a sinking fund for bonded indebtedness) of 5% of the corresponding U.S. duty for the first year, beginning Jan. 1, 1941, and increasing by 5% each subsequent year. This mas amended by the act of 1939 (public law 200), exempting cigars, scrap and filler tobacco, coconut oil and pearl or shell buttons, which were all subjected to free quotas, reducible by 5% each year. Hemp and copra were already on the free list. The U.S. immigration laws were applied, and the annual Filipino quota was limited to 50.

Pursuant to the act, a constitutional convention assembled in Manila July 30, 1934, and remained in session until Feb. 8, 1935, when a draft constitution was approved. It was certified by President Roosevelt on March 23 and ratified on May 14 of the same year by popular vote. It was on the whole a creditable document; but two of its unique features—a single six-year term for the presidency and a unicameral legislature—were eliminated by amendments adopted in 1939 and approved by President Roosevelt Dec. 2, 1940. Quezon. elected first president of the commonwealth in Sept. 1935, was re-elected for a four-year term Nov. 4, 1941. but with the understanding—not legally enforceable—that he would give way to Vice-Pres. Sergio Osmeiia after two years. The Philippine army, which had been trained under the supervision of Douglas MacArthur, son of the last American military governor, was called into the U.S. service on July 26, 1941, in time to help meet the Japanese invasion, Dec. 8 (Philippine time). (See WORLD WAR II.)

With the Japanese invasion, Quezon, Osmefia and the commonwealth cabinet left the Philippines to conduct a government in exile in Washington. Osmefia became president upon the death of Quezon in Aug. 1944 and returned to the Philippines when U.S. forces made their first Philippine landings on Leyte Island Oct. 20, 1944. General MacArthur proclaimed the liberation of the Philippines in July 1945 In general elections held in April 1946, Osmefia was defeated by Manuel Roxas y Acuna, who served as the last president of the commonmealth and within a few months became first president of the Republic of the Philippines.

C. The Philippines After Independence

On July 4, 1946, the commonwealth ended and the Republic of the Philippines came into existence as a sovereign independent state. In contrast with the transition which had been envisaged at the time of the Tydings-McDuffie act of 1934, the Philippines had suffered invasion, a three-year Japanese occupation and the added war damage of liberation. An estimated 1,000,000 lives had been lost as a result of the war. The damage to major industries was estimated as follows: shipping 85%, transportation 70%, mining 80%, sugar production 65% and coconut oil production 95%. Losses in production of rice, hemp, lumber and tobacco and in the fishing industry were estimated at $117,000,000. Damage to dwellings, port facilities and communications was extensive. Manila mas one of the world's most devastated capitals. In addition to a shattered economy, the Roxas government was confronted with political controversy and an incipient Communist-led rebellion.

Immediately prior to independence the United States had acted to assist the Philippine government in restoring the economy. On April 30, 1946, Pres. Harry S. Truman signed the Philippine Rehabilitation (mar damage) act and the Philippine Trade act of 1946. The Rehabilitation act authorized the appropriation of $620,000,000 to meet war damage claims and for Philippine government reconstruction programs and authorized 12 United States government agencies to engage in rehabilitation programs in the Philippines The Trade act extended the period of duty-free trade until 1954 with an increase of 5% of the full tariff rate to be applied thereafter. The act provided that no change would be made in U.S. import quotas of Philippine sugar and cordage for a period of 28 years. A military assistance pact authorizing the establishment of U.S. bases was signed March 14, 1947. This was followed by a mutual defense treaty signed Aug. 30, 1951.

Pres. Elpidio Quirino became chief executive upon the death of Roxas on April 15, 1948. Within one year the deficit in the general fund was reduced from 153,000,000 pesos to less than 1.000.000 pesos.

During the Quirino administration the Hukbalahap movement became a threat to the republic. This movement had developed during the Japanese occupation as a guerrilla army to fight Japan. After the defeat of Japan the Huks. as they were called, turned against landowners and. in the interest of gaining reforms, committed acts of violence and terror principally in central Luzon and in Panay. At the end of 1949 the Huks renounced reform by constitutional means, became identified with the Communist party and advocated the forceful overthrow of the government. In 1951 Secretary of Defense Ramón Magsaysay began a program of combined military pressure and granting of homesteads on the island of Mindanao to surrendered Huks. By Dec. 1955 the Huk rebellion had died out.

Magsaysay was elected president of the republic as candidate of the Nationalist party in the elections of Nov. 1953. He was elected on a platform promising real reform in government. During Magsaysay's first year in office, he succeeded in dominating the professional politicians of his Nationalist party. Early in May 1954 the president relinquished the post of minister of defense, feeling that the problems of internal security were under control. The chief Hukbalahap leader, Louis Taruc, surrendered to the government during that month. Major progress in opening new land settlements outside crowded Luzon had taken the edge off agrarian unrest, though the basic issues of land reform had not yet been carried out in Luzon itself. President Magsaysay had at least temporarily stopped trends of opportunism among his political opponents by committing the Philippines to participation in the free world's collective security programs against Communism, and to the maintenance of the strong traditional ties to the United States.

The main problem facing the Magsaysay administration in the mid-1950s was unemployment, a result in part of stagnation in the Philippine economy. Magsaysay, who died in a plane crash in March 1957, was succeeded by Vice-Pres. Carlos P. Garcia. Garcia. a member of the Nacionalista party, was then elected president on Nov. 12. 1957; his vice-president was Diosdado Macapayal of the Liberal party. For the most part Garcia continued the policies of the previous administration.

Following independence the United States and the Philippines joined in treaty arrangements for the defense of the islands. Under the terms of a military bases agreement concluded in March 1947. the use of designated military, naval and air bases was granted to the United States for a period of 99 years. In Aug. 1951 a mutual defense treaty was signed between the two countries. In Sept 1954, at a conference in Manila, the Philippines joined with seven other nations (Pakistan, Thailand, Australia, New Zealand, France, the United Kingdom and the United States) in signing the southeast Asia collective defense treaty, which committed the members to act against aggression, colonialism and internal subversion in the treaty area.

On May 15, 1958. a new U.S.-Philippine defense agreement was announced which established a mutual defense board and resolved the question of U.S. military bases. A memorandum signed

Oct. 12, 1959, shortened the 99-year lease originally signed in 1947, to 25 years.

IV. POPULATION

The population of the Philippines in 1948 was 19,234,182, an increase of more than 3,000.000 since 1939 (16,000,303), or an average annual increase rate of 2%. The 1960 census indicated a total population of 27,455,799.

Of the total population in 1948, only 14% lived in towns and cities with populations over 5.000, and more than half these were concentrated in Manila and its suburbs (1,405,000). Manila alone had a population of 983.906 ([1960] 1.145.723). Two other port cities, Cebu (167,503 [259,194]) and Iloilo (110,122 [150,976]), also had considerable population concentrations. Although the populations in these urban centres increased approximately 46% between 1939 and 1948, the larger percentage of the Philippine population continued to live in rural villages of fewer than 1,000 persons. Thus the Philippines can be characterized as a predominantly rural country. The average density of population in 1961 was 239.1 per square mile. The areas of greatest density were the provinces of Rizal (1,850), Laguna (1,016) and Cavite (763), while Palawan (29) and Mindoro Occidental (41) were the most sparsely populated.

Area and Population by Province

Province (with capital city)	Area (in sq.mi.)	Pop. (1960 census, prelim.)	Density per sq.mi.
Abra (Bangued)	1,471	116,700	79.3
Agusan (Butuan)	4,120	271,973	66.0

*Land area.

Nationalities of the population in 1948 were as follows: Filipino, 19,100,620; American, 6,955; Chinese. 121,702; Spanish 1.886; British, 555; Indian, 677; Swiss, 68; French, 86; Swedish, 82; Norwegian, 65; Italian, 70; Dutch, 410; other, 1,006.

V. ADMINISTRATION AND SOCIAL CONDITIONS

1. Government and Administration. — Duringthe period of United States control, from 1898 until the Philippine republic attained sovereignty on July 4, 1946, the Philippine citizens increasingly mere granted and assumed the responsibilities of self-government. With the end of military government on July 4. 1901, a civil government was established under a governor (later called governor general). On July 1. 1902, the U.S. congress passed an enabling act providing for a popularly elected assembly which would constitute the lower house of a Philippine legislature. The Philippine commission, which consisted of seven members appointed by the president of the United States, would serve as the upper house An election of members of the assembly mas held on July 30, 1907. Under the provisions of the enabling act two resident commissioners were appointed to the United States with power to speak on legislation affecting the Philippines but with no vote. In 1909 the Philippine commission was expanded to include four Filipinos.

The Jones act of Aug. 29, 1916. provided for the replacement of the Philippine commission by an elected senate of 24 members and for a house of representatives of 91 (later 92) members. The act proclaimed a bill of rights.

The Philippine Commonwealth and Independence act (Tydings-McDuffie act) abolished the office of governor general and placed remaining United States authority in a high commissioner. The commonwealth government was established in Nov. 1935 with Manuel Quezon as its first president.

While the islands were under Japanese occupation during World War II, the commonwealth government continued to operate in exile in the United States.

When the Republic of the Philippines became a sovereign and independent state. no substantial changes mere made in the structure of government provided in the constitution of 1935 (as amended in 1940 and 1946). By the amendment of 1940, executive power was lodged in a president and vice-president, elected for terms of four years uith eligibility for re-election.

The legislative power was vested in the congress of the Philippines, composed of the senate and the house of representatives. It was provided that the 24 members of the senate be elected at large by direct popular vote for six-year terms and the members of the house of representatives, representing 102 congressional districts, be elected for terms of four years.

Judicial power was vested in the justices of the supreme court (the highest tribunal), the court of appeals, courts of first instance, municipal courts of chartered cities and justices of the peace. All justices and judges were appointed by the president.

Each of the 53 provinces of the Philippines in 1958 (later increased to 55 provinces) was governed by a provincial board composed of the governor and two other board members, all elected. The 1,078 municipalities were administered by elected mayors and had municipal councils.

The governing body of each of the 30 chartered cities in 1958 was a municipal board composed of a mayor, vice-mayor and councilors. The members might be either appointed by the president or elected as provided by the charter Quezon City, east of Manila, was designated as the national capital and in the late 1950s construction of several government buildings was under way, but most of the functions of national government remained in Manila The 55 provinces, their areas and capital cities are shown in the population table.

2. Education. — The educational system of the Philippines is the most extensively developed in the orient. During most of the Spanish period. elementary education was undertaken only by the pastors and curates of parishes and was designed primarily to inculcate Christian values. A decree in 1863 established a compulsory educational system under civil control. Although this decree was never fully implemented. educational facilities and opportunities were expanded. A program of mass education was begun in 1901 under United States civil government; soldiers had acted as teachers for about two years prior to that time. The program sought to develop free political institutions through universal education. In 1901, 1.000 U.S. teachers were brought en masse to the Philippines. English was established as the medium of instruction and remained so. A system of scholarships was set up to train Filipinos in U.S. colleges and universities. The educational sys-

tem thereafter continued to expand rapidly. The Philippine people eagerly adopted the U.S. concept of education. Education is highly valued as a factor in individual advancement and national development. The republic is perhaps unique in that the majority of the rural elementary schools have been built directly by the people through private initiative and planning. The educational system is highly centralized. with administrative control in Manila. Public education embraces all levels: elementary school, four years; intermediate school, three years; secondary school, four years: college and university. There are public schools for arts and trades, commerce, agriculture and fishing. Tuition is paid from the secondary level on, but many scholarships are available. The private educational system is vitally important, particularly at secondary. normal. collegiate and university levels. All private schools are supervised and accredited by the government.

Education is the second largest item in the national budget, amounting each year to nearly 20% of the total. The literacy rate of those persons 10 years old and over in the late 1950s stood at about 65%, the highest in southeast Asia.

3. Defense. — There is a program of mutual defense and cooperation with the U.S. and SEATO (see HISTORY above). The Philippine constabulary and local police maintain public order. The former is part of the armed forces whose chief of staff has over-all command of the land, sea and air forces.

VI. THE ECONOMY

A. FINANCE AND TRADE

1. National Finance. — The Philippines entered the period after World War II under financial difficulties. Large reconstruction costs were only partly compensated by U.S. financial aid and war damage compensation. and government deficits, as well as trade deficits. were normal: owing in good part to large-scale development programs.

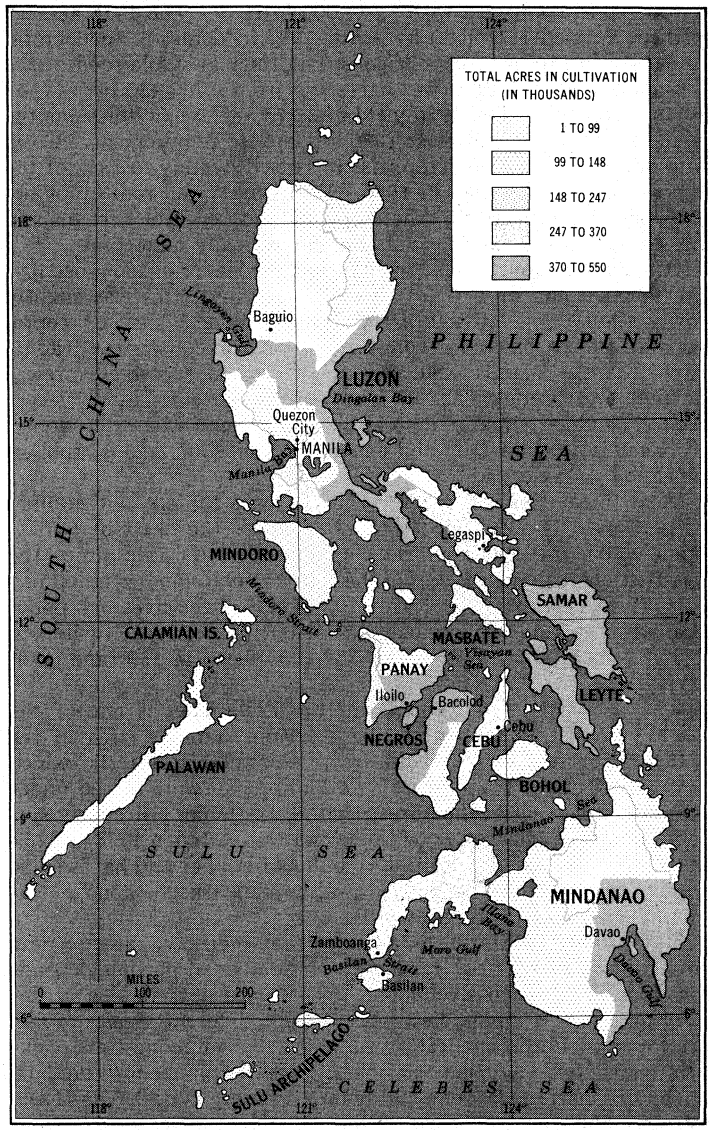
The Philippine Central bank's foreign exchange reserves fell from 800.000.000 pesos at the end of 1948 to 450.000.000 pesos on Dec. 9, 1949. On that date controls were imposed, placing all foreign exchange under licencing. The economic and fiscal position of the Philippines continued to decline, and the Bell mission recommended in 1950 that, among other measures, taxes be increased and reforms be made in tax collection procedure. During 1951 tax machinery was improved and new taxes were imposed. including a tax of 17% on the sale of foreign exchange.

During 1949 and 1950 import controls had been established as a measure to stimulate Philippine production and to conserve foreign exchange. This resulted in a decline in the yield of some internal taxes but it improved the general financial position. A partial relaxation of import controls in 1951 contributed to a government surplus in 1952. The degree of import control varied after 1952. Throughout the 1950s national government expenditures slightly exceeded revenue for each fiscal year.

The international reserve had reached a high point of 782,500,000 pesos on April 30. 1951, after the low level in 1949, but it declined slowly after that.

In addition to the Central bank, there are more than 15 commercial banks with more than 100 branches and agencies, a few savings and mortgage banks, and numerous rural banks. Banking operations are also conducted by the Postal Savings bank, the Agricultural Credit and Cooperative Financing administration, the Rehabilitation Finance corporation, building and loan associations and pawnshops.

2. Trade. — During the period the Philippines were under Spanish rule, external commerce for the most part was limited to trade with Spain and Mexico. Under Cnited States sovereignty, foreign trade expanded. With the passage of the Paine Tariff act of 1909 and later the Underwood act of 1913, providing for unrestricted free trade between the two countries, the Philippines became largely dependent on the U.S. market. In pre-World War II years more than 65% of Philippine trade was with the United States. During the years after independence trade with the United States declined from 86% of the total trade of the Philippines in 1945 to about 54% in 1959.



MAP OF THE REPUBLIC OF THE PHILIPPINES. SHOWING DISTRIBUTION OF ACREAGE UNDER CULTIVATION

Although the Philippine prewar exports were sufficient to offset imports the wartime scarcity of consumer and hard goods resulted in an unfavourable balance of trade in the postwar period. In 1958 total trade (exports dnd imports) nas valued at more than 2,000,000,000 pesos with an uniavourable trade balance of about 145.000.000 pesos. The leading postwar exports mere copra, sugar, abaci. abaci manufactures, coconut oil. base metals, lumber, canned pineapple, dried coconut and embroideries. Among the principal imports were textiles. grains and preparations, petroleum, automobiles, iron and steel and manufactures, tobacco, dairy products. paper manufactures and machinery.

B. PRODUCTION

1. Agriculture. — The fertile soil and tropical climate of the Philippines are well adapted to the raising of agricultural products, and farming engages about two-thirds of the employed population.

The total land area of the Philippines is 29,741,290 ha. (1 ha. = 2.471 ac.). Of this total, in 1956, about 11,415.000 ha. were commercial forest; 4,459.900 ha noncommercial forest; and 612,700 ha. in mangrove and swamp. About 5,726,580 ha. uere in cultivation and 2,453,810 ha, were classed as potential cropland. In 1940, 5,172,700 ha. had been planted, with 3,527,900 ha. (68%) in food crops: 1.644.800 ha. (32%) in export crops.

The index of agricultural production for 1955 reached 124% of the 1940 productivity, and the number of farms was approximately

1,720,000 as compared with 1,634,000 in 1939. The 1956 acreage planted totaled 5,726,580 ha., with 75% in domestic food crops. and 25% in export crops. Rice is the principal staple food of the Filipinos, and in 1936 it was harvested from 2,742,480 ha. (47%) of the cropland. The 1956 yield of 3,273,332 metric tons was the highest on record and close to the domestic requirement. Corn, another important food crop, also increased steadily to 28% of the cropland, 1,647.840 ha., in 1956. Fruits, nuts and root crops occupy significant shares of the cropland, and vegetables, beans and peas, coffee, cacao and peanuts are domestically important.

Among the export crops, coconut was the leader in 1956, occupying 992,000 ha., or 17% of the total cropland; this was slightly lower than the 1940 figure. Coconut products such as copra, coconut oil, desiccated coconut and copra cake form the leading export of the islands. Sugar cane revived to exceed its prewar acreage and production, but is no longer the chief money crop. Abacá declined slightly in relative importance in the economy. Tobacco is a minor crop and export, as are ramie, kapok, rubber, pineapple and derris.

Next to farming, livestock raising engages the greatest number of persons. The carabao (water buffalo) is the beast of burden upon which the Philippine farmer depends. As a result of the destruction of livestock during the war the total number remaining in 1949 was estimated at 1,972,859. By 1958 the livestock population was as follows: carabao, 3,596,400; cattle, 896,200; horses. 221,100; hogs, 6,083,600; goats, 537,100; sheep 17,150; and poultry. 52,468,700.

2. Forestry. — The Republic of the Philippines is one of the world's largest lumber-producing countries, ranking fifth in the ratio of forests to total land area. Commercial forests, which cover 34% of the total area of the Philippines, were placed under the administration of the bureau of forestry under a licencing system. The stand of hardwood timber was estimated in 1958 at 525,000,000,000 bd.ft. In addition to building lumber and hardwoods. forest products include dyewoods, rattan, tanbarks, bamboo, guttapercha, gum copal and fibres.

3. Fisheries. — Fishing is an important industry, ranking next to farming and livestock raising in the number of persons depending upon it for their livelihood. Fish comes next to rice in importance in the Filipino diet. About 1,900 different species of fish are found in Philippine waters, of which the commonest are milkfish, mackerel. snappers, sea bass. porgies, pompanos, mullets, anchovies, barracuda, tuna and bonito. Before World War II the average annual commercial inshore catch amounted to about 21.000 tons in addition to 25.000 tons produced in fish ponds. Total fish production in 1956 was 390.600 metric tons. Canned tuna is the principal fish exported. Other marine products include coral. pearls. shells and sponges. Among the shells and shell products are mother-of-pearl, trochus, tortoise, green snail shells and shells used for windows.

4. Mining. — The mineral wealth of the Philippines includes deposits of gold. silver, iron, copper. chrome, manganese and lead. In addition to the base metals, such nonmetallic minerals as asbestos, asphalt, marble, coal, gypsum, limestone, clay, petroleum and building stone are found.

Gold deposits are in Baguio on Masbate; and in Surigao, Davao and Zamboanga on Mindanao. Iron deposits are found in Camarines Norte and Bulacan on Luzon and in Surigao. Chromite and copper are mined in Zambales on Luzon. Manganese is found in Ilocos Norte and Zambales on Luzon; on Palawan and Siquijor.

Gold and iron mining are old industries, with records of gold mining by crude methods prior to the arrival of Magellan. Coal mining dates from the early Spanish period Petroleum formations are known to exist, and prior to World War II there were a few producing wells; in 1939. however, all petroleum lands were withdrawn from entry for five years pending the development of exploitation plans. During the Japanese occupation the mining industry suffered from lack of maintenance and the looting of equipment. After independence, the mining industry was the last of the major prewar industries to be rehabilitated.

While gold production had been 1,033,037 oz. in 1939, representing a 64% increase over production in 1929, in 1956 production was only 408,390 oz. Silver production in 1956 was 524,955 oz. as compared with the production of 1,175,192 oz. in 1938. The production of other minerals in 1956 (in metric tons) was: zinc, 420; lead, 2,261; copper, 21.482; iron ore. 1,372,529; coal, 146,306; chromite ore (refractory) 625,980 and (metallurgical) 125,037; and manganese ore, 4,470. Total value of mineral production in 1956 was 186,275.522 pesos.

5. Industry. — Industrial development. speeded during the period of the commonwealth, was devoted primarily to the manufacture and processing of agricultural products. Among these were: sugar, rope, cigar and cigarette. cordage, wood and rattan furniture factories; sugar, rice and lumber mills; pineapple and fish canneries; beer distilleries; and spinning mills. During the years immediately preceding the war, modern factories were established for producing shoes. hats, leather products. perfume and pearl buttons. Household industry produced embroideries, candies and fibre hats.

After independence in 1946, new industries were developed as a result of government-imposed import controls, government loans and legislation exempting new industries from taxation for a period of four years. These included an oil refinery and factories producing chemical products, fibre products, aluminum and enamelware, medical supplies, radios and musical instruments, wood and pulp products, knitted goods of rayon and cotton, plastics, rubber and steel products.

The National Development company, established during the commonwealth period and reorganized following independence, engaged in enterprises deemed in the interest of a systematic development of Philippine resources. Its subsidiary corporations included the National Food Products corporation, National Rice and Corn corporation, Peoples Homesite corporation, National Footwear corporation, Insular Sugar Refining corporation, National Tobacco corporation, Manila Railroad company and others.

The National Development company participated directly in the construction of hydroelectric plants, a steel mill, shipyards, steel-products plants, pulp mills, heavy-machinery shops and spinning mills. The Rehabilitation Finance corporation granted loans to private investors for approved industrial enterprises.

C. Transport and Communications

During World War II transportation and communication facilities were badly damaged, but after the war they were substantially rehabilitated. In 1959 there were 22,202 mi. of roads in the Philippines. Bridges numbered 11,090. The railways are of the narrow-gauge type. The Manila Railroad company, owned by the Philippine government, operates a system of 310 mi. in Luzon extending from San Fernando, La Union, in the north to Legaspi, Albay, in the south. The Philippine Railway company has 78 mi. of railways in the islands of Panay and Cebu.

Because of the republic's insular nature interisland shipping between the more than 200 local ports is an important factor in domestic trade and communications, and more than 3,000 vessels are engaged in this local trade. Foreign shipping, which more than doubled after World War II, is handled through the ports of entry. Manila being the largest and most important of these. Other ports of entry include Cebu, Iloilo, Zamboanga, Davao, Tabaco, Tacloban, Jolo, Jose Pañganiban, San Fernando and Aparri.

Philippine Air Lines services more than 40 stations within the islands and maintains international connections with Hong Kong. Several international airlines also stop at the Philippines.

In 1956 there were about 1.200 post offices and 500 telegraph offices. Of the more than 80,000 telephones in use throughout the republic in 1959, more than half were in Manila. (R. E. He.)

PHILIPPINE SEA, the name applied since 1944 to that part of the western North Pacific ocean lying east and north of the Philippines. The floor of the Pacific in this area is formed into a natural basin by a series of geologic folds and faults in the form of arcs. These arcs protrude above the surface in many places, forming a series of bordering islands. The Philippine Islands of Luzon, Samar and Mindanao are on the southwest; Palau, Yap and Ulithi of the Caroline Islands are on the southeast; the Marianas, including Guam. Tinian. Saipan and others, are on the east; the Bonin and Volcano Islands. including Iwo Jima, Kita Iwo and others lie to the northeast; the Japanese islands of Honshu. Shikoku and Kyushu lie to the north: the Ryukyu Islands, including Okinana, are to the northwest: Formosa marks the extreme western edge of the sea. Maximum measurements for the Philippine sea are 1.800 mi. from north to south and 1.500 mi east to nest Ocean trenches, or deeps, mark the eastern sides of the various folded arcs Within the Philippine sea are located the Ryukyu trench and the Philippine or Mindanao trench (htindanao deep) The latter reaches the second lowest depths known in any section of the ocean floors. Maximum depth is achieved about 120 mi. northeast of the town of Surigao on northeastern Mindanao. The depth here is 34 583 ft., recorded in 1951 by the Danish oceanographic ship "Galathea." correcting a 1945 reading of 34.440 ft. recorded by the U.S S. "Cape Johnson" and a 1927 reading of 35.400 ft recorded by the German cruiser "Emden." The warm North Equatorial current flons westward across the southern part of the sea Upon meeting the Philippine Islands the current divides; part swings north as the warm Kuroshio or Japan current and part swings toward the equator as the Counter Equatorial current.

During A'orld War II the U.Snavy achieved two significant victories over the Japanese fleet in the southern Philippine sea. The first nas fought by carrier planes alone on June 19–20, 1944 The second, sometimes called the battle of Leyte Gulf. involved the major units of both fleets and was a decisive American victory *See* WORLD WAR II: *The War at Sea.* (R. E. HE)

PHILIPPOPOLIS (Bulg. PLOVDIV), the second town of Bulgaria, capital of the district of the same name. is situated on the right bank of the Maritsa, 96 mi. E.S E. of Sofia. Pop. (1956) 162.518. The city lies on and between seven granite rocks which rise out of the flat and fertile plain of the Maritsa; the southern Balkans are distant about 25 mi., the northern Rhodopes about 12 mi It is a wealthy commercial city, centre of the trade in tobacco. wheat, silk and attar of roses of south Bulgaria. There is also a growing industry in flour-mills, tobacco factories, beer, soap, leather. ink. furniture and sugar.

History.—Eumolpia, a Thracian town, was captured by Philip of Macedon and made one of his frontier posts; hence its name of Philippopolis. Under the Romans, Philippopolis, or Trimontium. was the capital of Thracia. It is said that 100.000 persons were slain when it was captured by the Goths. In 762 it was in ruins when the Emperor Constantine Copronymus settled large colonies of Armenian Paulicians in and around it as frontier guards. It recovered its prosperity under the later Roman Empire. and excited the admiration of the crusaders. Frederick Barbarossa made it his headquarters (1189); in 1205 it was granted to Renier of Trit The next year the Greeks declared for the Byzantine emperor. nhereupon the Armenians betrayed the city to the Bulgarian tsar, Kaloyan, who massacred its Greek inhabitants. and razed the city. It recovered again, and became of extreme importance as the centre from which the Bogomils (*q.v.*) derived their doctrines through Armenian teachers. It was retaken by the Greeks in 1262, by the Turks in 1363. It was occupied by Russian troops in 1878, and under the treaty of Berlin was made capital of the autonomous province of Eastern Roumelia, being united nith Bulgaria in 1885 *(see* BULGARIA: *History).*

PHILIPPUS, MARCUS JULIUS, Roman emperor AD. 244 to 249. often called "Philip the Arab." was a native of Bostra in Arabia Trachonitis. Having entered the Roman army, he rose to be praetorian praefect in the Persian campaign of Gordian III. and. inspiring the soldiers to slay the young emperor, was raised by them to the purple (244). Of his reign little is known except that he celebrated the secular games with great pomp in 248, when Rome nas supposed to have reached the thousandth year of her existence. A rebellion broke out among the legions of Moesia, and Decius. who was sent to quell it, was forced by the troops to put himself at their head and march upon Italy. Philip was defeated and slain in a battle near Verona. According to Christian writers. he was a convert to Christianity.

PHILIPS, AMBROSE (1674–1749), English poet whose contemporary reputation rested chiefly on his *Pastorals,* was born at Shrensbury, Oct. 9, 1674. He was educated at Shrewsbury school and St. John's college, Cambridge, where he became a fellow~in 1699. In 1700 he published *The Life of John Williams,* an abridgment of J. Hacket's *Scrinia Reserta,* A *Memorial to Archbishop Williams* (1693). After traveling in Holland, he obtained a commission and served in Spain. In 1709 his *Pastovals* appeared in J. Tonson's *Miscellany* and won praise from Addison, Steele and Pope. They were later parodied by John Gay in *The Shepherd's Week* (1714). Philips became secretary to Daniel Pulteney. the British envoy at Copenhagen, in 1709 and there composed a widely admired verse epistle to the earl of Dorset, *A Winter Piece* (1709). After tutoring in Italy he returned to London, where *The Distrest Mother* (1712). his adaptation of Racine's *Andromaque,* was a success. His other plays are *The Bviton* (1722) and *Humfrey, duke of Gloucester* (1723). His quarrel with Pope, described by Dr. Johnson as a "perpetual reciprocation of malevolence," resulted from an article in *The Guardian* (No. 32 of 1713) in which Philips, and not Pope, whose *Pastorals* had also appeared in Tonson's *Miscellany,* was hailed as the successor of Theocritus, Virgil and Spenser.

Gradually Philips lost his literary friends. In 1714 he was made paymaster to the lottery. and justice of the peace for Westminster; but in 1724 he became secretary to Dr. Boulter, archbishop of Xrmagh, whom Snift detested, and found himself the butt of literary Dublin. His poems on the children of Lord Carteret and Daniel Pulteney, scoffed at by Swift as "little flams," were parodied, and he was nicknamed "Namby Pamby." He sat in the Irish parliament and held legal positions before returning to London in 1748. He died there. June 1 or 2, 1749. His *Poems* were edited with an introduction by M. E. Segar in 1937.

PHILIPS, JOHN (1676–1708/09), English poet and man of letters. son of Dr. Stephen Philips, archdeacon of Shropshire, was born at Bampton, Oxfordshire, on Dec. 30, 1676. He was educated at Winchester and Christ Church. Oxford. His poem, *The Splendid Shilling,* was called by Addison in *The Tatler* "the finest burlesque poem in the British language." Harley and St. John commissioned him to write a Tory counterblast (*Blenheim*) to Joseph Addison's *Campaign. Cyder* (1708), one of the earliest of the great didactic poems of the 18th century, is modeled on the *Georgics* of Virgil. *Cerealia, an Imitation of Milton* (1706), although printed without his name, may safely be ascribed to him. In all his poems except *Blenheim* he inserted a eulogy of tobacco. Phiips died at Hereford on Feb. 15, 1708/09.

Philips (1927), ed. *M.* **G.** Lloyd Thomas; and Johnson's *Lives* of *the Poets.*

PHILIPS, KATHARINE (1631–1664), English poet known to her contemporaries as the "Matchless Orinda," was born in London on Jan. 1. 1631. She married James Philips, a Welsh Puritan and parliamentary leader, in 1648. Her home in Cardigan became the centre of a "society of friendship," the members of which were known by romantic pseudonyms, Mrs. Philips being Orinda; her friend Mrs. Anne Owen, Lucasia; her husband, Antenor; and Sir Charles Cotterell, Poliarchus. Henry Vaughan exchanged poetical compliments with her and Jeremy Taylor addressed to her *A Discourse of the Nature, Offices and Measures* of *Friendship* (1657). The atmosphere of the circle is preserved in *The Letters of Orinda to Poliarchus* (1705). Her *Pompey* (1663). a translation from Corneille, was successfully acted and her poems appeared in a pirated edition (1664). An authentic edition by Sir C. Cotterell appeared in 1667. She died of smallpox in London on June 22, 1664.

Orinda's poems represent a transition from the old courtly poetry to the Augustan manner of the Restoration. One of her lyrics was praised by Keats and she wrote the heroic couplet with skill and dignity. *The Letters to Poliarchus* are lively and spirited.

The poems were edited by G. Saintsbury in his *Minor Poets of the Caroline Period,* vol. *1* (1905). *See* also **P.** *W.* Souers, *The Matchless Orinda* (1931) (V. DE S P.)

PHILIP THE BOLD (1342–1404), duke of Burgundy, fourth son of John II. of France and Bonne of Luxemburg, was born on Jan. 15, 1342. He earned his surname by his bravery on the field of Poitiers He accompanied King John into captivity in England. In 1360 he received the title of duke of Touraine, and in June 1363 was entrusted with the government of Burgundy, which John had united to the crown at the death of the last duke of the Capetian family, Philip of Rouvre, in 1361. In September 1363 John made Philip duke of Burgundy, and first peer of France. The donation was ratified at the accession of Charles V. of France; he took possession of the duchy at the end of 1364. Charles appointed him (in 1366) his lieutenant in Champagne and married him in 1369 to Margaret, daughter and heiress of Louis of Mâle. count of Flanders, and widow of Philip of Rouvre.

Philip proved a faithful ally to Charles. He took part in the almost bloodless campaign against the duke of Lancaster, who had landed at Calais; in 1377 he took several towns in French Flanders from the English; and in 1379 relieved Troyes, which had been besieged by the English. On Charles's death Philip found himself, with his brothers, the dukes of Anjou and Berry, in charge of the government of France in the name of Charles VI., who was a minor; and in the absence of the duke of Anjou, who left France in 1382 to conquer the kingdom of Naples, Philip occupied the most powerful position in the realm. He persuaded the young king to intervene in Flanders, where the citizens of Ghent, whose rebellious spirit had necessitated Philip's intervention in 1379, had again revolted under Philip van Artevelde and had expelled Louis of Mâle. On Nov. 27, 1382, the Franco-Burgundian chivalry crushed the rebels at Rosebecke, and on his return the duke of Burgundy took part in repressing the popular movements which had broken out in Paris and other French towns. In 1383 an insurrection in Flanders supported by England gave rise to another French expedition; but in January 1384 the death of Louis of Mâle made Philip master of the countships of Flanders, Artois, Rethel and Nevers; and in the following year the citizens of Ghent decided to submit. At this period Philip sought to ingratiate himself with the emperor by giving two of his daughters in marriage to two princes of the house of Bavaria; he also took an important part in bringing about the marriage of a princess of the same family, Isabel, to King Charles VI.

Hostilities, however, were renewed between France and England. A formidable expedition was prepared under the direction of the duke of Burgundy, and a fleet of 1,400 sail assembled at Sluys; but the enterprise failed owing to the dilatoriness of the duke of Berry. The fatiguing and inglorious expedition in the Netherlands weakened Philip's credit with his nephew, who on his return declared himself of age and confided the government to the ancient councillors of his father, the "Marmousets." The king's madness (1392) restored his uncles to power, and particularly Philip, who after assuring peace by treating with the duke of Brittany and by concluding a truce of twenty-eight years with England, made strenuous efforts to put an end to the Great Schism, visiting Pope Benedict XIII. at Avignon in 1395 in the hope of obtaining a voluntary resignation from him. For the discords in the king's council *see* CHARLES VI. For a brief period Philip was dispossessed of authority, but he regained it in 1402 and kept it till his death (April 27, 1404). The cathedral of St. Bénigne at Dijon contains his remains, and his tomb (formerly in the Chartreuse of Dijon) is in the Hôtel-de-ville. Philip appears to have governed his territories with sagacity and a certain moderation. He granted numerous privileges to the inhabitants of Dijon and created in 1386 two *chambres des comptes,* one at Dijon and the other at Lille. (R. P.; X.)

PHILIP THE GOOD (1396–1467), duke of Burgundy, son of John the Fearless, duke of Burgundy, and Margaret of Bavaria, was born at Dijon on June 13, 1396, and succeeded his father on Sept. 10, 1419. The assassination of John the Fearless (*q.v.*) drove his successor to the English side. In 1419 Philip signed with Henry V. of England the treaty of Arras, by which he recognized Henry as regent and future heir of the kingdom of France, and in 1420 gave his adherence to the treaty of Troyes. Early in December 1420 Philip entered Paris with the king of England, and subsequently took part in the defeat of the French at Monsen-Vimeu. By a treaty concluded by Philip at Amiens in April 1423 with the dukes of Brittany and Bedford, John, duke of Bedford, married Philip's sister Anne, and Arthur of Brittany, earl of Richmond, became the husband of Philip's sister Margaret. A few years later discord arose among the allies. When the duke of Bedford besieged Orleans the inhabitants offered to surrender, but to the duke of Burgundy; whereupon Bedford retorted that "he did not beat the bushes for others to take the birds." When this speech reached Philip's ears he withdrew his troops in dudgeon, and concluded a truce with France (1429). Bedford succeeded in conciliating him and in 1430 Philip took part in the campaign against Compiègne.

But another conflict arose between the duke of Burgundy and the English. Jacqueline, countess of Hainaut *(see* JACOBA) the divorced wife of the duke of Brabant and the heiress of Holland and Zeeland, had married the duke of Gloucester, who attempted to take forcible possession of his wife's territories. Philip claimed Brabant as a bequest from his cousin Philip, the late duke, with the result that the Burgundians repulsed the troops of the duke of Gloucester, and Jacqueline was forced to recognize the duke of Burgundy as her lieutenant and heir. Moreover, the duchess of Bedford had died in 1433. Charles VII., who in spite of the efforts of the cardinal of Ste-Croix had hitherto refused to return to France, finally decided to take part in the conferences which were opened at St. Vaast d'Arras on Aug. 6, 1435. Philip agreed to recognize the king of France as his legitimate sovereign on condition that he should not be required to pay him homage during his lifetime. Charles solemnly craved pardon for the murder of John the Fearless and handed over to the duke the counties of Mâcon, Auxerre, Bar-sur-Seine and Ponthieu, and the towns on and near the Somme (Roye, Montdidier, Péronne), reserving the option of redeeming the Somme towns for 400,000 gold crowns. Philip faithfully served the king, aiding him in re-entering Paris and preparing an expedition against Calais, which, however, failed through the ill-will of his Flemish subjects (1436). In 1440 he paid the ransom of Charles of Orleans and married him to Mary of Cleves. In 1442 Philip conspired to give the duke of Orleans a larger share in the affairs of the kingdom.

Philip was frequently disturbed by the insubordination of the Flemish communes. He had to quell seditions at Liége (1430), Ghent (1432 and 1448), Antwerp (1435) and Bruges (1438). Shortly after the final defeat of the citizens of Ghent at Gavre (1453) Philip vowed that he would lead a crusade against the Turks, who had seized Constantinople. The expedition, however, did not take place, and was but a pretext for levying subsidies. In 1459 Philip sent an embassy under the duke of Cleves into Italy to

take part in the conferences preparatory to a fresh expedition against the Turks, but this enterprise likewise fell to the ground. In 1456 the duke of Burgundy had given an asylum to the Dauphin Louis (afterwards Louis XI.), who had quarrelled with his father and had been forced to leave France. Louis repaid his protector by attempting to sow discord in the ducal family of Burgundy, and then retired to the castle of Genappe in Brabant. At Charles VII.'s death, however, Philip was one of the first to recognize the new king, and accompanied him to Paris. During the journey Louis won over the seigneurs of Croy, the principal counsellors of the duke of Burgundy, and persuaded Philip to allow him to redeem the Somme towns for the sum stipulated in the treaty of Arras. This proceeding infuriated Philip's son Charles, count of Charolais, who prevailed upon his father to break his pledge and declare war on the king of France On April 12, 1465, Philip handed over to his son the entire administration of his estates. The old duke died at Bruges on June 15, 1467.

Philip was a great lover of pomp and luxury and a friend of letters, being the patron of Georges Chastelain, Olivier de la Marche and Antoine de la Salle, and the founder of the collection of mss. known as the "Bibliothèque de Bourgogne" (now at Brussels), and also of the university of Dôle (1421). He administered his estates wisely; promoted commerce and industry, particularly in Flanders; and left his son a well-lined treasury. He was thrice married: in 1409 to Michelle (d 1422), daughter of Charles VI. of France; in 1424 to Bonne of Artois (d. 1425); and in 1429 to Isabel (d. 1472), daughter of John I., king of Portugal, when he founded the order of the Golden Fleece He was succeeded by Charles, afterwards known as Charles the Bold, his only surviving son by Isabel. (R. P.; X.)

PHILISTINES. "Philistine" was the general name for the people of Philistia (Assyr *Palaštu, Pilištu;* Egypt *p-r-s-t*), a district embracing the rich lowlands on the Mediterranean coast from the neighbourhood of Jaffa (Joppa) to the Egyptian desert south of Gaza On the subsequent extension of the name in its Greek form. Palaestina. *see* PALESTINE.

According to biblical tradition the Philistines are the remnant of Caphtor (Jer. xlvii. 4, Amos ix. 7), and the Caphtōrīm drove out the aboriginal Avvim from Gaza and district, as the Horites and Rephaim were displaced by Edom and Ammon (Deut. ii. 23). These Caphtōrīm, as well as Ludim (Lydians) and other petty peoples, apparently of the Delta, are once reckoned to Egypt (Gen. x. 14). By Caphtor the Septuagint has sometimes understood Cappadocia, which indeed may be valid for its age, but the name is to be identified with the Egyptian K(a)ptar, which in later Ptolemaic times seems to mean Phoenicia, although the earlier *Keftiu* connoted Crete, and possibly "the south Anatolisn coast as far as Cilicia" (Hall). The Cherethites, associated with the Philistine district (1 Sam. xxx 14, 16, Ezek. xxv. 16, Zeph ii. 5 *seq*), are sometimes recognized by the Septuagint as Cretans, and, with the Pclethites, they form part of the royal bodqguard of Judaean kings (2 Sam. viii. 18, xv. 18, xx. 7, 1 Ki. i. 38, 44; in 2 Sam xx. 23 the Hebrew text has Carites).

The earliest occurrence of the name "Philistines" outside the Old Testament is in Egypt, where the Purasati (Pulesati) are one of a great confederation from north Syria, Asia Minor and the Levant, which threatened Egypt in the 20th dynasty. They are not among the hordes enumerated earlier by Rameses II or Merneptah but in the eighth year of Rameses III (c. 1194 B.C.); the Purasati (Pulesati) take part in a widespread movement on land and sea. The Syrian States were orerahelmed and the advance upon Egypt seemed irresistible. Rameses, however, collected a large feet and an army of native troops and mercenaries and claimed decisive victories The Egqptian monuments depict the flight of the enemy. The sequel of the events is not known, though about a century later the Zakaray are found at Dor, and treat with scant respect the suzerainty of Egypt.

The Egyptian monuments represent the I'urasati with a very distinctive feather head-dress resembling that of the Lycians and Mycenaeans. Their general physiognomy is hardly Cilician or Hittite, but European, especially Greek. They fought with a broad-sword and carried a round shield. On archaeological grounds the Purasati were not Mycenaeans from Crete, despite tradition, but rather from Asia Minor (Lycia, Caria), though they may have passed some time in Crete.

Palestine and the West.—The Philistines appear in the Old Testament as a Semitic or at least a Semitized people. Both the language and the religion were Semitic. The male god Dagon has his partner Astarte (*q.v.*), and Baal-zebub, a famous oracle of Ekron (2 Ki. i.) resembles the local "baals" of Palestine. Philistia seems to be completely Hellenized after the Persian age; but it is not certain that Greek culture pervaded all classes; foreign influence probably always made itself felt upon the coast-towns The use of the term ἀλλόφυλοι in Maccabaean and later writings (cf. the contemptuous hatred of Ben Sira, Ecclesiasticus 1. 26, and the author of Jubilees xxiv. 30 *sqq*) expresses the conditions of the Greek age and the Maccabaean wars. The Mediterranean coast-land was always exposed to incursions of aliens; Carians appear as royal and temple guards at Jerusalem (2 Ki. xi. 4), and old Greek traditions tell of a Carian sea-power and relations between Philistia and Greek lands. Even the presence of Carians and Ionians in the time of Psammetichus I may be assumed. and as these are planted at Defneh it is noteworthy that this place is also closely associated uith a Jewish colony (viz, Tahpanhcs, Jer. xliii, *seq*). In fact, Palestinian intercourse with the West is fairly continuous; and excavation at Beth-shan. Gezer, and other sites, has shown many important indications of Western influence, so that some authorities even recognize a "Philistine" pottery.

History.—The Philistines form a confederation of five cities (Ashdod. Ascalon [Ashkelon], Ekron, Gath and Gaza), which remained unconquered by the Israelites (Josh. xiii. 2 *seq*, Judges iii. 3; contrast Josh. xv. 45–47, xix 43). The institution of the Hebrew monarchy (*c.* 1025 B.C.) follows upon periods of Philistine oppression (Judges iii. 31, x. 7, 11, xiii. 1, 5; *see* SAMSON; ELI; SAMUEL; SAUL; DAVID). Their subjugation is ascribed to Samuel (1 Sam. vii 13), Saul (xiv. 47), and David (2 Sam. viii. 1). They evidently recovered their independence, and twice within a short time the northern Israelites laid siege to the border fortress of Gibbethon (1 Ki. xv. 27, xvi. 1;). The interrelations of the south Palestinian peoples follows from the unchangeable geographical conditions, and Judah always depended upon its relations with the Philistines on the west and with the Edomites and Arabian tribes on the south-east. "Philistia," with Edom and Beth-Omri (*i.e.,* the Israelite kingdom), paid tribute to the Assyrian king, Adad-Nirari III. (c. 802 B.C.). The omission of Judah is noteworthy. In the later Assyrian period Philistia was mixed up in pro- and anti-Assyrian intrigues, and suffered from Tiglath-pileser (734), Sargon (720) and Sennacherib (700). In the 7th century Gaza, Ascalon, Ashdod and Ekron were Assyrian vassals, together with Judah, Rloab and Edom—in all, 22 kings of the "Hittites" Herodotus mentions the Scythian invasion and sack of the temple of Aphrodite Urania (Astarte) at Ascalon. also the prolonged siege of Ashdod by Psammetichus, and the occupation of Kadytis (? Gaza) by Necho Rut the Babylonian empire followed upon traditional lines and thrust back Egypt, and Nabonidus (553 B.C.) claims his vassals as far as Gaza. The Persians took over the realm of their predecessors, and Gaza grew in importance as a seat of international commerce. Nehemiah speaks not of Philistines, but of Ashdodites (iv. 7), speaking an "Ashdodite" dialect (xiii 24); just as Strabo regards the Jews, the Idumaeans, the Gazans and the Ashdodites as four cognate peoples having the common characteristic of combining agriculture with commerce. In southern Philistia, at least, Arabian immigration became more pronounced In the time of Cambyses Arabs were settled at Jenysos south of Gaza (Herod iii 5), and when Alexander marched upon Egypt. Gaza with its army of Arabs and Persians offered a strenuous resistance On the history of the district *see* further GAZA; JEWS; MACCABEES; PALESTINE.

Traditions of the Philistines.—The Philistines were prominent. in popular tradition, and the story of Isaac and the Philistine Abimelech (Gen. xxvi., *cf* xxi 32) is of great interest for its unbiased picture of enmity, alliance and covenant. But a parallel story (xx.) is without this *Philistine* background. Similarly,

one account of the Israelite invasion conceived a conquest of earlier giant inhabitants (Anakim), who survived in Gaza, Gath and Xshdod (Josh. xi, 21 *seq.*, contrast xiii, 3), but were driven out from Hebron by Caleb (Josh. xv, 14, *cf.* Num. xiii, 22, 28). The Philistines themselves are called the remnant of the Anakim (Jer. xlvii. 5, so the Septuagint), or as Caphtorim replace the earlier Avvim (Deut. ii. 23, *see* Josh. xiii, 3). Samuel's great defeat of the Philistines leads to "peace between Israel and the *Amorites*" (1 Sam. vii, 14); and the migration of the Danites is placed after Samson's conflicts with the *Philistines* (Judges xviii, seq.), or is due to the pressure of *Amorites* (i, 34). Even in David's fights with the Philistines in Judah, Jerusalem is Jebusite, neighbouring non-Israelite cities are Hivite or Amorite (Josh. ix, 7, 2 Sam. xxi, 2). and his strange adversaries find a close parallel in the semimythical sons of Anak (2 Sam. xxi, 16, 18, 20, 22). In another tradition, however, David is on intimate relations with a Philistine king, Achish (or Abimelech, Ps. xxxiv). Traditions agree that the Israelites had to fight for their freedom, but antagonism between Philistines and Israelites was not persistent.

(S. A. C.)

PHILISTUS, Greek historian of Sicily, was born at Syracuse about the beginning of the Peloponnesian War (432 B.C.). He was a faithful supporter of the elder Dionysius, and commander of the citadel. In 386 he was banished for secretly marrying the tyrant's niece. He commanded the fleet against Dion, but was defeated and put to death (356). He settled at Thurii, but afterward moved to Adria, where he remained until the death of Dionysius (366). He was then recalled by the younger Dionysius, whom he persuaded to dismiss Plato and Dion. At Adria, Philistus occupied himself with the composition of his history of Sicily in 11 books, down to 363, from which point the work was carried on by Athanas. Cicero calls him "the miniature Thucydides."

PHILLIMORE, SIR ROBERT JOSEPH (1810–1885); English judge, was born at Whitehall on Nov. 5. 1810. Educated at Westminster and Christ Church. Oxford, he was admitted as an advocate at Doctors' Commons in 1839 and called to the bar at the Middle Temple in 1841. He was soon engaged as counsel in many cases of importance before the admiralty, probate or divorce courts. He was appointed judge of the Cinque Ports in 1855, queen's counsel in 1858, advocate-general in admiralty in 1862, and judge of the court of arches five years later. Noted for his care and patience, combined with unusual lucidity of expression, he was the last judge of the old court of the lord high admiral; after the Judicature act he continued to sit as judge for the new admiralty, probate and divorce division until 1883.

PHILLIMORE, WALTER GEORGE FRANK PHILLIMORE, 1st BARON (1845–1929), British judge, was born in London on Nov. 21, 1845, the eldest son of Sir Robert Joseph Phillimore (*q.v.*). He was educated at Westminster and Christ Church, Oxford, and was called to the bar in 1868. He was made a judge in 1913, and promoted to the court of appeal in 1913. He retired from the bench in 1916, and in 1918 was raised to the peerage. He was English representative on the commission which sat at The Hague in 1920 to prepare the scheme of a permanent court of international justice. He died on March 13, 1929.

PHILLIPPS DE LISLE, AMBROSE LISLE MARCH (1809–1878), a leading figure in the 19th-century Roman Catholic revival in England, was born at Garendon Park, Leicestershire, on March 17, 1809, the elder son of Charles March Phillipps; he took the name De Lisle in 1862 from his paternal grandmother's family, then without heir. Converted to Roman Catholicism from evangelical Anglicanism at the age of 16, he founded in 1835 the first post-Reformation English Trappist monastery, called Mount St. Bernard, presenting an estate in Charnwood forest, Leicestershire, to a group of monks from Ireland.

He wrote a number of religious works and was the benefactor of other religious communities, the supporter of the Gothic revivalism of A. W. N. Pugin (*q.v.*), a friend of leading figures of the Oxford movement, and an overoptimistic worker for the corporate reunion of the churches. He died at Garendon on March 5, 1878.

See E. S. Purcell, *Life and Letters of Ambrose Phillipps De Lisle,* 2 vol. *(1900).* (M. DK.)

PHILLIPS, EDWARD (1630–?1696), English writer and biographer of Milton. who was his uncle, was born in London Xug. 1630. His father, who died in 1631, was Edward Phillips of the crown office in chancery, and his mother was Milton's only sister: Anne. Edward and his younger brother John were educated by Milton, in whose house they boarded and studied the classics, mathematics and music. Edward entered Magdalen hall, Oxford, in Nov. 1650, but left in 1651 to be a bookseller's clerk in London. He was tutor to John Evelyn's son (1663–65). and, later. in the families of Lord Herbert and the earl of Arlington. His interesting memoir of Milton (1694) is prefixed to his translation of Milton's *Letters of State.* John Aubrey states in his *Minutes* of *Lives* that all the poet's papers came into his nephew's hands. His other works include A *New World in Words, or a General Dictionary* (1658). which ran through many editions; an edition (1660–62) of Sir Richard Baker's *Chronicle* of *the Kings of England,* with the section on 1650–58 showing a strong royalist slant; and *Theatrum Poetarum* (1675), a list of great poets. principally English ones, with critical notes and a prefatory *Discourse of the Poets and Poetry* which may have been written by Milton. He also added a supplement (1676'1 to John Speed's *Theatre of Great Britain,* and wrote *Enchiridion linguae latinae* (1684), said to be based on Milton's notes. The date of his death is unknown. but his last book is dated 1696.

His brother JOHX PHILLIPS (1631–1706) has been proved to be the author of a biography of Milton which was long thought anonymous. He appears to have acted as Milton's secretary, and in 1652 published a Latin reply to the anonymous attack on the poet entitled *Pro Rege et populo anglicano.* In 1655 he wrote a bitter attack on Presbyterianism, *A Satyr Against Hypocrites,* much in line with Milton's disapproval of the sect. In 1656 he was summoned before the privy council for his share in a book of licentious poems. *Sportive Wit* (1656). which was suppressed, but only to be replaced by another. *Wit and Drollery* (1656). John Phillips was a voluminous writer, often obscene, but entertaining.

See W. Godwin, *Lives of Edward and John Phillips* (1815); H. Darbishire, The *Early Lives* of *Milton (1932).*

PHILLIPS, STEPHEN (1868–1915), British poet and dramatist. was born on July 28, 1868, at Somertown near Oxford. He was educated at Stratford and Peterborough grammar schools. and entered Queen's college. Cambridge; but during his first term at Cambridge. when F. R. Benson's dramatic company visited the town, he joined it, and for six years played various small parts. In 1890 a slender volume of verse was published at Oxford with the title *Primavera,* which contained contributions by him and by his cousin, Laurence Binyon, and others. In 1894 he published *Eremus,* a long poem of loose structure in blank verse of a philosophical complexion. *Poems* (1897) brought him many readers. George Alexander commissioned Phillips to write him a play. the result being *Paolo and Francesca* (1900). produced at the St. James's theatre in 1901. Other dramas in blank verse followed: *Herod: a Tragedy* (1900), *Ulysses* (1902), *The Sin of David* (1904), and *Nero* (1906). In these plays, three of which mere produced by Beerbohm Tree, the poet's avowed aim was to revitalize the method of the Greek drama. *Paolo and Francesca* was the most successful.

Phillips died at Deal, Kent. on Dec. 9, 1915.

PHILLIPS, WENDELL (1811–1884). U.S. orator and reformer, was born in Boston on Nov. 29. 1811. His father, John Phillips (1770–1823), became the first mayor of Boston. Wendell entered Harvard college before he was 16 and graduated in 1831. He graduated at the Harvard law school in 1834. and was admitted to the bar in Boston. He soon came under the influence of the antislavery movement. witnessing in 1835 the mobbing, in Boston. of William Lloyd Garrison.

A meeting was held on Dec. 8. 1837. at Faneuil hall, Boston, to express the sentiments of the people on the murder of Elijah P. Lovejoy, at Alton (Ill.) for defending his press from a proslavery mob. In the course of the meeting a speech was made in opposition to its general current by James T. Austin, attorney general of the state. who said that Lovejoy had died "as the fool dieth." and compared his murderers with the men who threw the tea into Bos-

ton harbour just before the War of Independence The speech seemed likely to divide the audience. when Wendell Phillips took the platform. "When I heard," he said. "the gentleman lay down principles which placed the murderers of Alton side by side with Otis and Hancock, with Quincy and Adams, I thought these pictured lips (pointing to their portraits) would have broken into voice to rebuke the recreant American. the slanderer of the dead" That successful appeal determined the sentiment of the meeting and gave Phillips his first fame and determined his career.

Accepting unhesitatingly the leadership of Garrison, and becoming like him a disunionist, he thereafter lived essentially a platform life, interested in a variety of subjects. but first and chiefly an abolitionist. After the Civil War, however, he broke with Garrison over the question of discontinuing the Anti-Slavery society; and from 186j until the society was diibanded in 1870, he. instead of Garrison. was its president. Phillips' style of eloquence was direct and brilliant, but eminently self-controlled. He may be said to have introduced the direct and colloquial manner upon the C.S. public platform. His logic, while never obtruded, was rarely at fault. but he loved the flash of the rapier, and was never happier than when he had to face a mob and utterly foil it by sheer superiority in fencing. The two volumes of his speeches, as edited by James Redpath, nere fortunately made from verbatim reports, and they wisely enclose in parentheses those indications of favour or dissent from the audience which transformed so many of his speeches into exhibitions of gladiatorial skill. After slavery had fallen Phillips associated himself freely with reformers occupied in other paths. He contended in later years for prohibition, woman suffrage and various penal and administrative reforms. He died in Boston on Feb. 2, 1884.

PHILLIPSITE, a mineral of the zeolite group, is a hydrated potassium, calcium and aluminum silicate. Like other natural and synthetic zeolites its unique crystalline make-up and structural porosity make it possible for the mineral to lose and regain water reversibly with little or no change in fundamental structure. Like other zeolites it has the property of exchanging electrically charged atoms (ions) with other substances. (For discussion of these properties *see* ZEOLITE.) Phillipsite is a mineral of secondary origin and occurs with other zeolites in cavities in basic volcanic rocks (basalts and phonolites); in red clay and deep sea deposits; and is formed from some hot spring waters. It has been found near Rome, Italy, in France, Germany and Australia, near Melbourne, and at the Giant's Causeway, County Antrim, N.Ire. The composition of phillipsite approximates $(K_2,Ca)Al_2(SiO_3)_4.4H_2O$. It varies somewhat in composition, the variety pseudophillipsite having the formula $(K_2,Ca)_2Al_4Si_5O_{18}.9H_2O$. Crystals are monoclinic, but only complex cruciform twins are known. Spherical groups with a radially fibrous structure and bristled with crystals on the surface are not uncommon. The hardness is 4.5, and the specific gravity 2.2.

The species was named in 182j after the English mineralogist William Phillips (1775–1828); it also has been called christianite after Christian VIII of Denmark.

PHILLPOTTS, EDEN (1862–1960), English novelist. poet arid dramatist, was born at Mount Abu, Rajputana. India. Nov. 4, 1862, and educated at Plymouth. A clerk for ten years in an insurance office, he then studied for the stage, but became a writer, producing over 100 novels, many of them with a Devonshire setting. Among his more important works are the novels *Children of the Mist* (1898); *Sons of the Morning* (1900); *Widecombe Fair* (1913); studies of boyhood and adolescence, *The Human Boy* (1899); *The Waters of Walla* (1950); plays, *The Farmer's Wife* (1917); *Yellow Sands* (with his daughter Adelaide, 1926); poems, *The Iscariot* (1912); *Brother Beast* (1928); *The Enchanted Wood* (1948); and *One Thing and Another* (poems and essays, 1954). He died at Broad Clyst, near Exeter, Dec. 29, 1960.

PHILLPOTTS, HENRY (1778–1869), English bishop, was horn at Bridgnater on May 6, 1778, and was educated at Gloucester College school and Corpus Christi college, Oxford. He was consecrated bishop of Exeter in 1831, holding with the see a residentiary canonry at Durham. In 1819 he had defended the existing poor law and the action of the government in the Peterloo (*q.v.*) massacre. In 182j he vehemently opposed Catholic emancipation, engaging in a fierce polemic on the subject with Charles Butler (1j50–1832). "Henry of Exeter" continued to support the Tory party, even when it passed the Roman Catholic Emancipation act of 1829. He died on Sept. 18, 1869. The famous Gorham judgment was the outcome of his refusal to institute to the living of Brampford Speke a clergyman George Cornelius Gorham (1787–1857), who had openly disavowed his belief in baptismal regeneration; he denounced the equally famous tract 90 in his episcopal charge of 1843.

PHILO, often called PHILO JUDAEUS (c. 30 B.C.–*c.* A.D. 40), Jewish philosopher, is the most important representative of Hellenistic Judaism, and his writings give us the clearest view of this development of Judaism in the Diaspora. He was probably a native of Alexandria, where he appears to have spent his whole life apart from his journey to Rome. His brother Alexander was alabarch or arabarch (*i.e.,* probably, chief farmer of taxes on the Arabic side of the Nile), from which it may be concluded that the family was influential and wealthy (Josephus, *Antiquities,* xviii, 8, 1). The only event of his life which can be actually dated belongs to A.D. 40, when Philo, then nearing the end of his years, went to Rome to persuade the emperor Gaius to abstain from claiming divine honour from the Jews. Of this embassy Philo has left a full account (*De legatione ad Gaium*).

The Hellenistic Jew.—Philo appears to have been the greatest of all the Jewish philosophers of the Alexandrian school and has been called "the first theologian." On one side he is quite a Greek, on the other quite a Jew. His language is formed on the best classical models, especially Plato. He knows and often cites the great Greek poets, but his chief studies had been in Greek philosophy. His system was eclectic, but the borrowed elements are combined into a new unity with so much originality that he may fairly be regarded as representing a philosophy of his own, which has for its characteristic feature the constant prominence of a fundamental religious idea.

Philo's closest affinities are with Plato, with the later Pythagoreans and with the Stoics. Yet with all this Philo remained a Jew, and a great part of his writings is expressly directed to recommend Judaism to the respect and, if possible, to the acceptance of the Greeks. He was not a stranger to the specifically Jewish culture that prevailed in Palestine; in Hebrew he was not proficient, but he had evidently made some study of that language. His method of exegesis is similar in form to that of the Palestinian rabbinic scholars, and there are coincidences in matter. Philo recognized the Mosaic Scriptures of the Pentateuch as of absolute divine authority and as containing all truth. The other Jewish Scriptures he also recognized as prophetic (*i.e.,* as the writings of inspired men) but he did not place them on the same lines with the Law: everything that is right and good in the doctrines of the Greek philosophers had already been quite as well, or even better, taught by Moses. Thus, since Philo had been deeply influenced by the teachings of Greek philosophy, he found in the Pentateuch everything which he had learned from the Greeks. From these premises he assumed as requiring no proof that the Greek philosophers must in some way have drawn from Moses, a view which had already been expressed by Aristobulus. These presuppositions were maintained by an allegorical interpretation of Scripture. With its aid he discovered indications of the profoundest doctrines of philosophy in the simplest stories of the Pentateuch. This method of allegory is borrowed from the Stoics.

Theology.—Philo's doctrine of God starts from the idea that God is a being absolutely bare of quality (ἄποιος), excluding any composition of body and soul, or of the four elements, or of substance and accidental quality, or of matter and form. No limitation can be predicated of God. who is eternal, unchangeable, simple substance, free, self-sufficient, better than the good and the beautiful. To predicate any quality of God would be to reduce Him to the sphere of finite existence. Of Him we can say only *that* He is, not *what* He is; and such purely negative predications as to His being appear to Philo, as to the later Pythagoreans and to the Neoplatonists, to constitute the only way of securing His absolute elevation above the world.

A consistent application of Philo's abstract conception of God would exclude the possibility of any active relation of God to the world, for a being absolutely without quality and movement cannot be conceived as actively concerned with the multiplicity of individual things. And so in fact Philo does teach that the absolute perfection, purity and loftiness of God would be violated by direct contact with imperfect, impure and finite things. But the possibility of a connection between God and the world is reached through a distinction which forms the most important point in his theology and cosmology; the proper being of God is distinguished from the infinite multiplicity of divine ideas or forces: God himself is without quality, but He disposes of an infinite variety of divine forces, through whose mediation an active relation of God to the world is brought about.

Mediating Forces.—Philo's conception of the nature of these mediating forces was self-contradictory. On the one hand they are nothing else than ideas of individual things conceived in the mind of God and, as such, ought to have no other reality than that of immanent existence in God; and so Philo says expressly that the totality of ideas, the *κόσμος νοητός*, is simply the Reason of God as Creator (*θεοῦ λόγος ἤδη κοσμοποιοῦντος*). Yet, on the other hand, they are represented as daemons or angels, hypostases distinct from God, individual entities existing independently and apart from Him. This vacillation, however, as E. Zeller and others have justly remarked, is necessarily involved in Philo's premises, for, on the one hand, it is God who works in the world through His ideas, and therefore they must be identical with God; but, on the other hand, God is not to come into direct contact with the world, and therefore the forces through which He works must be distinct from Him. The same inevitable amphiboly dominates in what is taught as to the supreme Idea or Logos. Philo regards all individual ideas as comprehended in one highest and most general idea or force—the unity of the individual ideas—which he calls the Logos or Reason of God and which is again regarded as operative Reason. The Logos, therefore, is the highest mediator between God and the world, the firstborn son of God, the archangel who is the vehicle of all revelation and the high priest who stands before God on behalf of the world. Through him the world was created, and so he is identified with the creative Word of God in Genesis (the Greek *λόγος* meaning both "reason" and "word"). Here again, we see, the philosopher is unable to escape from the difficulty that the Logos is at once the immanent Reason of God, and yet also an hypostasis standing between God and the world. The whole doctrine of this mediatorial hypostasis is a strange intertwining of very dissimilar threads; on one side the way was prepared for it by the older Jewish distinction between the Wisdom of God and God Himself, of which we find the beginnings in Job (xxviii, 12 seq.) and in Proverbs (viii, ix) and the fuller development in Ecclesiasticus and in the Book of Wisdom, the last of which comes very near to Philo's ideas if we substitute for the term "wisdom" that of (divine) "reason." The Stoic teacher Posidonius had already identified the Platonic ideas with the Stoic Logos. Philo goes a step further by placing the ideas in the Mind of God; but he makes it clear that they represent only God's relation to the world, not his essence.

The world and creation, in Philo's doctrine, rest on the presupposition of an absolute metaphysical contrast between God and the world. The world can be ascribed to God only in so far as it is a cosmos or orderly world; its material substratum is not even indirectly referable to God. Matter (*ὕλη*, or, as the Stoics said, *οὐσία*) is a second principle, but in itself an empty one, its essence being a mere negation of all true being. It is a lifeless, unmoved, shapeless mass, out of which God formed the actual world by means of the Logos and divine forces. Strictly, the world is only formed, not created, since matter did not originate with God.

Ethical Teaching.—Philo's doctrine of man is also strictly dualistic and is mainly derived from Plato. Man is a twofold being, with a higher and a lower origin. Of the pure souls which fill airy space, those nearest the earth are attracted by the sensible and descend into sensible bodies; these souls are the Godward side of man. But on his other side man is a creature of sense, and so has in him a fountain of sin and all evil. The body, therefore, is a prison, a coffin, or a grave for the soul which seeks to rise again to God. The highest maxim of Philo's ethics is therefore deliverance from the world of sense and the mortification of all the impulses of sense. In carrying out this thought, Philo differs from the Stoics. The Stoics cast man upon his own resources; Philo points him to the assistance of God, without whom man, a captive to sense, could never rise to true wisdom and virtue. Even in this life the truly wise and virtuous is lifted above his sensible existence and enjoys in ecstasy the vision of God, his own consciousness sinking and disappearing in the divine light. Beyond this ecstasy there lies but one further step, viz., entire liberation from the body of sense and the return of the soul to its original condition; it came from God and must rise to Him again. But natural death brings this consummation only to those who, while they lived on earth, kept themselves free from attachment to the things of sense; all others must at death pass into another body; transmigration of souls is in fact the necessary consequence of Philo's premises.

Works.—The titles of the numerous extant writings of Philo present at first sight a most confusing multiplicity. More than three-fourths of them, however, are really mere sections of a small number of larger works. Three such great works on the Pentateuch can be distinguished.

1. The smallest of these is the *Ζητήματα καὶ λύσεις* (Quaestiones *et solutiones*), a short exposition of Genesis and Exodus, in the form of question and answer. The work is cited under the Greek title by Eusebius and by later writers, but the Greek text is almost wholly lost, and only about one-half preserved in an Armenian translation. Genesis seems to have occupied six books. Eusebius tells us that Exodus filled five books. In the Armenian translation, edited by the learned Mechitarist. J. B. Aucher (Venice, 1826). are preserved four books on Genesis and two on Exodus, but with lacunae. A Latin fragment, about half the fourth book on Genesis (*Philonis* Judaei *CII* quaestiones et *totidem responsiones* morales *super Genesim*), was first printed at Paris in 1520. Of the Greek are numerous but short fragments in various *florilegia*. The interpretations in this work are partly literal and partly allegorical.

2. Philo's most important work is the *Νόμων ἱερῶν ἀλληγορίαι*, a vast and copious allegorical commentary on Genesis, dealing with chapters ii, iii and iv, verse by verse and with select passages in the later chapters. The readers in view are mainly Jews, for the form is modelled on the rabbinic Midrash. The main idea is that the characters which appear in Genesis are properly allegories of states of the soul (*τρόποι τῆς ψυχῆς*). All persons and actions being interpreted in this sense, the work as a whole is a very extensive body of psychology and ethics.

3. A work of a very different kind is the group of writings expounding the "Mosaic Law for Gentiles." These, in spite of their diverse contents, present on nearer examination indubitable marks of close connection. In them Philo seeks to give an orderly view of the chief points of the Mosaic legislation in the Pentateuch and to recommend it as valuable to Gentile readers. The method of exposition is somewhat more popular here than in the allegorical commentaries, for, though that method of interpretation is not wholly excluded, the main object is to give such a view of the legislation as Philo accepted as historical. This work has three main divisions: (a) the interpretation of the first two chapters of Genesis, *Περὶ Μωύσεως κοσμοποιίας* (De *opificio mundi*), as Moses put his account of the Creation at the beginning of the Pentateuch in order to show that his legislation was conformed to the will of nature and that therefore those who followed it were true cosmopolitans; (b) the *βίοι σοφῶν*, biographies of the three righteous men, Abraham, Isaac and Joseph—being, so to speak, the living unwritten laws which, unlike written laws, present the general types of moral conduct; (c) legislation proper, in two subdivisions (i) the ten principal chapters of the law and (ii) the special laws belonging to each of these ten. An appendix adds a view of such laws as could not be brought under the rubrics of the decalogue.

4. Of the miscellaneous writings attributed to Philo, some appear to have survived in their entirety, some are extant only in translation or in fragments and some have been held to be spurious.

The Greek texts of the three books Περὶ βίου Μωύσεως (*Vita Mosis*) and of the treatise Περὶ εὐγενείας (*De nobilitate*) have been preserved. Two of five books on the affairs of the Alexandrian Jews also survive in Greek: namely Εἰς Φλάκκον (*In Flaccum*), in which Philo relates how the governor Flaccus, early in Caligula's reign, allowed the mob to persecute the Jews in Alexandria; and Περὶ ἀρετῶν καὶ πρεσβείας προς Γάϊον (*De legatione ad Gaium*), in which he describes the persecution following Caligula's demand for divine honours and recounts his embassy to Rome to seek relief for the Jews of Alexandria. Of the two books Περὶ προνοίας (*De providentia*), the title of which is twice mentioned by Eusebius, we now possess only an Armenian version edited with Latin translation by J. B. Aucher (Venice, 1822); book i appears moreover to be in a Christian recension. Also in Armenian, except for two small fragments preserved in the *Florilegium* of Leontius and Johannes, is the surviving text of Philo's Ἀλέξανδρος ἢ περὶ τοῦ λόγον ἔχειν τὰ ἄλογα ζῶα (*De Alexandro et quod propriam rationem muta animalia habeant*), mentioned both by Eusebius and by Jerome. Eusebius (*Praeparatio Evangelica,* viii, 6, 7, 11) preserves fragments of the Ὑποθετικά and of Ἡ ὑπὲρ Ἰουδαίων ἀπολογία the latter being presumably identical with the Περὶ Ἰουδαίων that he mentions elsewhere.

The authenticity of the treatise Περὶ τοῦ πάντα σπουδαῖον εἶναι ἐλεύθερον (*Quod omnis probus liber sit*) was disputed by Z. Frankel and by R. Ansfeld but was defended by Paul Wendland, who believed it to be an early work of Philo's. The Philonic origin of the document on the Therapeutae, Περὶ βίου θεωρητικοῦ (*De vita contemplativa; see* THERAPEUTAE) was also disputed, notably by P. E. Lucius in *Die Therapeuten* (Strassburg, 1879), but was ably defended by L. Massebieau in the *Revue de l'histoire des religions,* xvi (Paris, 1887), by F. C. Conybeare in *Philo about the Contemplative Life* (Oxford, 1895) and by Wendland in *Die Therapeuten* (Leipzig, 1896). Against J. Bernays and others who denied Philo's authorship of the treatise Περὶ ἀφθαρσίας κόσμου (*De incorruptibilitate mundi*)—apparently one of the sources from which the supposititious Περὶ κόσμου (*De mundo*) was compiled —F. C. Cumont's vindication, *Philo de aeternitate mundi* (Paris, 1891) may be consulted. Two discourses extant only in Armenian, one on Samson, the other on Jonah, are inauthentic.

BIBLIOGRAPHY.—Editions of Philo's works include those by T. Mangey, 2 vol. (London, 1742); L. Cohn, P. Wendland and S. Reiter, 7 vol. (Berlin, 1896–1930); and F. H. Colson and G. H. Whitaker, 9 vol., with Eng. trans., Loeb series (London, 1929 *et seq.*).

PHILOCTETES, son of Poeas king of the Malians of Mt. Oeta, a celebrated hero of the Trojan War. Homer merely states that he was distinguished for his prowess with the bow; that he was bitten by a snake on the journey to Troy and left behind in the island of Lemnos; and that he subsequently returned home in safety. In the post-Homeric accounts, Philoctetes or his father were given the bow and arrows of Heracles (*see* HERCULES) as a reward for kindling the fire on Mt. Oeta, on which the hero immolated himself. Philoctetes remained at Lemnos till the tenth year of the war. An oracle having declared that Troy could not be taken without the arrows of Heracles, Odysseus and Diomedes (or Neoptolemus) were sent to fetch Philoctetes. On his arrival before Troy he was healed of his wound by Machaon, and slew Paris; shortly afterward the city was taken. On his return to his own country, finding that a revolt had broken out against him, he again took ship and sailed for Italy, where he founded Petilia and Cremissa. He fell fighting on the side of a band of Rhodian colonists against some later immigrants from Pallene in Achaea. His tomb and sanctuary were shown at Macalla, on the coast of Bruttium.

PHILODEMUS (*c.* 110–40 B.C.), Greek poet and Epicurean philosopher who did much to spread Epicurean doctrine among Roman men of letters, was born at Gadara in Coele-Syria. After studying at Athens under the Epicurean Zeno of Sidon, he became the mentor of a Roman of high rank, L. Calpurnius Piso, with whom he lived in the vicinity of Naples. Horace is thought to have been much influenced by him. Cicero implicates Philodemus in a personal attack on Piso in his speech *In Pisonem,* but knew his writings well and used them as a source for Epicurean doctrine. Of his poems, 34 epigrams are extant; these consist of light verse, not linked with his philosophy. Treatises by Philodemus predominate among the books of the great Epicurean library discovered at Herculaneum (*q.v.*); the library itself may have belonged to him, the house to Piso or to his heirs. But restoration of the severely damaged rolls is difficult. Much of what Philodemus says evidently comes from Zeno of Sidon; but he gives glimpses of controversies between the later Epicureans and their opponents, and among themselves. (D. J. A.)

PHILODENDRON, a genus comprising about 200 species belonging to the Araceae family which are chiefly tree climbers, rarely erect plants, of the American tropics. The stems are mostly woody, branching, internodes often elongated, leaves thick, entire or pinnately cut, the petioles sheathing, and unisexual flowers borne on erect spadices that are slightly shorter than the white, yellow or red fleshy spathes. Philodendrons are widely grown as foliage plants in greenhouses and homes or out-of-doors in frostless regions. They require supports on which to climb and abundant moisture. (J. M. Bl.)

PHILOLAUS (*fl.* in second half of 5th century B.C.), Greek philosopher of the Pythagorean school, was born at Tarentum or at Crotona (so Diogenes Laërtius viii, 84) in southern Italy. After the death of Pythagoras great dissensions prevailed in the Italian cities. According to some accounts, Philolaus fled, taking refuge first in Lucania and then at Thebes, where he had Simmias and Cebes as pupils, who subsequently, being still young men, were present at the death of Socrates. Before this Philolaus had returned to Italy, where, it is said, he taught Archytas. He entered deeply into the Pythagorean number theory, particularly dwelling on the properties inherent in the decad—the sum of the first four numbers, consequently the fourth triangular number, the *tetractys* (*see* PYTHAGORAS AND PYTHAGOREANISM). It is from a book of his that Plato's successor Speusippus is reported to have reproduced the doctrine. Pythagoras probably knew the construction of three of the regular solids, and Empedocles is stated to have been the first who maintained that there are four elements. Philolaus, connecting these ideas, held that the elementary nature of bodies depends on their form and assigned the tetrahedron to fire, the octahedron to air, the icosahedron to water and the cube to earth; the dodecahedron he assigned to a fifth element, ether or the pure air surrounding the universe. The elements themselves seem to have been the product of number, and they existed in a harmony produced by the normal Pythagorean principles of Limit and the Unlimited. Similarly, in an animate body health consisted in a balance of the two further opposites, heat and cold. Philolaus regarded the soul as a "mixture and harmony" of the bodily parts; he also assumed a substantial soul, whose existence in the body is an exile because of sin, showing the religious outlook that Plato attributes to him in the *Phaedo* (61 D *ff.*). For the important astronomical theory sometimes attributed to him, *see* PYTHAGORAS AND PYTHAGOREANISM.

If these contributions were indeed made by Philolaus, it would seem that he was the first systematizer of Pythagoreanism. But it has to be stated that the evidence for his having made them is a matter of dispute. Both the astronomy and the physics which are credited to him have been held to be inadmissible before Plato's *Timaeus.* Certainly

the discovery of how to construct the octahedron and the icosahedron is put after Philolaus' time on far better evidence. (And the only quotation about the five elements, it should be noticed, does not name the regular solids at all.) The man himself has even been considered a fanciiul invention of Plato; and Erich Frank argued that his works were forged by Speusippus. Ii his genuineness is accepted, it is certainly necessary to be discriminating about the quotations which have survived and still more so about the descriptions of his doctrine made by ancient writers.

BIBLIOGRAPHY.—Ancient testimonies and fragments are collected by H. Diels and W. Kranz, *Fragmente der Vorsokuatiker,* vol. i. 7th ed. (Berlin, 1954). For the case against their genuineness *see* E. Frank, *Plato und die sogenannten Pythagoräer* (Halle, 1923); for a reply to Frank's arguments, E. Zeller, *La Filosofia dei greci,* Italian trans. ed. by R. Mondolfo, pt. i, vol. ii, pp. 367–82 (Florence, 1938). (A. C. LD.)

PHILOLOGY, a comprehensive name for the study of language and literature: too wide to be exact and therefore tending to fall into disuse in favour of a clear distinction between literary and linguistic scholarship. A human society is apt to be bound together by a single language, in which its entire cultural tradition, written and unwritten, is composed. As time goes by the universe of tradition is seen to contain diverse subject matter, which for convenience of handling is classified broadly to correspond to the activities of the particular society, its law, religion, history, philosophy, for example. That part of tradition. the content of which is dominantly imaginative and the form artistic, excites its own interest and criticism and even devotion, for the sake of its better preservation and understanding: this is philology.

Sheer bulk of material and the essential differences of theory and method which separate the study of literature from the study of language, have led to distinct disciplines and, except in well-defined fields such as the classics. Slavonic, far eastern, Celtic (to give more familiar examples) where students are still expected to study both language and literature, it is rare to find the finished expert who is at home in both. The best scholars are; but usually the one or the other pursuit has become his chief preoccupation and linguistics and language (*qq.v.*) form an exacting study that claims full attention, with the result that students of literature tend more and more to leave it to specialists. In the middle ages and for long after the Renaissance there was no such separation, but in the western world beginning about 1800 A.D., it has steadily become more intense. Native scholars of far eastern languages and literatures, of Ugro-Finnish, Indic. or Semitic, still are likely not to recognize it. On the other hand there may be no written Literature, as among the Polynesians, American Indians or central African tribes even though there is much folklore and religious poetry, so language necessarily looms large.

In French, Italian, German and most European languages, the term corresponding to English philology: therefore. means the study of literature. In English it is sometimes used instead of comparative philology, which means linguistics, especially comparative and historical rather than descriptive linguistics.

Even the study of literature has given rise to its own specialities —palaeography and textual criticism (*qq.v.*) among others.

All the main languages of the world have articles of their own, *e.g.,* AMERICAN ABORIGINAL LANGUAGES; ARABIC LANGUAGE; CHINESE LANGUAGE; ENGLISH LANGUAGE; FRENCH LANGUAGE; GERMAN LANGUAGE; GREEK LAXGUAGE; HEBREW LANGUAGE; ITALIAN LANGUAGE; JAPANESE LANGUAGE: LATIN LANGUAGE; MANCHU LANGUAGE; MONGOLIAS LANGUAGE; POLYNESIAN LANGUAGE; RUSSIAN LANGUAGE; SERBO-CROATIAN LANGUAGE; SPANISH LAXGUAGE; TURKISH LANGUAGE. This is by no means an exhaustive list as many little-known languages are included, *e.g.,* BUSHMAN LANGUAGES. In the event of a language not receiving discussion under its own name it may be discovered under the name of the family to which it belongs, *e.g.,* INDO-EUROPEANS: *Language Classification;* CELTIC LANGUAGES! etc.

PHILO OF LARISSA (*c.* 159/158–86/85 B.C.), Greek philosopher, succeeded his teacher Cleitomachus as head of the academy, whose scepticism he, in advanced age, considerably toned down (*see* ACADEMY, GREEK), particularly in ethics (he in detail compared the tasks of the philosopher and the physician). He conceded, it seems, to the Stoics the existence of true, objectively certain sense-presentations but still denied that they were subjectively discernible from false ones. When in Rome (88 B.C.) he strongly influenced Cicero, thus contributing to the transplanting of Greek philosophy to the Latin world. None of his writings is extant. (PP. M.)

PHILOPOEMEN (253–184 B.C.), Greek general, was born at Megalopolis, and educated by the academic philosophers Ecdemus and Demophanes or Megalophanes. In 233–2 Philopoemen skilfully evacuated Megalopolis before the attack of Cleomenes III, and distinguished himself at Sellasia (222). The next 11 years he spent as a condottiere in Crete. Elected commander of the league's cavalry on his return, he reorganized that force and defeated the Aetolians on the Elean frontier (210). Appointed to the chief command two years later, he introduced heavy armour and close formation for the infantry, and with a well-trained army beat Machanidas of Sparta, near Mantinea. The new "liberator" was now so famous that Philip V of Macedon attempted to poison him. In 202–1 Philopoemen drove Nabis, the Spartan tyrant, from Messene and routed him off Tegea. After another long sojourn in Crete he again received the command against Nabis. Though unsuccessful at sea, he almost annihilated Nabis's land force near Gythium, but was prevented by the Roman Flamininus from taking Sparta.

In 190 Philopoemen protected Sparta, which meanwhile had joined the League and thereupon seceded, but punished a renewed defection so cruelly as to draw the censure of Rome. At Messene he likewise checked a revolt (189), but when that city again rebelled, in 184, he was captured in a skirmish and promptly executed. Philopoemen's great merit lies in his having restored that military efficiency without which the Achaean league (*q.v.*) could never stand.

Polybius' *Histories* (x–xxiii) are the chief authority. These and a special treatise on Philopoemen (lost) were used by Plutarch (*Philopoemen*), Pausanias (viii, 49–51), Livy (xxxi–xxxviii) and, indirectly, Justin (xxx–xxxiv).

PHILOPONUS, JOHN (5th–6th century A.D.), was a prolific writer of the philosophical school of Alexandria. As an expositor and critic of Aristotle he exercised a deep influence on later generations. The name John marks him as a Christian, and there is no good ground for supposing him to have been a convert. Since his earliest studies were in language and literature, he styled himself "Grammaticus," and he was also known by the surname Philoponus ("industrious"). which seems to have been the class-name of a group of active Christian laymen.

In philosophy John was a pupil of Ammonius Hermiae (*q.v.*). Among his works are several commentaries on treatises of Aristotle, which seem to be partly based on Ammonius' oral instruction. He frequently adopts, on religious grounds, a critical attitude toward Aristotle, which distinguishes him from other commentators of the age. His *De aeternitate nzundi,* written in 529, which has survived almost complete, is a refutation of Proclus, who, with other Neoplatonists, supposed the heavens to be divine and imperishable; a philosophical defense is given of the view that the world was created by God from nothing and will be destroyed. The work, written when Christianity was in the ascendant at Alexandria, may have been designed to shield the Alexandrian school of philosophy. Resides this, John wrote a treatise! the general outline of which is known to us from the bitter retort made by Simplicius (*q.v.*), against certain principles of Aristotle's physical science. John's theological writings, in which he supported

the Monophysites (*Opuscula* Monophysitica, edited by A. Sanda, Beirut, 1930), were condemned as heretical in 680. (D. J. A.)

PHILOSOPHY (ARTICLES ON). The article PHILOSOPHY AND PHILOSOPHICAL STUDIES provides a general introduction to the subject matter of philosophical inquiry. For an outline of the course that this inquiry has pursued in the western world *see* PHILOSOPHY: HISTORY OF. Parallel to the latter from the final period of antiquity are ARABIC PHILOSOPHY and JEWISH PHILOSOPHY. CHINESE PHILOSOPHY and INDIAN PHILOSOPHY are independent.

METAPHYSICS briefly indicates the type of inquiry traditionally included under this heading. For particular aspects *see,* for instance. ABSOLUTE; ANALOGY; BODY AND MIND; CAUSALITY; COSMOLOGY; DETERMINISM; DURATION AND TIME; FORM; FREE WILL; INFINITY AND THE INFINITE; LOGOS; PLURALISM AND MONISM; PRE-ESTABLISHED HARMONY; QUALITIES; SUBSTANCE; and UNIVERSAL.

KNOWLEDGE. THEORY OF, a key article, is supplemented by the following: BELIEF; EMPIRICISM; IDEA; INNATE IDEAS; INTUITION; PHENOMENALISM; RATIONALISM; SKEPTICISM; and TRUTH. A distinct group is formed by SCIENCE and SCIENTIFIC METHOD, together with INDUCTION and PROBABILITY, and the shorter HYPOTHESIS.

LOGIC and LOGIC, HISTORY OF, with SEMANTICS IN LOGIC, are supplemented by numerous articles including ABSTRACT AND ABSTRACTION; CATEGORY; CLASSIFICATION; CONVERSION: *Logic* and *Mathematics;* DEFINITION; EXPLANATION; FALLACY; MATHEMATICS, FOUNDATIONS OF; MEANING; NAME (IN LOGIC); PROPOSITION; SYLLOGISM; and THOCGHT, LAWS OF.

ETHICS and ETHICS, HISTORY OF, are supplemented by EGOISM; HEDONISM; and UTILITARIANISM. *See* also POLITICAL PHILOSOPHY. The subject of AESTHETICS stands by itself.

For schools and individual systems of philosophy the following articles, in roughly chronological order, may be consulted: PYTHAGORAS AND PYTHAGOREANISM; ELEATIC SCHOOL; SOPHISTS; ACADEMY. GREEK; PERIPATETICS; CYRENAICS; CYNICS; STOICS; NEOPLATONISM; SCHOLASTICISM; CARTESIANS; CAMBRIDGE PLATONISTS; IDEALISM; TRANSCENDENTALISM: NEO-KANTIANISM; NEO-HEGELIANISM; POSITIVISM; PRAGMATISM; PHENOMENOLOGY; LOGICAL POSITIVISM; and EXISTENTIALISM.

Of the many philosophers on whom there are separate biographical articles the following, also in chronological order, may be regarded as outstanding: LAO-TZU; CONFUCIUS; THALES; PARMENIDES; ZENO (of Elea); DEMOCRITUS; SOCRATES; PLATO; ARISTOTLE; MENCIUS; EPICURUS: LUCRETIUS; CICERO; PLOTINUS; AUGUSTINE, SAINT (Aurelius Augustinus); BOETHIUS. ANICIUS MANLIUS SEVERINUS; ERIGENA. JOHANNES SCOTUS; ABELARD. PETER; AVERROES; MAIMONIDES; AQUINAS, SAINT THOMAS; BACON, ROGER; DUNS SCOTUS. JOHN: OCCAM. PHILOSOPHY, HISTORY OF. The separate histories of the numerous philosophical schools, surveys also of the development of separate disciplines such as logic and ethics. accounts of the central problems such as scepticism and, finally, studies of individual philosophers are given under the appropriate headings throughout this encyclopaedia. Here, however. we shall attempt to give a more comprehensive view of the history of western philosophy from ancient Greece onward and to show the succession of the various schools of thought and their reaction in response to criticism from one another.

ANCIENT PHILOSOPHY

The name "philosophy" is itself Greek, and ancient philosophy will, in the survey which follows. be understood to be limited to the philosophy of the Greeks, with its continuation during the Roman period down to the reign of Justinian. Such a restriction sounds at first arbitrary but is perhaps justified by these considerations. The contact of the Greeks with foreign religion and ideas was only spasmodic. The mythologies of Babylonia and of Egypt, within which the germ of science was included. were not without influence upon the earliest Greek thought. Later, the Platonic academy (4th century B.C.) showed knowledge of and interest in the dualistic religion of Persia. Some scholars think that there are traces of oriental influence in the system of Plotinus, though others again assert its wholly Greek character. Alexandria, in any case. was a centre in which Jewish and Greek ideas came together. Yet these influences are not close or continuous or certain enough to make it worth while to compare Greek and oriental philosophy in one survey. and it seems to have been always the Greek genius which converted mythology into science or philosophy as we should today understand them. The mediaeval thinkers, Arabic and Jewish as well as Latin. derived their view of the scope and problems and methods of philosophy from the Greeks.

In the development of ancient philosophy, four phases may conveniently be distinguished.

1. Those who belong to the first phase, commonly termed pre-Socratic, try to give a rational account of the origin and existing state of the world and the powers operative within it. Parmenides and the Eleatics, who directed their attention not to the physical world but to being in general, nevertheless come within this first phase; it was their historical function to show the complexity and difficulty of the concepts of change and movement; and by doing this they deflected for some time the course of physical inquiry, though they did not arrest it. The science of mathematics probably emerged during this first period.

2. A new phase opens when, in the jth century B.C., moral and practical problems are brought to the front by Socrates and the Sophists. Socrates, however. did not urge men to desist from scientific inquiry (that is a false, though ancient, view of the part that he played) but, as will be explained. gave a new impulse to science itself. During this period. likewise under the impulse of Socrates, the question within what limits scientific knowledge is possible begins to be recognized as one of the problems of philosophy; and both logic and the theory of knowledge date from this time. Otherwise. the confident endeavour to gain the widest possible knowledge of nature, because of its intrinsic interest. goes forward. Aristotle and his immediate successors may in this way be considered the latest representatives of a movement having its centre at Athens and initiated by Socrates and the Sophists.

3. 4 third phase extends from the early 3rd century B.C. to the 1st century A.D. With the decline of the self-governing city-state, social conditions were transformed and at the same time the speculative spirit was beginning to grow weary. There now appeared rival systems of "philosophy." which agreed in offering such a world picture as might bring peace of mind to the individual, however little favoured by circumstances. Happiness was no longer associated with political exertion. The disinterested pursuit of knowledge mas no longer recognized as essential to philosophy, and ethics (in a practical sense) became its vital part. It is true, however. that the sciences were at this time beginning to flourish independently of philosophy.

4. Finally, from the 1st century A.D. onward: there is a revival of speculative confidence, accompanied by an intelligent and respectful interest in the classics of earlier philosophy.

Pre-Socratic Philosophy.— In the *Theogony* of Hesiod we have a description in epic style of the formation of the world from chaos, the emergence of several generations of gods and the successive ages of man. These, with frank pessimism, are depicted as a decline from the golden toward the iron age. This is already not far from philosophy. and the borderline will be crossed when the narrative form and the reference to personal agents are abandoned, when prose is employed instead of poetry and when a system resting on rational deduction and to some extent on observation is put

forward. In the 6th century B.C. these conditions are fulfilled in men who flourished at Miletus and elsewhere on the Greek fringe of Asia Minor. These thinkers all deal with the development of a varied world out of one basic substance (not yet called by that name). This is not supposed to be lifeless. but rather endowed with some intrinsic power of development. As for the law by which development is governed. Anaximander holds that there is a "justice" in the cosmos whereby each particular substance, having exceeded its bounds for a time, must pay recompense to others. It appears also that. in accordance with this law, the cosmos will at fixed intervals be dissolved to allow chaos to resume its rights. Anaximenes, somewhat later. introduces the influential idea that it is by a process of contraction and expansion that the one substance appears as many.

The use of systematic observation by these thinkers is at best occasional. they assume no necessary sequence of cause and effect. and their thought has many archaic features. They regard the world as "divine" and do not seem to see themselves as antagonists of the traditicnal religion. They come to fulfil. rather than to destroy. In Xenophanes of Colophon, however. we find a hard-hitting critic of the theology handed down from Homer and Hesiod. He seems to have asserted the unity and omnipresence of God; and he is ranked by Plato and Xristotle as a precursor of Parmenides.

In such cosmogonies as those of Hesiod and Anaximander. one basic entity is supposed to grow into many and to become possessed of diverse qualities. Parmenides, by an analysis of the idea of "being" itself. arrives at the view that this change is impossible. He returns to the poetical form of exposition and gives two alternative and, in his opinion. discontinuous accounts of the world. The first is an account of reality. which. as it is based on reason alone. is true. The second is a description of appearance and takes the form of a cosmogony not unlike those which previous thinker:: had offered. Only at this level are qualitative change and movement admitted. "Being" itself must be perfectly homogeneous, immune from change and timeless; *i.e.,* beyond any distinction of past, present and future. Being cannot have an origin. for this would have to be "not-being." which is unnamable and inconceivable. The being of Parnienides is not personified: and though a theology could be founded on his deduction, his own use of it is purely logical.

At this point some mention must be made of Heraclitus and of Pythagoras and his early followers. whose systems have always been supposed to precede Parmenides' but are only to be understood. according to the more probable view of Karl Reinhardt. as a later response to his thought. Heraclitus replies that the tension between opposites. governed by a rational principle which holds them in balance. is the key to an understanding of the world. (It seems to have been the self-styled Heracliteans of a later day who developed this into a belief in universal change. involving the consequence that all judgment is relative and science impossible. From such a conclusion Heraclitus was held back by his insistence that "measure" and "logos" [=reason] remain firm in a changing world.) As for Pythagoreanism. it seems to have been, in its first form, a system whereby the series of numbers was made to evolve from more abstract principles and the sensible world was in turn derived from number.

Whatever may be the relation between Parmenides and these two movements, the effect of his argument upon subsequent philosophy, for a long time to come. was decisive. No one was able to question this reasoning. which seemed to show the need for a persistent substance; but no one could resign himself to the belief that a moving. physical world is forever beyond the range of rational explanation. Systems therefore now arose in which, in deference to Parmenides, qualitative change was abandoned. hut plurality and local movement were retained. This is the procedure of Empedocles, of Anaxagoras and of the first atomists. Leucippus and Democritus. There are important differences between these systems. The Parmenidean attack on "not-being" involved the denial of empty space or void. and in this hoth Anaxagoras and Empedocles concurred. professing to be able to explain movement without such an assumption. The atomists, being persuaded that the void was really essential to the possibility of movement. sought to establish its existence hoth experimentally and by reasoning. Again. Anaxagoras in contrast with the atomists boldly accepted the view that matter is infinitely subdivisible. precisely as abstract extension is. Moreover. Anaxagoras and Empedocles raised two new questions and gave contrasted answers to them: how does movement first originate? and what is the cause of structures and processes which seem to be purposive in character, especially in the plant and animal world? Greek philosophy was now passing beyond the belief that the power of movement might be assumed as a datum in the original substance.

Apart from such indirect influence. Parmenides also had followers of his own. Zeno of Elea. Melissus and the rhetorician Gorgias. Zeno of Elea is responsible for a modification of the Eleatic thesis, inasmuch as he starts not. as Parmenides did, from "being" but from "the one." For Parmenides, unity was rather the first attribute of being. Zeno shows that plurality in any form, including the abstract units demanded by the arithmetician, is monstrous and inconceivable. His famous paradoxes about movement, reported by Aristotle in the *Physics*, have a similar purpose. In Zeno and Gorgias, the dialectical technique which Parmenides had adopted with a metaphysical purpose in view has obviously become an end in itself; the latter should probably be regarded as a critic, not as a follower, of Parmenides. (*See* also articles ELEATIC SCHOOL; and IONIAN SCHOOL OF PHILOSOPHY.)

From **Socrates** to **Aristotle.**—There is a change of atmosphere during the second half of the 5th century B.C., and the principal scene of events during this and the following century is not Ionia or Italy but Athens. To this change there were two sides. On the one hand, there was a general tendency to turn from natural science and speculative cosmology toward human affairs and practical problems. Socrates (c. 470–399 B.C.) certainly pointed out this road (see Plato, *Phaedrus,* 229e–230d); and in this he was assisted or preceded by the older Sophists. such as Protagoras, who made it their business to provide an intellectual training for the man of action in the democratically governed Greek states. On the other hand. there was the aspect in which Socrates alone was the innovator: it was his mission to propound basic questions hitherto overlooked. both in the sphere of physics and in that of ethics. and thereby to bring to light latent dogmatism and to make his contemporaries aware, for the first time, of problems concerning philosophical and scientific method; and here the Sophists were no longer the allies of Socrates but his opponents. His classic debate with them. recorded in several of Plato's earlier dialogues, turns on the questions whether moral virtue can be taught and whether there is one form of moral goodness or several: and the Sophist professes to *know* the answer to these questions. while Socrates does not. Hence the difficulty of deciding whether to range the Sophists together with Socrates or in the earlier period.

The former aspect of Socrates' work is well enough expressed in the aphorisms which Cicero derived from his Greek teachers; namely, that he brought philosophy down from heaven to earth, introduced it into the cities and houses and made it inquire into manners and morals. Yet if this were all, he would have been only one moralist among others, and full justice is not done to his achievement unless he is viewed as an innovator in the sphere of method. who opened up new possibilities to physical science itself and posed new problems to the philosophers. He was no despiser of physical science and did not wish to make other men desist from it as fruitless or impossible. He himself had soon abandoned it, but only in order to raise problems which were not without a bearing on its future progress. The earlier physicists had emphasized matter at the expense of form. and the Sophistic contemporaries who shared his interest in practical questions were more concerned with describing the moral qualities than with defining them. He inferred. apparently from the example of the practical arts. that the great test of knowledge is the ability to state what a thing is, what is the unvarying essence which a word. if rightly used, denotes. His persistence in posing this question and subjecting others to cross-examination led, in due course. to the discipline which came to be known as logic: and another offshoot of the same demand for a definition of moral ideals was the Platonic doc-

trine of transcendent ideas or forms (see FORM).

This view, whereby Socrates is an important figure within the progress of science, is stressed by Plato, in the Phaedo, and by Aristotle, in the *Metaphysics*, both of whom would claim to be following in the Socratic tradition. (See further the articles ETHICS, HISTORY OF; LOGIC, HISTORY OF; SOCRATES; SOPHISTS. The first two of these are relevant also for all that follows.)

Plato was only one of several writers who commemorated Socrates, and various schools were commonly supposed to be affiliated to him. Antisthenes seems to have held up for admiration the physical sturdiness of Socrates, his self-control and his contempt for worldly goods; he declared himself an enemy to pleasure, and he opposed the Platonic doctrine of ideas (presumably in what he thought to be the true spirit of Socrates). From him, through Diogenes of Sinope, descend the Cynics, preachers and moralists contemptuous of all conventions, who reappear in one guise or another on several occasions in the Hellenistic and Roman periods. On the other hand. the Cyrenaics, who considered that pleasure in itself is good and pain evil, were affiliated to Socrates through Aristippus; such a thesis is, in fact, maintained by Socrates in Plato's dialogue *Protagoras*. Another member of the Socratic circle founded a school which lasted for several generations; this was Euclid of Megara (see also MEGARIAN SCHOOL OF PHILOSOPHY). He upheld the Socratic procedure of teaching by dialogue and, like Socrates, had a moral and practical purpose. In other respects his doctrine owed something to the Eleatics. Later there was some hostility between his followers and Plato's, and the Megarian school became a nursery of dialecticians.

Whereas the sources for all the doctrines mentioned above are fragmentary, the entire writings of Plato (c. 428–*c.* 348 B.C.) are extant and there is even, from Aristotle and Theophrastus, some indication of his unwritten teaching. Plato remains throughout faithful to the dialogue form, and. until a late stage in his career as a writer, uses Socrates as the principal interrogator; but Socrates then subsides into a listener's role. other speakers come to the front and Plato begins to define his position with reference to the older systems—to Parmenides, to Heraclitus, to Pythagoras and their surviving representatives. The subjects treated are: the nature of the soul and of causation; the presence of design in the physical world; "being" and its various senses; human knowledge and the relation between thought and sense perception and language. It is convenient here to concentrate upon the first two of these. The doctrine of the Phaedo is that the soul is akin to the permanent and invisible, the body to the changing and perceptible. The nature of this affinity was not, at that time, further explored (the soul is never declared to be a "form"); but, together with other arguments, Socrates says that it is enough to give us confidence that the soul will survive the body. The soul is not, at this stage, regarded as a source of change, but rather as a perfectly unchanging being. In the Theaetetus, Plato demonstrates that the senses alone can present only a series of changing impressions. They cannot even relate these to one another, still less convey knowledge of forms which have no sensible counterpart. In the *Phaedrus* and in the Laws, he develops a new doctrine of the soul which is also a theology (since God is a perfect soul). The soul is by its essence a self-motion, the source of every movement which bodies display. Bodies, once they have received movement from soul, can impart it to one another; but there is no movement not initiated by soul. This does not mean that the soul is in space, for the primary movement with which soul stirs itself is that of reflection or foresight, and the physical movement is secondary.

There are, however, random and irregular movements in the cosmos; and it is only soul with mind or reason (*nous*) inherent in it which can impart regular movement. The word *nous* has a complex previous history. Plato tells us repeatedly that *nous* cannot exist alone, that it must inhere in a soul (*Sophistes*, Philebus and Timaeus). The doctrines of forms and reminiscence do not seem to have been abandoned by Plato at the time when he was working out this later system; and presumably a soul with *nous*, or rational soul, mould be one which is guided by steady intuition of the forms. Making the best use of the science available at the time, Plato undertakes to show, or rather says it can be shown, that the principal movements in the cosmos, including that of the sun and planets, are in fact perfectly regular. Given the principles that he has just stated, it follows that the world is controlled by divine beings, perfect souls to whom we are akin. He presents this teaching (Laws, books x and xii) as the exact reverse of what many persons, under the influence of the Sophists, were coming to believe. In the Timaeus there is an account of the origin of the world in which the following factors are involved: (1) the forms; (2) the "artificer," a personal agent who is guided by intuition of the forms and from whom regular movements in the physical world, as well as all adaptation of things to a purpose, are derived; (3) the world-soul, which is formed by the artificer and serves, as it were, as his representative; (4) the "receptacle," within which qualities or powers exist in shuffling disorder, until the artificer regulates them by measure and number. This last factor is identified with space, but also has some of the functions which in Aristotle's terminology belong to "matter." In view of later developments in theology, it is to be noticed that Plato's "artificer" is not the source of all reality and is not the creator, in the full sense, of either form or matter. Another important metaphysical distinction made in the later dialogues is that between "limit" and "the unlimited," two factors which combine to form a "mixture"; the mixture must have a "cause" and, where this cause is "reason," will be harmonious and durable. Here there is an even closer approach to the Aristotelian distinction of form and matter (*Philebus*, 23–26).

According to Aristotle (384–322 B.C.) there are four factors in every process of causation, whether natural or artificial: form and matter, which never exist apart from one another, being correlative; the motive cause, from which the change immediately proceeds; and the end "for the sake of which" the process occurs. This analysis is meant to be applied not only to physical change but also to such processes as teaching a science or imparting moral discipline to a child. The "matter" upon which form is imposed will in that case be the untrained capacities or emotions, and it is plain from this that the Aristotelian "matter" is quite different from what is so termed in modern physics. Another point to be noticed is that Aristotle is here distinguishing factors in causation rather than causes in the modern sense and that his "causes" may be contemporary with, or even subsequent to, the processes caused; *e.g.*, if a man walks for the sake of health, health is a "final cause."

Aristotle applied his analysis to the criticism of his predecessors, including Plato. For a long time, matter had been the only one of the causes to be recognized; subsequent thinkers had had a glimpse of the efficient and formal causes, but no one had yet succeeded in naming all four. No addition to the analysis was conceivable, and in this respect it was the completion of all previous thought, the goal to which others had struggled without clearly perceiving it. Plato is complimented by Aristotle for his clear recognition of the formal cause (and here Aristotle shows the genesis of his doctrine from Socrates and the Pythagoreans); moreover, in his physical doctrine and in his unwritten teaching, he recognizes the need for a material or nonformal factor; but he has failed to give any consistent account of efficient causation (Plato's derivation of movement from the soul is, apparently, viewed in this criticism not as a part of his regular doctrine, but as a tentative suggestion).

Aristotle's positive views grow naturally out of this criticism. By "movement" is meant a transition from a "potential" state to one of "actuality," and such transition will take place only under the influence of a subject which is itself actual and can bring out the potentiality in another ("movement" here has a wider sense than in modern usage and applies to all qualitative change, whether physical or not). Once the thing has reached maturity (a state for which Aristotle coins the term "entelechy"), it will from time to time, but not continuously. display its powers in action. This display of powers ("activity," or "energy") is not exactly "movement" in the sense above defined, for it is not the realization of something incomplete. An illustration may be drawn from the acquisition and use of scientific knonledge: a boy's power of learning is developed under the influence of a teacher, this

transition corresponding to "movement"; but once he has acquired the scientific knowledge. it will be latent in him nhenever it is not in actual use. Hence a new contrast between possession and use is. as it were, superimposed on that between the potential and the actual. We ourselves and the beings who surround us are complex and have to inhibit one activity in order to engage in another. Growth and change in the physical world are to be explained in analogous fashion.

This conceptual analysis is then applied by Aristotle in the following way. God alone is fully actual—a form nithout matter, who does not have to be raised from the potential to the actual state. His activity is the uncaused cause of all change; but he is its "final cause" or goal and he does not, as in the Platonic system. design the world. The efficient cause of change is "nature"; *i.e.*, an inherent impulse in things. both living and lifeless, leading them to develop their capacities and to make use of them when developed. The Platonic definition of soul as a self-moving agency is rejected on the ground that soul cannot participate, even incidentally. in movement; and instead. soul is regarded as the "form" proper to an organic body. Such a definition does not apply to God. who is incorporeal (and. perhaps, not to the human soul *qua* rational). God is therefore viewed not as a soul but as a mind engaged in unbroken reflective activity: and Plato's axiom that "mind" must always inhere in "soul" is also silently discarded.

This survey. concentrating on the theory of causation. will perhaps have shown why Xristotle is the parent of biological science and Plato rather of mathematical physics. (For other aspects of their thought. *see* the articles ARISTOTLE; ETHICS, HISTORY OF; LOGIC. HISTORY OF: PLATO.)

From Aristotle to the 1st Century A.D.—The years from approximately 310 B.C. to the 1st century A.D. form another distinct epoch. Philosophy was now regarded primarily as a way of life. Scientific knowledge was no longer pursued with enthusiasm by the philosopher as such; he valued it only in so far as it made clear the position of man in the world. This was an era of increasing specialization in scientific. historical arid philological studies. Because of the changed circumstances. the philosophical idea of the good life was no longer bound up with the city-state. Slavery persisted, but the division between Greek and barbarian began to break down. and men recognized one another as brothers. with one God for their parent. whether this view was developed by the Stoics or, as Sir W. W. Tarn maintained, by Alexander the Great himself.

After the first generation. the schools of Plato and Xristotle themselves began to succumb to these dominant influences *(see* ACADEMY, GREEK; and PERIPATETICS). Among newer systems, that of Epicurus (341–270 B.C.) may be considered first. Epicurus held that the physical world came into being from the spontaneous downward movement of atoms in an infinite void and that nothing further is needed to explain its existing state. It is. however, destined to be destroyed; *i.e.*, not annihilated, but dissolved into its component atoms. which will then enter into fresh combinations. Similar worlds doubtless exist else\\-here and have existed in the past. The soul is material and is enclosed in the body, from which it will escape and be dispersed at death. The gods live at peace in the spaces between the worlds. which they did not organize and for which they assume no responsibility. For the demonstration of these truths physical science is essential: beyond this it becomes supertluous. The one criterion of truth. which cannot possibly be disputed, is sense perception. The wise man will live in prudent enjoyment of physical pleasures, free from all anxiety about the future life, unconcerned with fame and other dubious goods. He will, however. for this very purpose need to acquire justice and the other commonly recognized virtues. Epicurus showed, as no one before him had done, the happiness of an inner life which is available to all; and no doubt this was why he was hailed by his followers as a "saviour." Rut his theory of knowledge is weak (the "ultimates" in his system. the atoms and the void, lie beyond perception. which he says is the criterion of truth'), and he frankly discouraged all innovation which would disturb the basis of the system.

Stoicism on the other hand was a more flexible system which could and did develop in response to circumstances or to effective criticism from without. For a general view of this system. *see* STOICS. The doctrine was first laid down by Zeno of Citium (born 335 B.C.) and re-established with far greater precision by Chrysippus (*c.* 280–206 B.C.). The Stoic ethical system at this time was strange and uncompromising, oriental rather than Hellenic in character. In the 2nd century B.C. appeared Panaetius of Rhodes (horn c. 185), who reinterpreted the psychology and ethics of the Stoa in such a way as to stress its close affinity with Platonism and the common descent of both doctrines from Socrates. Soon after this. Poseidonius (*c.* 13j–c. 50 B.C.) gave a new form to the physical and theological doctrine inherited from the older Stoics. As a result of the work of these powerful thinkers, Stoicism secured a new lease of life and awakened great and enduring interest in Roman circles. But throughout the last two centuries B.C. the Stoics. as the most prominent dogmatic school, came under fire from sceptics of more than one variety. The scepticism of Pyrrho of Elis. though founded on epistemological arguments which he collected from earlier writers. was really a moral doctrine; he made "indifference" in face of all external circumstances into a cardinal principle of ethics *(see* SKEPTICISM). The scepticism of the New Academy. associated mainly with the name of Carneades. was of a more intellectual character and arose rather within the main Greek philosophical tradition.

The history of the years from 200 to *c.* 50 B.C. is roughly, therefore, as follows. Epicureanism. always attractive, but not participating in any development. stood in the background. The leading dogmatic system (and the only one which. in the sphere of morals, could put forward ideas acceptable either to the Roman rulers or to their subjects) was Stoicism. And while the Stoics had appropriated the moral teaching of Plato (and probably some part of the system of Xristotle), the Academy, which had surrendered those doctrines. had become the focus of scepticism. In the 1st century B.C. there was. however, the attempt of Antiochus of Ascalon to revive the atmosphere of the "Old Academy" and to pretend that Zeno. in spite of the appearance of novelty which his terminology creates. contributed nothing new to the Platonic doctrine. The debates arising from this situation are reflected in the philosophical writings of Cicero (106–43 B.C.). Historians sometimes write of a specific phase of Eclecticism. which pieces together a system from previous systems. But if there ever was such a movement. Cicero at least ought not to be assigned to it. He is a consistent representative of the New Academy, wielding a method, but hostile to the very idea of system.

When Zeno and Epicurus first established their systems, they seem to have been less conscious of opposition toward one another than of the need for joining forces in the attack on the two reigning schools. the Xcademy and the Peripatos. Aristotle, being judged mainly from his dialogues, was still ranked as an idealist; Zeno and Epicurus had in common a thoroughgoing materialism. The Platonic theory of knowledge, in which the mystical belief in reminiscence always played a part, was disparaging to the senses, whereas the new schools refused to accept any foundation except the unshakable certainty of perception. Both Platonists and Aristotelians held that a wide culture in the sciences was necessary to the philosopher; Zeno and Epicurus made physics subordinate to ethics and gave it a form which even the late learner (who to Plato and Theophrastus is a comic figure) could grasp. The Platonists maintained. and both the Stoics and the Epicureans denied, the eternity of the physical world. Even in ethical doctrine the two latter schools were linked by the wish to offer some means of attaining independence of mind. When, however, their joint attack had been crowned with success. the equally important contrasts between them could not for long be disguised: one was a system of duty. the other one of hedonism. The Stoics were believers in divine providence and regarded the world as a single divine being permeated by *logos* (reason). which attains to self-consciousness in man. In the Epicurean "theology." the gods are not allowed to design the worlds but placed in the interspaces where they cannot do harm or have harm done to them. Thus after an interval Panaetius was able to bring round the Stoic school into alliance with the Xcademy in the manner above described.

Later Greek Philosophy. — Stoicism itself after the 1st century A.D. has little history as an organized school, though it produced writers whose names are still famous, such as Epictetus and Marcus Aurelius Antoninus. It had, honever, far-reaching influence as a fertilizer in many different fields. The Stoic ethics remained prevalent. both among philosophers and among the public, as the best that pagan antiquity had to offer; the important conception of a law of nature. which all men as rational beings ought to recognize in their dealings with one another, rests on a Stoic foundation. From the Stoic armoury, Christian theologians were able to borrow many arguments concerning design in the physical world. As a coherent system Stoicism did not survive. Not only had its dogmatic pretensions been fatally injured by criticism from the Academy; but also. from the Augustan age onward, men sought more and more a religious view of the world such as no materialistic creed could provide.

Those thinkers who did not lapse into scepticism, which was revived by Aenesidemus, turned naturally toward some version of Platonism or to Neopythagoreanism, which is by this time not easy to distinguish from Neoplatonism. The works of Plato were edited in the 1st century A.D. by Thrasyllus, and the treatises of Aristotle, after centuries of obscurity,. had been brought to light and edited in the previous century by Andronicus of Rhodes. These are the editions from uhich modern texts descend. Both Plato and Aristotle were now classics in the philosophical schools and became the subject of learned expositions still preserved, in which much valuable information is embedded.

The revival of interest in Plato took various forms. As has been mentioned above. Antiochus (1st century B C.) went back to the ethical doctrine of the early Academy and cast doubt on the originality of the Stoics. Far more thinkers were inspired by the cosmology of Plato and by his theory of the soul: for example, a treatise by Albinus, of uncertain date. consists of a systematic exposition of Platonism, free use of Aristotelian terminology being made in it; in Philo is found another such exposition, this time from the point of view of a Jew of Alexandria: and in Plutarch of Chaeronea interest in the religion of Plato is especially prominent. Plutarch's attack in some of his treatises upon Stoic and Epicurean doctrines. from a Platonic point of view. seems to show that these still had some vitality.

The system of Plotinus (c. A.D. 205–270) resembles these in its general intention but is much bolder and rests on a broader historical basis. He and his follo ers were profound students of Aristotle as well as of Plato and were deeply interested in the pre-Socratic philosophy. Giving a relatively unimportant place to the doctrine of forms. Plotinus develops Plato's doctrine that soul is the motive principle from which bodies (if they can be said to exist at all) derive their power of action; and by this means he corrects the materialism of the Stoics and others influenced by them. He proceeds to draw, much more firmly than Plato. the general picture of a graduated immaterial world. For the soul, though it is the principle of physical change, occupies only a middle position in the entire scale of reality. Above particular human souls is the world-soul, above this again the mind (Plato's "artificer") which fabricates the world-soul and in which the highest knowledge is located. Beyond mind, knowledge and existence lies the One, which no human language can suffice to describe The heavenly bodies are divine beings (and in defense of this view the Neoplatonists make use of arguments dating back to Plato and Aristotle); the part of the visible world in nhich we live is admittedly imperfect by absolute standards. but has its proper place in the graduated scale and ought not to be regarded as the nork of a malicious spirit working against the Good. Astrology is condemned, as presupposing a false view of the mode of action of the celestial deities.

Plotinus entered into no controversies resulting from his work, but Porphyry (c. 233–*c.* 304) took the offensive in a criticism of Christian doctrine and the Athenian Keoplatonists Proclus (410–485) and Simplicius (6th century) assembled all the resources of Greek philosophy in the attempt to present a religious view that could be set up in rivalry to Christianity. Christian thinkers naturally protested against the belief in the divinity of the stars and in the eternity of the physical world and against the associated belief in precisely similar cycles of human history. On their side, the Neoplatonists thought it impiety to deny the divinity and intelligence of the stars. regarded the Incarnation as unthinkable and held fast to their arguments which seemed to show the eternity of the world. (See NEOPLATONISM.)

From the point of vièw of a later age, this controversy seems to tend toward an issue of which none of the disputing groups was at the time aware. The created world of the theologians is a possible object of science (and. indeed, as proceeding from the inscrutable will of God, of humble experimental science). whereas the besouled cosmos of the Neoplatonists. to which man feels himself akin. is not such an object. This is a defect which neither the genius of Plotinus nor the learning of his various successors could outweigh, though it did not become obvious for many centuries. Although Greek philosophy failed in its last contest, it had provided many of the arms by which it was defeated.

(D. J. **A.**)

PATRISTIC AND MEDIAEVAL PHILOSOPHY

Early Christian thinkers could not be indifferent to philosophical doctrines aiming at human happiness and dealing with the questions which religion also was intended to answer. For similar reasons some Jews, for example Philo, had interpreted Scripture in terms of philosophy and vice versa. Philosophy (particularly Platonism and Stoicism), when it was not rejected as impious, was in turn accepted as supporting revelation and used for apologetic purposes, being considered as foreshadowing, or sharing in, Christian doctrines, or as likely to add something. in certain fields, to the incompletely revealed truth. or again as ready to be combined, in a semimythological form, with elements derived from religious texts and traditions. In the first five centuries A.D. there were no Christian philosophers in a strict sense, but the influence of Greek and Roman philosophy was widespread and deep; some doctrines were developed with originality, and the new problems of the relation between reason and faith. of the possibility of rationalizing dogmas and of fitting new historical facts or interpretations and psychological experiences into the usual categories of thought, were faced in ways which were important for the future of philosophy.

Philosophical speculation from the 6th century to the 16th was mainly concerned with the issues already debated. in Greek and in Latin, by pagan and Christian thinkers and was based on their doctrines. Interest spread to new provinces, east. west and north. Philosophical language was created on the Greek pattern in Armenian, in Georgian and in Persian, in Syriac, in Arabic and in Hebrew; it developed enormously in Latin and, mainly from Latin. was inserted into the European vernaculars. French. Spanish. Catalan. Italian, English, German and Irish; it thus became part and parcel of modern speech both technical and ordinary.

The continued interest in philosophical studies was ensured above all by the late Greek schools of Constantinople, Athens, Alexandria, etc Teaching in Greek was never completely extinct until 1453. Foreign students transplanted in their countries some of the Greek doctrines and methods from the jth century onward; thus the Armenian. Georgian and Syriac schools came to life, and Latin thought was being enriched until early in the 6th century. Refugees from Athens in the 6th century and from Alexandria in the 7th carried the philosophical tradition into Persia and strengthened the Syriac schools. From these and through new contacts with Constantinople, there arose in the 9th century the cosmopolitan philosophical tradition in Arabic: and later this tradition appears in Hebrew. The Greek inheritance passed again (and much more extensively) into Latin in the 12th–I jth centuries. both from Constantinople and from the Arabic west. On the other hand. Latin philosophy influenced the Greek. Hebrew and Armenian cultures in the 14th and 15th centuries. The works which contributed most to speculation were Aristotle's treatises on logic, psychology. metaphysics, physics. ethics and politics, several Peripatetic and Neoplatonic commentaries on the same texts and a few independent Neoplatonic works, principally Proclus' Elements of *Theology*. Plato was directly known almost only

through his cosmology (*Timaeus*) and, among the Arabs, through the *Republic* and the *Laws* The logical principles of philosophical method, the dualities of matter and form, substance and accidents, potency and act the four causes, the notions and classifications of virtues, the idea of man as a "political animal" and the doctrine of experience as the basic of knowledge were taken over from Aristotle and became instruments of thought through these ten centuries. Among the permanent Neoplatonic contribution5 to mediaeval speculation were the doctrines of a hierarchical organization of the norld. subject to the law of efficient causality and to the one First Cause: of spiritual beings ("Intellects." etc) as intermediaries between man and God; and of the tendency of everything to return to its origin.

The purely philosophical tradition was often supplemented, sometimes almost superseded, in those ten centuries by the philosophico-theological tradition of the Fathers of the church and of some heretics; Christian, Moslem and Jewish philosophers had to face all or some of the problems which they had faced. The Fathers provided. directly or indirectly. inspiration. materials for discussion and solutions. They also added to the purely philosophical legacy by passing on Platonic and Stoic doctrines and original theories of their own. Above all. St. Augustine was ever present as an authority and a model for those who read Latin; and Dionysius Areopagiticus powerfully affected philosophy and theology among Greeks and Latins. Armenians and Syrians.

Starting from these premisses and often accepting the older doctrines. mediaeval philosophers (especially those of the Latin and Xrahic tradition. to a smaller extent those of the Byzantine, and Jewish) pushed farther and deeper the study of the workings of the mind; attempted new or more convincing answers to old questions (*e.g.*, those of the existence of God and of the immortality of the soul): examined with refined techniques the claims of *a priori* and *a posteriori* knowledge; considerably advanced the inquiry into the functions and pitfalls of language: debated and clarified the concepts of knowledge, certainty. belief, faith and probability; tried to organize all human knoll-ledge systematically: often asserted the supreme value of intelligence in a humanistic sense: reasserted the importance of sense experience and induction; enlarged and made more concrete the scope of social and political philosophy: and opened the way to the mathematical interpretation of physical phenomena.

Patristic Philosophy. — St, Paul's words "the invisible things of God from the creation of the world are clearly seen. being understood by the things that are made" (Rom. i. 20) suggested to Christian thinkers how to combine philosophy and religion: and the obviously philosophical use of *logos* at the beginning of St. John's Gospel would give a doctrinal basis to such a combination. The apologists of the 2nd century took a definite stand with regard to philosophy: Justin Martyr and Athenagoras confirmed Christian doctrines by showing that they agreed either with Plato's or with the Stoics' views and borron-ed Philo's idea that the Greelr philosophers derived their best opinions from Moses; Tatian. on the contrary. claimed that philosophy is misleading and God unknowable to human reason. At the same time, new half-philosophical doctrines were propounded which took into account the basic worry to which religion was to be a remedy: the problem of evil. The best among the gnostics, Valentinus and Marcion (see also GNOSTICISM). opposed the view of evil as a positive being to the optimism of most Greek philosophy. The history of the world is one long or ever-renewed strife between Good and Evil; Evil will disappear with the destruction. not with our perfect knowledge. of this world (see also MANICHAEISM). In Clement of Alexandria (c. 1 jo–c. 215) philosophy appears partly as the best instrument for moulding Christian theology, partly as a forerunner of revelation; this view was to reappear in Abélard nine centuries later. Origen (c. 18;–c. 254) answered Celsus' objections to Christian doctrines with philosophical arguments: the Christian God is still the "eternal immutable activity" of the philosophers, because before creating our world He may have created others and because the Incarnation meant a change in the mind of men, not in the nature of God.

St. Augustine (354–430) transformed some aspects of Platonism and Stoicism, the two doctrines which most inspired him after he abandoned Manichaeism. According to him knowledge is. above all. the result of illumination coming from God and manifesting itself within and through our own mind. whether it is concerned mith dispelling the ultimate doubts about our existence or with the highest notions. Matter was not created as a barren receptacle of forms. but enlivened by mtiones *seminales*, principles of development. Thence forms will supervene, each as a mark or imitation of the "exemplar" which is in the perfection of God's nature: each thing may have many forms. but every created thing, however spiritual (souls. angels). will have its own matter; this distinguishes creatures from Creator. The idea of mankind's forming the *civitas terrena* in its passing on earth looked backward to the cosmopolitanism of the Stoics and forward to the *humana civilitas* of Dante and to the more modern doctrines of a universal polity.

The so-called Dionysius Areopagiticus (late jth century) interpreted much of the Neoplatonic metaphysics of Proclus in terms of Christian theology. His analysis of the "names of God" suggested discussions on the philosophy of language, not only of theology; his *Caelestis Hierarchia* and *Ecclesiastica* Hierarchiu gave the blessing of a supposed friend of St. Paul's to the theory of the degrees of being which. also from a work of Proclus summarized in the Dr *Causis*, implanted itself in most philosophical systems of the 13th century; while his negative theology often set the rules for the doctrines on the limits between rational and revealed knowledge.

Byzantine Philosophy. — After the closing of the Athenian schools (529), philosophical activities continued for more than a century in Alexandria and other centres: the Theodosian university of Constantinople probably kept them alive through the 6th, 7th and 8th centuries. while St. Maximus interpreted and expanded Dionysius Areopagiticus' doctrines and St. John of Damascus presented philosophy as a discipline introductory to theology. Photius and Michael Psellus, respectively in the 9th and in the 11th century, upheld the primacy of rational inquiry over mythological fiction and over mysteries and magic. the former supporting Aristotelianism and positive research, the latter preferring Platonism and intellectual intuition. The revival of Aristotelian studies in the 11th and following centuries (John the Italian, Michael of Ephesus. Eustratius. Theodorus Metochites) spread from Constantinople into the Latin west. In the 1 jth century the philosophical optimism of the Platonist Gemistus Pletho. according to which all men may agree on the same "philosophical religion." and the view of Cardinal Bessarion on the fundamental agreement between Platonism and Aristotelianism directly influenced philosophers in Italy. To Italy was transferred. after the fall of Constantinople (1453), what remained of the Byzantine philosophical tradition.

Arabic Philosophy. — After the early Mutazilites (8th century), who confined themselves to philosophical apologetic of Islam, mainly discussing the unicity of God. free will. evil and creation, a more definite philosophical tradition in the Arabic language arose in Baghdad and spread to Persia and to Spain. The attempts of Al-Kindi (*see* KINDI), an Arab. in the 9th century to combine n-ith Islam Aristotelian and Neoplatonic theories, particularly concerning the noneternity of the world, the independence of the soul and prophetic knowledge, were succeeded by more constructive thinking. The Persian Rhazes (*i.e.*, Razi: d. *c.* 930), a rationalist for whom science and philosophy stand higher than religion and a man of great medical doctrine and experience, expounded a system based on five eternal principles: the Creator, the soul of the world. matter, time and space. Al-Farabi (see FARABI; *c.* 870–950), a Turk, again asserted the superiority of philosophy as the highest of human achievements. accessible to all men and the best instrument for establishing a sound political organization.

Avicenna (979–1037), another Persian. a more systematic and universal thinker (his *Shifa* is the first great philosophical encyclopaedia, mainly organized on the model of the traditional order of Aristotle's works), examined and elaborated most problems discussed and solutions given by authors known to him. Religion

and philosophy have. according to him. an equal status. or religion is superior: this attitude is reflected in his doctrine of prophecy (*i.e.,* that it is one of the highest intellectual faculties) and in his interpretations of Aristotle's theory of the soul and of active and passive intellect. A strong reaction against philosophy came from Algazel (*see* GHAZALI; 1058–1111), who "demolished" philosophy by exposing its inner contradictions and established the primacy of sacred texts and rationalized dogmas. But he was soon powerfully contradicted by the greatest Spanish Arab. Xverroes (1126–98) of Córdova.

According to Averroes. philosophy alone leads to complete, pure. final truth, while sacred texts contain at best a simplified and childish account for less-gifted people. and rational theology is muddled. pretentious and misleading (the theory oi "double truth" which often goes under his name was completely alien to his doctrine). His penetrating, extensive analysis of Aristotle's works was a model and a mine of ideas and information for philosophers of the Latin tradition from the 13th century onward. His commentaries and his views on philosophical truth led. probably more than anything else, to the establishment of a "free" philosophy in the west; while Avicenna's systematic order and his psychological and gnosiological analyses were of continuous inspiration in the 13th century, particularly to Duns Scotus. (*See* ARABIC PHILOSOPHY.)

Jewish Philosophy.— If we except the syncretism of Philo and the philosophical elements in the Kabbalah, Jewish philosophy is closely connected with the Arabic tradition and often, indeed. written in Arabic. Jewish attempts at adapting Platonism and Aristotelianism so as to avoid contradictions with the Bible anticipated and sometimes influenced the views of Christian thinkers. Saadia hen Joseph (*q.v.*) proved against Aristotle that the world has a beginning and that the soul is a substance: against the Platonists. that every soul is created for its body: against the Neoplatonists. that the world resulted from creation, not from emanation. The doctrines of the plurality of forms and of the presence of matter in spiritual creatures were expounded by Avencebrol (*see* IBN GABIROL; c. 1021–C.1058) in more definite and clearer terms than by St. Augustine and thus were taken up by the most representative Latin thinkers of the 13th century. Judah ben Samuel Halevi (*c.* 1085–c. 1140).a Jewish Algazel. opposed philosophy; but Maimonides (1135–1204), a man from Córdova as was Averroes. maintained that theology and philosophy necessarily agree in spite of their different methods (this view mas later held by St. Thomas Aquinas, who knew Maimonides' work). His theory that immortality consists in participation in knowledge (*i.e.,* in the eternal "active intellect") is comparable with that of Spinoza, one of his later admirers. Hillel hen Samuel, Levi hen Gerson (Gersonides). Hasdai ben Abraham Crescas and others in the 13th and 14th centuries did not produce any important or independent doctrine. The only prominent thinker of the 14th–I jth centuries. Judah ben Isaac (Leo Hehraeus), already belongs to the Platonism of the Italian Renaissance. (See JEWISH PHILOSOPHY.)

Western Philosophy.—Boethius (*c.* 480–524) did not carry out his plan of harmonizing Plato and Aristotle; hut his translations and unoriginal elahorations of Aristotelian. late Peripatetic. Stoic and Porphyrian logic provided the basis for much of the philosophical revival of the 9th and following centuries and for most logical studies until recent time. His application of philosophical methods and categories to theological problems was followed and carried farther in the 12th and 13th centuries. His exaltation of philosophy as the greatest of human possessions was influential in less professional philosophical circles. Three centuries later an Irishman. Johannes Scotus. or Erigena (*c.* 815–*c.* 877), favoured by the Frankish kings' cultural policy and influenced by Greek and Latin Fathers, especially by Dionysius Xreopagiticus. produced the first great synthesis of the Latin middle ages, the almost pantheistic *De Divisione naturae.* This. however, was to be less important than the frequent theological debates on substance and accidents and the scholastic training on Porphyry's *Isagoge* and on Aristotle's *Categories* and *De Interpretationc.* On the basis of these texts much thought was given to the relations between words and things and to the different functions of words. In particular, the question whether universal words ("man," "animal." "white." "humanity." etc.) correspond or not to definite things provided the opportunity for shaping and expounding various metaphysical and epistemological views; for example, the "nominalism" of Roscellinus (*c.* 10jo–c. 1122). the "realism" of Anselm (1033–1109), etc. On the other hand. logic was often but an instrument of apologetics; even Xnselm's famous proof that God exists because we have in our mind an idea of Him harnesses some rules of logical consistency in order to make explicit a religious intuition. (*See* also ONTOLOGY.)

In the 12th century dialectic is still in the forefront. For Peter Abélard (*i.e.,* Ahaelardus. 1079–1142) philosophy meant the dialectical elaboration of religious and moral problems. supported by views from ancient philosophers. His interest was often more genuinely philosophical: systematic doubt and inquiry into the meanings of words and into the propriety of their usage were his rules in the Sic *et non;* and the true value of words, their functions in clauses and the psychological processes connecting things and words were the subject matter of the best sections in his commentaries. At this time, the pre-eminence of philosophy of language is also manifest in the study of sophisms (a new and henceforward permanent feature of philosophical studies) and in other new chapters of logic (*suppositiones, relationes,* etc.). A more metaphysical interest was shown by Gilbert de la Porrée (c. 107j–1154), who thought it possible to separate universals, such as "humanity" or "divinity." from particulars. such as "men" or "God"; while cosmological doctrines, partly inspired by Plato's *Timaeus,* were prominent in the school of Chartres.

The bulk of the Greek and Arabic legacy was then discovered. Scholars of the western world collected and translated books of science. philosophy. theology: Aristotle's physical, psychological, ethical and metaphysical treatises. something of Plato, texts from Proclus. some sections of Avicenna's encyclopaedia, something of Al-Kindi and of Al-Farabi. Xvencebrol. Euclid. Ptolemy, Archimedes. Galen and Hippocrirtes, John Chrysostom and 'John of Damascus.

Some logical works of Aristotle in Boethius' translation were also rediscovered. The first signs of the assimilation of some of these works are found in Spain (with Dominicus Gundisalvij and possibly in the pantheistic doctrine of Amalric of Bena and in the materialistic monism of David of Dinant.

Complete assimilation was the work of the 13th century. The church's cautious attitude toward unknown doctrines slightly delayed it: but in Oxford and soon in Paris (where a few works were excluded from the schools for some time) the process of analyzing and commenting upon many of these writings led to the newly discovered doctrines' being used in debates and for new constructions. Averroes became available in Latin in the 1230s, and other Aristotelian works, including the Politics, followed. Doctrines already popular in Latin had to be revised and refined. The theory of light as an element in the world and a means of knowledge was Augustinian in origin but was advanced by Robert Grosseteste (c. 1175–1253) in a new, more scientific spirit. Franciscan philosophers. such as St. Bonaventura (1221–74), would still accept the theories of the multiplicity of forms. of exemplarism. of matter in spiritual creatures, of knowledge by illumination, of *rationes seminales,* hut they tempered them under the impact of the new texts; they faced the new doctrines or tried to find in them some support for their views. Philosophy asserted itself as something valuable in its own right; according to Roger Bacon (c. 1220–*c.* 1292) it can be a means of domination and well-being for mankind. The new urge to discover truth. either in the writings of philosophers, or by deduction, experience and experiment. led to the encyclopaedic works of Xlbertus Magnus (c. 1206–80) and Bacon.

Competition between theology and philosophy, between faith and reason, became a burning issue. Although criticisin was alert on all sides and Aristotle was more often than not simply *an* authority and hardly ever *the* authority. nevertheless some views that were either his or ascribed to him, as well as certain views of other "pagans" (Proclus, Avicenna, Averroes), were such as might

carry too much conviction and endanger more "orthodox" doctrines (*e.g.*, the doctrine of creation or that of individual immortality). Enthusiasts and reasoning thinkers (such as Albertus) would alike proceed with their philosophical inquiries, fearless of possible conflicts. but add from time to time the rider that "this is what philosophers teach." implying or stating that in case of disagreement they themselves would be on the side of orthodoxy. Thus philosophy would be pursued for its own sake, and its value as a giver of truth would be impaired only slightly. This was notably the case with the "Averroists" like Siger de Brabant (*c.* 1235–*c.* 1284), who would adhere as much as possible to Aristotle and try to develop a more coherent Aristotelian system than Xristotle had ever produced. They avoided speaking of double truth, but came near to it: their ideal was a satisfactory account of reality independent of theological interferences.

An attempt at producing a comprehensive philosophical doctrine based on the conviction that faith and reason — philosophy on the one hand and Scripture and Fathers of the church on the other — are in agreement was made by St. Thomas Aquinas (*c.* 1225–74): a magnificent compromise between orthodoxy and Aristotelian philosophy. Some provinces of knowledge are the preserve of faith: but sense experience. aided by the "first principles" (which are present in the "active intellect" of every man) and by logic, reveals the structure of the universe and allows men to approach the less accessible realities, including the existence of God. Thomas took Aristotle as his model for most basic doctrines (matter and form. efficient and final causes. categories of being, movements and elements) but often "adapted" him and sometimes abandoned him. Thus the matter of each thing, not form, bears the marks of individuality: the highest level of reality (being) characteristic of each thing is its *one* form ("rationality" in man supersedes "animality" and other forms, it is not added to them); human soul is the form of the body. but, being individually created, is separable from it; the world is created, although "created *ab aeterno*." The Aristotelian theory of knowledge is systematized, the emphasis being put on sense experience. In this lies the philosophical importance of Thomas' criticism of the a priori (ontological) proof of the existence of God and its replacement by the hardly original "five ways": all of these start from sense experience. It is mainly due to Thomas that Aristotle's ***Politics*** and the naturalistic view of rnan as a political animal became the starting point of all future social and political philosophy. to which he also contributed his doctrine of the fundamental agreement between individual and common good and his elaboration of the idea of natural law.

Duns Scotus (c. 1265–1308) extended. in a sense, the province of philosophy. His theory of the "univocity of being," contrasted with Thomas Aquinas' "analogy of being." allowed him to apply to God, significantly and positively. our categories of thought as expressed by means of the verb "to be." His Neoplatonic vision of a perfectly organized world in which various degrees of causality keep things closely knit together is coupled with an extreme doctrine of individuality: perfect knowledge is knowledge of individuals (but again, universals are somehow existent in things). On the other hand, our rational knowledge is limited — it even seems to he made insecure — by the absolute freedom of God. who might even change the order of the world. Duns's individualism and doctrine of God co-operated with Thomas' emphasis on experience to prepare the ground for the more extreme doctrines of the 14th century.

The 14th century was a period of constructive criticism: the process of assimilation was over, and philosophy had its own independent life. Absolute determinism or indeterminism. probabilism, empiricism and rationalism and extreme Averroism were being propounded. defended and faced. According to Petrus Aureolus (Peter of Auriole; d. 1321) knowledge is appearance of objects: we know what exists by direct impressions, more or less clearly. but without intermediaries; forms, essences and universals are fictions. For Nicolas of Autrecourt knowledge is a bundle of appearances giving probability, never certainty. According to William of Occam (*c.* 1300–49) we know onlv individuals, and only through our senses: the structure of the world, relations, classes. space and time are constructions of our mind. The order of our world of knowledge is the logic of our construction. Analyzing our language, we discover all that has been ascribed to the extramental world; only individual things resist this analysis. God's existence cannot be proved; even the "five ways" lead us beyond experience, away from the truth. Knowledge of God belongs to faith; according to which God is absolutely free; "laws of nature" or knowledge of immutable facts and entities would impair God's freedom. The fideistic side of these doctriries recommended them also to less extreme thinkers such as John Gerson and Pierre d'Ailly. The opposition to what was termed "nominalism" or "Occamism" failed to produce positive constructions; such "realists" as Walter Burley were not very original. Even the extreme deterministic doctrine of Thomas Bradwardine seems to be partly inspired by Occam's idea of God's absolute power. The Averroism of John of Jandun followed a middle course. A positive doctrinal contrast to those trends is to be found in the speculative mysticism of Johannes Eckhart (c. 1260–1327) and his follon-ers; by reviving the Neoplatonic doctrines of the unity of the real, of the negative nature of individuality and of the inherent need for every thing to annihilate itself in God. they strongly influenced later German philosophy.

"Free" inquiry into metaphysical issues mas accompanied by new developments in several sciences and sectors of philosophy. These included formal logic (Albert of Saxony) and the mental grammar of the *modi significandi* (Thomas of Erfurt); the doctrine of the independence of political life from ecclesiastical power and of the right of citizens to choose their rulers (William of Occam, Dante Alighieri and Marsilius of Padua); the theory of "impetus" and the numerical interpretation of qualitative changes (Jean Buridan, Thomas Bradwardine and Nicole Oresme); and the study of the nature of money (Oresme).

In the 15th and 16th centuries the main trends of thought of the 13th and 14th (Thomism, Scotism, nominalism) were kept alive in the schools (hence the term "scholasticism"); but Platonism and the idea of life as animating all things in nature inspired. outside the schools, more original thinkers. A restatement of Neoplatonism, bordering on mysticism and foreshadowing idealism, accompanied by a penetrating analysis of the incongruities of the traditional doctrines of definition and noncontradiction if metaphysically applied to things. was presented by Nicolas of Cusa (1401–64); the mathematical problems of the limits of infinite series are for him examples of the *coincidentia oppositorum*. This is the fundamental rule of a world where everything somehow includes everything else. where God (the expanded. "explicit" being) can be compared with things (the contracted. "implicit" being). Together with Marsilio Ficino (1433–99), Nicolas shared Gemistus Pletho's optimistic aspiration toward a universal philosophical religion.

In the latter half of the 16th century and early in the 17th, however. Platonism was interpreted in a more pantheistic and naturalistic vein by the south Italian philosophers Bernardino Telesio, Giordnno Bruno anti Tommaso Campanella. Telesio wanted to provide an explanation of nature that would start from "its own principles" and forgo all *a priori* doctrines; for Bruno, the whole world is a living "animal" that renders explicit what its essence (*i.e.*, God) contains implicitly; and Campanella professes an extreme animism (things "sense," they are because they sense: cognosccrc est *esse*). Pietro Pomponazzi (1462–1525), the leading Averroist. also tries to find in nature the solution to all problems; he thus denies the immortality of the soul. Direct concern with nature leads such men as Michel de Montaigne (1533–92) to pursue detailed observation of how beings, particularly human beings, behave: and their keen sense of realities in limited spheres is accompanied by scepticism as to the possibility of solving the "great problems" of philosophy. Similar interests. coupled with knowledge of mathematics and mechanics, made of Leonardo da Vinci (1452–1519) the pioneer of the new science of nature.

(L. M-Po.)

MODERN PHILOSOPHY

More than any other intellectual discipline, philosophy derives

its stimulus from events outside its own immediate sphere. Behind the rise of a new philosophy in the 17th century lay two major happenings the Reformation and the scientific movement initiated by Copernicus (1473–1543) and continued by Kepler (1571–1630) and by Galileo (1564–1642). The Reformation had little immediate effect on philosophical speculation, for the reformers laid primary stress on faith and inspiration rather than on reason and learning; it was not till the time of Kant that Protestantism found philosophical expression. Nevertheless, by challenging the old order in the sphere of religion Luther and Calvin facilitated its overthrow in other fields. The scientific movement, by contrast. exercised a ponerful and direct influence on philosophical thought almost from the first. The neu scientific attitude, with its emphasis on those aspects of natural phenomena nhich nere quantitatively comparable as opposed to those nhich were qualitatively different, had it is true. been partially anticipated in Platonism; and Platonism was not only influential in the thought of the early middle ages but had survived as an undercurrent throughout the period when Xristotle was in the ascendant. to be revived at the Renaissance in the manner just described. The break mith familiar conceptions was. however. sufficiently sharp to present an intellectual challenge of the first importance. It became imperative for thinking men to ask what were the implications of the new view of nature and to nhat extent they could be reconciled with existing beliefs in other fields, in particular that of religion. The great impression made by Descartes on his contemporaries owed much to the fact that he answered this question in a way which seemed to do justice to religion and to science at once. The whole of nature constituted a great machine; there was nothing in it—not even the human body—which could not be explained in mechanical terms. But the mind or spirit of man belonged to another order altogether an order to which God also belonged, and had to be dealt with in quite another way. Hence the new science could be admitted to the community of learning without its being necessary to show religion the door.

Cartesianism.—The common ascription to René Descartes (1596–1650) of the title "father of modern philosophy" has been disputed by some in favour of Francis Bacon (1561–1626). Bacon's reputation rose as that of Descartes fell The shortcomings of Descartes's philosophy of nature. cast in the form of a rigid deductive system, stood in contrast with Bacon's preoccupation with induction; and it was asked whether Bacon. a precursor of modern empiricism. had not a better grasp of the truth. In fact, however, Descartes's account of scientific method seems. despite its obvious errors. to correspond better than anything in Bacon to the procedures of the advanced physical sciences today. and historically there can be no question of the comparative influence of the two thinkers. For all his acuteness, Bacon could scarcely claim to have provided his age with a new philosophy; nor was it Bacon's ideas which. for good or ill. set the stage for philosophical discussion during the next 300 years.

Even the briefest sketch of the Cartesian system must take some account of its genesis, for Descartes is important not merely for his positive conclusions but also for the nay in which those conclusions were reached. He began, in effect. as a logician. Confronted by the confusion and stagnation which characterized many forms of learning in his day. he sought a method or standard procedure for attaining to truth in the sciences. The method. closely based on mathematics. was to start from premisses of uhich our knowledge was "sure and indubitable" and to proceed only to conclusions clearly seen to be implied by those premisses. But though he began as a logician, Descartes did not remain long on the purely logical level. Sceptical doubts about the applicability, as opposed to the internal consistency. of scientific systems had troubled him from an early date, and it was to quieten them that he proceeded to construct a metaphysic. The sceptical arguments which. he believed. showed the untrustworthiness for theoretical purposes of all sense judgments were powerless when directed against the existence of the self; for to doubt the self was itself to affirmit, since to doubt is to think. There was thus one firm fact on which knowledge could be built. What the argument proved, however, was very limited: only the existence of the self as a thinking thing, not that of body or matter. To prove the latter. Descartes maintained further steps were required We must first demonstrate the existence of God; then show that, if God exists. whatever we conceive clearly and distinctly must be true; finally establish that we have a clear and distinct idea of body or matter. Descartes proceeded to try to make good each of these points. The final system which emerged incidentally thought of by its author as no more than the prelude to a comprehensive philosophy of nature. was a simple dualism of mind and matter as separate substances, a substance being defined *(Principles of Philosophy*, i, 51) as "a thing which so exists that it needs no other thing in order to exist."

Modern historians of philosophy. notably Étienne Gilson, have stressed the extent to which Descartes's thought connects with mediaeval ideas; and the terminology in nhich his views found expression was certainly often that of his predecessors. Nevertheless. it nould be wrong to ignore the profound novelty of the Cartesian system as a nhole. We have already seen how by his metaphysical dualism Descartes met one of the primary intellectual needs of his age. in a manner which may now seem crude but was certainly effective at the time. by assigning distinct spheres of influence to scientists and to theologians. At the lowest estimate this must be counted a service. though perhaps an unintended one. to the cause of science. But the novelty did not stop there. The method sketched in the second part of the *Discourse on Method* and norked out in more detail in the unfinished *Rules for the Direction of the Mind* was revolutionary not only in its bold refusal of the name of knowledge to whatever was capable of being doubted, but still more in its author's conviction that "all the sciences are conjoined uith one another and interdependent" Knowledge was one and hence any suggestion that method should vary n-ith subject matter could be ruled out. This conclusion stood in such sharp contrast with the Aristotelian assumptions hitherto prevalent that men forgot that in many points Descartes and Aristotle were in agreement about scientific method. But it uas in the field known now as "theory of knonledge" that Descartes's thought was newest and most influential; indeed, he may be said to have discovered (or invented) the subject in its modern form. The famous arguments at the beginning of the *Meditations* provided a starting point for the many subsequent discussions of knonledge and certainty, uith the respective cognitive claims of sense and reason; while Descartes's contention in the same context that he could be certain that he had ideas but not certain that anything independent of himself corresponded to them generated the celebrated problem of the external world. It is worth noting that on this and similar topics philosophers of an empiricist turn of mind accepted Descartes's statement of the question equally with rationalists though they disagreed with his way of answering it. (See further KNOWLEDGE, THEORY OF; LOGIC. HISTORY OF.)

The power of Descartes's thought was clearly appreciated by his contemporaries and immediate successors and it was not long before a flourishing school of Cartesians developed *(see* CARTESIANS). Of these Nicolas Malebranche (1638–1715), who gave an Augustinian or Platonic twist to Descartes's doctrine of ideas, is perhaps the most notable. Among Descartes's own contemporaries there nere. however, two thinkers of major stature uho would certainly not have called themselves Cartesians, though each felt the force of Descartes's ideas: Thomas Hobbes (1588–1679) and Blaise Pascal (1623–62). Hobbes, remembered today primarily for his views on politics, agreed with Descartes in his acceptance of mechanical principles of natural explanation and in his confidence in the powers of human reason; where he differed from Descartes was in believing that nothing existed except matter in motion and thus that there was no such thing as mental substance. Pascal. a genius of the first order whose contributions to mathematics physics and Christian apologetics were alike remarkable, found himself entirely out of sympathy both with Descartes's observations on method, which struck him as much too dogmatic, and with his metaphysical synthesis, which he thought did something less than justice to religion. In a century notable for its intellectualism Pascal had the insight to ask if intellectualisin was

enough; but since he was not strictly a philosopher (and indeed doubted the value of any kind of constructive philosophy), his influence on subsequent philosophical thought was small.

Spinoza and **Leibniz.**—Benedictus de Spinoza (1632–77) and Gottfried Wilhelm Leibniz (or Leibnitz, 1646–1716) shared many of Descartes's fundamental assumptions as well as much of his terminology and were much preoccupied with difficulties which had arisen inside the Cartesian system, about the relationship of mind and body, the role of sense experience in knowledge and the question of innate ideas or a *priori* knowledge, as it was later to be called. In addition, Spinoza was so far in agreement with Descartes's account of method that he attempted to set out his own philosophical conclusions in the form of a deductive system in his *Ethics*. Nevertheless, each was too original a philosopher to be described as a mere follower of anyone.

Spinoza began by accepting the Cartesian definition of substance (quoted above) and went on to argue that there could be only one substance. which he called indifferently God or Nature. Descartes himself had allowed that mind and matter were substances only in a secondary sense for though each was otherwise complete in itself they each needed the concurrence of God in order to exist; God alone was "absolutely self-sustaining." Spinoza's version of this was to make mind and matter attributes of his single substance, the reality of which was, he said, presupposed by the reality of anything less than itself. God was to be thought of as a being of infinite attributes, but two attributes only were known to human beings. Since each attribute was complete in itself, interaction between the mental and the material was strictly speaking impossible; but since God manifests Himself in every attribute, whatever happens in one has its counterpart in all the rest. Thus to every mental event there corresponds a physical event, and vice versa.

The originality of Spinoza lay in his presenting a de-Christianized version of Cartesianism. Descartes had accepted the orthodox Christian conception of God as pure spirit endowed with will and intellect and had followed Augustine in laying particular stress on freedom of the will both in God and in man. All this disappeared in Spinozism. God was as much body as spirit, and there could be no question of His doing other than acting according to the necessities of His nature; free will was an illusion fostered by ignorance. Spinoza added that the philosopher could attain to freedom of a sort by recognizing the true nature of things and accepting it. It was in this sense that he sought to deliver men from "human bondage," as expressed in the eloquent concluding sections of the *Etkics*.

Spinoza's philosophy, though it had a semimystical side which was later to appeal to the Romantics, seemed in his own time to be dangerously close to materialism; Hume's (perhaps ironical) description of him as "that famous atheist" with his "hideous hypothesis" represented a common reaction. Certainly Leibniz, though he had known Spinoza personally as a young man, was anxious to avoid being thought to share his views. His own philosophizing can be represented as a sustained if not very successful attempt to avoid falling into Spinozism. Against Spinoza's all-embracing monism he maintained the existence of a vast number of individual substances, each complete in itself, of which the human soul was the most familiar example. These "monads" nere spiritual realities and, indeed, the only realities, for material things did not in the strict sense exist; it was only at the confused level of sense perception that men took them to be real. Each monad was self-determining, the internal nature of each being the source of whatever happened to it, though thanks to God the activities of all were harmonized. Determinism nas avoided (or so Leibniz thought) by distinguishing between truths of reason, which were logically necessary and therefore could not be other than they mere, and truths of fact, which mere contingent and depended only on God's decision to bring into existence the best of all possible worlds.

Leibniz had a mind which was at once highly acute and comprehensive in its range; on many points of detail he made suggestions which later philosophers found instructive. In some branches of philosophy, notably in logic, his ideas uere revolutionary. But he was not a gifted writer, and he lived at a time when a new method of philosophizing was beginning to come in, making his own approach appear dogmatic and uncritical. Except in his native Germany, a backwater in European culture at the time, his philosophical work had little immediate effect. *(See* further BODY AND MIND; IDEALISM; RATIONALISM.)

Locke and the "New Way of Ideas."—The new method of philosophizing just referred to owed its origin to John Locke (1632–1704). More than any other philosopher of his time Locke bridged the gap between two ages and two traditions, for though he shared much of the rationalistic outlook of the 17th century and icdeed was in some respects a very conservative thinker (as witness his political theory, which falls firmly into the natural law tradition), he even so initiated methods and procedures which were to be typical of the following century. His work led to a shift in the interests of philosophers and to a diminution in their ambitions.

Descartes, Spinoza and Leibniz had each sought to construct an elaborate metaphysical system, and Descartes at least had hoped to make his metaphysics the basis for a speculative physics. Locke, as he made clear in a famous passage at the beginning of his *Essay Concerning Human Understanding*, was more modest. "In an age that produces such masters as the great Huygènius, and the incomparable Mr. Newton," he wrote, "it is ambition enough to be employed as an under-labourer in clearing the ground a little, and removing some of the rubbish that lies in the way of knowledge." This task could be achieved if philosophers would turn their attention from the construction of systems to the examination of ideas and to the question of their significance; in more recent terminology, to problems of philosophical analysis. It was with the analysis and clarification of the idea of knowledge that the *Essay* was explicitly concerned.

What makes this passage of special interest is that here for the first time in modern philosophy there is suggested a clear division of function between philosopher and scientist, hitherto thought of as one. But Locke's innovations were not confined to this major step. He suggested not only a task for philosophers but also a way of solving philosophical questions: by the use of what he called the "historical, plain method." This was, in effect, an appeal to experience and, in particular, to the experience of consciousness as revealed in introspection. By taking this simple step, Locke believed, men could eliminate from their thought much pretentious but unfounded dogma, for instance that associated with the contemporary doctrine of innate ideas. Men had only to look at their own thoughts to see that there was nothing to be said for that doctrine. In introducing the "historical: plain method" Locke gave a psychological twist to philosophical investigation which remained a prominent feature of the study till the beginning of the 20th century.

Locke was neither a wholly consequential nor even a very powerful thinker, yet the *Essay* proved a fertile starting point for subsequent discussion. The problem of the origin of ideas, which so largely occupied 18th-century philosophers, was clearly stated there; and the ideas to which they gave particular attention, substance, "power" and self-identity, for instance, had all been examined by Locke. The difference between Hume and Kant about the function and status of *a priori* propositions arose, in effect! out of the treatment of knowledge in book iv. Similarly, Locke's interpretation of "reflection" as a kind of "inner sense" set the stage for later discussions of the problem of self-knowledge. On these and other points Locke may often have proved misleading, but that he was influential could not be denied. (See further CAUSALITY; INNATE IDEAS; PSYCHOLOGY. HISTORY OF.)

Sense and Reason in the 18th Century.— The 18th century, so often described as the Age of Reason, began philosophically with a sharp reaction against rationalism. The prestige of Descartes and the Cartesians slumped, partly because of the work of Locke. but still more because of the supersession of Cartesian physics by the less speculative theories of Newton. It was only in the field of mathematics, as Hume observed, that the claims of reason had been vindicated, anu they were successful there because what was in question was relations between ideas. not matters of fact. For knowledge of matters of fact and of existence, experi-

ence (by which was meant sense experience) was essential.

This movement toward empiricism, as it was subsequently called. had its counterpart in the ethical sphere when the intellectualistic accounts of such writers as Ralph Cudworth and Samuel Clarke gave way to the "moral-sense" theories of the 3rd earl of Shaftesbury and of Francis Hutcheson *(see* also ETHICS, HISTORY OF). It was carried to its farthest extent when Hume declared *(Treatise of Human Nature,* ed. by L. A. Selby-Bigge, p. 183, 1896) that belief *(i.e.,* what had traditionally been called "judgment") was "more properly an act of the sensitive, than of the cogitative part of our natures." It should be pointed out. however, that despite such remarks Hume's outlook was rationalist in a different sense. in so far as he attached no importance to immediate feeling or "enthusiasm" in the sphere of religion. In this respect he and other writers of the Enlightenment did not diverge from the Cartesian tradition.

'Hume's philosophy is partly built on certain theories of George Berkeley (1685–1753), who in turn was much indebted to Locke. The debt was, however, negative rather than positive. in so far as passages in the *Essay* set Berkeley thinking and provided him with premisses from which he drew conclusions of his own. These conclusions principally concerned the status of the so-called "external" world. Locke, following Descartes. had held that the immediate objects of human perception are ideas in the mind. but had added that we must suppose these ideas to be caused by independently existing material things. of which we could have no direct knowledge. Berkeley showed that. given Locke's premisses, no such inference was warranted. There could be no causal inference from the occurrence of ideas to the existence of "inert" material bodies, for nothing in experience justifies us in thinking that such bodies could be causes. and indeed we had difficulty in attaching a meaning to the very idea of such entities. The only possible cause of our ideas was a "spirit." Hence Berkeley drew two conclusions: first, that the familiar things of sense must be thought of as collections of ideas, having no existence "without the mind"; and second, that we must suppose the existence of an infinite spirit who excites ideas in us and thus makes our experiences correspond.

Berkeley's philosophy was written. as the title of his *Three Dialogues* put it. "in opposition to Sceptics and Atheists"; but it is doubtful whether it ever achieved much for the anticeptical cause. Plain men from Samuel Johnson onward have found its argument against matter paradoxical in the extreme. while its constructive side is too lightly sketched to be convincing. Historically. its main effect was on David Hume (1711–76), himself a notorious sceptic. who drew from it arguments to strengthen his own radical empiricism. The features in Berkeley on which Hume fastened were (1) his polemic against abstract ideas. which had been introduced by Berkeley to discredit the notion of material substance, but the antimetaphysical implications of which were, as Hume saw, much wider; and (2) his explanation of the causal relation as met with in nature as being no more than a relation of regular succession or. as Berkeley had it. of "sign" and "thing signified." Using (1) as a means of eliminating spiritual as well as material substance. Hume went on to argue that the analysis given in (2) was valid for all cases of causation, including the activities of human agents. All events are "loose and separate." no one happening relates intrinsically to any other. Connections between events there are. but they are external connections only, for "*A* causes *B*" means no more than, roughly, that (1) *A* precedes B in time; that (2) similar sequences have been observed in the past; and that (3) as a result there is a strong tendency in the mind to expect something like B when *A* occurs. It should be noticed that accepting this analysis of causality means recognizing that causal relations can hold only between what is capable of being experienced—a consequence which casts grave doubt on the use of the concept made by many earlier philosophers.

Hume's thought is misrepresented if we lay exclusive stress on his empiricism. There is another side to it. which he himself called "scepticism." though he used the word in a different sense from Berkeley's. The object of his scepticism was human reasoning. or rather that part of it which concerns questions of fact. the reasoning which we employ in history and in daily life as opposed to that n-hich we employ in mathematics. Hume pointed out that all such "probable" or "moral" reasoning. as he calls it. proceeds on a principle which cannot be proved, the principle that the future will resemble the past: and he argued that because our confidence in this principle cannot be rationally justified. it must be derived from custom and habit: that is. it must have a nonrational basis. Men therefore deceive themselves if they suppose that their possession of reason makes them superior to animals. for in this all-important matter both are in precisely the same case. Outside the field of strict demonstration. human thought and animal thought proceed on the same lines. *(See* further INDUCTION: SKEPTICISM.)

These challenging observations were little appreciated by Hume's contemporaries. The *Treatise of Human Nature,* as its author complained. "fell dead-born from the press"; and the two *Enquiries,* in which Hume served up his ideas again in a somewhat emasculated form. attracted little intelligent comment. It was not till the time of Kant that the force of Hume's thinking was recognized. Meanwhile his fellow countryman Thomas Reid (1710–96) sought to answer scepticism by elevating common sense to be the criterion of philosophical truth. in a way that interestingly anticipates the work of G. E. Moore in the 20th century. The Scottish school founded by him *(see* COMMON SENSE, PHILOSOPHY OF) was. however, largely undistinguished and left little permanent mark on philosophical thought.

The Enlightenment, Kant and Hegel.—The most striking feature of the intellectual life of the 18th century was the way in which traditional Christian beliefs. still largely accepted by Descartes and even by Locke. lost their hold over men's minds and gave way to a different creed. There were. of course. many educated men, including some of the most eminent. such as Newtop. who remained pious Christians: and indeed it was the exception rather than the rule for a man to proclaim himself an atheist or a materialist. But the atmosphere of the age. that of the Enlightenment. was hardly congenial to the claims of religion. Emphasis was everywhere laid on the need for tangible evidence and for clarity of thought. in a way hostile to anything that savoured of the mysterious. Science, which had already done so much to explain the wonders of nature. was confidently expected to proceed to fresh triumphs. and it was widely believed that these would be in the world of human affairs. Meanwhile the banishment of superstition and "metaphysics" (already a term of abuse) was an essential condition of further advance.

It is against this background that we must judge the philosophies of Kant and his successors. Kant himself was in many respects a child of the Enlightenment: he shared its great respect for science and sympathized with its humanist ideals. But he emphatically protested. in the name not so much of religion as of morality. against the prevailing tendency toward naturalism. The belief of the *philosophes* that the moral nature of man could be compassed in scientific terms was. he maintained. plainly false. His successors, notably Hegel, n-ent farther. Living at a time when Romanticism was in the ascendant, they put forward radical criticisms of the Enlightenment's whole outlook, alleging that its intellectualism stood condemned for utter failure to do justice to the rich individuality of things as we are immediately am-are of them and demanding a more adequate philosophy that should do just this. Yet it is notable that Hegel at least did not propose to turn the clock back to the simplicities of a prescientific age: if he questioned the omnicompetence of science. this did not blind him to its achievements. Whatever defects the Enlightenment's ideal of clear and precise thinking might have, it was no remedy to proceed to the opposite extreme and abandon the attempt to think altogether. Mere feeling was as one-sided and inadequate as mere thought.

Immanuel Kant (1724–1804) was a student at Konigsberg at a time when the prevailing philosophy in the German universities was that of Christian Wolff (1679–1754), a follower and popularizer of Leibniz. Kant, however, had the good iortune to be introduced by his teachers not only to the ideas of Leibniz but also to those of Newton, whom he never ceased to admire. His early work was as

much scientific as philosophical, and though the balance of his interests shiited later he continued to follow scientific developments with close attention. Philosophically, he was influenced by Hume as well as by Leibniz, while Jean Jacques Rousseau, with his emphasis on the priority of the moral over the intellectual nature of man, also affected his thought decisively. His development mas slow; it was not till the 1760s that he began to write philosophical essays of importance and not till 1781 that his first major work, the Critique *of* Pure Reason, was published. Thereafter he poured out an astonishing series of treatises on a wide variety of philosophical topics. His ideas were, more often than not, obscurely and pedantically expressed, but their force and originality were apparent irom the first.

The aim of the *Critique* of Pure Reason, in the words of its author, was "to abolish knowledge in order to make room for faith." The declaration can easily be misunderstood. Kant was far from being antirationalist in his general outlook; on the contrary, he pointed out — indeed overemphasized — the role of reason in natural science, and questioned its pretensions only when employed outside what he thought to be its proper sphere. The target of his polemic, in fact, was metaphysics, understood as a study which claimed to give knowledge of a suprasensible world. There were three issues, Kant declared, which were of fundamental concern to human beings: the existence of God, the freedom of the will and the immortality of the soul; and metaphysicians claimed to deal with each of these burning topics. Unfortunately for their pretensions, however, they had never been able to establish anything definitive on any one of them, and the time had now come, Kant thought, to make clear why they never had and never could. The truth was that such questions were beyond the competence of human reason, which could be put to work effectively only mhen it had empirical data on which to operate and could continue to function properly only if it remained within the sphere of experience. Since God and the soul as discussed by metaphysicians were not objects of experience, reason could decide neither for nor against them. But Kant did not draw the conclusion, as some later philosophers have done, that all talk about such topics must be meaningless; he argued rather that belief in God, freedom and immortality, though not capable oi justification on intellectual grounds, was none the less necessary for moral purposes. The moral agent, whether conscious of it or not, acted as if he accepted these beliefs, and indeed his'actions made no sense without them. Thus morals or "practical reason," as Kant called it, filled the gap which critical scrutiny of the pretensions of speculative reason had revealed. (See further ETHICS, HISTORY OF.)

Kant is important historically not only for his attempt at a large-scale synthesis but also for many of his detailed suggestions. He succeeded in sharpening many old issues and in bringing to the fore many new ones. Thus his dichotomy oi analytic and synthetic judgments, with the accompanying attempt to show that there are judgments which are at once synthetic and a *priori,* made possible a fresh treatment of the problem of innate ideas in the celebrated doctrine of categories. while his stimulating handling of the concept of teleology in the Critique *of Judgment* both illuminated old controversies and revealed iresh problems implicit in the language of the newly developing science of biology. For better or worse, his philosophical vocabulary affected the usage of philosophers for the nest century and more. His introduction of the notion of a "transcendental" argument, alleged to be neither deductive nor inductive, was part of an attempt to distinguish clearly between philosophy on the one hand and the empirical and exact sciences on the other; ii not wholly successful, it nevertheless called attention to logical questions which previous philosophers had overlooked. (See further CATEGORY; KANT, IMMANUEL; TRANSCENDENTALISM.)

Kant wrote his main works at a time of intellectual ferment in Germany, and his ideas had scarcely been made public beiore they were criticized by his younger contemporaries. The cautious empiricist strain in his disposition, his antipathy to speculation which could not be tested by evidence. his liking ior cut-and-dried formulas and sharp dichotomies — none of these mere to the taste of a generation already iniected with Romantic ideals. Johann Gottlieb Fichte (1762–1814), who at first claimed to be his disciple, developed Kant's ideas in a way that tended to play up the role of the a *priori* factor in knowledge, which Kant had recognized but strictly circumscribed, and to play down that of the empirical element. F. W. J. von Schelling (1775–1854) carried the same tendency farther and at the same time attempted a fresh metaphysical synthesis, in which the idea of life mas made central at the expense of the mechanical concepts on which Kant had laid particular stress. Neither of these writers made much of a lasting impression. however; the thought of both was too lightly sketched to bear serious examination. It mas not long beiore both mere superseded in the public eye by Hegel.

The reputation of Georg Wilhelm Friedrich Hegel (1770–1831) has varied more than that of any other major philosopher. Admired almost to the point of adulation by some of his contemporaries, he has subsequently been denounced as guilty of almost every intellectual crime. A metaphysical word-spinner, seeking to replace clear thinking and patient empirical inquiry by alleged speculative insight and intuition: the father of political fascism and the grandfather of political communism; an enemy to science and the patron of obscurantism: these are among the descriptions which have been applied to him. In fact his views were often sober in comparison with others current at the time; they were not deliberately obscurantist though they were oiten obscurely expressed; and if they were opposed to the intellectual and political ideals of the Enlightenment, the opposition was openly avowed and an attempt made to offer a rational justification of it.

The basis of Hegelianism, as already indicated, lay in a contrast between life as immediately experienced and thought as commonly conceived in the generation immediately preceding Hegel's own. Like Schelling, Hegel was opposed to the mechanical interpretation of nature favoured by the physicists and by Kant; but his philosophy was not biologically centred as Schelling's was. The models irom which he drew his key notion of a whole which combines unity with self-differentiation were rather, as his early writings show, certain human experiences and institutions; it is notable that his earliest criticisms of Kant were not of the latter's general philosophy but of his ethics. Hegel held that a more adequate logic than the logic of tradition was needed to think the world as it really is; and he believed that he had found the key to such a logic in his dialectical principle. Traditional logic applied only to the operations of the understanding (illustrated par excellence in the thinking of natural scientists), which certainly had their uses but could issue only in abstractions; dialectical logic alone was sufficiently supple to do justice at once to the similarities and to the differences of things.

Hegel was a great systematizer; and one result of his work was to reverse, temporarily at any rate, that tendency to make a modest estimate of philosophy's competence which had set in with Locke. The Hegelian philosopher, like Plato, took all knowledge and all existence for his province. What is more, Hegel was not content simply to affirm this as a matter of principle; he himself had considerable knowledge in many diverse fields and brought his philosophical theories to bear on all of them. Not surprisingly, the degree of success that he achieved in attempting a uniiorm philosophical interpretation of a wide variety of phenomena varied; he himself showed more understanding in some fields than in others, and his principles (which sprang irom reflection on particular conceptual schemes) could not be applied with equal iacility to all types of material. Later critics have tended to fasten on those parts of his system, philosophy of nature in particular, in which he was least successful. From the historical point of view, however, it is well to stress not these, where his influence was negligible, but rather his writings on such topics as religion, law, aesthetics and history, where he often displayed real insight and where his detailed suggestions have proved of interest even to those who disagree with his philosophy. (See HEGEL, GEORG WILHELM FRIEDRICE; ETHICS, HISTORY OF.)

19th and 20th Centuries.—Philosophy after the death of Hegel no longer presents the spectacle of order which it is possible to discern without undue distortion in the thought of the two preceding centuries. There were a number of reasons for this state of affairs. One was quite simply that, in the rest of the 19th century at any rate, no major thinker of outstanding originality arose to dominate the philosophical scene. Men of ability worked at the subject, but they mostly followed one of the existing traditions rather than tried to branch out on lines of their own. The fact that many of them were professional teachers in universities, well acquainted with the work of past philosophers, may be partly responsible for this. At all events it is noteworthy that the publication of Charles Darwin's *Origin* of Species in 1859, while it had its philosophical repercussions, led to no development of importance inside philosophy in the way in which Galileo's work had led to Descartes and Newton's to Kant. A further factor was the increasing effect of national differences on philosophical practice. Descartes, Spinoza and Leibniz were men of international repute, who had their correspondents in most of the countries of western Europe; that one was a Frenchman, one a Dutch Jew and the third a German had little importance. But by the end of the 18th century the most original and significant contributions to European philosophy were being made by men who wrote a language which few outside Germany could understand and whose background included elements, such as German mysticism, which were certainly not the common possession of the whole continent. The result was not only that Kant and Hegel won little general appreciation in their own lifetimes, but, more serious, that philosophers in different countries tended to conceive of their subject on widely different lines. While Germans tried to construct elaborate metaphysical systems: Frenchmen carried on the Enlightenment tradition of empirical psychology as practised, for instance, by E. B. de Condillac, and Englishmen engaged. in philosophical analysis in the manner of Locke and Hume. There was indeed, as the remainder of this article will show, a good deal of cross-fertilization among these different strains; yet, to speak broadly, the divergences remained and indeed were still to be found in the middle of the 20th century.

It will be possible here to give only the brieiest of sketches of some of the main philosophical currents after Hegel.

Hegelian Influence.—The system of Hegel came under sharp attack within a few years of its author's death, yet Hegelian ways of thinking were persistently influential throughout the 19th century. The notion that philosophy is a synoptic study appealed to the age, and there were many attempts, by writers who acknowledged no debt to Hegel as well as by professed Hegelians, to construct metaphysical

syntheses. Herbert Spencer (1820–1903), who tried to apply the concept of evolution throughout the sciences, may be mentioned as belonging to the first class; even Auguste Comte (1798–1857), despite the hostility to metaphysics which was so prominent a part of his "positive" philosophy, recalls Hegel in his attempt to present a unified picture of the whole of knowledge and in trying to find a law of development in history. Comte's preoccupation with the social sciences also has its parallel in Hegel. The "dialectical materialism" of Karl Marx and Friedrich Engels is easily the most celebrated system to admit indebtedness to Hegel, though few non-Communists have ranked it high from the purely philosophical point of view. Among more academic thinkers who continued the Hegelian tradition or felt Hegel's influence may be mentioned Thomas Hill Green, Francis Herbert Bradley, Josiah Royce, Alfred North Whitehead, Henri Bergson and Benedetto Croce (see further NEO-HEGELIANISM).

In Germany a revival of Hegelian studies in the early 20th century, initiated by Wilhelm Dilthey, himself in some respects a latter-day Hegelian, led to renewed interest in Hegel's first writings, where his criticism of the Enlightenment's outlook is developed without any of the rigidity of the later system. One result of this has been that certain of Hegel's doctrines and techniques are reflected in the work of writers who, at first sight, stand in a very different tradition; the most notable example of this unexpected reflection occurs in the work of Martin Heidegger (see below).

Empiricism and Logical Analysis.—Throughout the period of the Romantic movement and its philosophical counterpart there were philosophers in Great Britain and France who remained true to the ideals of the 18th century. Jeremy Bentham (1748–1832), whose main debts were to the associationism of David Hartley, to C. A. Helvétius and, through these two, to Hume, is only the best-known example. His follower James Mill (1773–1836), more important as a philosopher if less noteworthy for his practical influence, is another instance. The Benthamites as a group were strongly rationalist in their outlook; they were also passionately convinced that mental phenomena can all be explained in natural terms. They could see only coniusion, or worse, in talk about philosophy's needing to engage in "transcendental" arguments, or in attempts to distinguish the faculties of reason and understanding. As a contemporary said, the Germans were "metaphysically mad," an opinion which seemed to be confirmed when S. T. Coleridge spoke up for them in Biographia *Literaria*.

Bentham and James Mill would doubtless have described themselves as empiricists, yet neither contributed much to the theory of empiricism (Bentham was primarily interested in ethics and politics and hlill in psychology). James's son John Stuart Mill (1806–73) is more notable in this connection. J. S. Mill's *System* of Logic (1843) contains a iairly comprehensive restatement of the case for empiricism. as well as an attempt to work out the inductive logic which he thought to be of far greater utility than the deductive logic of tradition. Mill had little difficulty in exposing the hollow character of the "intuitions" on which his opponents, whose affinities were with the Scottish school, mostly relied; but the case that he made out for his own positive principles was iar irom watertight, as Bradley and others were later to show. It is astonishing, indeed, that he could have written so naively with the discussions of Hume's Treatise before him. (*See* iurther INDUCTION; LOGIC, HISTORY OF.)

Mill's conception of deductive logic was wholly conservative; he equated "ratiocination," as he called it, with syllogism and took his account of syllogism, on the formal side at least, entirely from Aristotle. The rest of the century, however, saw considerable changes in the state of formal logic, changes which, in time, had important philosophical repercussions. George Boole (1815–64) in his *Mathematical Analysis* of Logic (1847) began a process which served to bring out the restricted and incomplete character of the common textbook account of deduction. 30 far from all demonstration's being syllogistic, syllogism was only one of a wide variety of patterns of demonstrative inference. Meanwhile Gottlob Frege (1848–1925) was concerning himself with questions about the foundations of mathematics (a subject on which Mill had touched unsatisfactorily) and arguing that logic and arithmetic were continuous, since arithmetical notions can all he explained in purely logical terms. The work of Boole and of his successors was brought together with that of Frege and the whole extended and given definitive expression in the *Principia Mathematica* (3 vol.; 1st ed., 1910–13) of A. N. Whitehead and Bertrand Russell.

This work more than any other gave impetus to the analytic and empiricist movements which became so prominent a feature of philosophical life in the English-speaking countries in the first half of the 20th century. It should be pointed out, however, that the supporters of these movements were by no means united in their philosophical outlook. They fell into two main groups. The first: deriving from Bertrand Russell (1872–) himself, had as its program the introduction of scientific method into philosophy. Metaphysics having been set aside, in the approved Enlightenment manner, as nonsense, there yet remain residual problems ior the philosopher to solve, a proccss which can be accomplished by the introduction of a carefully defined technical vocabulary and the full use of modern logical techniques. Rudolf Carnap (1891–), formerly of Vienna, later of California, was, apart from Russell, the most illustrious representative of this way of thinking in the 1950s. The other group owed most to George Edward Moore (1873–1958), originally associated with Russell in his criticism of Bradley, and to the later work of Ludwig Wittgenstein (1889–1951), also a iormer associate of Russell's. Moore developed a "defence of common sense" which led him to assert the correctness of the plain man's everyday convictions in face of the sceptical doubts raised by philosophers. Wittgenstein generalized his procedure to show the hollow character of many of the traditional problems of philosophy, including those still taken seriously by the other group of analysts; philosophical puzzles, as he called them, arose out of inattention to the manifold nuances of speech and could be cleared up by examining those nuances with care.

Both groups of logical analysts agree in recommending the resolution of philosophical difficulties by linguistic methods; in this respect their work constitutes a break with the tradition oi psychologism which goes back to Locke. But whereas Russell and Carnap sought for an "ideal" language which should be free of philosophical ambiguity? Wittgenstein did not even recognize the possibility of philosophy's having a special vocabulary of its own. To introduce technical terms in philosophy was to generalize prematurely, a disease to which philosophers were all too prone. The philosopher should neither generalize nor try to explain; he should only describe. And, ii he described correctly, any temptation to make false generalizing statements mould disappear. (*See* iurther LOGICAL POSITIVISM.)

Pragmatism and *Antirationalism*.—Where a British philosopher calls himself an empiricist, an American tendc to call himself a pragmatist. Not that pragmatists would allow an absolute antithesis between the two. William James (1842–1910), who did most to put pragmatism on the philosophical map, described himself as a "radical empiricist"; and C. S. Peirce (1839–1914), who invented the word "pragmatism," not only shared the common empiricist interest in natural science but had a far better grasp of scientific procedures than any oi his British contemporaries. Historically, the difference between the two doctrines rests on the fact that, whereas British empiricism looks straight back to the 18th century, American pragmatism, despite James's suspicion of Bradley with his "block universe," clearly owes a debt to Hegel. The debt comes out in the distrust of formal logic shown by such a writer as John Dewey (1859–1952) and in the related refusal to consider concepts and statements in isolation from the contexts in which they are used. The Hegelian polemic against the "abstractions" oi the pure understanding reappears here.

There is a iurther and more substantial difference which deserves to be noted. The British empiricists, irom Locke to Russell, tended to assume with Descartes (and for that matter with Plato) that there are always two distinct components in knowledge: the knowing subject and the known object. They agreed with Descartes again that knowledge ideally occurs where the subject, which they identified with mind, is in the presence of, or directly acquainted with, the object, so that the latter can be grasped by the former. The whole operation is conceived as passive, like seeing: the object imprints itself on the mind without effort on the mind's part. This analysis is decisively rejected by pragmatists. The typical cognitive situation for them is one where an animate body seeks through its sense organs to learn about its environment, with a view to acting on it later. A living thing is most truly itself not when it is passive but when it is doing something, with the result that knowledge is an activity and, for that matter, an activity of the whole organism. It should be obvious that this divergence brings to light a profound contrast of metaphysical outlooks, a contrast which may even reflect a significant difference of national temperaments. (See further PRAGMATISM.)

James is sometimes described as "anti-intellectualist" because he said that men's "passional and volitional" natures were, in certain circumstances, entitled to consideration when it was a question what to believe; the same charge was brought against Henri Bergson (1859–1941) for arguing that the intellect is a practical instrument which distorts the nature of fact even if it distorts it to good biological purpose, and ior maintaining that the road to ultimate truth must accordingly be through "intuition." Later thought, however, showed a more thoroughgoing antirationalism than is to be found in either of these writers. Soren Kierkegaard (1813–55), a Danish theologian, developed a bitter criticism of what he took to be the panlogism and optimism of his older contemporary Hegel. The notion that reality can be comprehended by reason, however refined that faculty was taken to be, broke down in face oi the facts, for there were elements of the "absurd" in the real world which could not be fitted into any tidy intellectual scheme. It was decision, Kierkegaard argued, which introduced these elements. No amount of comprehension of the facts of a situation would make a man's mind up; a man had to commit himself when he made a decision, and his doing so was a leap in the dark which at once affirmed his existenee and could not in principle be predicted. Kierkegaard had little influence in his own time or immediately after (though some oi his views have parallels in the thought of Arthur Schopenhauer and Friedrich Nietzsche); but the rediscovery of his work in the 20th century gave his outlook wide currency. The German philosopher Martin Heidegger (1889–), the first part of whose obscure but original work Sein *und Zeit* appeared in 1926–27, was profoundly affected by him; and it is from the thought of Kierkegaard and of Heidegger that the various existentialist philosophies which were so popular on the continent of

Europe immediately after World War II drew most of their ideas. (W. H. W.)

PHILOSOPHY AND PHILOSOPHICAL STUDIES.

"Philosophy" is a word whose range of usages can scarcely be explained without some account of its history. It is derived from the composite Greek noun φιλοσοφία which means the love or pursuit of wisdom. Herodotus uses the corresponding verb φιλοσοφεῖν when writing of Solon's travels in search of knowledge; and Thucydides puts it into the mouth of Pericles in his account of the famous funeral speech about the Athenian way of life. In these passages it suggests especially the attempt to satisfy curiosity; but σοφία like the English word "wisdom," implied not only wide knowledge but also sound judgment about the values of different things in life (*i.e.,* about what is most worth pursuing for its own sake) and even sometimes shrewdness in practical decisions; so that φιλοσοφία was in origin a very general word for the pursuit of mental excellence. Pythagoras is said to have been the first to call himself a philosopher (φιλόσοφος), but we know so little for certain about him that we cannot tell what nuances of meaning the word had in his usage. In the Platonic dialogues it is often used by Socrates to describe a man engaged in the sort of inquiry that he himself pursued; and there can be little doubt that the historical Socrates called himself a philosopher, while disclaiming the title of σοφός, which was given traditionally to Solon and the other sages of antiquity. There is here the beginning of a specialized or technical usage of the word, and Plato's representation of Socrates has had so great an influence on western thought that philosophy is still thought of as a study which deals for the most part, though not exclusively, with the subjects of Plato's dialogues and proceeds by the Socratic method.

The earliest of the Greek thinkers whose names were afterward included in histories of philosophy recognized no divisions of knowledge. The records of their sayings contain material of all sorts, from speculations about the constitution of the world by condensation and rarefaction of a single stuff to reflections about forms of government, and from observations of eclipses to advice on the management of children. By the end of the 5th century B.C., however, arithmetic, geometry, astronomy and music had been recognized as distinct studies. They are the μαθήματα, or disciplines, from which the word "mathematics" is derived, and for a long time they retained their special position as the first of the special sciences; thus they were still grouped together as the *quadrivium* in the curriculum of seven liberal arts taught at the mediaeval universities. The historical Socrates seems to have had no more than an intelligent layman's appreciation of these studies, and we are told that he gave up speculation about the nature of the physical world in order to concentrate attention on the search for definitions of universal notions and especially of those notions that have to do with human conduct and human character. But in the dialogue of Plato called the *Republic* he is represented as saying that the mathematical studies are a necessary preliminary to philosophical training. According to the scheme of education outlined there, anyone who would be a philosopher must learn the interconnections of the various sciences that are commonly taught separately, and no one can hope to make progress who lacks the power of *synopsis* (*i.e.,* of seeing things together). But all this is preparatory to the understanding of a system in which all "forms" (*i.e.,* characters in which individual sensible things may participate) have their places determined by their relation to the supreme Form of the Good.

It is difficult to work out any really convincing development of the scheme suggested by Plato in this dialogue. where his thought seems to be most ambitious; and we may reasonably suspect that Plato himself was unable to produce any detailed formulation that satisfied him. For he had recourse on various occasions to various analogies and sometimes even used the language of mystical illumination. But there can be found here already a number of features which recur constantly in the work of those later writers who are coinmonly accounted philosophers and which may therefore be taken as marks of philosophical thought.

Plato's Four Marks **of** Philosophical Thought.—First, there is the notion of a study in which the various special sciences are to be related together and understood as parts of one system. In recent times the increase of knowledge has been so rapid that it is difficult if not impossible for anyone to be master of the whole of a science such as chemistry, and we have therefore much more reason than Plato ever had to be worried about the dangers of specialization in education. So long as our plans for counteracting these evils do not take us beyond the boundaries of a single science, such as chemistry, we do not think that they have any connection with philosophy; but if we are more ambitious and try to provide a conspectus of all the sciences, this seems to us still a philosophical enterprise. To make clear the distinction between the a *priori* and the empirical sciences and to show the relations within the latter group between the physical, the biological and the psychological sciences—these are philosophical tasks, whether or not they are performed by professional philosophers. So too is the clarification of notions of high generality such as that of causation. If, as in physics, the development of a science makes it necessary to raise questions about concepts of this level, the scientist who tries to answer them is conscious that he is engaged for the time being in philosophy. Sometimes, indeed, the word "philosophy" is used popularly to mean any formulation of very general basic principles for a practical activity such as politics or strategy.

Second, there is a contrast between sensible appearance and intelligible reality. Only those are philosophers who "contemplate things as they are in themselves and as they exist ever permanent and immutable" and "set their affections on that which in each case really exists" (Plato, *Republic,* 479–480). According to Plato's account, the realm of appearance is the ordinary world of γένεσις, or happening, about which we can never have more than opinion, while the realm of intelligible reality is the timeless system of mathematical objects and of "forms" such as goodness and justice (*i.e.,* the realm of ideas in the original sense of the word "idea," from which our modern colloquial usage is derived through a long and devious history). In the thought of some later philosophers (*e.g.,* Leibniz, Kant and Hegel) the contrast of sensible appearance and intelligible reality is drawn in a different way, and it may therefore be objected that our second common trait is no more than a superficial resemblance in terminology. Yet, however it may be evaluated, the resemblance is there; it can be found in the works of Indian and Chinese philosophers uho have not been bewitched by the powerful magic of Plato's style and also in the philosophical utterances of modern physicists, who are certainly not Plato's disciples, though subject to his influence, like all other men of western civilization.

Third, in Plato's writings there is the suggestion that there

can be no finally satisfactory account of the system of the sciences which does not connect all reality with the Form of the Good by showing why it is best that things should be as they are. In the *Republic* he makes Socrates assert that the Form of the Good is the source both of being and of intelligibility. Almost certainly Plato did not wish to identify it with the god of whom he speaks in other places; but his language in this passage is like that of theists, and the intellectual satisfaction which he promises is like that which many later philosophers have hoped to furnish by relating all things to God. In Plato's argument the study which enables certain carefully selected guardians of his state to understand the system of "forms" by relating each to the Form of the Good is supposed to be also of the greatest practical importance because it enables the guardians to discern the best way of life for men and so to guide their fellow citizens aright; and again similar claims have been made by many later philosophers on behalf of their study. When men speak of a philosophy, they commonly mean a very general account of things which is likely to affect the outlook or emotional attitude of those who accept it (*e.g.*, by making them more contented or more confident) and also possibly to influence their conduct by making them prefer some course that they might otherwise have found uninteresting or even distasteful. In the west such claims have most often been made on behalf of systems which are in some way descended from Plato's, but talk of philosophy as a world view which affects practical life is to be found also among thinkers whom Plato would condemn as heretics (*e.g.*, among materialists of the Marxist persuasion). Nor is this surprising, since to most persons of any education "philosophy" still suggests the pursuit of wisdom.

Fourth, the intellectual insight of the philosopher-guardians in Plato's *Republic* is supposed to be gained by practice of a special method called dialectic. If we may judge by etymology, this word originally meant the art of discussion, but it was used by Zeno of Elea as a name for his own technique of establishing a conclusion by showing that the opposite thesis. put forward by a critic. led to self-contradiction. One of the difficulties in the interpretation of Plato's account of philosophy is to know whether he fully accepted Zeno's account of philosophical method and, if so. how in detail he thought this would help him to carry out his program. There is a less strict sense in which Socrates might be said to have practised dialectic when he asked his companions for definitions and then tested their suggestions for consistence with ordinary usage. In Aristotle's works an argument is called dialectical when it proceeds from commonly received opinions as distinct from premisses already known to be necessarily true. In later times, for example among the Stoics and again in the middle ages, the word "dialectic" was often used as a general name for logic; and later still it was applied by Hegel and Marx to a special pattern of development by thesis, antithesis and synthesis which they supposed to be characteristic of philosophical thought. Clearly there is room here for a great deal of misunderstanding, and we may suspect without much uncharitableness that a great deal of misunderstanding and muddle has in fact occurred. But it is safe to say that when philosophical method has been explicitly distinguished from the method of other studies it has commonly been held to consist in the clarification of concepts by a technique like Zeno's *reductio ad absurdum.*

"Natural Philosophy" and "Moral Philosophy."—Here, then, in Plato's work we can find four marks of that kind of thought which we in retrospect call philosophical. But it was a long time before the name "philosophy" came to be restricted in ordinary usage to such thought. In the work of Aristotle and his successors for many centuries it still covers all that now would be called science. When he required a name for the Platonic study, including his own criticism of Plato's theses. Aristotle called it "first philosophy"; but the collection of treatises which he wrote about it came to be called the *Metaphysics*, because it was placed "after the *Physics*" (μετὰ τὰ φυσικά) in the ordering of his works by his pupils. His other works were treatises on logic (though not under that name), physics. botany. animal anatomy and physiology, psychology, ethics, politics, rhetoric and poetics. For many centuries to come these treatises were regarded as sections in an encyclopaedia of philosophy; and, long after their authority had been attacked by thinkers of the Renaissance, the subjects of nhich they treated were still described as parts of philosophy. Apparently this usage continued in England when it had become obsolete in some other countries; at the beginning of the 19th century Hegel found it curious that opticians and the like should advertise themselves in English learned periodicals as "philosophical instrument makers." And even now there are survivals of the usage in the titles of certain old foundations: the *Philosophical Transactions* contain papers of all sorts submitted to the Royal society; and there are professors of "natural philosophy" who are engaged on nuclear research.

When the term "natural philosophy," which is a rendering of Aristotle's "physics," was appropriated in the 17th century to the new natural science of Galileo and Newton, it became customary to use the phrase "moral philosophy" to cover not only the field of Aristotle's "ethics" and "politics" but also psychology and all the other traditional parts of philosophy except logic. When he published his first work in 1739, David Hume called it *A Treatise of Human Nature, Being an Attempt to Introduce the Experimental Method of Reasoning Into Moral Subjects.* Except in such survivals as the name of the moral science faculty at Cambridge, the usage has now disappeared, but the explanation of its origin throws light on the development of men's conception of philosophy.

After the time of Aristotle, observational science was continued for a time in the museum of Alexandria and in some of the medical schools, but it ceased to have any place in the curriculums of the philosophical colleges which existed side by side in Athens until the time of Justinian. It is true that the Stoics and the Epicureans talked much of physics in their courses of instruction; but they meant by "physics" speculative systems of cosmology not subject to empirical test, and the philosophers of each school valued their own system chiefly for the bearing that they thought it to have on the way in which men should think of themselves and of their destiny. Thus universal determinism was an important doctrine for the Stoics because it suggested to them an attitude of religious resignation such as that found in Cleanthes' *Hymn to Zeus;* and atomism (which was later to inspire great scientific discoveries) found favour with Epicureans such as Lucretius because it could be made to furnish arguments against superstition. When a young man of Cicero's age went to study philosophy in Athens, the lectures that he heard consisted mostly of arguments for a certain way of life. No intelligent man could find a sufficient guide in the public religion of the time, and an interest in philosophy was not a sign that a man was more unsettled than his neighbours but rather a sign that he was more serious. All the schools preached imperturbability (*i.e.*, the calm which we still call philosophical), but they differed in the accounts which they gave of the good life; and so it was, for example, no accident that in the imperial period many great servants of the state belonged to the Stoic school.

The idea of philosophy which educated men of the 17th and 18th centuries got from their classical reading was that of a study concerned before all else with ends and duties; it was therefore not surprising that they called it moral philosophy when they wished to distinguish it from the new experimental science, then called natural philosophy. If they had read the works of the mediaeval schoolmen, they might perhaps have come to think of philosophy as something more ambitious; but they had no taste for the metaphysical subtleties of St. Thomas Aquinas or of Duns Scotus. Moreover, apart from all literary influences, there was a special reason why they should be interested at this time in moral philosophy. According to the new physics, nature was like a vast machine and all its parts, including living bodies, like smaller machines. If this was correct. how could men be held responsible for their behaviour? How indeed could purposive action of any kind be explained? Stoics and Epicureans had both said that all things were corporeal, but in their time such a declaration meant little more than a rejection of Platonism, because their natural philosophy was vague and undeveloped. Having said that souls consisted of a special sort of matter. they had been

content to go on talking about their thoughts and actions in the usual nay. Now such talk seemed silly, because men had come to think of matter as that which obeyed the laws of mechanics and this conception left no room for spiritual attributes. At this time there was therefore a great need for some account of human life which would show how talk of purpose and responsibility could be reconciled nith talk of mechanical regularity, and the attempt to find such an account was not unreasonably called moral philosophy, though it included difficulties that had never seriously worried the ancients.

Many of the books written to satisfy this need had titles such as *An Essay Concerning Human Understanding*. Sometimes the authors explained their choice by saying that they thought philosophy must begin nith an examination of the faculties by which men acquire knonledge, but there were many nho thought that a correct theory of knowledge nould provide also an immediate solution of the problem about the status of minds and their connection with bodies. In their different ways Spinoza. Leibniz. Berkeley Hume, Kant and Hegel all held this view of the task of philosophy Dugald Stewart probably went too far when he wrote at the beginning of the 19th century for the *Encyclopedia Britannica* (8th ed , vol i, p 227) that a change in the pursuits of philosophers had so altered the meaning of the word "metaphysics" that it nas now applicable to "a11 those inquiries. which have for their object to trace the various branches of human knouledge to their first principles in the constitution of our nature." But it is true that all ph~losophyother than natural science was thought to be concerned with the mind. If, as sometimes happened. the title "moral philosophy" seemed too narrow. it was replaced by the fuller phrase "mental and moral ph~losophy."

Philosophy Distinguished From the Special Sciences.— Since the middle of the 19th century it has become customary to describe physics, chemistry and biology as natural sciences rather than as branches of natural philosophy. and some parts of what was once called mental and moral philosophy have also attained independent status. Psychology, economics comparative philology, social anthropology and the theory of political institutions are all now established as empirical sciences. We may hesitate to call them natural sciences, "nature" being still used in some contexts to make a contrast with "man"; but we no longer count them parts of ph~losophysince they are now studied by specialists without regard to the other parts of the traditional field. In the 20th century even formal logic has become independent as the basic discipline of mathematics. What then is left for the philosopher? Only a study like that nhich Plato prescribed for his guardians, but one which is inevitably more complicated than his because of what has happened in the interval.

When we in our time say that philosophy is concerned with the relations of the sciences. we must take account of the distinction between the *a priori* and the empirical sciences and. within the latter group. of the distinctions betneen the physical, the biological and the psychological. None of these distinctions is wholly nen. but none of them could norry the ancients as they norry us. Plato was content to say that the study of the sensible world never deserved the name of science. and even Aristotle, uho was himself a good observer, had no clear conception of the inductive method by nhich the empirical sciences have advanced since the 17th century. There are also now difficulties of another kind that arise from the development of philosophy itself since antiquity. The demands that Plato and Aristotle hoped to satisfy seem to be natural in the sense that they arise whenever men think seriously about their situation; but it has been argued that some of them are misconceived and that there must therefore be included within the scope of ph~losophythe question whether some parts of the traditional enterprise are possible. Discussion of this matter is not wholly nen : it began with the sceptics of antiquity and was reviled many times notably by Hume and Kant in the 18th century. But it has become especially important in the 20th century when philosophy has been finally disentangled from the special sciences and criticism is more vehement than ever before.

No one wishes to deny that there are genuine problems about the relations of the sciences that can be solved only by hard thinking. The status of a ***priovi*** truth in relation to empirical science—in particular, the problem of the foundation of mathematics—is obviously one such. Another that looks as though it could never be solved by empirical methods is that of the connection between mind and body. From time to time we may despair of our ability to answer these questions, because none of the suggestions that has been put forward seems satisfactory and we can think of nothing better; but to admit this is not to say that there are no such questions. Similarly. no one wishes to deny that the hard thinking required to solve philosophical problems must be dialectical in a large sense of that word; *i.e*, not Hegelian or Marxian, but simply thinking in which we clarify concepts by exhibiting the relations betweem them and showing that denial of these relations would lead to absurdity. Many modern philosophers follow G E Moore in calling such thinking "analysis," and some use that nord as a synonym for philosophy much as Plato used his nord "dialectic." There are advantages in the adoption of a new name for the philosophical method. since "dialectic" may lead to misunderstandings for the reason explained above. But "analysis" in its turn may introduce the misleading suggestion that it is the business of philosophers to find what Lord Russell once called logical atoms.

So far there is no radical departure from the Platonic tradition. On the other hand, there has been strong opposition in the 20th century to all talk of a distinction between appearance and reality (in any but the common-sense way in which it may be said that someone appears bad-tempered but is really quite amiable) and to all talk of justifying a religious outlook by proving something about the norld as a whole (as. for example. that it was created by a benevolent God or that it will inevitably evolve toward some highly desirable consummation such as a classless and stateless society). The writers who are most active in this opposition sometimes call themselves positivists: but unlike Auguste Comte, who invented the name. or Kant. who preceded Comte in rejection of transcendent metaphysics. they do not base their case on the supposed difficulty or impossibility of getting any knowledge about objects that cannot be investigated by the methods of the positive sciences. Their thesis is more like the contention of Hume that it makes no sense to speak of such objects, but is based on considerations about language derived in large part from Ludnig Wittgenstein.

Positivist Criticism.— At first the philosophers of this modem positivist school maintained that no utterance in statement form could be literally significant unless it was either (a) a tautology, interesting only as an expression of conventions for the use of words, or (*b*) verifiable in experience. According to one epigrammatic formulation of their view, the meaning of a statement is the method of its verification. Taken strictly. this thesis commits the holder not only to phenomenalism (*i* e , to the doctrine that statements about material objects are reducible to statements about the sense experiences to be expected in various conditions) but also to solipsism (i e., to denial of the existence of other minds) and even to the assertion that statements about the past are meaningless unless they can be taken as predictions of the experiences which would be said to establish their truth. Phenomenalism was once favoured by many philosophers, in particular by positivists like Ernst Mach who disliked talk of imperceptible physical objects such as atoms; but solipsism is a doctrine that no one outside a lunatic asylum can find congenial, and the reduction of statements about the past to statements about the future is plainly absurd. There have therefore been various attempts to avoid these unpleasant consequences; it was argued by some enthusiasts. for example. that the really important task for a positivist philosopher is to show the possibility of the unification of science by the formulation of all significant statements in the language of physics. Whether this thesis about the sufficiency of the language of physics is true or false (and it seems to be false), it clearly involves a large departure from primitive positivism, since modern physics is full of statements about objects that are essentially imperceptible.

When theoretical physicists constantly make successful use of hypotheses about electrons that are much farther from the realm

of common sense than any speculations of St. Thomas about the behaviour of angels. even those who pride themselves most on the hardness of their heads must allow that there can be no objection in principle to talk of nonsensible objects. But critics of traditional philosophy may still argue with justice that it is powerless to prove all those propositions about suprasensible objects which have been asserted by philosophers in the past; for instance, such propositions as that the world was created by a benevolent God or that souls survive the death of their bodies. For the special method of philosophy is dialectical analysis, and it is evident (or can be made so without much difficulty) that a proof of such a proposition cannot be merely the clarification of a concept. In the past there has been some confusion about this because different kinds of inquiry have not been distinguished clearly one from another. Thus the proposition that there is a God has been taken by most people to be one that can receive empirical confirmation (*e.g.*, from events that look like answers to prayers), and philosophers who have tried to prove it have usually made some appeal to empirical evidence. But this same proposition has also been treated by some philosophers as one that cannot be weakened empirically (*e.g.*, by the absence of events that look like answers to prayers). The two views are incompatible, since no hypothesis can receive confirmation from experience unless it is also at least open to infirmation by experience. Another example of such confusion is to be found in the Marxist account of the evolution of society. According to its supporters, this is not only a scientific theory, well supported by historical evidence and useful for the making of predictions, but also a metaphysical principle that could never be thrown into doubt by the failure of the predictions which enthusiasts professed to have derived from it.

Since the peculiarity of such theses was first nqticed it has sometimes been suggested that it is characteristic of metaphysics to present as a *priori* truths propositions which could be established, if at all, only empirically. This is an unfortunate generalization (or, on another interpretation, an unfortunate proposal for a definition), because the work of Xristotle called *Metaphysics* contains only one book to which the criticism applies. For the most part he and his followers have discussed under this title such questions as the status of universals, the existence of substances (or basic entities) and the nature of causation: in short, problems that can be solved only by dialectical analysis, since they arise from puzzlement about concepts.

Clarification and Discovery. — In an account of the task of philosophy in the 20th century it is not necessary to strike out Plato's suggestion that dialectic will lead to knowledge of the nonsensible; for even positivistic philosophy is concerned with abstractions. But it must be appreciated that this study is something quite different from the concern with nonsensible objects noted in theology or in modern physics. Whereas the theologian and the physicist both profess. to give us information of which we should otherwise have no inkling. the philosopher, whose work is clarification. not discovery. can only set the familiar in a new light. As Socrates said, the answers to the questions which he asks must be known already in some fashion, though never before explicitly formulated Admittedly. philosophers in all ages have discussed questions about the existence of God and the survival of human souls, and many have professed to give proofs or disproofs of these theses. But this is not surprising; for such inquiries are closely connected nith the conceptual inquiries of the philosopher. If. for example, the immortality of the individual soul were proved empirically, we should say that the conclusion was of philosophical interest, not only because it has in the past interested some persons called philosophers, but also because the settlement of the question would involve the drawing of conceptual boundaries in a field which has so far been mapped only with dotted lines and pictures of monsters.

It may perhaps be thought curious that empirical discoveries should have any bearing on conceptual Inquiries: for we have an inclination to say that all questions about meaning must be settled before any questions about fact can be raised. But this is a mistake. In ordinary language, as distinct from the language of a strictly axiomatized system such as geometry, the boundaries of the applicability of nords are not drawn in advance of all applications; on the contrary, such rules as exist are established by usage. and it is often quite easy to think of circumstances for which there is as yet no rule. When the need arises, a rule is established by the adoption of some analogy which seems decisive at the time, and from then on the language is more determinate than it was before.

"Soul," which is the key word of the example. does not occur in ordinary talk. except in such phrases as "the life and soul of the party." It has, indeed, a usage in religious contexts but this depends on assertions that have not been verified in a fashion generally acceptable to scientists or even developed imaginatively to any satisfying degree of detail. We are therefore unable to understand exactly what we are asked to believe. Sometimes it seems relatively easy to imagine situations in uhich we should feel constrained to say that the survival of a soul had been proved; but at other times the supposition seems senseless. because personal identity is connected so intimately with bodily continuity that no incidents of the kind described by spiritualists could ever satisfy us. Getting messages through a medium from a dead man would undoubtedly be something like getting messages through the post from an absent friend; and, if the latter is to be taken as evidence of personal survival. why, it may be asked should not the former also? On the other hand, the survival of a friend who sends messages through the post cannot consist solely in our receipt of the letters; we must assume that he wrote the letters and dispatched them. Do we know even in outline what it means to say that the soul of a dead man has sent a message through a medium? And if not. what is the use of making the remark? The bewilderment which these reflections produce is a sign of the incompleteness of our intellectual map; but the recognition of that incompleteness is itself a philosophical achievement. In ordinary life continuity of memory and bodily continuity are both used as criteria of personal identity. Often one is used without the other, but only because they alnays give the same result when they can be applied together; and so our present use of the word "person" is tied to both, though we might come to use the word differently if the normal association of phenomena were not maintained.

Philosophy and Language. — In the latest phase of the philosophical movement started by Wittgenstein there is no longer any attempt to formulate a general principle for distinguishing between sense and nonsense, not because the supporters of the movement are less critical of the utterances of older philosophers but because they have come to appreciate that language is much more complicated than they once supposed and may therefore "go wrong" in very many different ways. According to this view, ordinary language — that is. the language in which men conduct their practical affairs — is part of the way of life to which it belongs, and all philosophical troubles arise from perversion of it. Words and phrases have meaning not necessarily by standing for things, as proper names may be said to do, but by having a customary use in communication. So long as speakers observe the customs. what they say must at least make sense. though it may of course be unfortunate in various ways. If. however, speakers depart from ordinary usage and introduce novelty. there is always a danger of their talking nonsense, even though the novelty has been suggested by an analogy with something in ordinary usage. Bad philosophy is the theorizing which arises in such situations. and good philosophy consists in making clear the conventions that have been violated. When ne are caught by bad philosophy. we are like flies trapped in a bottle; we buzz about continually, hurting ourselves against invisible barriers, unless we are clever and patient enough to crawl out slowly by the way by which we came in. In short, good philosophy is just liberation from bad philosophy, and its method is a therapeutic technique something like that of psychoanalysis.

It is not difficult to find examples of bad argument into which great philosophers have been led by false linguistic analogies. One about nhich there is no longer any serious dispute is the ontological argument for the existence of God. According to this, God must exist, because we mean by "God" a being such that nothing more perfect could be conceived, and there would there-

fore be a self-contradiction in saying that God does not exist. The reasoning is obviously based on the assumption that the word "exists" may be said to ascribe a perfection; that is, a character for the possession of which a thing is to be praised. But the word "exists" is not in fact used to ascribe a character to things. When we say that a so-and-so exists. we mean that something is a so-and-so: *i.e.,* we assert a proposition which is entailed by every proposition to the effect that a particular thing is a so-and-so. This truth has been accepted as a notable result of analysis in the philosophy of logic, and so there is here a clear case in which good and bad philosophy are related according to the account given above. It would be a serious mistake. however, to suppose that the history of philosophy is nothing but a succession of linguistic muddles. Even the debate about the ontological argument has an interest that is not explained by this description. In a society whose language did not allow for an assertion of existence by any such formula as "God exists" or "God is," the argument could never have occurred to anyone; but what made it seem plausible to Anselm and to a number of very intelligent men after him was something in their religious attitude. They used the word "God" to refer to the object on which that attitude could be appropriately directed, and it seemed to them plainly absurd to say that God's existence was contingent; *i.e.,* that there might have been no God. Now the fact that men have a disposition to take up a certain attitude furnishes no proof of the existence of anything that would be an appropriate object of that attitude; and it might be contended that our ancestors fell into a new and even more serious mistake when they passed from polytheism. with its stories of the birth of the gods, to monotheism, with its assertion of the absolute independence of God. But if there was any such mistake, it occurred long before anyone thought of the ontological argument, and there can be no satisfactory philosophy of religion which ignores this fact.

So too in other fields of philosophy, linguistic confusions when they occur are only incidental to larger problems that cannot be posed or solved without reference to the progress of the special sciences. Men do indeed misuse their language from time to time, but when such misuse has a philosophical interest it is a symptom rather than a cause of intellectual malaise. The patient who has brought himself to a metaphysical neurosis by a purely grammatical eccentricity does not exist outside the imagination of the would-be therapist. Nor is it much better to say. as some modern philosophers do, that all philosophical questions are concerned with "logical grammar." For if "logical" is to be taken in its usual sense (*i.e.,* as signifying connection with the science of logic). the statement is false: and no one has explained any other sense for the word that allows the statement to be both true and useful.

Relation of Philosophy to the Sciences.—The chief point of interest that has emerged from modern attempts to characterize philosophy is the importance of distinguishing dialectical or analytical inquiries about meaning from empirical inquiries about fact. Recognition of this should produce a becoming modesty in those who profess philosophy, but it should not make them abandon the Platonic ideal of a study that is synoptic, gives mastery of abstractions and leads to wisdom of attitude. By continuing to make the last of these traditional claims they do not commit themselves in advance to support of any religious system but simply undertake to present things in such a light that men's feelings may be reasonably grounded. The need for this is especially obvious in moral philosophy, since persons who are conceptually muddled often manifest great moral earnestness in defense of positions that are quite irrelevant to morality. But the need remains the same in all philosophical inquiries, including even discussions of the foundations of mathematics. For it is obvious to a careful observer that persons who put forward theses about the nature of mathematics are emotionally involved. and while it must be supposed that some of them are just confused. it must also be allowed that a certain attitude may perhaps be a necessary condition for the making of discoveries. Thus it can scarcely be an accident that no great mathematician has ever accepted the conventionalist view according to which mathematical truths are manmade.

It follows from the account of philosophy given here that it is impossible to summarize its results in the way appropriate to an article on any of the special sciences. The results of the philosophical work that has been done in the past are to be found in the present organization of studies. It cannot, indeed. be claimed yet that there is a single, coherent world view; but apart from the observations and hypotheses of scientists, there are some pieces of conceptual framework about which there is no serious disagreement among educated men. These are the principles used for the classification of studies in the universities and in encyclopaedias. In order to convince himself of their philosophical character the reader need only contrast. say, the *Encyclopædia Britannica* with Pliny's *Natural* History and notice that. the intellectual progress of the intervening 2.000 years has involved a clarification of ideas of explanation as well as an accuniulation of discoveries. If anyone claims that the clarification of ideas was incidental to the development of the special sciences. we can agree without difficulty; for the distinction made here between clarification and discovery is not supposed to be a division of labour among different faculties.

Organization of Philosophical Studies.—There must nevertheless be some division of academic labour in the modern world, since it is no longer possible for any one man to be a leader in all branches of learning. Perhaps Leibniz, who died in 1716, was the last universal scholar. and his life is a warning rather than an example. In this situation the teaching of philosophy is more difficult than ever before, but also more important. Since no one can hope to contribute much to the clarification of ideas in mathematics n-ho is not himself a mathematician: or to the clarification of ideas in physics who is not himself a physicist, and so on throughout the table of the sciences, it seems inevitable that there should be evolved a number of philosophical disciplines corresponding to the various branches of study whose concepts need investigation. We have philosophy of mathematics (or the theory of foundations). philosophy of physics (including cosmology), philosophy of history (no longer understood in the Hegelian sense as the setting out of a plan to be realized by events, but consisting in a study of historical ideas and methods), philosophy of law (or jurisprudence), philosophy of criticism (or aesthetics), philosophy of language and philosophy of religion. We may expect to hear also of philosophy of biology and philosophy of psychology. Whereas previously many scientists were frightened by talk of philosophy (and not without reason, since professional philosophers were sometimes obscurantists who opposed the growth of new studies), it seems now to be admitted that discussion of the philosophy of his subject (preferably in connection with its history) may be a useful part of the education of a future specialist.

Although some philosophical studies can be distributed among the various faculties of a university in the way suggested. there are others, including some of the most important. that cannot be associated with any specialism because the ideas with which they deal are common to all studies or not involved in any.

First there is epistemology, or the theory of knowledge and its relation to experience, to belief and to language. For Plato this was already an important philosophical inquiry, and in the 17th century it came to be regarded as the necessary preliminary to all other philosophical studies. The reasons for which epistemology obtained this primacy may have been bad; but if philosophy is the dialectical clarification of concepts. it may reasonably be expected to include some explanation of the need for such clarification. and the explanation should come early in a systematic course of study. At the beginning we need some examples of philosophical work taken from one of the special branches of philosophy mentioned above; but when we have learned to distinguish this kind of inquiry from others, we can profitably investigate the nature of the thinking that gives rise to it. This leads on naturally to a philosophical inquiry about the status of minds in the world.

Next there is metaphysics. Here belong not only the task of clarifying very general notions. such as those of substance and causality, but also attempts to throw light on the relations of the

sciences (in particular of physics and psychology) by philosophical method. System building has led to so many failures in the past that it must always be regarded with caution; yet it is important that the project should never be wholly abandoned by academic persons. For if academic persons behave as though they had no interest in the intellectual questions that seem most important to other men, the gap that they leave will soon be filled by others less qualified.

By the study and transmission of the history of thought academic persons can at least make it possible for men to see modern difficulties in perspective, and if the difficulties are of a sort to be solved by philosophical analysis, this is some contribution toward a solution.

Third there is ethics, or the philosophy of moral judgment. This cannot be assigned to any specialism other than philosophy itself, because moral judgment is not an activity for experts but something in nhich we are all authorities. In the past the teaching of ethics has often been confused nith casuistry (*i.e.,* the attempt to set out a detailed moral code by the compilation of moral judgments on situations of all possible varieties) or with exhortations to virtue. Like all other branches of philosophy, ethics is in fact a theoretical study in which we try to clarify concepts. If it has more immediate practical importance than any of the others. that is because muddles about the fundamental notions of morality can have serious consequences in human action. (W. C. K)

PHILOSTRATUS, "THE ATHENIAN" (c. 170–245), the author of the Life of *Apollonius* of *Tyana,* which he dedicated to Julia Domna. wife of Alexander Severus and mother of Caracalla (see APOLLONIUS OF TYANA). He wrote also Lives of the Sophists, *Gymnasticus* and *Epistolae* (mainly of an erotic character). Very little is known of his career. He was probably born in Lemnos, studied and taught at Athens and then settled in Rome. He is said by Suidas to have been living in the reign of Philip (224–249). The common authorship of *Apollonius* and Lives of *the* Sophists is presumed from internal evidence. The Lives are not biographical but picturesque impressions. The *Gymnasticus* contains interesting matter concerning the Olympic games and contests. The *Letters* breathe the spirit of the New Comedy and the Alexandrine poets; portions of Letter *33* are almost literally translated in Ben Jonson's "Song to Celia," "Drink to me only nith thine eyes." The Heroics, formerly attributed to Philostratus the Athenian but probably by another Philostratus ("of Lemnos"), is a disquisition on the heroes of the Trojan War. His other work is the Eicones, ostensibly a critical description of 64 pictures in a Neopolitan gallery.

PHILOXENUS, of Cythera (435–380 B.C.), Greek dithyrambic poet. On the conquest of the island by the Athenians he was taken as a prisoner of war to Athens, where he was purchased by the dithyrambic poet Melanippides, who educated him and set him free. Philoxenus afterward lived in Sicily, at the court of Dionysius, tyrant of Syracuse, whose bad verses he declined to praise; in consequence he was sent to work in the quarries. He later traveled in Greece, Italy and Asia, reciting his poems. and died at Ephesus. According to Suidas. Philoxenus composed 24 dithyrambs and a lyric poem on the genealogy of the Aeacidae. His dithyramb seems to have been a sort of comic opera, and the music, composed by himself, of a debased character. His masterpiece was the Cyclops, a pastoral burlesque on the love of the Cyclops for the fair Galatea, written to avenge himself upon Dionysius. who was wholly or partially blind of one eye. Aristophanes parodied it in the *Plutus* (290). Philoxenus' popularity is attested by a complimentary resolution passed by the Athenian senate in 393.

PHILOXENUS (Syriac, AKSENAYA) (*fl.* c. 500) of Mabbog, one of the best of Syriac prose writers and a champion of Monophysite doctrine was a Persian, born at Tahal in the district of Beth Garmai east of the Tigris. Educated at Edessa, Philoxenus soon attracted notice by his strenuous advocacy of Monophysite doctrine, and on the expulsion of Calandio (the orthodox patriarch of Antioch) in 485 was ordained bishop of Mabbog (Hierapolis) by his Monophysite successor Peter the Fuller. Probably during the earlier years of his episcopate Philoxenus composed his 13 homilies on the Christian life. Later he revised the Syriac version of the Bible and with the help of his chorepiscopus Polycarp produced in 508 the so-called Philoxenian version, used by the Monophysites during the 6th century. He bitterly opposed Flavian II, who had accepted the decrees of the council of Chalcedon and was patriarch of Antioch from 498 to 512. In 512 the Monophysites finally ousted and replaced him by their partisan Severus. But Justin I, nho succeeded Anastasius in 518, was less favourable to Severus and Philoxenus, and in 519 they were sentenced to banishment. Philoxenus was sent to Philippopolis in Thrace and afterward to Gangra in Paphlagonia, where he met his death by foul play in 523.

PHIPS or PHIPPS. **SIR WILLIAM** (1651–1695), colonial governor of Massachusetts, was born Feb. 2. 1651, at Woolnich. Me.. near the mouth of the Kennebec river. In 1687, with a commission from the British crown, he found after a search of many years a wrecked Spanish treasure ship for which he was knighted by James II and appointed sheriff of New England. Poorly educated and ignorant of law, Phips could accomplish little and returned to England. In 1689 he returned to Massachusetts He was appointed commander of an expedition against the French in Canada which sailed in April 1690 and easily captured Port Royal. A larger expedition led by Phips in July against Quebec and Montreal ended disastrously. In 1690 he returned to England and with Increase Blather urged a restoration of the colony's charter, annulled during the reign of Charles II. The crown, at Mather's suggestion, appointed him the first royal governor under the new charter. On reaching Boston in May 1692, Phips found the colony in a disordered condition and, though honest and persevering. he was unfitted for the position. Numerous complaints to the home government resulted in his being summoned to England to answer charges. While in London awaiting trial, he died Feb. 18, 1695.

PHITSANULOK, a province (changwat) and town in north central Thailand. Pop. (1956 est.) 296.358. Area 3,729 sq mi. The province extends from the Laos border in the northeast to the Nan-Yom river system in the southwest. The population is concentrated in the western plains. the eastern districts of Nakhonthai and Wangthong being isolated and underdeveloped. The province is a major producer of rice and has several commercial rice mills. The provincial capital Phitsanulok, pop. (1957 est.) 26.778. is situated about 240 mi. from Bangkok on the railroad to Chiengmai, which runs along the east bank of the Nan. During most of the Ayutthayan period (1350–1767), Phitsanulok town ranked second in size and importance to the royal capital; two of the greatest kings of the era, Naresuan and Ekathotsarot. were native sons. Near the centre of the old walled city is one of Thailand's most revered Buddhist temples. Wat Phra Si Rattana Mahathat. which houses an early bronze Buddha famed for its beauty. The town's commercial centre, which lies south of the city walls, grew rapidly after the construction of the motor road to Sukhothai and Tak in the 1940s. (G. W. SK.)

PHLEBITIS, a medical term for inflammation affecting veins. A distinction is being made between an inflammation of the vein with a blood clot (thrombophlebitis) and a noninflammatory clot in a vein (phlebothrombosis).

Usually the venous condition results from inflammation in tissue surrounding the vessel and extending to its walls. The vein becomes thickened and can be recognized as a definite, perhaps reddened. and very painful cord if it is a superficial vein. When the inflammation extends to the inner coat of the vessel and nutrition of the lining endothelium is impaired, local clotting of blood occurs, the clot being adherent to the vessel wall where it is first formed and extending upward and downward within the lumen (see THROMBOSIS AND EMBOLISM). From the primary focus clotting extends also into the tributaries of the vein, thus inducing widespread obstruction to the return of blood from the part with consequent edema. The condition calls for complete rest because of the danger of dislocating the clot and causing embolism, the danger being greatest when the condition is septic. In most cases, under rest, the inflammation subsides and the primarily affected vein becomes permanently occluded by newly formed

fibrous tissue, but circulation in the part formerly drained by the vein is restored by the opening up of collateral channels. In some regions phlebitis is particularly dangerous; *e.g.*, the lateral sinus to which inflammation from middle ear disease may extend with subsequent cerebral abscess or purulent meningitis or general pyemia. In such cases surgery is the sole hope for the patient.

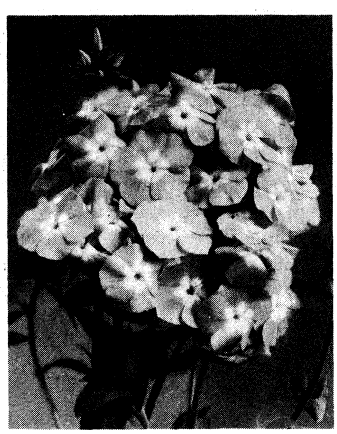
PHLOGISTON: *see* CHEMISTRY: *Theory of Phlogiston.*

PHLOGOPITE, a mineral of the mica group used as an insulator for electrical purposes. Mica mined in Canada and Ceylon is mainly phlogopite, a magnesium mica differing from biotite (black mica) in containing little iron. Sometimes brownish-red and coppery in appearance. it is named from the Greek for "fiery-looking." Usually yellowish-brown, sometimes quite colourless and transparent, it often has a silvery lustre on the cleavage surfaces, hence the names "amber mica" and "silver mica" for some varieties. Phlogopite occurs chiefly as scales and plates embedded in crystalline limestones. The cleavage flakes are not so elastic as those of muscovite (white mica). In Canada it occurs with apatite in pyroxene rocks associated with Laurentian gneisses and crystalline limestones. The principal mining district is in Hull county, Quebec, and near Burgess in Lanark county, Ontario. In Ceylon the mineral forms irregular veins, rarely exceeding one or two feet in width, traversing granulite, especially near the contact of this rock with crystalline limestone. . For the chemical formula and optical and other characters, *see* MICA.

PHLOX, the type genus of the phlox family (Polemoniaceae); the genus consists of about 60 species, mostly perennial hardy plants of great beauty, natives of North America (one Asian), with entire, usually opposite, leaves and showy flowers generally in terminal clusters. Each flower has a tubular calyx with five lobes, a salver-shaped corolla with a long slender tube and a flat flaring edge. The five stamens are given off from the tube of the corolla at different heights and do not protrude beyond it. The ovary is three-celled with one to two ovules in each cell; it ripens into a three-valved capsule. Many species and varieties are tall herbs yielding a wealth of bloom throughout the summer and early autumn. They require a deep, rich, rather heavy loam and a cool moist position.

The dwarf perennial species and varieties, the moss pinks of gardens (P. *subulata),* are suitable plants for the rockery, and as edging to beds and borders. They are trailing and tufted in habit, the branches rooting at the nodes. They succeed in poorer soil and drier situations than the tall kinds. Seed is seldom produced. Propagation is effected by cuttings in July and early August (placed in a cold frame) and by division of the plants, which should be lifted carefully and cut into rooted portions as required. The tufted kinds decay in patches in winter if the situation is too moist.

Phlox drummondi (often called Texan pride) and its numerous varieties are annual, small-growing, hairy plants up to 1½ ft. in height. flowering profusely during the summer months. For earlv flowering they should be sonn indoors in March and April and transferred out-of-doors in June; they succeed if sown out-of-doors in midspring, but the flowering season is later and shorter.



J HORRCE MCFARLAND COMPANY

PHLOX (PHLOX DRUMMONDI)

The tall-growing border phloxes are divided into early and late flowering kinds respectively, the former derived mainly from P. *glaberrima* and *P. carolina,* the latter from *P. maculata* and *P. paniculata,* both common in moist woods in eastern North America. Over 200 horticultural varieties comprising some of the finest garden perennials have been derived from these by selection and hybridization. Phlox come in a large variety of colours, but there are no yellows or true blues. Many of the popular garden sorts have been successfully grown in England; P. *drummondi* and varieties: *P. subulata* and some of the taller border sorts are widely used there as colourful garden subjects.

Since practically all the phlox species are natives of North America, with handsome representatives in every section of the Cnited States, adoption of the genus as the floral emblem or national flower of the U.S. has been urged.

The so-called blue phlox (really a mauve colour) or wild sweet william (P. *divaricata*) is found throughout the woods of east coastal and southern North America. The night phlox is *Zaluzianskya capensis* and the prickly phlox is *Gilia californica.*

(N. TR.)

PHNOM PENH, capital of Cambodia, is situated 125 mi. N.W. of Saigon at the confluence of the Mekong river and the Tonle Sap. The estimated population in 1958, including communities of far eastern nationalities and Europeans, was 400,000.

According to the legend of the town's history, a woman called Penh came in the 14th century to live on the slopes of the hill (Phnom in Cambodian) overlooking the town. A bronze statue of Buddha, which she found in a tree trunk, swept to the foot of the hill during a flood and attracted a crowd of pilgrims, many of whom settled in the vicinity. In 1434 King Ponhéa Yat built his capital on the site. Subsequent kings chose Oudong, but in 1865 King Norodom I once again established the capital in Phnom Penh.

It is a picturesque town at the centre of which is the royal palace with its silver pagoda, throne room and museum. As well as archaeological museums there is the Jayavarman VII art museum. In the associated art school the traditional crafts of weaving and goldsmith's work are taught with modern adaptations. Mimed performances of Buddhistic and Brahminical legends are given by the Royal Company of Cambodian Dancing Girls, wearing gorgeously embroidered clothes. There are schools and a Buddhist university for Pali and Buddhist studies. Although 173 nautical mi. from the sea, Phnom Penh is a major trading port in the Mekong valley. It is accessible all year round to shipping. Cattle, dried fish, rice, maize! cotton and pepper are the chief items of trade. Textiles and soft drinks are manufactured. Steamers connect Phnom Penh with Saigon and many towns on the Mekong and Tonle Sap. Excellent roads lead to Saigon, Angkor and Bangkok; Phnom Penh is also connected by road with Kompong Som, the new seaport being built on the Gulf of Siam about 137 mi. from the capital. There are railways to Bangkok, Saigon and (via Bangkok) Singapore. The airport, from which services operate to Bangkok, Hong Kong and Saigon, is at Pochentong, 5 mi. from the city.

PHOCAEA (mod. *Fokia* or *Fokha),* an ancient city on the western coast of Asia Minor, famous as the mother city of Marseilles. It was the most northern of the Ionian cities, and was situated on the coast oi the peninsula which separates the Gulf of Cyme, occupied by Aeolian settlers, from the Hermaean gull, on which stood Smyrna and Clazomenae. According to Herodotus the Phocaeans were the first of all the Greeks to undertake distant voyages, and made known the coasts of the Adriatic, Tyrrhenia and Spain. Eventually they determined to seek a new home in the west, where they already had flourishing colonies; *e.g.,* Alalia in Corsica and Massilia (mod. *Marseilles*).

Phocaea continued to exist under the Persian government, but greatly reduced in population and commerce. Though it joined in the Ionian revolt against Persia in 500 it was able to send only three ships to the combined fleet which fought at Lade. But a Phocaean took the supreme command. The modern town in the immediate neighbourhood, still known as Fokia, was founded by the Genoese in 1421 on account of the rich alum mines in the neighbourhood.

PHOCAS, East Roman emperor (602–610), a Cappadocian.of humble origin. He was only a centurion when chosen by the army of the Danube to lead it against Constantinople. A revolt within the city resulted in the abdication of the reigning emperor Maurice and the elevation of Phocas to the throne: he proved incapable of governing. When the African governor Heraclius declared against him, Phocas was deposed with scarcely a struggle (610). He died in the same year on the scaffold.

PHOCION, Athenian statesman and general, was born about 402 B.C., the son of a small manufacturer. He became a pupil of Plato and in later life was a close friend of Xenocrates. Under

Chabrias he distinguished himself in the great sea-fight of Naxos (376), and subsequently won the confidence of the allies by his justice and integrity. In 351–349 he entered the Persian service and helped to subdue a rebellion in Cyprus. Henceforward he always held a prominent position in Athens. and although he never canvassed he was elected general forty-five times in all. In politics he is known chiefly as the consistent opponent of the anti-Macedonian party. He countered the eloquence of Demosthenes and his supporters by the plain facts of Athens' situation. He helped to defend Aeschines in 343, and secured lenient terms from Philip after the disaster of Chaeroneia (338). He also rendered good service in the field: in 348 he saved the force operating against the philo-Macedonian tyrants in Euboea by the brilliant victory of Tamynae. Under the Macedonian predominance his reputation increased. Though by no means inclined to truckle to the Macedonians, as is shown by his protection of the refugee Harpalus and his spirited campaign in defense of Attica in 322, he won the confidence of the conquerors, and in the restricted democracy which Antipater enforced he became the virtual ruler of Athens. On the restoration of the democracy in 318, Phocion was deposed. He fled to Polyperchon, but was sent back to be tried at Athens. The assembly shouted Phocion down and condemned him to death unheard. Not long after, the Athenians decreed a public burial and a statue in his honour.

See Plutarch, *Life of Phocion;* Holm. *Gk. Hist.* vol. iii. (Eng. trans., London, 1896).

PHOCIS, an ancient district of central Greece (now two departments, Phthiotis and Phocis; area 1,620 sq.mi. and 802 sq.mi.; pop. 148,322 and 51,472, respectively), bounded west by Ozolian Locris and Doris, north by Opuntian Locris, east by Boeotia and south by the Corinthian gulf. The massive ridge of Parnassus (8,061 ft.) traverses the heart of the country. Between this and the northern frontier range of Cnemis (3,000 ft.) is the narrow fertile valley of the Cephissus, along which lie most of the Phocian townships. South of Parnassus the small plains of Crisa and Anticyra are separated by Mt. Cirphis. Phocis was mainly pastoral.

Its early history is obscure. Its population was reckoned Aeolic, but the dialects are of the West-Greek group, more akin to Doric. There was a tradition that the Phocians once owned land round Daphnus opposite Euboea, and had their frontier at Thermopylae. Later restriction of territory was due to the hostility of Boeotia and Thessaly. The latter in the 6th century even raided the Cephissus valley. In early days Phocians controlled the sanctuary of Delphi. But Delphi constantly strove for independence and about 590 B.C. induced a coalition of Greek states to proclaim a "Sacred War" and free the oracle from Phocian supervision. Thus Phocian influence at Delphi was restricted to the possession of two votes in the Amphictyonic Council.

During the Persian invasion of 480 the Phocians at first joined in the national defense, but their irresolute conduct lost Thermopylae for the Greeks; and at Plataea they were on the Persian side. In 457 an attempt to control the head waters of the Cephissus in the territory of Doris brought a Spartan army into Phocis in defense of the "metropolis of the Dorians." A similar attack on Delphi in 448 was again frustrated by Sparta, but not long afterwards the Phocians recaptured the sanctuary with the help of the Athenians, with whom they became allied in 454. When Athenian land-power declined, Phocian friendship waned, and in the Peloponnesian War Phocis was nominally an ally of Sparta, and had lost control of Delphi.

In the 4th century Phocis was constantly endangered by Boeotian oppression. After helping Sparta to invade Boeotia during the Corinthian War (395–394), the Phocians received assistance from Sparta in 380, but afterwards submitted to the growing power of Thebes. Phocians took part in Epameinondas' earlier inroads into the Peloponnesus, but abstained from the campaign of Mantineia (370–362). In return for this negligence the Thebans secured a penal decree against them for religious offenses from the Amphictyonic synod (356). The Phocians, led by two capable generals, Philomelus and Onomarchus, replied by seizing Delphi and using its riches to hire mercenaries with whose help they invaded Boeotia and Thessaly, and though driven out of Thessaly by Philip of Macedon, maintained themselves for ten years, until the exhaustion of the temple treasures and the treachery of their leaders placed them at Philip s mercy. In 339 the Phocians began to rebuild their cities; in 338 they fought against Philip at Chaeroneia; in 323 they took part in the Lamian War against Antipater, and in 279 helped to defend Thermopylae against the Gauls.

During the 3rd century Phocis passed into the power of Macedonia and of the Aetolian League, to which in 196 it was annexed. Under Roman rule its league was dissolved, but was revived by Augustus, who also restored to Phocis the votes in the Delphic Amphictyony which it had lost in 346 and enrolled it in the new Achaean synod. The Phocian League is last heard of under Trajan.

PHOCYLIDES, Greek gnomic poet of Miletus, contemporary of Theognis, was born about 560 B.C. A few fragments of his "maxims" have been preserved (chiefly in the *Florilegium* of Stobaeus). A complete didactic poem called Ποίημα νουθετικόν or γνῶμαι, and which bears the name of Phocylides, is now considered to be the work of an Alexandnan Christian of Jewish origin who lived between 170 B.C. and A.D. 50.

See fragments and the spurious poem in T. Bergk, *Poetae lyrici graeci,* ii. (4th ed., 1882); J. Bernays, *Über das Phokylideische Gedicht* (1858); *Phocylzdes, Poem of Admonition,* with introduction and commentaries by J. B. Fenling, and translation by H. D. Goodwin (Andover, Mass., 1879). There is an English verse translation by W. Hewett (Watiord, 1840), *The Perceptive Poem of Phocylzdes.*

PHOEBE (*Sayornis phoebe*), the name given to a familiar American bird belonging to the family *Tyrannidae* (the "American flycatchers"). Distinguished by its dark crown-cap, olive-grey plumage, and the white outer vane to the outer tail feather, the phoebe breeds in eastern North America from the south-west Mackenzie southwards, wintering in southern U S A. and Mexico. The bulky nest of moss and mud, lined with grass, hair and feathers, is placed on a beam or under a bridge or bank, often close to or on a building. Say's phoebe (*S. sayi*) is a more westerly species, abundant west of Kansas and Nebraska. The black phoebe (*S. nigricans*) has a more southern range.

PHOEBUS, a common epithet of Apollo (*q.v.*).

PHOENICIA, in ancient geography, the name given to that part of the seaboard of Syria and Lebanon which extends from the Eleutherus (Nahr el-Kebir) in the north to Mt. Carmel in the south, a distance of more than 2° lat. These limits, however, mere exceeded at various times; thus, north of the Eleutherus lay Aradus and Marathus, and south of Carmel the border sometimes included Dor and even Joppa (Jaffa). The harbours which played so important a part in antiquity are nearly all silted up, and, with the exception of Beirut, afford no safe anchorage for large modern vessels. Sidon, Tyre and Aradus, though now connected with the mainland, were built originally upon islands; the Phoenicians preferred such sites, because they were convenient for shipping and easily defended against attack.

The chief towns of ancient Phoenicia. as we know of them from the Amarna tablets (15th century B.C.) and from Egyptian, Assyrian and the Old Testament documents were the following: Acco (now Acre or ʿAkkā, Judg. i. 31), Achzib (now ez-Zib, ibid.), Ahlab (in Assyrian Mahalliba, *ibid.*)—three towns on the coast south of Tyre, Kānāh (Josh. xix. 28). Tyre (Phoen. Sōr, now Sūr), Zarephath or Sarepta (1 Kings xvii. 9 [now Sarafand]), Sidon (now Ṣaidā), Berytus (Biruta in Egyptian. Biruna in the Amarna tablets. now Beirūt), Byblus (in Phoen. and Hebr. Gebal, now Jebeil), Arka, 80 mi. north of Sidon (Gen. x. 17, now ʿArkā), Sin (Assyr. Siannu, ibid.), Simyra (Gen. x. 18, now Ṣumrā), Marathus (non Amrit) not important till the Macedonian period, Arvad or Aradus (in Phoen. Arwād. now Ruād Gen. x 18; Ezek. xxvii. 8, 11), the most northerly of the great Phoenician towns:

Race and Language.—The Phoenicians nere an early offshoot from the Semitic stock. and belonged to the Canaanite branch of it. The Phoenicians themselves believed that they had migrated from an eastern shore, probably meaning Babylonian.

By settling along the Syrian coast they developed a strangely un-Semitic love for the sea, and advanced on different lines from the other Canaanites who occupied the interior. They called themselves Canaanites and their land Canaan; such is their name in the Amarna tablets, *Kinaḫḫi* and *Kinaḫni;* and with this agrees the statement assigned to Hecataeus (Fr. *hist.* gr., i. 17) that Phoenicia was formerly called Χνᾶ (*Chnâ*) a name which Philo of Byblus adopts into his mythology by making "Chna who was afterwards called Phoinix" the eponym of the Phoenicians (Fr. *hist.* gr., iii. 569). In the reign of Antiochus IV. and his successors the coins of Laodicea of Libanus bear the legend "Of Laodicea which is in Canaan" (Cooke, North-Semitic Inscriptions, quoted as *NSI.,* No. 149 B 8); the Old Testament also sometimes denotes Phoenicia and Phoenicians by "Canaan" and "Canaanites" (Isa. xxiii. 11; Obad. 20; Zeph. i. 11), though the latter names generally have a more extended sense. But "Sidonians" is the usual designation both in the Old Testament and in the Assyrian monuments (Sidunnu); and even at the time of Tyre's greatest ascendancy we read of Sidonians and not Tyrians in the Old Testament and in Homer; thus Ethbaal, king of Tyre (Jos., Ant., viii. 13, 2) is called king of the Sidonians in 1 Kings xvi. 31. In the Homeric poems we meet with Sidonioi, *Sidoniē* (Od., iv. 618; *Il.,* vi. 290; *Od.,* xiii. 285; Il., vi. 291) and Pkoinikes, *Phoinikē* (Od., xiii. 272, xiv. 288 seq., etc.), and both terms together *(Od.,* iv. 83 seq., *Il.,* xxiii. 743 seq.). And the Phoenicians themselves used Sidonians as a general name; thus in one of the oldest Phoenician inscriptions (CIS., i. 5=*NSI.,* No. 11), Hiram II., king of Tyre in the 8th century, is styled "king of the Sidonians." But among the Greeks "Phoenicians" was the name most in use, *Phoinikes* (plur. of Phoinix) for the people and *Phoinikē* for the land. The former was probably the older word and may be traced to *phoinos*="blood-red"; the Canaanite sailors were spoken of as the "red men" on account of their sunburned skin.

Language.— Inscriptions, coins, topographical names preserved by Greek and Latin writers, names of persons and the Punic passages in the *Poenulus* of Plautus, all show conclusively that the Phoenician language belonged to the North-Semitic group, and to that sub-division of it which is called the Canaanite and includes Hebrew and the dialect of Moab. A comparison between Phoenician and Hebrew reveals close resemblances both in grammatical forms and in vocabulary; in some respects older features have been preserved in Phoenician, others are later, others again are peculiar to the dialect; many words poetic or rare or late in Hebrew are common in Phoenician. Hence we may conclude that the two languages developed independently from a common ancestor, which can be no other than the ancient Canaanite, of which a few words have survived in the Canaanite glosses to the Amarna tablets (written in Babylonian). But in forming an estimate of the Phoenician language it must be remembered that our material is scanty and limited in range; the Phoenicians were in no sense a literary people; moreover, except the inscriptions found at Gebal, now Jebeil, (10th century) and NSI. No. 11, most of the inscriptions are subsequent to the 6th century B.C.; the majority belong to the 4th century and later, by which time the language must have undergone a certain amount of decay. Indirectly, however, the Phoenicians rendered one great service to literature; they took a large share in the development and diffusion of the alphabet which forms the foundation of Greek (Herod., v. 58) and of all European writing. The Phoenician letters in their earlier types are practically identical with those used by the Hebrews, the Moabites, and the Aramaeans of north Syria (NSI., Plates xii., xiii). They passed through various modifications in the course of time; after leaving the mother country the script acquires a more cursive flowing style on the stones from Cyprus and Attica; the tendency becomes more strongly marked at the Punic stage; until in the neo-Punic, from the destruction of Carthage (146 B C.) to the 1st century AD., both the writing and the language reached their most degenerate form. As a rustic dialect the language lasted in north Africa till the 5th century A.D. In his sermons St. Augustine frequently quotes Punic words. The oldest specimens of Phoenician writing at present known have been found at Gebal. In 1922 Montet unearthed the sarcophagus of Ahiram, incised with a Phoenician inscription in an archaic form of lettering, which bears a close resemblance to the inscription of Abi-baal, discovered some years ago on the same site.

History.— The Phoenicians, in imitation of the Egyptians, claimed that their oldest cities had been founded in remote antiquity; but no certainty can be attached to the traditional chronologies; *e.g.,* Herod., ii. 44; Justin, xviii. 3; Menander in Jos., Ant., viii. 3, 1 and c. Ap., i. 18.

Phoenicia comes into history proper c. 1600 B.C., when the Egyptian empire began to extend in the direction of Asia under Ahmosi (Amasis) I.; who carried his arms into Syria, and conquered at least Palestine and Phoenicia, the latter being the country called Da-hi on the Egyptian monuments (Miiller, As. u. *Eur.,* p. 181), Thothmes III. (1503–1449) repeated and consolidated the 'earlier conquest, and established Egyptian suzerainty over all the petty states of Syria and Phoenicia (*see* EGYPT: History). For the geography and civilization of Canaan about 1400 B.C. we have valuable evidence in the Egyptian papyrus Anastasi I., which mentions Kepuna (Gubna, Gebal-Byblus) the holy city, and continues: "Come then to Berytus, to Sidon, to Sarepta. Where is the ford of Nat-'ana (?Nahr el-Ḳāsimīyeh, or a town)? Where is 'Eutu (?Ushu, Palaetyrus)? Another city on the sea is called a haven, D'ar (Tyre) is its name, water is carried to it in boats; it is richer in fish than in sands." But the fullest information about the state of Phoenicia in the 15th and 14th centuries B.C. comes from the Amarna tablets, among which are many letters from the subject princes and the Egyptian governors of Phoenicia to the Pharaoh. It was a time of much political disturbance. The Hittites (*q.v.*) were invading Syria; nomads from the desert supported the invasion; and many of the local chiefs were ready to seize the opportunity to throw off the yoke of Egypt. The towns of Phoenicia were divided; Aradus, Simyra, Sidon supported the rebellion; Rib-addi, the regent of Byblus, and Abi-melech, king of Tyre, held out for Egypt; but while all the towns made professions of fidelity, they were scheming for their own interests, and in the end Egypt lost them all except Byblus. The tablets which reveal this state of affairs are written in the language and script of Babylonia, and thus show indirectly the extent to which Babylonian culture had penetrated Palestine and Phoenicia; at the same time they illustrate the closeness of the relations between the Canaanite towns and the dominant power of Egypt. After the reign of Amenophis IV. (1376–66) that power collapsed altogether; but his successors attempted to recover it, and Ramses (Rameses) II. reconquered Phoenicia as far as Beirut, and carved three tablets on the rock beside the Nahr el-Kelb (Gressmann, Texte *u.* Bilder[2] ii. Pl. lxv.). In the reign of Ramses III. (c. 1200) many great changes began to occur owing to the invasion of Syria by peoples from Asia Minor and Europe, which ended in the establishment of the Philistines on the coast near Ashkelon. The successors of Ramses III. lost their hold over Canaan; the 21st dynasty no longer intervened in the affairs of Syria; but Sheshonk (Shishak), the founder of the 22nd dynasty, about 928 B.C. endeavoured to assert the ancient supremacy of Egypt (cf. 1 Kings xiv. 25 sqq.), but his successes were not lasting, and, as we learn from the Old Testament, the power of Egypt became henceforward ineffective.

Independence of **Phoenicia.**—Between the withdrawal of the Egyptian rule in Syria and the western advance of Assyria there comes an interval during which the city-states of Phoenicia owned no suzerain. Gebal had kings of its own, Ahiram, Ithobaal, Abi-baal, in the 10th century, as recent excavations have shown. The history of this period is mainly a history of Tyre, which not only rose to a sort of hegemony among the Phoenician states, but founded colonies beyond the seas (p. 769). From 970 to 772 B.C. the bare outline of events is supplird by extracts from two Hellenistic historians, Menander of Ephesus and Dius (largely dependent upon Menander), which have been preserved. by Josephus, Ant., viii. 5, 3 and c. *Ap.,* i. 17, 18. From the data given in these passages we learn that Hiram I., son of Abi-baal, reigned in Tyre from 970 to 936 B.C. The Tyrian annals, more-

over, alluded to the connection between Hiram and Solomon. Before this time, indeed, the Phoenicians had no doubt lived on friendly terms with the Israelites (cf. Judges v. 17; Gen. xlix. 13); but the two nations seem to have drawn closer in the time of Solomon. 2 Sam. v. 11, which brings David and Hiram together, probably antedates what happened in the following reign. For Solomon's palace and temple Hiram contributed cedar and fir trees as well as workmen, receiving in exchange large annual payments of oil and wine, supplies which Phoenicia must have drawn regularly from Israelite districts (1 Kings v. 9, 11; cf. Ezek, xxvii. 17; Ezr. iii. 7; Acts xii. 20; Jos., *Ant.* xiv. 10, 6); finally, in return for the gold which he furnished for the temple, Hiram received the grant of a territory in Galilee (Cabul, 1 Kings ix. 10–14). This alliance between the two monarchs led to a joint expedition from Eziongeber on the Gulf of Xkaba to Ophir (?on the east coast of Arabra, see Ophir) for purposes of trade. The list of Hiram's successors given by Josephus indicates frequent changes of dynasty until the time of Ithobal I., priest of Astarte, whose reign (887–855) marks a return to more settled rule In contrast to Hiram I., king of Tyre, Ithobal or Ethbaal is styled in 1 Kings xvi. 31 "king of the Sidonians," *i.e.,* of the Phoenicians, showing that in the interval the kings of Tyre had extended their rule over the other Phoenician cities. Under Ethbaal further expansion is recorded; Botrys north of Byblus and Aoza in north Africa are said to have been founded by him (Jos., Ant., viii. 13, 2); the more famous Carthage owed its origin to the civil discords which followed the death of Metten I. (*c.* 851), his next successor but one. According to tradition, Metten's son Pygmalion (c 860–814) slew the husband of his sister Elissa or Dido; whereupon she Aed and founded Carthage (*q.v.*) in Libya (Justin, xviii. 4–6). At this point Josephus's extracts from Menander end, see Schrader, KAT., 3rd ed. 12G ff.).

Assyrian Rule, 876–605 **B.C.**—From the time of Ethbaal onwards the independence of Phoenicia was threatened by the advance of Assyria. In 868 B C. Assur-nasir-pal II. "washed his weapons in the great sea," and exacted tribute from the kings of Tyre, Sidon. Byblus and other cities, including Arvad (*Keilinschr. Bibliothek,* i. 109). The inscriptions of his son Shalmaneser III. mention the taking of tribute from the Tyrians and Sidonians in 842 and again in 839; the Byblians are included at the latter date, and among the kings defeated at Karkar in 8j4 or 853 was Metten-baal, king of the Arvadites (ibid., pp. 141, 143, 173). Thus Shalmaneser established a supremacy which lasted for over a hundred years and was acknowledged by occasional payments of tribute In 741 Tiglath-pileser III. mentions on his tribute-lists "Ḥirûm of Tyre"; and here a piece of native evidence becomes available. An early Phoenician inscription (CIS. i. 5 = *NSI.* No. 11), engraved upon the fragments of a bronze bowl, mentions a certain governor of Qarth-hadasht (or Karti-Hadasti. "New City," *i.e.,* Citium), "servant of Hiram king of the Sidonians to Baal of Lebanon," showing that this Hiram II. was not only king of Tyre. as the Assyrian inscription calls him, but of Sidon too: and further, that by this time Tyre has established a colony in Cyprus (q v.). In Tiglath-pileser's Philistine campaign of 734 Byblus and Xradus paid tribute. and a king of Tyre, Metten. nas forced to do the same (*KB.* ii. 23). For the period which follows a certain amount of information is furnished by Menander (in Jos, *Ant.*, ix. 14. 2). Elulaeus IX., in Assyrian Luli, nho ruled under the name of Pylas, mas king of Tyre. Sidon. and other cities at this time (c. 725–690), and at the beginning of his reign suffered from an invasion by Shalmaneser V.; this was probably the expedition against Hoshea of Samaria in 725; "the king of Assyria . . . overran all Phoenicia, but soon made peace with them all and returned back." In the reign of Snrgon Phoenicis itself seems to have been left alone, though Cyprus submitted to him in 709; but in the reign of Sennacherib Elulaeus joined the league of Philistia and Judah, in alliance aith Egypt and Ethiopia, nhich aimed at throwing off the oppressive ty ranny of Assyria. In the great campaign of 701 Sennacherib came down upon the revolting provinces; he forced Luli, king of Sidon. to fly for refuge to Cyprus, took his chief cities, and set up Tuba'lu (Ethbaal) as king, imposing a yearly tribute (KB. ii. 91). The blockade of Tyre by sea, significantly passed over in Sennacherib's inscription, is described by Menander; the Assyrian king, however, so far accomplished his object as to break up the combination of Tyre and Sidon, which had grown into a powerful state. At Sidon the successor of Ethbaal was Abd-milkath; in alliance with a Cilician chief he rebelled against Esarhaddon about the year 678, with disastrous consequences. Sidon was annihilated; Abd-milkath fell into the hands of Esarhaddon, who founded a new Sidon on the mainland, peopled it with foreigners, and called it after his own name. The old name, however, survived in popular usage; but the character of the city was changed, and till the time of Cyrus the kingdom of Sidon ceased to exist (KB. ii. 12j seq., 145; KAT^3., 88). Tyre also came in for its share of hardship. Elulaeus was followed by Baal, who in 672 consented to join Tirhaka, the Ethiopian king of Egypt, in a rebellion against Assyria. Esarhaddon, on his way to Egypt for the second time, blockaded Tyre, but he did not capture the city itself. His monument found at Zenjirli represents the great king holding Baal of Tyre and Tirhaka of Egypt by cords fastened in their lips; there is no evidence, however, that he actually took either of them prisoner (Gressmann, Texte u. Bilder^2, ii. Pl. lxiii.). Early in the reign of Assur-bani-pal Tyre was besieged again (668), but Assur-bani-pal succeeded no better than his predecessors. Nevertheless Baal submitted in the end, along with the princes of Gebal and Arvad, Manasseh of Judah, and the other Canaanite chiefs; in the island of Cyprus the Assyrians carried all before them (KB. ii. 149 seq., 169, 173). On his return from the Arabian campaign Assur-bani-pal severely punished the rebellious inhabitants of Ushu (Palaetyrus) and Akko (ibid., 229). In Phoenicia, as elsewhere, Assyrian rule created nothing and left nothing behind it but a record of barbarous conquest.

The **Neo-Babylonian** Period, 605–538 **B.C.**—In the last crisis of the dying power of Assyria the Egyptians for a short time laid hands on Phoenicia; but after their defeat at the battle of Carchemish (605), the Chaldaeans became the masters of western Asia. Jeremiah's allusion (xxv. 22) in 604 to the approaching downfall of the kings of Tyre and Sidon and the coastland beyond the sea, *i.e.,* the Phoenician settlements on the Mediterranean, seems to imply that the Phoenician states recovered some measure of independence; if they did it cannot have lasted long. In j88 Apries (Pharaoh Hophra) made an attempt to displace the Chaldaean supremacy; he defeated Tyre and Sidon, and terrorized the other cities into submission (Herod., ii. 161; Diod. Sic., i. 68). Some of the Phoenician chiefs, among them Ithobal II., the new king of Tyre, while forced to yield to a change of masters, were bold enough to declare their hostility to the Babylonians. This state of affairs did not escape the vigilance of Kebuchadrezzar. After the fall of Jerusalem he marched upon Phoenicia; Apries withdrew his army, and the siege of Tyre began. For 13 years the great merchant city held out (585–573; Jos., c. Ap., i. 21: cf. Ezek. xxvi. 1 seq.). Ezekiel says that Nebuchadrezzar and his host had no reward for their heavy service against Tyre, and the presumption is that the city capitulated on favourable terms; for Ithobal's reign ends with the close of the siege, and the royal family is subsequently found in Babylon. The king appointed by Kebuchadrezzar was Baal II. (574–564), after whose death a republic was formed under a single suffete or "judge" (*shōfēt*). Josephus (*loc. cit.*) is again our authority for the changes of government which followed until the monarchy was revived. At length under Hiram III. Phoenicia passed from the Chaldaeans to the Persians (538), and at the same time Amasis II. of Egypt occupied Cyprus (Herod., ii. 182). There seems to have been no struggle; the great siege and the subsequent civil disorders had exhausted Tyre, and Sidon took its place as the leading state. About this time, too, Carthage made an effort for independence under Hanno the Great (538–521), the real founder of its fortunes; the old dependence upon Tyre was changed for a mere relation of piety observed by the annual sending of delegates (*θεωροί*) to the festival of Melkarth (Arrian, ii. 24; Polyb., xxxi. 20, 12). The disasters which befrll Tyre during this and the foregoing period might suggest that its prosperity had been seriously damaged. But Tyre always counted for

more in commerce than in politics; and in the year 586, just before the great siege, Ezekiel draws a vivid picture (ch. xxvii.) of the extent and splendour of its commercial relations.

Constitution.—At this point it is convenient to mention what little is known about the constitution of the Phoenician states. All Canaanite analogy speaks for kingship as the oldest form of Phoenician government. In the native inscriptions the chief of the city in Phoenicia itself and in Cyprus is always called king. The royal houses claimed divine descent, and the king could not be chosen outside their members. His power. however, was limited by the wealthy merchant families, uho possessed great influence in public affairs. The priest of Melkarth at Tyre was the second man in the kingdom. Associated with the prince was a council of elders; such was the case at Gebal (Byblus) from the earliest times to the latest (Ezek. xxvii. 9); at Sidon this council consisted of 100 members (Diod., xvi. 45), perhaps also at Tyre (NSI. p. 129). Inscriptions of the 3rd and 2nd centuries B.C. mention a *Rab* (chief) in Sidon, Cyprus and Gaulus (Gozo); what nis position was it is difficult to say; in the colonies he may have been a district governor. Luring Nebuchadrezzar's time, as we have seen, a republic took the place of the monarchy at Tyre, and the government was administered by a succession of suffetes (judges); they held office for short terms, and in one instance two ruled together for six years. Much later, in the 3rd century B.C. an inscription from Tyre mentions a suffete (NSI. No. 8) without adding more to our kno ledge. Carthage, of course, was governed by two suffetes, and these officers are frequently named in connection with the Carthagininn colonies (NSI. p. 115 seq.); but we must be careful not to draw the inference that Phoenicia itself had any such magistrates. Under the Persians a federal bond was formed comprising Sidon, Tyre and Aradus, whose duty it was to contribute 300 triremes to the Persian fleet (Herod., vii. 89), the lesser towns being under the command of the great cities. But federation on a larger scale was never possible in Phoenicia, for the reason that no sense of political unity existed to bind the different states together. Commercial interests dominated everything else, and while these stimulated a municipal life not without vigour, civil discipline and loyalty were but feebly felt. On occasion the towns could defend their independence with strenuous courage; the higher qualities which make for a progressive national life the Phoenicians did not possess.

The Persian Period, 538–333 **B.C.**—Phoenicia now became part of the fifth satrapy of the Persian empire, and entered upon a spell of comparative peace and growing prosperity. At this period Sidon occupied the position of leading state; in the fleet her king ranked next to Xerxes and before the king of Tyre (Herod., viii. 67); her situation afforded advantages for expansion which Tyre on its small and densely populated island could not rival. In the first half of the 4th century Straton I. (in Phoen. 'Abd-'ashtart or *Bod-'ashtnrt)* was king, c. 374–362. He cultivated friendly relations with Athens, indicated in a decree of *proxenia* (Michel, Rec. *d'inscr.* gr. No. 93=*CIG.* No. 87); and the extent to which phil-Hellenic tendencies prevailed at this time in Sidon is shown by the royal sarcophagi, noble specimens of Greek art, which have been excavated in the necropolis of the city. It was in the reign of Straton that Tyre fell into the hands of Evagoras, king of Salamis, who had already supplanted Phoenician with Greek civilization in Cyprus (Isocr., *Evag.*, 62, Paneg., 161; Diod. xv. 2). Straton made friends with Nicocles, son of Evagoras, and with him came to an untimely end through their implication in the great revolt of the satraps, 362 B.C. A new revolt of Sidon against the Persians took place under King Tennes; with the aid of Nectanebus of Egypt, the Sidonians carried the rest of Phoenicia with them and drove the satraps of Syria and Cilicia out of the country. Tennes, however, betrayed his people and opened the city to Artaxerxes III.; then he was executed after he had served the ends of the great king (346 B.C.; Diod., xvi. 41–45). The last king of Sidon was Straton II. ('Abd-'ashtart, 346–332) before the Persian empire came to an end.

Towards the close of the 5th century the Phoenician coins begin to supplement our historical sources. From the time of Darius the Persian monarchs allowed their satraps and vassal states to coin silver and copper money at discretion. Hence Aradus, Byblus, Sidon and Tyre issued a coinage of their own, of which many specimens exist; the coins are stamped as a rule with the emblem or name of the city, sometimes with the ruler's name. Thus from the coins of Byblus we learn the names of four kings, 'El-pa'al, 'Az-ba'al (between 360 and 340 B.C.), Adar-melek, 'Ain-el; from the coins of the other cities it is difficult to obtain much information. The native inscriptions, however, now become available, though most of them belong to the period which follows, and only a few have been discovered in Phoenicia itself. One of the earliest of these is the inscription of Byblus (CIS. i. 1=*NSI.* No. 3), dating from the Persian period; it records a dedication made by Yehaw-milk, king of Gebal, and mentions the name of the king's grandfather, Urimilk, but the exact dates of their reign are not given.

The Macedonian Period, 333–69 **B.C.**—When Alexander the Great entered Phoenicia after the battle of Issus (333 B.C.), the kings were absent with the Persian fleet in the Aegean; but the cities of Aradus, Byblus and Sidon welcomed him readily, the last-named showing special zeal against Persia. The Tyrians also offered submission, but refused to allow the conqueror to enter the city and sacrifice to the Tyrian Heracles. Alexander was determined to make an example of the first who should offer opposition, and at once began the siege. It lasted seven months. With enormous toil the king drove out a mole from the mainland to the island and thus brought up his engines; ships from the other Phoenician towns and from Cyprus lent him their aid, and the town at length was forced in July 332; 8,000 Tyrians were slain, 30,000 sold as slaves, and only a few notables, the king Azemilkos, and the festal envoys from Carthage who had taken refuge in the sanctuary of Melkarth, were spared (Diod., xvii. 40–46). It is not unlikely that Zech. ix. 2–4 refers to this famous siege. For the time Tyre lost its political existence, while the foundation of Alexandria presently changed the lines of trade, and dealt a blow even more fatal to the Phoenician cities.

During the wars of Alexander's successors Phoenicia changed hands several times between the Egyptian and the Syrian kings. From the year 275 "the people of Tyre" reckoned their era (CIS. i. 7=*NSI.* No. 9, cf. 10). The Tyrian coins of the period, stamped with native, Greek and Egyptian symbols, illustrate the traditional relations of the city and the range of her ambitions. A special interest attaches to these silver tetradrachms and didrachms because they were used by the Jews for the payment of the temple tax as "shekels of the sanctuary" (NSI pp. 351, 44).

Among the Phoenician states we know most about Sidon during this period. The kingship was continued for a long time. The story goes that Alexander raised to the throne a member of the royal family, Abdalonymus, who was living in obscure poverty and working as a gardener (Justin, xi. 10; Curt., iv. 1; Diod., xvii. 47 wrongly connecting the story with Tyre). In 312 Ptolemy, then master of Phoenicia, appointed his general Philocles king of the Sidonians, and a decree in honour of this king has been found at Athens (Michel, No. 387, cf. 1,261); but he cannot have reigned long. For at the end of the 4th and the beginning of the 3rd century we have evidence of a native dynasty in the important inscriptions of Tabnith, Eshmun'azar and Bod-'ashtart, and in the series of inscriptions (repeating the same text) discovered at Bostan esh-Shēkh near Sidon (*NSI.* Nos. 4, 5, 6 and App. i.). With Bod-'ashtart, so far as we know, the dynasty came to an end, say about 250 B.C.

After the death of Antiochus IV. Epiphanes in 164 B.C., the kingdom of the Seleucids began to collapse. Berytus was destroyed by the usurper Trypho in 140 B.C. Tyre in 120 and Sidon in 111 received complete independence, and inaugurated new eras from these dates. Byblus and Tripolis fell into the hands of "tyrants" (Strabo, xvi. 2, 18; Jos., Ant., xiv. 3, 2); from 83–69 B.C. the entire kingdom was held by the Armenian Tigranes.

Roman Rule.—At last in 64 B.C. Pompey arrived upon the scene and established order out of chaos. Phoenicia was incorporated into the Roman province of Syria; Aradus, Sidon, Tyre and Tripolis were confirmed in their rights of self-government and in

the possession of their territories. Under the beneficent government of Rome the chief towns prospered and extended their trade; but the whole character of the country underwent a change. During the Macedonian period Greek influences had been steadily gaining ground in Phoenicia; relations with the Greek world grew closer; the native language fell into disuse. and from the beginning of the Roman occupation Greek appears regularly in inscriptions and on coins, though on the latter Phoenician legends do not entirely vanish till the 2nd century A.D.; while the extent to which Hellenic ideas penetrated the native traditions and mythologies is seen in the writings of Philo of Byblus. For the purposes of everyday life, however, the people spoke not Greek, but Aramaic. As elsewhere, the Roman rule tended to obliterate characteristic features of national life, and under it the native language and institutions of Phoenicia became extinct.

Navigation, Trade, Colonies.—The Phoenicians were essentially a seafaring nation. Fearless and patient navigators, they ventured into regions where no one else dared to go, and, always with an eye to their monopoly, they carefully guarded the secrets of their trade routes and discoveries, and their knowledge of winds and currents. At the beginning of the 7th century B.C. a Phoenician fleet is said to have circumnavigated Africa (Herod., iv. 42). To the great powers Phoenician ships and sailors were indispensable; Sennacherib, Psammetichus and Necho, Xerxes, Alexander, all in turn employed them for their transports and seafights. Even when Athens had developed a rival navy Greek observers noted with admiration the discipline kept on board the Phoenician ships and the skill with which they were handled (Xen., *Oec.*, viii.); all the Phoenician vessels from the round merchant-boat (γαῦλος — after which the island of Gaulus, now Gozo, near Malta, was called) to the great Tarshish-ships, the "East-Indiamen" of the ancient world, excelled those of the Greeks in speed and equipment. As E. Meyer points out, the war between the Greeks and the Persians was mainly a contest between the sea-powers of Greece and Phoenicia. At what period did Phoenicia first rise to be a power in the Mediterranean? We are gradually approaching a solution of this obscure problem. Recent discoveries in Crete (*q.v.*) have brought to light the existence of a Cretan or "Minoan" sea-power of remote antiquity, and it is clear that a great deal of what used to be described as Phoenician must receive quite a different designation. The Minoan seapower was at last broken up by invaders from the north, and a Carian rule became dominant in the Aegean (Herod., i. 171; Thucyd., i. 4, 8). It was a time of disorder and conflict due to the immigration of new races into the ancient seats of civilization, and it synchronized with the weakening of the power of Egypt in the countries which bordered on the eastern Mediterranean. This was in the 12th century B.C. The Tyrian trader saw that his opportunity was come, and the Aegean lay open to his merchant vessels. Where much is still obscure, all that seems certain is that the antiquity of Phoenicia as a sea- and trading-power has been greatly exaggerated both in ancient and in modern times; the Minoan power of Cnossus preceded it by many centuries; the influence of Phoenicia in the Aegean cannot be carried back much earlier than the 12th century B.C.

A vivid description of the Phoenicians' trade at the time of Tyre's prosperity is given by Ezekiel (xxvii. 12–25), and it shows how extensive were their commercial relations not only by sea, but by land as well. It was they who distributed to the rest of the world the wares of Egypt and Babylonia (Herod., i. 1). From the lands of the Euphrates and Tigris regular trade-routes led to the Mediterranean with trading-stations on the way, several of which are mentioned by Ezekiel (xxvii. 23). In Egypt the Phoenician merchants soon gained a foothold; they alone were able to maintain a profitable trade in the anarchic times of the 22nd and 23rd dynasties (825–650 B.C.), when all other foreign merchants were frightened away. Though there were never any regular colonies of Phoenicians in Egypt, the Tyrians had a quarter of their o n in Memphis (Herod., ii. 112). The Arabian caravan-trade in perfume, spices and incense passed through Phoenician hands on its way to Greece and the west (Herod., iii. 107). Between Israel and Phoenicia the relations naturally were close; the former provided certain necessaries of life, and received in exchange articles of luxury and splendour (Ezek. xxvii. 16–18). Israelite housewives sold their homespun to Phoenician pedlars (Prov. xxxi. 24 R.V.M.); in Jerusalem Phoenician merchants and money lenders had their quarter (Zeph. i. 11), and after the Return we hear of Tyrians selling fish and all manner of ware in the city (Neh. xiii. 16), and introducing other less desirable imports, such as foreign cults (Isa. lxv. 11). The Phoenician words which made their way into Greek at an early period indicate the kind of goods in which the Phoenicians traded with the west, or made familiar through their commerce; the following are some of them—χρυσός, χιτών, βύσσος, ὀθόνη, μύρρα, νάβλα, κύπρος, φῦκος, μνᾶ, παλλακίς, βαίτυλος. Another article of commerce which the Phoenicians brought into the market was amber.

The Phoenician colonies were all supposed to have been founded from Tyre: with regard to the colonies in Cyprus and north Africa this was undoubtedly true. Cyprus possessed resources of timber and copper which could not fail to tempt the keen-eyed traders across the water, who made Citium (from Kittim, the name of the original non-Semitic inhabitants) their chief settlement, and thence established themselves in Idalium, Tamassus, Lapethus, Larnaka, Qarth-hadasht (Karti-hadasti) and other towns. In the inscriptions of the 4th to 3rd centuries, the Phoenician potentates in the island call themselves "kings of Kition and Idalion" (N.S.I. pp. 55–89).

Homer represents the Phoenicians as present in Greek waters for purposes of traffic, but not as settlers (*Il.*, xxiii. 744). They occupied trading-stations on some of the Aegean islands and on the Isthmus of Corinth. One of their objects was the collection of murex, of which an enormous supply was needed for the dyeing industry; specially famous was the purple of the Laconian waters, the isles of Elishah of Ezek. xxvii. 7. But a great deal of what was formerly assigned to Phoenician influence in the Aegean at an early period—pottery, ornaments and local myths—must be accounted for by the vigorous civilization of ancient Crete. In the Greek world the Phoenicians made themselves heartily detested by their passion for gain (Plato, Rep. iv. 436 A.).

Farther west in the Mediterranean Phoenician settlements were planted first in Sicily, at Heraclea or Ras Melqarth; the islands between Sicily and Africa, Melita (Malta) on account of its valuable harbour, Gaulus and Cossura were also occupied (Diod., v. 12); and a beginning was made with the colonization of Sardinia and Corsica; but farther west still more permanent colonies were established. It was the trade with Tarshish; *i.e.*, the region of Tartessus in south-west Spain, which contributed most to the Phoenicians' wealth; it was said that even the anchors of ships returning from Spain were made of silver (Diod., v. 35). From Gadeira (Punic *Gādēr*, Lat. Gades, now Cadiz), the Sidonian ships ventured farther on the ocean and drew tin from the mines of north-west Spain or from the richer deposits in the Cassiterides; *i.e.*, the Tin Islands. These were discovered to be, not a part of Britain as was imagined at first, but a separate group by themselves, now known as the Scillies; hence it is improbable that the Phoenicians ever worked the tin-mines in Cornwall.

The rich trade with Spain led to the colonization of the West. Strabo dates the settlements beyond the Pillars of Hercules soon after the Trojan War (i. 3, 2), in the period of Tyre's first expansion. Lixus in Mauretania, Gades and Utica, are said to have been founded, one after the other, as far back as the 12th century B.C. Most of the African colonies were no doubt younger; we have traditional dates for Aoza (887–855) and Carthage (813). A large part of north-west Africa was colonized from Phoenicia; owing to these first settlers, and after them to the Carthaginians, the Phoenician language became the prevailing one, and the country assumed quite a Phoenician character.

In the days of Tyre's greatness her power rested directly on the colonies, which, unlike those of Greece, remained subject to the mother-city, and paid tithes of their revenues to its chief god, Melqarth, and sent envoys annually to his feast. Then at the beginning of the 8th century B.C. the colonial power of Tyre began to decline; on the mainland and in Cyprus the Assyrians

gained the upper hand; in the Greek islands the Phoenicians had already been displaced to a great extent by the advancing tide of Dorian colonization. But as Tyre decayed in power the colonies turned more and more to Csrthage as their natural parent and protector. For effective control over a colonial empire Carthage had the advantage of situation over far-away Tyre; the traditional bonds grew lax and the ancient dues ceased to be paid, though as late as the middle of the 6th century Carthage rendered tithes to the Tyrian Melqarth. And the mother-country cherished its claims long after they had lost reality; in the and century B.C., for example, Sidon stamped her coins with the legend, "Mother of Kambē (*i.e.*, Carthage), Hippo, Kition, Tyre" (NSI. p. 352).

Manufactures, Inventions, Art.—From an early date the towns of the Phoenician coast were occupied, not only with distributing the merchandise of other countries but with working at industries of their own; especially purple-dyeing and textile fabrics (*Il.*, vi. 289 sqq.), metal work in silver, gold and electrum (*Il.*, xxiii. 741 *sqq.*; *Od.*, iv. 615 *sqq.* xv. 458 *sqq.*), and glass-work, which had its seat at Sidon. The iron and copper mines of Cyprus (not Sidon, as Homer implies, *Od.*, xv. 424) furnished the ore which was manufactured into articles of commerce. Egyptian monuments frequently mention the vessels of gold and silver, iron and copper, made by the Dahi, *i.e.*, the Phoenicians (W. M. Müller, *As. u. Eur.*, 306); and in Cyprus and at Nimrud bronze and silver paterae have been found, engraved with Egyptian designs, the work of Phoenician artists (see table-cases C and D in the Nimrud gallery of the Brit. Mus.). The invention of these various arts and industries was popularly ascribed to the Phoenicians, no doubt merely because Phoenician traders brought the products into the market. But dyeing and embroidery probably came from Babylon in the first instance; glass-making seems to have been borrowed from Egypt; the invention of arithmetic and of weights and measures must be laid to the credit of the Babylonians. The ancients believed that the Phoenicians invented the use of the alphabet (*e.g.*, Pliny, *N.H.*, v. 13, *cf.* vii. 57; Lucan, *Bell. Civ.*, iii. 220 *seq.*); but it is unlikely that any genuine tradition on the subject existed, and though the Phoenician theory has found favour in modern times it is open to much question.

The art of Phoenicia is characterized generally by its dependence upon the art of the neighbouring races. It struck out no original line of its own, and borrowed freely from foreign, especially Egyptian, models. Remains of sculpture, engraved bronzes and gems, show clearly the source to which the Phoenician artists went for inspiration; for example, the uraeus-frieze and the winged disc, the *qnkh* or symbol of life, are Egyptian designs frequently imitated. It was in the times of the Persian monarchy that Phoenician art reached its highest development, and to this period belong the oldest sculptures and coins that have come down to us. A characteristic specimen of the former is the stele of yehaw-milk, king of Gebal (*CIS.* i. 1), in which the king is represented in Persian dress, and the goddess to whom he is offering a bowl looks exactly like an Egyptian Isis-Hathor; (Gressmann, *Texte u. Bilder*², ii. Pl. ccviii.). The whole artistic movement in Phoenicia may be divided into two great periods: in the first, from the earliest times to the 4th century B.C., Egyptian influence and then Babylonian or Asiatic influence is predominant, but the national element is strongly marked; while in the second, Greek influence has obtained the mastery, and the native element, though making itself felt, is much less obtrusive. Throughout these periods works of art, such as statues of the gods and sarcophagi, were imported direct at first from Egypt and afterwards mainly from Rhodes. The finest sarcophagi that have been found in the necropolis of Sidon (now in the Imperial Museum, Constantinople) are not Phoenician at all, but exquisite specimens of Greek art. The Phoenicians spent much care on their burial-places, which have furnished the most important monuments left to us. Thus, on the site of Gebal, now Jebeil, the French excavators, under the leadership of Montet, 1921–23, have unearthed the fine sarcophagus of Aḥîram, Egyptian in style, and engraved with the earliest Phoenician inscripition so far known; see Gressmann; Texte *u. Bilder*², i. 440; ii. 189–192 and Pl. ccliv. (1927). Besides busts and figurines, which belong as a rule to the Greek period, the smaller objects usually found are earthen pitchers and lamps, glass-wares, tesserae and gems. 'Of buildings which can be called architectural few specimens now exist on Phoenician soil, for the reason that for ages the inhabitants have used the ruins as convenient quarries. Not a vestige remains of the great sanctuary of Melqarth at Tyre; a few traces of the temple of Adonis near Byblus were discovered by Renan, and a peculiar mausoleum, Burj al-Bezzāq, is still to be seen near Amrit; excavations at Bostan esh-Shēkh near Sidon revealed parts of the enclosure or foundations of the temple of Eshmun (NSI. p. 401); the conduits of Ras el- 'Ain, south of Tyre, are considered to be of ancient date.

Religion.—Like the Canaanites of whom they formed a branch, the Phoenicians connected their religion with the great powers and processes of nature. The gods whom they worshipped belonged essentially to the earth; the fertile field, trees and mountains, headlands and rivers and springs, were believed to be inhabited by different divinities, who were therefore primarily local, many in number, with no one in particular supreme over the rest. It seems, however, that as time went on some of them acquired a more extended character; thus Ba'al and Astarte assumed celestial attributes in addition to their earthly ones, and the Tyrian Melqarth combined a celestial with a marine aspect. The gods in general were called *'elōnīm, 'elim;* these plurals go back to the singular form 'El, the common Semitic name for God. The god or goddess was generally called the Ba'al or Ba'alath of such and such a place, a title which was used not only by the Canaanites, but by the Aramaeans (Be'el) and Babylonians (Bel) as well. There was no one particular god called Ba'al; the word is not a proper name but an appellative, a description of the deity as *owner* or *mistress;* and the same is the case with Milk or Melek, 'Adon, 'Amma, which mean *king, lord, mother*. The god himself was unnamed or had no name. Occasionally we know what the name was; the Ba'al of Tyre was Melqarth which again means merely "king of the city"; similarly among the Aramaeans the Ba'al of Harran was the moon-god Sin. Sometimes the god received a distinguishing attribute which indicates an association not with any particular place, but with some special characteristic; the most common forms are Ba'al-hammān, the chief deity of Punic north Africa, perhaps "the glowing Ba'al," the god of fertilizing warmth, and Ba'al-shamēm, "Ba'al of the heavens" (*cf.* Dan. xii. 11, xi. 31, etc.). The latter deity was widely venerated throughout the north Semitic world. The worship of the female along with the male principle was a strongly marked feature of Phoenician religion.

To judge from earliest evidence on the subject, the Ba'alath of Gebal or Byblus, referred to again and again in the Amarna letters (*Bêlit ša Gubla*, Nos. 68–125), must have been the most popular of the Phoenician deities, as her sanctuary was the oldest and most renowned. The *mistress of Gebal* was no doubt 'Ashtart (Astartē in Greek, 'Ashtōreth in the Old Testament, a name which is obviously connected with the Babylonian Ishtar, and, as used in Phoenician, is practically the equivalent of "goddess." She represented the principle of fertility and generation; the common epithets Κύπρις and Κυθέρεια (of Kuthera in Cyprus), Cypria and Paphia, show that she was identified with Aphrodite and Venus. Though not primarily a moon-goddess, she sometimes appears in this character, and Herodotus describes her temple at Ashkelon as that of the heavenly Aphrodite (i. 105). We find her associated with Ba'al and callrd "the name of Ba'al"; *i.e.*, perhaps his manifestation. Another goddess, specially honoured a t Carthage, is Tanith; she is regularly connected with Ba'al on the Carthaginian votive tablets. Two or thred other deities may be mentioned here: Eshmun, the god of vital force and healing, worshipped at Sidon especially, but also at Carthage and in the colonies, identified by the Greeks with Asclepius; Melqarth, the patron deity of Tyre, identified with Heracles; Reshef or Reshūf, the "flame" or "lightning" god, especially popular in Cyprus and derived originally from Syria, whom the Greeks called Apollo. A tendcncy to iorm a distinct deity by combining the attributes of two produced such curious fusions as Milk-'ashtart, Milk-ba'al. Milk-'osir, Eshmun-melqarth, Melqarth-resef, etc. As in the case of art and industries so in religion the Phoenicians readily assimilated foreign ideas. The influence of Egypt was specially strong.

(loser intimacy with the Greek world naturally brought about modifications in the character of the native gods, which became apparent when Ba'al of Sidon or Ba'al-shamēm was identified with Zeus, Tanith with Demeter or Artemis, 'Anath with Athena, etc.; the notion of a supreme Ba'al, which finds expression in the Greek βῆλος and βααλτίς or βήλθης (the goddess of Byblus), was no doubt encouraged by foreign influences. On the other hand, the Phoenicians produced a considerable effect upon Greek and Roman religion, especially from the religious centres in Cyprus and Sicily. A great number of divinities are known only as elements in proper names. It was the custom among the Phoenicians, as among other Semitic nations, to use the names of the gods in forming proper names and thus to express devotion or invoke favour; thus Hanni-ba'al, 'Abdmelqarth, Hanni-'ashtart, Eshmun-'azar.

The proper names further illustrate the way in which the relation of man to God was regarded; the commonest forms are *servant* ('abd, *e.g.,* 'Abd-'ashtart), *member* or *limb* (bod, *e.g.,* Bod-melqarth), client or *guest* (ger, *e.g.,* Gereshmun).

Sacred Objects and Worship.— Probably like other Canaanites the Phoenicians ofiered worship "on every high hill and under every green tree"; but to judge from the allusions to sanctuaries in the inscriptions and elsewhere, the Ba'al or 'Ashtart of a place was usually worshipped at a temple, which consisted of a court or enclosure and a rooied shrine with a portico or pillared hall at the entrance. In the court sometimes stood a conical stone, probably the symbol of Astarte, as on the Roman coins of Byblus. Stone or bronze images of the gods were set up in the sanctuaries; and besides these the *baetylia* (meteoric stones) which were regarded as symbols of the gods. Pillars, again, had a prominent place in the court or beiore the shrine; but it is not known whether the sacred pole *('asherah),* an invariable feature of a Canaanite sanctuary, was usual in a Phoenician temple. The inscriptions mention altars of stone and bronze, and from the sacrificial tariffs which have survived u-e learn that the chiei types of sacrifice among the Phoenicians were analogous to those in the Old Testament. The practice oi sacrificing human victims was resorted to in times of great distress or to avert national disaster; it was regarded as a patriotic act when Hamilcar threw himself upon the pyre aiter the disastrous battle of Himera. The god who demanded these victims, and especially the burning of children, seems to have been Milk, the Molech or Moloch of the Old Testament. In this connection may be mentioned the custom of burning the chief god of the city in effigy, or in the person of a human representative, at Tyre and in the Tyrian colonies, such as Carthage and Gades. Another sacrifice mas regularly demanded by Phoenician religion; women sacrificed their virginity at the shrines oi Astarte in the beliei that they thus propitiated the goddess and won her favour. These temple prostitutes are called *qedēshīm qedēshōth, i.e.,* sacred men, women, in the Old Testament (Deut. xxiii. 18; I Kings xiv. 24, etc.). Other persons attached to a temple were priests, augurs, sacrificers, barbers, officials in charge of the curtains. masons, etc.; we hear also of religious gilds and corporations, perhaps administrative councils, associated with the sanctuaries.

Mythology and Religious Ideas.— No doubt the Phoenicians had their legends and myths to account for the origin of man and the universe; to some extent these would have resembled the ideas embodied in the book of Genesis. Two cosmogonies have come down to us which, though they differ in details are fundamentally in agreement. The one, of Sidonian origin, is preserved by Damascius and received at his hands a Neoplatonic interpretation; the other and more elaborate work mas composed by Philo of Byblus; he professed that he had used as his authority the writings of Sanchuniathon, an ancient Phoenician sage, who again derived his information from the mysterious inscribed stones in the Phoenician temples. Philo's cosmogony has been preserved, at least in fragments, by Eusebius. It cannot, however, be taken seriously as an account of genuine Phoenician beliefs. At the same time Philo did not invent all the nonsense he has handed down; he drew upon various sources, Greek and Egyptian, some of them ultimately of Babylonian origin. He shows at any rate that some sort of a theology existed in his day. It is evident that the gods were regarded as being intimately concerned with the lives and fortunes of their worshippers. The vast numher of small votive tablets found at Carthape prove this; they were all inscribed by grateful devotees "to the lady Tanith. Face of Ba'al, and the lord Ba'al-ḥammān, because he heard their voice."

The care which the Phoenicians bestowed upon the burial of the dead has been alluded to above; pillars (*maṣṣēbōth*) were set up to commemorate the dead among the living; if there were no children to fulfil the pious duty, a monument mould be set up by a man during his lifetime. Any violation of the tomb was regarded with the greatest horror. The grave mas called a resting-place, and the departed lay at rest in the underworld with the *Refāim,* the weak ones. The notion prevailed, as it did also among the Greeks and Romans, that it was possible to communicate with the gods of the underworld by dropping into a grave a small roll of lead inscribed with the message, generally a curse, which it was desired to convey to them.

PHOENIX, capital and largest city of Arizona, U.S., and seat of Maricopa county, occupies approximately 188 sq.mi. of an arid saucer-shaped valley formed by the Salt river, midway between El Paso and Los Angeles. The city is the commercial focus of large irriqation projects, important to its growth. which are fed from the Roosevelt dam. 70 mi. N.E. The hub of an area of scenic grandeur, it is also a health and tourist centre.

The Salt river valley was occupied as early as 1300 A.D. by prehistoric Indians known to anthropologists as Hohokarn (*q.v.*) or "the people who have gone." They developed a system of primitive irrigation canals. erected early buildings and then vanished mysteriously. An historic gap followed until the first white men came during the American Civil War. One, an imaginative prospector, Jack Swilling, noticed the visible remnants of ancient Indian canals and realizing irrigation possibilities, organized an irrigation company. Canals and harvests followed and a crude village was founded.

An associate of Swilling's, Darrel Duppa, English adventurer and scholar, was impressed by the evidences of prehistoric culture. Like the legendary phoenix which, consumed by fire. arose from its own ashes. so. Duppa predicted. would the Salt river city be born from ancient Indian ruins. Thus the settlement was named Phoenix. Incorporated in 1881, it acquired its first railroad in 1887. Phoenix, with a population of about 3,000, became the seat of the territorial government in 1889, and remained the capital when Arizona attained statehood in 1912. The city has been council-manager governed since 1914.

The economy is based on agriculture, tourists and manufacturing. The fertile Salt river valley produces long staple cotton, forage, vegetables and fruits. Manufacturing. almost nonexistent before 1940, later became the chief source of income. Aircraft and electronic components, aluminum extrusions, air-conditioning equipment and many small manufacturing enterprises add to the economic wealth of the city.

More than 30 secondary schools and Phoenix college, a two-year college established 1920, are in the city proper. Independent school districts are in outlying communities. Parks, playgrounds. an adult recreational centre, an active little theatre, a professional winter theatre, a symphony orchestra and professional baseball provide recreational and cultural opportunities. Notable annual events are the Copper Bowl parade and football game, the World's Championship rodeo and the Arizona state fair.

The state capitol consists of an original building of native tufa and of neoclassic design. with two additional wings for the house of representatives and the senate. These buildings are set in a 10-ac. park, where trees and shrubs indigenous to the region are represented. I'apago park (1,094 ac.) lies within the city limits to the east and to the south is the city's South Mountain park of 14,000 ac.

The Phoenix standard metropolitan statistical area comprising Maricopa county includes: Mormon-founded Mesa, site of the state experimental farm: Glendale, a farming community with nearby Luke air force base; and Tempe, location of Arizona State university (established in 1885 as Arizona Territorial Normal school). A post-World War II population boom, with Arizona's warm climate and clear air (85% average "possible" sunshine) as the main enticements, made Phoenix one of the fastest growing cities in the United States. Between 1950 and 1960 its population increased from 106,818 to 439,170 within the city limits and from 331,770 to 663,510 within the metropolitan area. (Jo. S.)

PHOENIX, a fabulous bird, sacred to the sun (Gr. *Plzoinix,* apparently "bright-coloured"; *phoinix* also means "a palm-tree").

From statements in a large number of classical and postclassical authors. ranging from the 5th century B.C. (Herodotus, perhaps Hecataeus) to the middle ages (Isaac Tzetzes), the following account is obtained: The phoenix was a large bird of very gorgeous plumage, having, according to one or two authorities, a sweet voice. It was always male. the only one of its kind, and lived a long time (various authors give periods ranging from 500 years, the commonest account. up to 12.954; Tacitus, *Annales,* vi, 28, 4, gives 1,461 years, which is an Egyptian Sothis period).

At the expiration oi that time it made itself a nest of twigs of spice trees, on which it died by setting the nest on fire and burning itself alive. From its body, its ashes or the nest, which it had fertilized, came forth another phoenix, either perfect or at first in the shape of a white grub. This young bird, as soon as it was strong enough, took up the body of its father, covered in spices, or the ashes, nest and all, and flew to Heliopolis in Egypt, where it deposited them on the altar of

the sun. There are numerous variants in detail; sometimes the phoenix goes to Egypt to die, having produced its offspring before dying.

It was not doubted by the majority that the phoenix really was seen now and then in Egypt; Tacitus, *Annales*, and Pliny, *Historia Naturalis*, x, 2, mention recorded appearances, genuine and otherwise. Attention is thereiore drawn by A Wiedemann to the facts that a bird of the stork kind, the bennu or *bannu*, was sacred at Heliopolis and connected with the local sun worship, and, moreover, that its name also means a palm tree. This certainly gives a plausible origin for some parts of the Greek story and accounts for Herodotus's statement (ii, 73, 1) that he saw a picture of it in Egypt; ior the *bennu* is to be found on surviving monuments. But it fails to account for the persistent statement that the phoenix is not a native of Egypt, but lives in Arabia, Assyria, Ethiopia or India, nor does the real or pictured *benny* at all resemble the phoenix as described. Hence it is likely that the ultimate origin of the story, however it may have reached Greece, is to be sought in the mythology of one or another of these countries.

Many commentators still understand the word חול, chol, in Job xxix, 18 (in King James version, "sand"), to apply to the phoenix. This interpretation is perhaps as old as the (original) Septuagint, and is current with the later Jews. Among the Arabs the story of the phoenix was coniused with that of the salamander; and the samand or samandal is represented sometimes as a quadruped, sometimes as a bird. It was firmly believed in. for the incombustible cloths woven of flexible asbestos were popularly thought to be made of its hair or plumage, and were in fact called by the same name. The 'anka (Pers. *simurgh*), a stupendous bird like the roc (rukh) of Marco Polo and the *Arabian Nights*, also borrows some features of the phoenix According to Kazwini (i, 420) it lives 1,700 years, and when a young bird is hatched the parent of opposite sex burns itself alive.

PHOENIX, an important genus of palms native to Africa and Asia. The date palm (Phoenix dactylifera) is a member of the genus. and several other species are grown in the open in warm regions for ornament. See DATE PALM; PALM.

PHOLIDOTA, an order of placental mammals, comprising only the scaly anteaters or pangolins of Asia and Africa. The pangolins were at one time grouped with the true anteaters, sloths and armadillos in the order Edentata, mainly on account of their likeness to the South American anteaters in the absence of teeth, the weakness of the jaws, the enlargement of the salivary glands and the length of the wormlike, extensile tongue; and to the armadillos in the possession of a hard dermal exoskeleton. But the resemblances to the edentates are adaptive and due to similarity of diet and of habitat. The exoskeleton is of a totally different type from that of the armadillos, since it consists of large, erectile, overlapping horny scales, composed of cemented hairs, there being no trace of bony matter in the skin They show, indeed, no resemblances to the edentates of any systematic importance and differ from them fundamentally in many anatomical characters

The head is short and conical. with functionless facial whiskers and a moist elongate muzzle; the ear sometimes has a distinct pinna, but may be represented by a vertical slit only The legs are short: but the feet, whose five toes are armed with large claws (curved on the forefeet), vary in structure according to habit. The tail, sometimes excessively long and prehensile and sometimes comparatively short, forms. nith the hind legs, a kind of tripodal support. The anus and external genitalia are situated close together on an eminence formed mainly by the enlarged anal glands, and the anus is sunk in a depression into which the ducts of the glands open; both the penis (male) and clitoris (female) are quite small.

Pangolins range in Asia from north India and south China to Ceylon and Borneo and in Africa from Sierra Leone and Uganda to the Cape of Good Hope. There are several different kinds. Some are almost entirely arboreal, some purely terrestrial and others intermediate in habitat; all, however. are nocturnal and are able to swim a little. They feed mostly on termites, ripping open the nests of these insects with the strong claws of the forefeet. Their means of defense are emission of a repulsive odour from the large anal glands and rolling into a compact ball with the hard, often sharp, erected scales presented to the enemy and the soft-skinned hairy underside protected from injury.

There are several fairly distinct types, all usually referred to genus *Manis* and to the family Manidae, but there is some dispute about the scientific names In the Asian pangolins the hinder end of the breastbone is shaped like the blade of a spade. having a convex posterior edge and two forwardly directed spinous angles. To this group belong the northern Indian and Chinese eared pangolin, the Indian and Ceylonese thick-tailed pangolin and the Javanese and Bornean pangolin, all of which differ in many external characters.

In the African pangolins the end of the breastbone is prolonged into two long rods running back to the posterior ribs. There are two groups differing in habitat and correlated structural characters. the terrestrial. including the so-called giant pangolin, with the feet and tail adapted for ground life; and the arboreal containing the small west African pangolins, which differ from all other pangolins in being exclusively adapted to life in the trees, the tails being exceedingly long and prehensile, and the feet with only four functional toes, the upper side of the forefoot being without scales.

The earliest evidences of the Pholidota are the bones of a large pangolin, indistinguishable from those of the African gaint pangolin. found in a cave in Madras. India. These remains date to the Pleistocene. beginning about 1,000,000 years ago.

PHONEMATICS: *see* LINGUISTICS; PHONETICS.

PHONETICS is the study of speech sounds, their physiological production and acoustic qualities. It deals with configurations of the vocal tract used to produce speech sounds, the resulting acoustic patterns and the manner of combining sounds so as to make syllables, words and sentences. On another level it compares the speech sounds of different languages.

Phonetics, since it is part of the analysis of the phenomenon of human language and speech behaviour, contributes to the fields of anthropology, linguistics, psychology, sociology and related fields. Furthermore it has several practical objects: (1) to help in learning to pronounce foreign languages; (2) t~ contribute to speech therapy; (3) to record previously unwritten languages and to develop writing systems for them; (4) to develop more efficient electrical and electronic speech transmission systems (speech compression).

History.—Although phonetics as an independent field of study did not come into being until the 19th century, speculations regarding the nature and origin of human speech, usually connected with magical or religious practices, are found in ancient civilizations. The use of alphabetic or syllabic notation, as opposed to pure ideographs, to record human speech shows an at least intuitive knowledge of speech units and their relationships. One of the earliest attempts at a systematic description and classification of speech sounds was that of the Sanskrit grammarians. whose work came to its climax with Panini (4th century B C). From the classical era until the end of the 17th century, however, more emphasis was placed on the process of phonation rather than on an explicit analysis of speech units. Such descriptions can be found among the works of Hippocrates, Aristotle, Galen and, later, Leonardo da Vinci. Near the end of the 18th century considerable interest was shown in speech synthesis. In 1791 Wolfgang von Kempelen invented a machine which could produce speechlike sounds.

During the 19th century a number of recording devices, such as the kymograph, became available for the quantitative measure of speech phenomena. These devices, along with the artificial palate and X-ray photography, gave impetus to the quantitative study of the physiology of speech. Comparable studies in the acoustic structure of speech were made available through Helmholtz resonators and phonographic devices By 1881, when Eduard Sicvers published his *Grundzüge* der Phonetik, phonetics had become an independent discipline. While the quantitative aspects of speech developed into experimental or instrumental phonetics under the influence of the abbé Jean Pierre Rousselot, another group of phoneticians became preoccupied with the classification of speech sounds and the creation of a notation system for recording speech in a written form. Leaders among this group were Paul Passy, Henry Saeet and Daniel Jones, all of them prominent in the sponsorship of the International Phonetic association nhich was inaugurated in France in 1886. The association soon drew up the International Phonetic Alphabet, which was designed to be applicable to all languages and which has become not only the most widely used phonetic alphabet but also the basis for many suc-

ceeding systems.

Jan Baudouin de Courtenay (1845–1929) is credited as being the first to insist on the distinction between the speech sound and the phoneme, although Henry Sweet (1845–1912) also was aware of the necessity to make this distinction. With the formation of the Cercle Linguistique de Prague in 1926, led by V. Mathesius, N. S. Trubetskoi, Roman Jakobson and S. Karcewski, new impetus was given to the development of phonemics and phonemic theory as distinct from phonetics.

After World War II, improvements in recording devices made available such instruments as the sound spectrograph, which permitted the analysis of speech sounds in great detail, and brought the acoustic study of speech sounds into the foreground. The interest in speech phenomena on the part of communication engineers and others outside the field of phonetics gave rise to an unprecedented study of all aspects of human speech.

Phonetic Analysis.—Speech sounds are recorded and analyzed in two general ways, either by ear or by machine. In the former method, the phonetician listens to a person speaking and writes what he hears in the symbols of a phonetic transcription system, recording in as detailed a manner as he can or as suits his purpose. In the latter method, speech is recorded with an instrument such as the oscilloscope, kymograph, spectrograph or X-ray camera. This usually transforms the speech behaviour into a visual form which can then be measured, and various samples of speech can be compared. In either case, when the object of the analysis is to describe the speech sounds of a given language, the nature and mode of formation of every speech sound of the language must be ascertained with the greatest possible accuracy; long passages of the language must then be transcribed phonetically as accurately as possible with the object of finding out how the sounds may be grouped into distinctive sounds, or phonemes. The usage of the particular language as regards the duration of sounds, the stress of syllables and the intonation (pitch, musical accent) of words and sentences must be examined in detail. To obtain the best

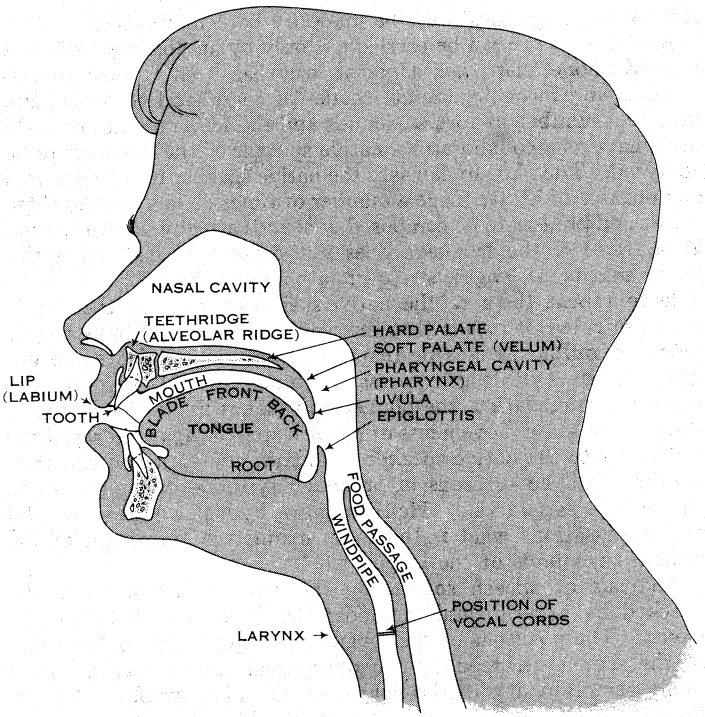

FIG. 1.—THE ORGANS OF SPEECH

TABLE I.—*The International Phonetic Alphabet*

		Bilabial	Labio-dental	Dental and alveolar	Retroflex	Palato-alveolar	Alveolo-palatal	Palatal	Velar	Uvular	Pharyngal	Glottal
Consonants	Plosive	p b		t d	ʈ ɖ			c ɟ	k g	q ɢ		ʔ
	Nasal	m	ɱ	n	ɳ			ɲ	ŋ	ɴ		
	Lateral Fricative			ɬ ɮ								
	Lateral Nonfricative			l	ɭ			ʎ				
	Rolled			r						ʀ		
	Flapped			ɾ	ɽ					ʀ		
	Fricative	ɸ β	f v	θ ð | s z | ɹ	ʂ ʐ	ʃ ʒ	ɕ ʑ	ç j	x ɣ	χ ʁ	ħ ʕ	h ɦ
	Frictionless Continuants and Semivowels	w | ɥ	ʋ	ɹ				j (ɥ)	(w)	ʁ		

Vowels	Rounded	Front	Central	Back
Close	(y ʉ u)	i y	ɨ ʉ	ɯ u
Half-close	(ø o)	e ø	ə	ɤ o
Half-open	(œ ɔ)	ɛ œ		ʌ ɔ
Open	(ɒ)	æ ɐ a		ɑ ɒ

(Secondary articulations are shown by symbols in brackets.)

OTHER SOUNDS.—Palatalized consonants: t̠, d̠, etc. Velarized or pharyngalized consonants: ɬ, ɖ, ʐ, etc. Ejective consonants (plosives with simultaneous glottal stop): p', t', etc. Implosive voiced consonants: ɓ, ɗ, etc. r̆ fricative trill. ʊ, ɻ (labialized θ, ð, or s, z). ɺ, ǯ (labialized ʃ, ʒ). ɻ, ɭ, ɺ (clicks, Zulu *c*, *q*, *x*). l (a sound between ɾ and l). ʍ (voiceless w). ɪ, ʏ, ʊ (lowered varieties of i, y, u). ɜ (a variety of ə). ɵ (a vowel between ø and o).

Affricates are normally represented by groups of two consonants (ts, tʃ, dʒ, etc.), but, when necessary, ligatures are used (t͡s, t͡ʃ, d͡ʒ, etc.), or the marks ‿ or ‿ (f‿s or t‿s, etc.). c, ɟ may occasionally be used in place of tʃ, dʒ. Aspirated plosives: ph, th, etc.

LENGTH, STRESS, PITCH.—ː (full length). ˑ (half length). ˈ (stress, placed at beginning of the stressed syllable). ˌ (secondary stress). ˉ (high level pitch); ˍ (low level); ˊ (high rising); ˏ (low rising); ˋ (high falling); ˎ (low falling); ˆ (rise-fall); ˇ (fall-rise).

MODIFIERS.—˜ nasality. ̥ breath (l̥ = breathed l). ̬ voice (s̬ = z). ʻ slight aspiration following p, t, etc. ̩ specially close vowel (e̩ = a very close e). ̞ specially open vowel (e̞ = a rather open e). ̫ labialization (n̫ = labialized n). ̪ dental articulation (t̪ = dental t). ʲ palatalization (ż = ʒ). ̺ tongue slightly raised. ̻ tongue slightly lowered. ̹ lips more rounded. ̜ lips more spread. Central vowels ï (= i̽), ü (= ʉ̽), ë (= ə̽), ö (= ɵ̽), ë, ɔ̈. ̍ (e.g. n̍) syllabic consonant. ̯ consonantal vowel. ʃˢ variety of ʃ resembling s, etc.

results, investigations must be made by both methods.

Analysis by ear can be carried out only by an observer who is a trained phonetician; *i.e.,* a person who has been trained to distinguish and recognize minute shades of sound and recognize and imitate a number of foreign sounds and sound combinations. He must have as a collaborator a native speaker of the language to be analyzed. The phonetician asks the native speaker to repeat words and phrases of his language a number of times. He may find these words and phrases to be composed of sounds already known to him. If so (and if the language does not present special difficulties in the matter of length, stress or intonation), he will at once be able to repeat them to the native's satisfaction. If the native is not satisfied, it means that the word or phrase contains one or more unfamiliar sounds or that the language contains some unusual features of length, stress or intonation. To acquire the correct pronunciation, the phonetician makes fine adjustments in the positions and movements of his own speech organs in repeating the words to the native speaker. He tries one variation and then another until he succeeds in pronouncing the word or phrase to the native's satisfaction. He then knows by his own muscular and tactile sensations what is the exact manner of formation of the unfamiliar sounds of the language.

Analysis of speech sounds by the acoustic method may be checked by experimental methods; *i.e.,* investigation by instruments. The positions of the tongue and velum (soft palate) and of the shapes assumed by the pharyngeal cavity may be more easily ascertained with the help of X-ray photography. Indications of tongue positions may also be found by the use of a special kind of artificial palate.

Phonetic Symbols.—In nearly every language the number of distinguishable sounds is greater than the number of letters in the Roman (Latin) alphabet. It is therefore impossible to represent most languages unambiguously by means of the ordinary Roman letters only. Any "romanic" phonetic system, therefore, whether designed as a current orthography or as a transcription for the use of language learners, must contain new letters to supplement those of the present Roman alphabet.

Classification of Speech Sounds. — Table I, showing the International Phonetic Alphabet (IPA), taken in conjunction with the chart of the organs of speech (fig. 1), shows the chief principles of sound classification. The meanings of most of the technical terms describing the various classes of sounds are self-evident. Attention may be called, however, to the following, which require some explanation: The back of the tongue is the part which lies normally opposite the soft palate; the front is the part which lies normally opposite the hard palate; the blade is the part which lies normally opposite the teethridge (upper gum, alveolars). Palatal consonants are those formed by the front of the tongue against the hard palate, such as the English sounds of *y* or the German *ch* in *ich.* Retroflex consonants are those made by the tip of the tongue against the hard palate, such as the Hindi sounds of ट ड. (See also VOICE; PRONUNCIATION.)

Intonation. — An important branch of phonetics is that which deals with intonation, or the rise and fall in the pitch of the voice. In the languages called tone languages (*e.g.,* Chinese and most Sudanic and Bantu languages) intonation is used to distinguish one word from another. Thus in Cantonese the syllable *fan* said with a high falling tone means "divide"; said with five other tones it means "powder," "sleep," "burn," "courageous" and "duty," respectively. In the Sechuana language (Bantu) of South Africa, *metse* said with a mid-level tone on each syllable means "villages," but with a mid-level tone on the first syllable and a high-level tone on the second it means "water."

In languages which are not tone languages intonation affects the meaning of whole sentences, but it is not an integral part of any word. Intonation gives expression to sentences; it conveys shades of meaning which cannot conveniently be expressed by other means. Thus in English the two meanings of I *beg your pardon* ("I am sorry" and "What did you say?") are distinguished by intonation. It is not practicable to mark this kind of intonation in orthography, though slight indications of it may be given by the use of punctuation marks or italics.

Phonetic Description. — The sounds of speech are usually described either in articulatory or in acoustic terms.

Articulatory descriptions are based on the parts of the vocal tract which are used in forming a given sound (*see* fig. 1). For instance, vowel sounds can be classified according to several positions of the articulators such as the tongue, the lips and the degree of mouth opening. Fig. 2 shows the tongue positions for several vowels. Fig. 2 (left) shows a series of front vowels, so-called because the tongue is bunched forward in the mouth as opposed to the back vowels in fig. 2 (right) in which the tongue is bunched toward the back of the mouth. In fig. 2 (left) the letter [i], which is the phonetic symbol for the "ee" sound in "meet," is the highest of the front vowels, and [a] as in "cat" is the lowest of the front vowels, since the tongue is not so high toward the roof of the mouth. In fig. 2 (right), [u] as in "who" and [a] as in "father" are the highest and lowest back vowels, respectively.

In some languages, such as Russian and Spanish, it is more efficient to describe the vowel sounds in terms of lip rounding and mouth opening. In such languages [i] is described as an unrounded close vowel since the mouth opening is slight and the lips are not rounded or pursed as they are in [u], which is a close rounded vowel. These two vowels differ from the vowel [a] which is open and has no significant rounding or unrounding. (It is rather difficult to drop the jaw and purse the lips at the same time!) Nasal vowels are produced by dropping the velum (soft palate) so that the nasal passage is open. (In the case of nasal vowels, the air does not usually pass through the nose, which is used only as an additional resonator for the sound.)

Consonantal sounds are described in terms of point of articulation. For instance, [p] is called a bilabial because both lips are brought together to produce the sound, as opposed to the [t], which is called a dental sound because the tip of the tongue is at or near the upper front teeth. Both of these differ from [k], which is articulated with the back part of the tongue somewhere in the region of the velum; hence it is called a velar sound. Consonants are also described in terms of the activity of the air stream in the mouth and the activity of the vocal cords. When the vocal cords are vibrating the sound is said to be a voiced sound; otherwise it is voiceless. When the air stream must pass through a narrow opening, as in [f] or [s], the sound is called a fricative. The air stream is continuous in the fricatives but interrupted in the plosives or stops ([p], [t], [k]).

In the case of the nasal consonants such as [m] and [n], the velum is dropped, as it is for nasal vowels, and part of the air stream passes through the nose. Finer degrees of articulation are shown in the IPA chart (Table I).

In describing the acoustic qualities of speech sounds it is convenient to consider their source and transfer functions. The former refers to the kind of excitation involved; *i.e.,* whether the sound is periodic or random (turbulent). When the vocal cords vibrate they produce a complex periodic wave form composed of a fundamental and its harmonics. On spectrograms (narrow band) such a wave form appears as a series of horizontal lines, longer or shorter depending on the duration of the sound. When the air stream is caused to pass through a narrow constriction, as in the fricatives (*e.g.,* [s], [f]), the spectrogram shows a gray smear

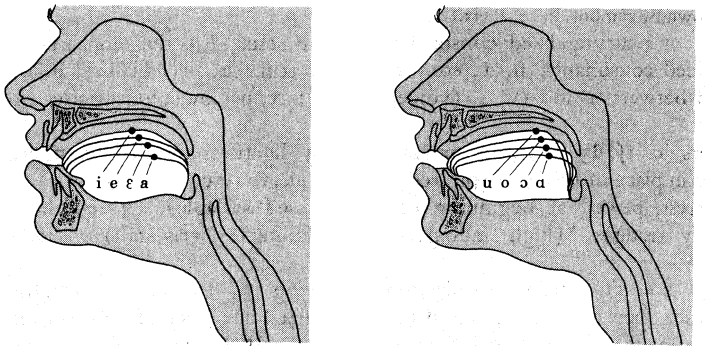

FIG. 8.— TONGUE POSITIONS OF (LEFT) THE FRONT AND (RIGHT) THE BACK CARDINAL VOWELS

covering the entire frequency range.

The various cavities in the vocal tract act as resonators which either reinforce or cancel out some frequencies or frequency regions of the original excitation function. Hence it is convenient to consider the source function to be the substance of the sound and the transfer or resonance function as its form. In vowels, for instance, the source is periodic and the resonators cancel out certain groups of harmonics and reinforce others. **A** typical sound spectrogram of a vowel resembles music notation paper, a series of staves composed of lines, with blank spaces between. Such a staff of harmonics is called a formant or a bar, and indicates a resonance region.

Except under very special circumstances, these formants are independent of the pitch or fundamental frequency at which the vocal cords are vibrating, since they are given their form by the shape of the resonating cavities in the vocal tract. Since the vocal tract assumes a different shape for each of the vowels, as explained above, the resonances or formant frequency regions of each vowel differ from those of other vowels.

It has been found that the vowels of most languages can be differentiated by describing the lowest two (or three) formants, which occur between 250 and 3,000 cycles per second (c.p.s.). Thus the two significant formants of the [i] sound occur at the lower and higher limits of this region, those of the [u] both at the lower end of the region and those of [a] in the centre of the region.

When the source function is not periodic, the resonators also reinforce certain frequency regions and cancel out others, but these regions are usually called resonance regions rather than formants. Thus a spectrogram of [s] will show a gray smear in a high-frequency region (around 6,000 c.p.s.) and [f] a weak smear at a very-low-frequency region. The stops differ from the fricatives in the way they begin. The stops begin abruptly and have a short spike-like appearance on spectrograms, whereas the fricatives begin smoothly and are longer in duration.

The Phoneme. — The only significant difference between the English words "ban" [bæn] and "man" [mæn] is in the first sound. While both are labial sounds, one is a nasal and the other is a stop. When a word can be transformed into another word by such a change, the two sounds are said to be distinctive or phonemic. They are, or they represent, two different phonemes. Phonemics (an alternate term, phonematics, is preferred by some linguistic authorities) is the analysis of the distinctive sounds or phonemes of a language.

Phonemic distinctions differ from one language to another, hence each ianguage has its own set of phonemes or distinctive sounds. For instance, in Czech there is a difference between long and short vowels: *náraz* [na:ras], "shock"; *naráz* [nara:s], "at once." This distinction does not hold for most varieties of English, although there is a phonetic difference in vowel length between "hit" [hɪt] and "hid" [hɪ:d]; changing the length of the vowel in "hit," however, will not transform it into another word, and the same holds true for shortening the vowel in "hid." Phonemic transcriptions indicate only the distinctive qualities of the sounds and are enclosed in slanted lines to differentiate them from phonetic transcriptions, which are not committed to indicating only distinctive differences:

	Phonetic	*Phonemic*
"hit"	[hɪt]	/hɪt/
"hid"	[hɪ:d]	/hɪd/

When two words differ by only one phoneme, such as English "bat" /bæt/ and "sat" /sæt/, the words are said to be a minimally distinct pair. In a minimally distinct pair of words, if there is a difference of only one distinction between the two phonemes in question, then the two phonemes are minimally distinct phonemes. Thus in English "pat" /pæt/ and "bat" /bæt/, /p/ and /b/ are both stops, both are bilabial and the only difference is that /p/ is unvoiced (or tense) and /b/ is voiced (or lax). The phonemes /b/ and /s/ in the previous example are not minimal because one is a fricative, the other a stop; one is bilabial, the other is dental; one is voiced and the other is unvoiced.

Distinctive Features. — For both phonetic and phonemic purposes it is often necessary to describe the relations existing between sounds, the "structure" of relations between the phonemes of a language. Most phoneticians and linguists achieve this end

*TABLE 11.—Distinctive Features of American English**

Compact	Grave	H	T				W		
			P		F		N	J	V
0	0	h							
−	−		t	d	s	z	n	j	ɪ
±	−		ʃ	ʒ	ʃ	ʒ	ŋ		ɛ

by using the phonetic classifications, either articulatory or acoustic (or both), such as those outlined above. A system for describing these distinctive features in binary terms was developed by Roman Jakobson and his collaborators shortly after World War II. This system describes the phonemes of a language in terms of the presence or absence of a small number of distinctive features based on articulatory or acoustic terms.

Table II shows such an analysis based on one variety of American English. The plus (+) indicates the presence of that feature, the minus (−) its absence, the zero (0) its irrelevance. The (t) sign usually is used only where the feature can be described in terms of a scale of such values as high, mid or low, and is avoided wherever possible.

This type of classification, utilizing as it does the binary notation system of the mathematical theory of communication, can be used to great advantage wherever phonetics and phonemics play a role, from the learning of foreign languages to the development of more efficient electronic speech compression systems.

PHONOGRAPH, an instrument for reproducing sound by transmitting to the air (directly or indirectly) the mechanical vibrations of a stylus in contact with a sinuous groove in a moving record. In a wider sense a phonograph is any instrument for reproducing recorded sound. In this expanded view the record may be mechanically, optically (photographically) or magnetically recorded and reproduced as sound by appropriate apparatus.

Information on related phases of sound reproduction can be found in the articles HIGH-FIDELITY SOUND SYSTEMS; LOUDSPEAKER; and TAPE RECORDING, MAGNETIC. This article consists of the following parts:

I. HISTORY

A prototype of the phonograph appeared in 1857 when Leon Scott constructed a device he called the Phonautograph, which recorded, as a wavy line on the smoked surface of a rotating cylinder, the movements of a diaphragm or other vibrating body. The first record of vibrations which could be played back to reproduce sounds was invented by Thomas A. Edison in 1877. The record was in the form of indentations pressed into a sheet of tin foil by the vibrating recording stylus, which was attached to a diaphragm. The tin foil was wrapped around a cylinder that rotated as the sounds were being recorded. A thread on the shaft moved the cylinder axially as it rotated, so that the record groove was helical. A small helical groove having the same pitch was cut in the surface of the cylinder, and the recording diaphragm and stylus were positioned to bring the groove directly under the slightly rounded point of the stylus, thus making it easier to produce the indentations in the tin foil. The sound waves were recorded as variations in the depth of the groove. For reproduction the groove was again run under the stylus tip, with only enough pressure to maintain contact with the groove bottom. The term "embossing" has been widely used to designate the method of recording in which the groove is impressed in a yielding material by a rounded point.

Edison took steps toward the exploitation of his invention, which he called the phonograph, but he was soon diverted to the development of the incandescent lamp and electric power systems. Several years after the first flare of publicity which followed Edison's demonstrations, Alexander Graham Bell became interested in the phonograph, and with two associates, Chichester A. Bell and Charles Sumner Tainter, began experiments in Bell's "Volta" laboratory in Washington, D.C. They had best results with an arrangement much like Edison's except that their machine cut or engraved the groove in a cylindrical surface of wax with a sharp tool carried by the vibrating diaphragm. This gave much better sound reproduction than had been possible with Edison's indented tin foil. In 1885 C. A. Bell and Tainter applied for a U.S. patent on this principle and other features of their developments, and in 1887 they organized a company to manufacture and sell Graphophones, as they called their machines. Edison returned to his experiments with the phonograph, and he too became convinced of the superiority of the engraved wax groove.

Various promotional and organizational activities took place in the next few years, the most important results of which were that the Columbia Phonograph Co. became the manufacturing and selling organization for the Bell and Tainter developments, and rights under both the Edison and the Bell and Tainter patents became available to both the Columbia and Edison companies.

1. Disc Recording.—Another inventor, German-born Émile Berliner, was responsible for a radical departure in sound recording. The initial Step in Berliner's recording operation resembled that of Scott's Phonautograph, except that Berliner's mechanism traced its wavy line as a spiral on a flat disc, instead of as a helix on a cylindrical surface. The disc was of zinc, coated with a thin layer of fatty substance which protected it from the action of acid except where the scribe had traced its line. An acid bath then left a groove, the width and depth of which could be controlled by the duration and strength of the acid treatment. Berliner thus obtained a record which could be played by means of an appropriately designed reproducing mechanism.

However, he did not contemplate using this etched master as the record to be played; rather, a negative was made from the master by electroforming, and the negative then was used to mold records in some thermoplastic material, a procedure that subsequently became standard. Berliner first proposed using vulcanite or hard rubber as the molding material, but he later found a company that could mold records for him in a material much like that which later became common for all records. Berliner's records were far harder and more durable than the waxes of which the cylinders were being made. The harder material, plus somewhat greater amplitudes due to the fact that the recording stylus did not have to work against any cutting resistance, made somewhat greater volume possible in the reproduced sound.

Of still greater importance to the success of Berliner's discs, however. were the ease of molding from a flat surface and the fact that he could make his grooves deep enough to guide the reproducing stylus across the record without the need for an auxiliary feed screw. It was to the latter feature that the most important of Berliner's patent claims were directed.

Small-scale manufacturing of the Gramophone, as Berliner

called his machine, was started in 1894. The Gramophones were much simpler than the cylinder machines of Edison and Columbia, and could be sold relatively cheaply, while records for them could be made at much lower cost. But driving the record by means of a hand crank was unsatisfactory for anything but demonstrating a principle. Berliner recognized the need for a clockwork drive and controlled speed. He sought outside help, and the problem was eventually brought to Eldridge R. Johnson, who operated a small machine shop in Camden, N.J. Johnson soon worked out a practical design for a spring-driven motor with a friction governor, and in a short time (1896) was building for the Berliner Gramophone Co. not only the spring motors but all the mechanical parts of the Gramophones. Besides developing the spring motor, Johnson made various improvements in the Gramophone, including a better "sound box," the principal features of which were retained with little change throughout most of the history of the acoustic phonograph.

Johnson's experiments soon convinced him that the noisiness of the Gramophone records arose from the roughness of the etched surfaces, and he began to study the possibilities of cutting the groove in wax as Bell and Tainter had done; however, instead of recording the vibrations as variations in depth of the groove (commonly called vertical or hill-and-dale recording), he followed Berliner's practice of recording them as sidewise deflections of a groove of uniform depth (commonly called lateral recording). Johnson mastered the techniques of rendering the wax surface conductive by dusting with graphite and then electroplating, thereby producing a "negative" of the grooved wax. This negative, built up in the plating process to sufficient thickness for needed strength, could then be used to press records in thermoplastic material. The records so made were much clearer and less noisy than those produced by Berliner's process.

For several years the sale of Gramophones and records grew and Berliner prospered, but in 1900 his one sales outlet stopped ordering, and then a court injunction was obtained by competitors (based on alleged infringement of a detail patent) forbidding his company to make or sell Gramophones. Johnson had an enlarged factory and a large inventory of machines. He decided to do his own selling. He started with an advertising campaign featuring greatly improved records produced by a newly developed process and offering a free sample. The business grew and prospered.

In addition to his own technical contributions Johnson now had a going business to offer in exchange for rights under the basic Berliner patents. In Oct. 1901 a new company was formed, the Victor Talking Machine Co., the stock of which went partly to Johnson and partly to Berliner, with the controlling interest in Johnson's hands.

A serious threat to the Victor company arose shortly after its formation, when the Columbia company acquired a patent describing and claiming the process of recording by cutting a laterally varying groove of constant depth in wax, exactly as Johnson was doing. The Columbia company was just beginning to make disc machines, but in so doing it was sure to fall afoul of Berliner's patents. Rather than engage in costly litigation the Victor and Columbia companies arranged for cross-licensing. Thenceforward, competition was in terms of such factors as costs, merits of machines, prestige and quality and popularity of available records.

2. European Developments. — The beginnings of the phonograph business in Europe were limited largely to the activities of sales agents from the already established American companies. Demonstrations of Edison's tin-foil machine were given in 1878 in England and Germany, where they created much interest but little else. A decade later Edison made a serious effort to extend his beginning business by demonstrating his wax cylinder system for many distinguished persons and making recordings of the voices of celebrities. The prices of machines imported from the U.S. were too high for any considerable sales for private use, but, as in the United States, many people were willing to pay a small fee to satisfy their curiosity and hear a machine talk.

As an attraction for their tavern, two Frenchmen, Charles and Emil Pathé, procured a phonograph from England. But when customers showed more interest in the possibility of buying a phonograph than in the other Path6 business, the brothers decided to start making phonographs. They started with a small shop and by 1894 were doing a thriving business, making machines and wax blanks. They were also active in recording, using mechanical methods of duplicating the records, and by 1899 had a large list of available cylinders, principally of popular French singers.

In Italy there was no large market for machines, but the music-loving public would pay at some public installations to hear their favourite operatic songs.

Aside from a short-lived venture of making Gramophones in their simplest (hand-cranked) forms, started in 1889 by a German toymaker, there was little commercial phonograph activity in Europe, except that of the Pathé brothers, until the arrival of emissaries from the then-prospering Berliner group: William Barry Owen in 1897 to establish a branch in England, and Joseph Sanders in 1898 to help Émile Berliner's brother start a record pressing plant in Hanover, Ger. By this time the quality of reproduction had reached a point that made the Gramophone of interest as a source of home entertainment and that induced well-known artists to permit their voices to be recorded. Owen eventually interested certain British investors, and the Gramophone company was organized there in 1898; it imported parts from the U.S. and assembled Gramophones in England. Records, at least at first, were processed and pressed at the Hanover plant. As soon as machines and records became available, extensive advertising was begun, and in the autumn of 1898 sales reached the full capacity of the manufacturing facilities. Owen opened branches for Gramophone sales and recording activities in Berlin and in Russia and Austria, and finally in France and Spain. It was in Russia in 1900 that red labels were first used to distinguish recordings of celebrated artists. For these discs the size was increased from seven to ten inches. In 1899 Owen purchased for the Gramophone company the original painting of a dog listening to a phonograph, to which the name "His Master's Voice" was given. This was soon used as a trademark by the Victor company, and about a decade later also by the Gramophone company, whose records were designated by the initials "H.M.V."

Recording the lateral-cut gramophone discs in wax began in Europe as well as in the U.S. in 1900 but did not entirely supersede the etching system for a year or so.

3. Technical Developments in Acoustic Recording. — Aside from the great growth in the phonograph business and refinements from time to time in recording equipment and techniques, the history of the acoustic phonograph was marked by the following developments:

Methods of molding cylinder records of a relatively hard thermoplastic were introduced by the Edison and Columbia companies in 1901. Since these were announced as "gold molded," it is presumable that gold sputtering was used to give an electrical conducting surface to the wax original.

The Odeon company was formed in Berlin in 1903. The following year it introduced discs with recordings on both sides. Columbia began issuing double-sided records in 1908. Path6 began making hill-and-dale cut discs in 1906 and in 1908 offered 11-in. double-sided discs.

In 1908 Edison brought out cylinders of a new material which he called Amberol, which was harder than the materials previously used. By increasing the number of grooves per inch from 100 to 200 he could offer four minutes of playing time. In 1912 Edison introduced a further improvement in material; he called the new material, which was more resistant to abrasion, Blue Amberol. Roland Gelatt noted that the Blue Amberols were relatively noiseless and, when played with an Edison diamond reproducer, produced better results than any other type of music reproducer then available. In 1913 Edison began making discs and a phonograph to play them. However, he continued to make cylinders for owners of cylinder machines until his company ceased operations in 1929.

The advent of radio broadcasting in the early 1920s brought severe depression to the phonograph industry. The Columbia company went into receivership in 1923; the competition of the

fast-growing radio industry did not seriously affect the Victor company until *1925*. The introduction of electrical recording (by both Columbia and Victor), improved phonographs and combination radio receivers and phonographs soon brought recovery. The British Columbia company had fared much better than the U.S. company (now unaffiliated), and its president, Louis Sterling, bought controlling interest in the American company and took licences for both companies to use the new developments.

The Victor Talking Machine Co. was purchased by Radio Corporation of America in *1929*. Its plant at Camden, N.J., became the production centre for radio equipment as well as phonographs and records.

4. Horns. — The performance of an acoustic phonograph is greatly affected by the size and shape of the horn; and while there was little in the way of technical study during the era of the acoustic phonograph, there was some progress toward better horns. Ear trumpets and megaphones had long been familiar, and the developers of phonographs were quick to take advantage of what horns could do for their machines. The horns assumed various shapes according to the ideas of those who made them. The easiest horn to construct is of simple conical shape, but after about *1920* the exponential horn was the nearly universal choice of engineers. A theoretical analysis of its characteristics was published by A. G. Webster in *1919*, and the subject was further elucidated by C. R. Hanna and J. Slepian in *1924*.

An exponential horn is one whose cross-sectional area doubles with each increase of x inches in distance along the axis from the small end; or, if it is a round horn, the diameter doubles with each increase of $2x$ in axial distance. A small value of x therefore yields a horn of rapid flare, while a large value yields a slowly expanding horn. Every exponential horn has a critical frequency, known as its cutoff; below this frequency the horn is of practically no use, while for higher frequencies it will reproduce very effectively. The cutoff frequency is that at which the wave length is approximately $20x$; hence, to extend the range of response to lower frequencies, x must be made large. To avoid horn resonance, Hanna and Slepian recommended that the expansion be carried to the point at which the surface (of a horn of circular cross section) makes an angle of 45° with the axis. This results in a large bell or final opening.

From the time of the very first phonographs it was customary to funnel the total air displaced by a diaphragm into a horn opening of considerably smaller diameter. This results in greater loading of the diaphragm. reducing its tendency to resonate (*i.e.*, damping it) and deriving from it increased sound power. The volume of air nithin the sound box must be small so that appreciable compression will not take the place of air flow.

Horns can be bent or "folded" to conserve space without too seriously impeding their performance, provided the difference between the shortest and longest paths around the bend is not over about one-third the shortest wave length to be transmitted.

Comparing a conical horn with an exponential horn of the same length and initial and final openings, the cone expands much more rapidly at its small end and much more slowly near the large end. The result is that the conical horn gives some multiplication of air flow at frequencies well below the cutoff frequency of the exponential horn. and the output climbs gradually through a long range of frequency, without ever quite overtaking that of the exponential horn above its cutoff.

The horns of the early phonographs were in some cases frustums of simple cones, but more frequently they ended in a rapidly flaring bell. like a trumpet. In some cases the angle between side and axis increased toward the large end, giving a shape between that of a cone and an exponential horn. However, early horns were relatively small and were not designed to avoid resonances due to reflections at the bell. Some of the resonant points may have been regarded as desirable for increasing sensitivity. The feeble response at low frequencies was of less consequence, since there was little of low frequency on the records. Recording equipment was usually provided with larger horns, often of simple conical shape.

As experience accumulated, the sizes of horns increased, at least on the better machines. In *1906* the Victor company marketed a machine with the horn built into the cabinet. This facilitated increasing the horn size and also made it desirable to keep down the size of the middle part of the horn, thus favouring a shape somewhat closer to the exponential. The slight taper of the swinging pickup arm, which constituted the first part of the horn, increased the general resemblance to the exponential shape. In later models with larger cabinets, larger and still better-shaped horns were employed. However, it was not until the introduction of the Orthophonic design in *1925* that a definitely planned exponential expansion was followed, with considerable increase in length and with an end opening occupying practically the whole front of a large cabinet.

II. ELECTRICAL RECORDING AND REPRODUCTION

Prior to *1925* the phonograph had been developed almost wholly on an empirical or "cut-and-try" basis, with little theoretical analysis and all decisions based on listening tests. Recording was looked upon as an art, and rightly so, for the judgments of an experienced recording engineer as to balance and choice of selections were of utmost importance. Certain voices and instruments recorded well while others did not, and early recognition of poor qualities could often forestall wasted recording sessions. Details of recording equipment and practices were often treated as trade secrets. To the old-line phonograph organizations, the rapidly developing and expanding radio and electronics industries seemed almost unrelated to their own, and few of them sought any help from electronics technicians.

The great difficulty in all direct recording lay in the extremely limited amount of acoustical power which could be collected and applied to actuate the diaphragms of the record-cutting devices. Only in the electronics field was there such a thing as an amplifier capable of multiplying sound power a thousandfold and more, with almost no loss of quality. The initiative in the development of electrical recording was taken by the Western Electric Co. Some work looking toward phonograph applications had been started as early as *1915*, interrupted by the war, and then resumed soon afterward under the direction of J. P. Maxfield. The men who took part had extensive experience not only in amplifier applications but in the many electrical and mechanical problems encountered in telephone apparatus and transmission. Much use had been made of electrical-mechanical analogies which helped make experience in the electrical field applicable to mechanical problems and vice versa.

1. Theoretical Aspects. — In the development of electrical recording and reproducing apparatus an important principle of design of vibrational apparatus was introduced. The essential moving parts of either a recorder or reproducer have a certain amount of mass. Forces to actuate these masses must be produced magnetically in the case of the recorder or by the action of the record on the needle tip in the case of the reproducer. It is desirable to minimize the required forces. It happens that it is not necessary for all of the moving elements of either device to be combined into a single mass. In the recorder the armature of the electromagnetic motor can be separate from the stylus bar and stylus. In the reproducer the needle with its clamp and the lever which connects it to the diaphragm constitute one part; the diaphragm constitutes the other principal mass. If a phase difference can be permitted between the motions of the two related parts, the maximum force that must be applied to the needle to vibrate these masses can be practically halved. The introduction of an elastic connection or "compliance" permits this phase difference. In the recording cutter the torsional flexibility of a short shaft, between the motor armature and the bar carrying the stylus, offers the compliance, and there is another such flexible shaft between the stylus bar and a disk to which the mechanical resistance device is attached. The moment of inertia of each mass element, and the flexibility of each shaft, must be closely adjusted to predetermined values, and the structure of alternate masses and compliances (which is the mechanical equivalent of an electrical low-pass filter) must be terminated by a true mechanical resistance of correct value; otherwise there will be irregularities

in its response. A pure mechanical resistance is not easy to provide.

Some recording heads employed oil for viscous damping; others used special solid materials. In the case of the reproducing device employed in the Orthophonic Victrola, the compliance was provided by a springy "spider" through which the lever actuated the diaphragm, and the required mechanical resistance was obtained by the reaction of the air in the "sound box" and horn throat on the diaphragm. With appropriate proportioning of the sound box volume and the relative areas of horn throat and diaphragm, and with a sufficiently slowly expanding horn, the energy was radiated as useful sound and the diaphragm worked against a substantially pure resistance. The Orthophonic design not only reduced the reaction of the needle on the record but, because of its higher efficiency in radiating the vibrations, gave greatly increased sound output.

While the input impedance of the recording device was practically pure resistance throughout most of the frequency range covered, the springs that centred the motor armature between the pole pieces added a stiffness reactance which predominated over resistance below about 300 cycles per second (c.p.s.). The resulting characteristic of the recording system (expressed as stylus movement for constant electrical input) was of constant amplitude up to 300 c.p.s., and of constant velocity from 300 to 5,000 c.p.s., the upper limit being determined by the cutoff of the mechanical filter previously discussed. Were the constant velocity range extended much lower, the amplitudes at the lowest frequencies would be excessive, necessitating wider groove spacings.

Since the sound level needed for satisfactory operation with a microphone and amplifiers was far lower than had been needed for direct recording, the introduction of electrical recording made it no longer necessary to group the players close together around the recording horns, nor to resort to instruments of special construction. Orchestras and choral groups could perform under conditions similar to those to which they were accustomed in concerts. It was not necessary to give preference to instruments of high acoustical power nor to singers with powerful voices.

Licences were taken by the Victor and Columbia companies to use the Western Electric recording system and equipment, and to build phonographs utilizing the principles and design features described above. The name Orthophonic Victrola was applied to the Victor machine. The horn in this model had considerably greater length (six feet) and final opening area (about eight square feet) than any in previous machines, the rate of expansion being slow enough to make the horn effective down to 115 c.p.s. To accommodate the length within the cabinet the passages were bent or folded several times. The improvements in records and phonographs were quickly recognized and resulted in great increases in sales.

2. Electrical Reproduction. — Although the sound quality of the Orthophonic machine (which was nonelectrical) was excellent, the advantages of electrical reproduction — ease of control, high amplification and simplification by combining the phonograph and radio receiver — made it inevitable that the electrical system would sooner or later supplant the mechanical. The electrical loud-speakers of the early 1920s left much to be desired, and the transition would scarcely have taken place when it did were it not for the advent of a greatly improved loud-speaker described in April 1925 by C. W. Rice and E. W. Kellogg of the General Electric Co. It was marketed by Radio Corporation of America (RCA) in 1925 as a separate loud-speaker for radio, known as the Radiola 104. It has frequently been called the "dynamic cone speaker." In addition to employing the dynamic or moving-coil drive and a conical paper diaphragm (about six inches in diameter), it had the following features which were equally important to the successful results: a very flexible suspension of the diaphragm (fundamental resonance about 60 c.p.s.); a baffle to prevent air circulation between the front and back of the diaphragm; and an amplifier of adequate power capacity to avoid overloading. Prior to this, the means most widely employed for actuating loud-speaker diaphragms depended on the varying pull of a polarized electromagnet on an iron armature. To maintain the armature at the proper spacing from the magnet poles, it had to be held by a stiff spring, and therefore the very flexible diaphragm mounting was not feasible with such "magnetic motors." The first electrical phonograph using the new loud-speaker was the Panatrope of the Brunswick Balke Collender Co., first demonstrated in the autumn of 1925; it employed an electromagnetic pickup. Outstanding in its sound quality was the abundant bass. Early in 1926 the Victor Talking Machine Co. brought out several models of electrical phonographs, some of which were combined phonographs and radio broadcast receivers. These used pickups of the same (General Electric) design as the Brunswick, but for a short period the loud-speaker given preference was one utilizing a large horn built into the cabinet like that of the Orthophonic, with an electrical unit employing a relatively small diaphragm, driven by a balanced armature "motor." Another electrical phonograph which achieved considerable popularity was the Majestic, similar in general principles to the Brunswick but differing in design details.

The baffle loud-speaker offered an important practical advantage for use in homes, because the space requirements were much less than needed for horns of adequate size to give good bass, but for theatre and auditorium applications the directivity of horns was important and space was not so restricted. Designs varied, but practically without exception the horns were exponential in expansion rate and after about 1926 the diaphragms were coil driven. The improved loud-speakers for auditoriums, with improved pickups for reproduction from discs, were applied in the motion-picture field, and resulted in the rapid conversion from silent to sound motion pictures. The commercial realization of this change started in 1926, and the earliest commercially successful sound pictures made use of lateral disc records 16 in. in diameter operating at a turntable speed of 335 r.p.m. and synchronized with the motion-picture film. (See also LOUD-SPEAKER.) (E. W. KE.)

3. Evolution of Fine-Groove Records. — A number of factors played a part in the evolution of fine-groove records. The demonstrations by H. C. Harrison and H. A. Frederick in 1931 of their new hill-and-dale acetate records showed what could be done in greatly reducing surface noise through use of refinements in record processing and a pickup with low vertical force and low mechanical impedance; the pickup permitted use of softer record material, free of any filler such as was used in the shellac records. The development of feedback recorders, the vertical recorder by L. Vieth and C. F. Wiebusch, and the lateral feedback recorder by G. R. Yenzen, also helped contribute to low distortion, extended range and smoother response obtainable with a feedback control that included the vibrating system.

But there were obstacles to change in the home phonograph field, obstacles that applied in much less degree to broadcast transcription service. The first magnetic pickups had rather high output, so their signals could be fed to the first audio stage of radio receivers without additional amplification. But they were also of high mechanical impedance (stiff needle mounting), the correction of which would reduce the output, and high mechanical impedance necessitated high vertical force. Cost-conscious designers were reluctant to put in more amplification. Because there were in existence, millions of records hard and tough enough to stand such forces, incentive to make a change was lacking. It was not until H. J. Hasbrouck's work on elimination of noise from the pickup and record that a pickup having truly low mechanical impedance was adopted. This permitted reducing the vertical force on the stylus to a few grams, but such small forces were insufficient to trip some record changers; consequently, full advantage could not be taken of the new pickups without improvements in record changers.

The reduction in necessary vertical force was so great as to make it feasible to use stylus tips of reduced radius, resting against the sloping sides of the groove instead of on the bottom; furthermore, this could be done while using records of clear vinylite, free from fillers. The advantages of using a finer stylus tip — in reduced tracing distortion, in finer groove pitch and in permitting some reduction in linear velocities — had been realized for a number of years but were especially convincingly shown in the analytical papers of F. V. Hunt, J. A. Pierce and W. D. Lewis, who also demonstrated a practical design for a low force, jewel-tipped pickup. They also showed the superior tracing possible with

lateral-cut records, provided the spherical stylus tip maintained contact with the sloping side walls of the groove and cleared the bottom.

The dimensions of a record groove are determined by the lateral displacement of the groove resulting from the signal, or music, and by the dimensions of the reproducing stylus. It is evident that a reduction in either or both of these factors permits a reduction in the dimensions of the groove and thus makes possible a smaller record or a record having longer playing time. The use of less noisy record materials permits a reduction in the lateral displacement of the groove without reducing the signal-to-noise ratio. The use of pickups with a lower value of mechanical impedance permits the use of a smaller reproducing stylus. Experimental evidence proved that up to 300 grooves per radial inch and a reproducing stylus with a radius of 0.001 in. were practical.

The amount of distortion in the signal reproduced from the record groove increases as the stylus moves toward the centre of the disc—that is, as the relative circumference of the groove decreases and the relative speed of the groove past the stylus decreases. Therefore, the speed at which a disc record should rotate is related to the amount of recorded material it contains, and both speed and amount of material are governed by the circumference of the innermost groove that will give the maximum permissible distortion.

In addition, there is a definite relationship between the diameters of the outermost and innermost grooves that gives the maximum playing time per unit surface area. This relationship is such that maximum playing time for a disc of given size will be achieved if the diameter of the innermost recorded groove is one-half the diameter of the outermost groove; this relationship also is governed by the amount of permissible distortion in reproduction obtained from the innermost groove.

It is important to note that any major change in playing-time calls for a change in speed of the record in order to achieve the least area or amount of record material, as the case may be. This assumes no change in the other factors, such as the radius of the reproducing stylus, the lateral displacement of the groove or the reproduced distortion at the innermost groove.

Modern disc records are designed with full knowledge of these principles. Other factors of a practical nature have resulted in some deviations from the purely theoretical considerations of disc record design. In 1948 both Columbia and RCA introduced fine-groove records of clear vinylite. The Columbia version was 12 in. in diameter, rotated at 333 r.p.m. and had a maximum playing time of 30 minutes. The RCA version was seven inches in diameter, rotated at 45 r.p.m. and had a maximum playing time of eight minutes. After several months of testing the market, the change to fine-groove records became complete, with Columbia and RCA each making both versions.

The justification for these two records results from the wide difference in the playing time of "popular" and "classical" music. Each of the new records offered major improvements in cost, convenience and performance over the older 10- and 12-in. 78.26-r.p.m. records. (A. D. B.)

4. Stereophonic Phonograph Records.—Stereophonic phonograph records with two separate channels of information recorded in a single groove became a commercial reality in 1958, less than a year after the adopted system had been publicly demonstrated. A stereophonic system utilizes two or more independent channels, with separate microphones in recording and separate loud-speakers in reproduction, so arranged as to produce a sense of realism of recording hall acoustics and of location of the instruments of the orchestra with respect to directivity and depth. The effectiveness of stereophonic reproduction was demonstrated by the Bell Telephone laboratories in 1933 when the sound of an orchestra playing in Philadelphia was reproduced over loud-speakers located in Washington. The material was not recorded but was transmitted directly over telephone lines. Two-track stereophonic tape for the home became common in the 1950s, and Emory Cook produced some commercial stereophonic disc records, laterally recorded, in which the two channels of information were carried as separate inside and outside bands on the record; reproduction was through a forked arm carrying two pickups, one riding in each band.

The system finally adopted as standard used a dual-channel feedback recorder and a single stylus with its axes of movement inclined at 45° to the record surface, the pickup being designed to produce two practically independent signals in accordance with the motion components along the two (90° displaced) axes. Since the record groove is V-shaped and ordinarily has an included angle of 90°, the groove walls are 45° with respect to the record surface. Consequently, for the 45°–45° system the signal from one channel varies the position of one groove wall about a mean (no-signal condition) without changing the position of the other.

Operation at 45° provides a symmetrical arrangement that offers advantages both in design of recorders and reproducers and in quality of reproduction, since frequency response, distortion and other characteristics of the two channels are alike. In addition, good reproduction is possible over a single channel (monophonic) system since information from both stereophonic channels is contained in the resultant lateral modulation. However, due to the vertical modulation, monophonic pickups must have greater vertical compliance than normally required for lateral records. P. C. Goldmark recognized this problem in earlier work on stereophonic disc recording and proposed that the vertical modulation be dynamically held within limits that would not exceed the tracking capabilities of existing lateral reproducers. Such a record could be designated as "compatible" and could be reproduced either monophonically over phonograph systems designed for lateral-cut records or stereophonically over stereophonic systems. However, not wishing to risk possible reduction in quality, record manufacturers decided to follow the recommendation of the Record Industry Association of America and produce the two types of records, monophonic and stereophonic, separately. (H. E. R.)

III. RECORD MATERIALS AND PROCESSING

The early tin foil and other recording media ultimately were supplanted by materials of two general types: the wax disc (actually a heavy-metal soap with wax gel) intended for subsequent processing and duplication, and the instantaneous media intended mainly for playback directly from the embossed or engraved original record.

The necessary accuracy of the recorded groove can be judged by the requirements established for fine-groove records: that the bottom radius of the groove be less than 0.00025 in. and the width about 0.0025 in., giving a depth of about 0.00125 in. This is less than one-half the groove size of the 78-r.p.m. record.

In cutting or engraving the master record the stylus must be sharp and accurately ground so that the cut will be very clean. Lacquer-coated discs, usually on an aluminum base, were developed as an instantaneous recording medium, but because of the slightly rubbery nature of lacquer a smooth, low-noise groove was not obtained. The development of a burnishing facet on the stylus cutting edge resulted in quieter grooves but increased cross-modulation (echo) between adjacent grooves. The introduction of the heated cutting stylus about 1950 improved lacquer recording to the point where wax discs became practically obsolete for commercial master recordings.

1. Electroforming.—To make copies of the recording, dies must be made whose surface is a negative replica of the master record surface. Electroforming techniques which reproduce the surface to an accuracy of better than 0.000001 in. are utilized. In electroforming, the surface is made the cathode in an electrolyte solution containing the metal to be deposited. The neutralization (reduction) of the positive metal ions at the cathode surface forms a metal sheet whose thickness is proportional to the current and time.

Before this can be done, however, the master record surface must be made electrically conductive. Prior to 1938 wax recordings were made conductive by brushing graphite or bronze powder into the wax surface. In the 1930s Western Electric introduced gold sputtering, which was widely adopted by the major record manufacturers. With the improvements in lacquer discs and recording techniques, it was found that wet-silvering methods (*e.g.*, the chemical reduction of an ammoniacal silver solution such

as that used for silvering mirrors) led to improved results. By the early 1950s, in view of the more stringent requirements of the unfilled-plastic records and particularly the fine-groove records, lacquer discs with wet-silvering metallizing had been universally adopted by major record manufacturers.

After separation from the recording, the electroformed metal master disc can be used in a plastic molding press to press records, and in cases where only up to 100 or so records are desired this usually is done. In the case of commercial records, many pressing masters, called stampers, may be needed. Therefore, it has been the practice to electroform a metal positive from the metal master. This positive, called a "mother" or mold, can be played as a record for quality approval and then used to generate a number of stampers by electroforming. By using a metal master to generate a number of molds and each mold to generate a number of stampers, it is possible to make many stampers, and thus thousands of records, from each recording.

2. Record Materials. — Commercially, records are molded from thermoplastic materials, which become soft and flow under pressure when heated but when cooled to room temperature become rigid. Shellac, a natural thermoplastic, was used in combination with a finely ground filler such as clay for many years, but after the early 1930s synthetic thermoplastic resins gradually replaced it. High-quality record compositions without filler were first used for transcription records for radio broadcast. With the introduction of the fine-grooved records, use of the higher-quality compound became necessary to reduce the noise caused by the filler particles. Of the synthetic materials, the vinyl plastics are most commonly used for records.

IV. PHONOGRAPHS AND RECORD CHANGERS

1. Stylus Shapes and Materials. — Except for the Edison hill-and-dale phonograph, which had a diamond reproducer stylus, most phonographs prior to 1935 required frequent changes of stylus or needle. Heavy pickups, weighing from 100 to 200 g. and bearing upon the small area of contact at the tip of the stylus, can exert pressures far in excess of the strength of record materials. Shellac-compounded mixtures used in records included a large proportion of abrasive filler, usually fine limestone and clay, which soon ground the tip to conform to the groove shape. In this way the contact area between stylus and groove was increased materially, thus decreasing the unit pressure so that record wear was reduced. When, between 1933 and 1935, attempts were made to use sapphire styli with electrical pickups weighing 50 to 150 g., record wear was found to be excessive, probably because the sapphire could not quickly be worn sufficiently to reduce the unit pressures at the stylus tip to a satisfactory level. It was not until the introduction in the late 1930s of pickups weighing less than 35 g. that sapphire and diamond styli became practical. The lighter pickups also permitted the use of unfilled-plastic record materials.

When comparatively large forces were necessary to extract the signal from the groove, the output was affected by the type of needle used. A short, stubby steel needle resulted in high output with good high-frequency response, but this also brought out the surface noise of the record. With a longer, thinner-shanked and more flexible needle, the over-all output was reduced but the high frequencies were attenuated to a greater degree, making the surface noise less audible. Steel needles were used most commonly during this period, although "low-noise" fibre or thorn needles, more compliant than steel, also were used.

Steel needles had to be changed after every play with abrasive-filled records. In the 1930s chrome-plated needles, which could be used somewhat longer, were introduced, and needles with hard metal tips such as osmium were also available. With the advent of light-weight pickups, jeweled styli (sapphire and diamond) became predominant.

Record styli are made to precise specifications. The point should be spherical, tapering off to a 50° cone. For the 78-r.p.m. record a 0.003-in. point radius is desirable, and for the fine-groove records a 0.001-in. radius. Specifications for the stereophonic records call for a stylus point with a maximum radius of 0.0008 in.

There is no permanent stylus. Even a diamond point will wear with time. With light pickups a sapphire stylus should give satisfactory performance for about 1,000 hours of playing, a diamond about ten times this.

The needle should make contact on the sides of the groove for best reproduction. As the stylus wears, its sides become flat and the stylus rides more closely to the bottom of the groove. A stylus riding on the bottom of a record groove results in noisy and distorted reproduction. (A. M. MA.)

2. Reproducer or Pickup. — A phonograph pickup is a device which, when actuated by the record groove, will produce a usable signal proportional to the signal (music) recorded in the groove. Common forms of phonograph pickups produce an electric signal proportional to the amplitude or velocity of the signal in the record groove.

Phonograph pickup designers have explored nearly all of the known principles of electric generation, including the piezoelectric effect from certain crystals, variable resistance, variable capacity, variable magnetic flux cutting, variable magnetic reluctance and variable light-beam photoelectric effects. In general, it is possible to design a pickup using any principle that will produce an electrical signal from a mechanical signal. The selection of the principle and the design of the pickup is usually determined by cost, environmental conditions, etc.

Because of relatively high electric output, crystals of Rochelle salts, properly cut and designed into a pickup, have been extensively used in low- to medium-priced phonographs. Barium titanate and lead titanate zirconate also have been used, as these materials are less affected by moisture and temperature variations than Rochelle salts (*see* PIEZOELECTRICITY). Mechano-electromagnetic principles have found considerable use, moving-iron and moving-coil devices being commonest. Mechano-electro-capacity principles also have been employed.

Pickup designers, for the most part, have directed their efforts toward designs of low cost, low mechanical impedance, low distortion and high reliability. Low mechanical impedance has received considerable attention because its attainment permits a low value of stylus force. The less the stylus force, the less will be the wear of the stylus and the record groove. Concentrated effort on the part of pickup designers reduced the mechanical impedance to the point where only a fraction of an ounce of stylus force was necessary to hold the stylus in contact with the walls of the groove. It was this development which permitted the use of clear vinylite record materials and a stylus radius of 0.001 in. or less. To appreciate the magnitude of this accomplishment, it is only necessary to consider that many mechano-acoustic pickups required a stylus force of over six ounces with a stylus radius of 0.003 in.

Stereophonic pickup design followed the same basic principles used for monophonic pickups. The so-called universal pickups used for hill-and-dale and lateral transcription equipment were the forerunners of the 45°–45° stereophonic pickups. In the stereophonic pickup, it was the design objective to produce two independent signals using a single stylus actuated by two independent signals recorded in a single record groove. Thus the pickup has two independent electric generating units connected to and actuated by a common stylus.

3. Record Changers. — A record changer is a mechanism designed to permit a stack of selected records to be played without further attention.

While a number of early patents were granted on automatic record-changing devices, very few machines reached the hands of the public until after the mid-1930s. The low-cost, single-play phonograph attachment, for use with a radio, stimulated interest in the playing of records. As record collections grew, the need for record changers became apparent. By 1940 many manufacturers were equipping their phonographs with record changers.

The record-changing mechanisms were of varied designs. Commonest in the early period was the edge-selector type in which the records were placed over the centre spindle and supported at their circumference on two or more shelves. Blades or knives, above the shelves, sliced in between the bottom record and the next above to drop the bottom record onto the turntable. In an-

other design the record stack was supported at the centre on an offset portion of the spindle and at the circumference by a shelf. The top portion of the spindle was tilted slightly to provide stability to the stack. The shelf support included a mechanism designed to push the bottom record from the off-set portion of the spindle. Edges and centre holes of shellac records were damaged by these types of mechanisms.

After World War II, many improvements were made in record-changer mechanisms. The use of vinylite record material practically eliminated damage to the record by the selector mechanism. In addition, improvements were made in the turntable drive system, tone arm, tone arm landing and tripping mechanisms, etc. (A. D. B.)

4. Phonograph Motors and Drive Systems.—The first experimental machines were hand cranked, usually with some steadying effect by flywheels, but in one of his early patents Edison stressed the importance of correct and uniform speed. Battery-operated electric motors were soon used, but these were sensitive to changes in load and voltage; flyball governors were used to reduce speed variations. The most satisfactory of these governors were those with a friction disk, the friction of which increased rapidly if the speed exceeded the desired value. While Edison was reluctant to give up the electric motor, a spring-driven, governed motor developed by Frank Capp, a pioneer in many phonograph improvements, was demonstrated to Edison and adopted, and spring motors also were developed by the Columbia company and by Berliner. At the end of 1896 all three companies were using governed spring motors,

For recording, weight-driven machines with friction governors were used for many years. The weight supplied a constant torque, and the governor was connected to the turntable spindle through a worm gear. These were precision-built machines.

Electric motors did not come into very extensive use until radio-phonograph combinations were introduced, and then for many years the motor served only to provide a reasonably uniform driving torque, and friction governors, geared to the turntable, regulated the speed. The induction disk motor (like those used in watt-hour meters) was widely used in this manner. Small, high-speed, split-phase or shaded-pole induction motors with governors were among the many forms used during the 1930s, and a true synchronous motor, resembling a clock motor, was used in some machines. The latter had a multitoothed steel disk which, once started, was kept rotating by the intermittent pull of its toothed pole pieces.

"Rumble" due to vibration of the turntable or pickup pivot presents a problem. The vibration is primarily caused by the high-speed motor and transmitted through the motor supports or the speed-reduction system. Cushion mounting of the motor is therefore necessary. Problems arise because the ear is especially sensitive to slow pitch fluctuations. Successful filtering is increasingly difficult as the frequency of the disturbance is lowered. Belting between motor and turntable can give excellent results in reducing rumble. Transmission of rumble by the belts can be almost completely avoided. Very light, thin, flexible belts of exceptional uniformity are required, especially if one of the pulleys is small; usually, two stages of reduction are used. Friction drives with rubber tires also are widely used because the rubber tires can be ground to a high degree of concentricity. By grinding the end of the motor shaft in its own bearings (after balancing the motor), the shaft end can serve very satisfactorily for the first unit of the drive train, even though it is as small as $\frac{3}{16}$ in. in diameter. The inside of the flanged turntable, machined to concentricity, can be the final friction drive surface. The rubber tires can then be on the intermediate wheels. Since the load is light, the slip or "creep" is negligible. (E. W. KE.)

V. MAGNETIC RECORDING

The advantages of magnetic recording were quickly appreciated by the phonograph industry, once its excellent low-noise and audio-quality characteristics had been demonstrated. Greater recording time, immediate playback, the possibility of erasing and reusing the medium and the feasibility of editing, a feature never possible in disc recording, soon made magnetic tape a popular medium for phonograph recordings and broadcasting. In a very short time all original recordings were being made on magnetic tape; these were transferred, after editing, to discs.

Magnetic tape also offered another means of bringing recorded music into the home, with the advantage that more than one track could be recorded simultaneously, thus permitting stereophonic recording. Prerecorded tapes soon became available for home use for both monophonic and stereophonic reproduction. These appeared as two-track recordings on tape $\frac{1}{4}$ in, wide, on spools either seven or five inches in diameter, depending upon the playing time. The operating speed was $7\frac{1}{2}$ in. per second. For monophonic recordings each track was used separately and a total playing time of approximately one hour was possible. For stereophonic recordings where both tracks were used simultaneously the total playing time was about 30 minutes. After tape having a thinner base became available, the playing time was increased by about 50%, thus permitting a playing time of about 45 min. for a stereophonic recording. (See TAPE RECORDING, MAGNETIC.)

VI. PHONOGRAPH MUSIC

The day in 1877 when Thomas Edison reproduced his own voice on a tin-foil cylinder, reciting "Mary Had a Little Lamb," marked the beginning of an activity with potentialities unforeseeable even in the most extravagant dreams. Edison's "talking machine," generally regarded as an elaborate toy but offering the novelty of hearing one's voice reproduced, preserved the voices of many prominent people of the time, such as those of William Gladstone, P. T. Barnum and Robert Browning. An early musical recording was that of Brahms playing one of his own works.

Commercial recording was established in the 1890s and in spite of quantity production problems had an amazing growth. Many early records were of vaudeville skits, monologues and descriptive accounts, with some musical selections by bands, whistlers and singers. By the early 1900s many first-rank artists were to be heard on both discs and cylinders. The fact that the voice reproduced better than instruments made singers much in demand. Among the earliest artists to record were Medea Figner, Nikolay Figner and Enrico Caruso, whose great success undoubtedly influenced other artists favourably. In the United States, "Celebrity Disks" were issued by the Columbia company, followed by the Red Seal list of Victor. By 1910 nearly every first-ranking singer was represented on records. Orchestral accompaniment to vocal records began in 1906 after an unsuccessful start in 1900. Many instruments did not reproduce well; since brass instruments recorded better than others, there was a tendency toward their overemphasis, the musical result often being far removed from the composer's intention. Orchestras had to be small because of the necessity for grouping the musicians close around the recording horn. Among the first instrumental soloists to record were Pablo de Sarasate y Navascues, Joseph Joachim, Raoul Pugno, Fritz Kreisler, Jan Kubelik, Ignace Jan Paderewski, Eugène Ysaye, Vladimir von Pachmann and Efrem Zimbalist.

Recording of orchestral repertory began in London in 1909 when the Odeon company issued the Tchaikovsky Nutcracker Suite, played by the London Palace orchestra under Herman Finck. The increased interest in instrumental recording brought forth a variety of works, played by various orchestras, often in condensed versions. In the United States in 1912, the Columbia company engaged Felix von Weingartner to conduct an enlarged staff orchestra for several discs. In 1917 Columbia engaged the Chicago symphony under Frederick Stock, the Cincinnati symphony under Ernst Kunwald and the New York Philharmonic under Josef Stransky; and in

1918 Victor began a series by the Boston symphony under Karl Muck and by the Philadelphia orchestra under Leopold Stokowski. Chamber music made its appearance in 1916 in Europe with recordings by the London string quartet. An occasional full-length large work was recorded, one of the earliest being a La Scala performance of Leoncavallo's opera I *Pagliacci* under the composer's direction. The main interest, however, seemed to centre on the artist rather than the music.

The introduction of electrical recording in the 1920s marked the beginning of the second period of phonograph development, during which the emphasis shifted to production of complete works. The use of microphones eliminated crowding around a recording horn; this, along with improved quality of sound and increased tonal range. opened up new fields of instrumental literature. Record catalogues listed complete symphonies, operas and chamber works by nearly all the well-known composers of the past as well as works by many contemporaries. The composer and the composition, rather than the artist, became the chief points of interest. Ironically, progress in electronics, which made such technical advances possible in the recording field, served to work against increased use of the phonograph because of the rapid growth of radio broadcasting. World War II was another restraining influence, though the end of the war brought an increased activity in recording and several improvements in reproduction techniques, such as full-frequency-range recording introduced in England by the Decca company. The real revolution, which marked the beginning of the third great period of phonograph history, was the introduction of fine-groove records in 1948. Their almost total lack of surface noise, improved faithfulness of reproduction, and the fact that they allowed recording of complete works on one or two sides of a single record meant that the fine-groove records almost immediately supplanted older types.

A development of equal importance was the introduction of magnetic tape for making original recordings. In a time of rising production costs. the advantages of tape were obvious: no longer did soloists and orchestras have to repeat compositions many times to achieve a performance satisfactory for public sale on records; instead, sections containing flaws could be rerecorded and these sections could then be patched into the tape to make a final master tape from which the master disc was transcribed. Some critics maintained that the too-perfect results thus obtained lacked the realism of actual performance, but the reaction of musicians and record purchasers was in general enthusiastic. In addition, the mobility of tape-recording equipment made it much easier to record actual performances in concert halls and theatres, thus putting on discs many performances otherwise unattainable.

Tape-recording and playback equipment was available for home use, in both monophonic and stereophonic types, and recording companies offered extensive lists of prerecorded tapes; in general, when reproduced on good equipment, the quality of these tapes exceeded that of the best disc recordings.

The educational possibilities of the phonograph were realized early in such collections as the *History of Music by Eye and Ear,* edited by Percy Scholes, *Two Thousand Years of Music,* edited by Curt Sachs, and numerous other sets of similar nature. Other special issues were tests for measuring musical talent or accomplishment. discs for technical instruction of various kinds, missing-part records for learning chamber music and numerous others. A remarkable result of the new recording techniques was the issuing of many of what might be termed rerecorded old acoustical records, making it possible to hear artists of earlier days under more favourable conditions of reproduction. Popular music, of course, was one of the mainstays of the industry, the material made available in this field being even more complete than the extensive listing of the classical field. The popularity of dance bands on records began in 1913, gaining increasing interest each year. Folk songs from nearly every area of the world appeared both as special studies and as regular releases. Nonmusical lists. in addition to the usual numerous sketches. monologues and similar short offerings, showed an increasing number of complete plays and musical shows, as well as recordings of noted poets and authors reading from their own works. Of documentary importance as well as general interest were the collections of statements by prominent people and comments on newsworthy current events. Foreign language and other instruction, children's stories and Bible stories were among the many choices of instruction and entertainment made available. An important development for scholars was the establishment of archives by museums and libraries for preserving old and new records for their historical value.

Information regarding available records was to be found in magazines such as the *American Record Guide,* the *Gramophone* and *Disques,* devoted solely to dispensing record information, as well as in others having record sections. Numerous books on the subject were also published, some surveying the entire field and others dealing with only limited portions. (AY. D.)

PHONOLITE, in petrology, a group of alkaline lavas rich in nephelite (*q.v.*) and sanidine, an alkali (potash) feldspar (*q.v.*). The name is a Greek rendition of the German *Klingstein (phone,* "sound," and *lithos,* "stone"), referring to fine-grained compact lavas which split into thin, tough plates and give out a ringing sound when struck with a hammer. The presence of a feldspathoid mineral was suspected from gelatinization tests (decomposition by hydrochloric acid, with separation of gelatinous silica) as early as 1828, but it was not until 1867 that nephelite was shown to be a major constituent of the matrix.

The most important constituent of phonolite is alkali-feldspar, either sanidine or anorthoclase, which forms not only the bulk of the ground mass, but most of the large crystals in porphyritic varieties.

Nephelite rarely appears in large crystals but may occur either interstitially or in well-formed microphenocrysts. The principal ferromagnesian mineral is a pyroxene, titanaugite, aegirine or cores of the former mantled by the latter. Pyroxene in phenocrysts is sharply euhedral; in the matrix it occurs characteristically in slender unterminated needles, often so abundant as to impart a green colour to the rock.

Amphibole (*q.v.*) is practically confined to phenocrysts and is usually an alkaline variety, barkevikite, riebeckite or arfvedsonite. Feldspathoids other than nephelite may be present in accessory amount, the commonest being nosean, sodalite (*q.v.*) and leucite (*q.v.*). Glass has been reported occasionally but only in small amount.

Occurrences. — Mcst phonolites are of Tertiary or Recent age, but excellent examples are found at several localities in the Carboniferous strata of Scotland and also of Brazil. In terms of the numbers of recorded occurrences, though not perhaps in total volume, Tertiary or Recent phonolites are common in Europe, in the Auvergne (Mont Dore), the Eifel, the Laacher See and Bohemia. They have been described from a number of sites in the Mediterranean area, chiefly in Italy, as well as from Cripple Creek in Colorado, and the Black hills, South Dakota. The famous Devils Tower, Wyoming, is variously described as tinguaite or phonolite, depending on whether it is considered a plug or a flow.

Leucite phonolites are perhaps best known from the vicinity of Naples. Apachite, from the Apache mountains, west Texas, is an amphibole phonolite. Kenyite, from Mt. Kenya, east Africa, is rich in cossyrite and olivine. The phonolite of Ölbruck. Ger., a rather popular local building stone, is said to contain about 15% of noselite and 8% of leucite.

Phonolitic trachytes are found on St. Helena and a number of other oceanic islands. (F. Cs.)

PHORMION, Athenian admiral in the 5th century B.C., was the son of Asopius, of the deme Paeania. He first appears in 440 B.C. when he was sent with reinforcements to the Athenian troops before Samos.

In 432 he took out reinforcements to the force blockading Potidaea, took over the command from Callias and completed the circumvallation of the city. He seems to have stayed in the north-east. as in 431 he was co-operating with Perdiccas against the Chalcidians. In 430 he was sent with 30 ships to help the Acarnanians against the Ambraciots. That winter there followed the operations on which his fame is based. He was given 20 ships and stationed at Naupactus to effect a blockade of Corinth from that

side.

In the summer of 429 a superior Peloponnesian fleet arrived and was decisively beaten by Phormion. In a second engagement he was forced to retreat, but turned and again routed his pursuers. He was probably dead by 428.

See PELOPONNESIAN WAR.

PHORMIUM (NEW ZEALAND FLAX; also termed NEW ZEALAND HEMP). The plant (Phormium *tenax*) is a perennial of the Liliaceae family and is propagated either by rhizomes or by seed. While termed "New Zealand flax" and also "New Zealand hemp," the plant has no relationship to either flax (*Linum usitatissimum*) or hemp (Cannabis *sativa*). Phormium is a native of New Zealand and, while known to be adapted in many other countries, is not commonly grown for commercial fibre production in any country other than New Zealand.

The thick sword-shaped leaves grow in tufts from the tips of the rhizomes and reach a length of four to six feet. The flowering stem. which also starts from the tip of the rhizome, grows out through the centre of the tuft of leaves and reaches a height of 5 to 15 ft. The flowers are usually cross-pollinated though some self-pollination occurs. The parts above ground die soon after the flowering stage, but the plant continues to live from year to year by new growth from short, thick underground stems (rhizomes).

Much of the phormium fibre of commerce has come from harvesting the volunteer growth, but considerable quantities have been obtained from cultivated fields. The crop is adapted to a wide range of New Zealand soils, but the greatest yields have been obtained from well-drained swamp lands.

The plant is grown principally for the fibre which develops in the leaves, and which is separated from the nonfibrous tissues by a process of scraping and washing. This processing is done in fibre mills by means of special machines designed for the purpose.

The cleaned, dried fibre is arranged in hands ("heads") and then packed in bales, in which form it is exported. The fibre is similar in appearance to such other leaf fibres as abaca (Manila hemp), henequen (Yucatan sisal) and "true" sisal. Its principal use has been for twines and ropes. (A. H. WT.)

See H. J. Critchfield, "Phormium Tenax—New Zealand's Native Hard Fiber," *Econ. Bot.*, vol. 5 (1951).

PHORONIDA is a phylum of small, marine, wormlike animals which live in self-secreted tubes embedded in the sea bottom or attached to solid surfaces. They are found in shallow tropical and temperate waters of many parts of the world—Europe, North and South America, Australia, South Africa and Asia. Phoronids, constituting a small and relatively homogeneous group, are considered to be a separate phylum because they are structurally unique; they cannot clearly be related to any other group of animals. In the past, however, attempts were made to relate them to the Annelida, Mollusca and Chordata among other phyla. Two genera, *Phoronis* and Phoronopsis, and about 16 species are recognized.

Structure and Function. — In all phoronids the body is more or less elongate—most species ranging in length from less than a centiinetre to 20 cm.—and bears a crown of tentacles at one end. The tentacles are arranged in a double row surrounding the usually crescent-shaped mouth. The mouth is partly covered by a flap of tissue known as the epistome. The anus occurs at the same end of the body as the mouth and is borne on a small papilla located immediately outside the double row of tentacles. The digestive tract is therefore U shaped. The tentacles may form a slightly indented circle or a complex double spiral. Situated near the bases of the tentacles is a supporting structure made of connective tissue and known as the lophophore. Depending on the species, there may be from about 50 to over 300 tentacles, each one bearing fine hairs or cilia. The movements of the cilia create currents which carry food particles from the surrounding water into the mouth and waft waste particles away from the anus. Feeding and excretory currents have not been studied in great detail.

The digestive tract consists of esophagus, stomach. intestine and rectum. These various regions differ from one another in size and in the nature of the cells forming the internal lining. In some species there is a distinct muscular valve between the esophagus and the stomach. The junction of the stomach and intestine occurs at the proximal end of the body, that is, the end which does not bear tentacles, mouth and anus. The tentacular end of the body is known as the distal end. The food seems to consist chiefly of microscopic phytoplankton. Diatom shells may frequently be found in the digestive tract and in the fecal pellets.

There is a system of blood vessels in which circulate elliptical, nucleated corpuscles containing the red pigment hemoglobin, similar to the hemoglobin found in human blood. Two longitudinal vessels, known as the afferent and efferent vessels, are continuous with one another at the proximal end of the body. At the distal end both vessels connect with a pair of semicircular vessels located at the level of the lophophore, immediately below the tentacles. Within each tentacle is a single, blind vessel which branches into two at its base and so connects with both semicircular vessels. In the living animal the red blood corpuscles can easily be seen pulsating up and down in the transparent tentacular vessels. Associated with the longitudinal vessels are a blood sinus surrounding the digestive tract and a large number of short, blind vessels which are particularly numerous in or may be restricted to the proximal end of the body. Associated with these blood vessels is a jellylike tissue known as the fat body or the vasoperitoneal tissue. Among the large, semifluid cells of this tissue are a number of granules of varying size and shape. Some of them probably consist of guanine and may be considered to be deposits of waste material. Others may represent the products of hemoglobin breakdown.

The body cavity is subdivided by a series of long, thin membranes known as mesenteries, which extend from the digestive tract to the body wall. In most phoronids there are four such mesenteries dividing the body cavity into four longitudinal chambers. There is also a horizontal mesentery near the tentacular end of the body separating a lophophoral cavity from the four larger cavities occupying the rest of the body. In the living phoronid the body cavity is filled with a fluid which is responsible for the turgor or relative firmness of the otherwise soft body.

On either side of the papilla which bears the anus is a small pore connecting with an organ of excretion known as a nephridium. Each nephridium consists of a duct, coiled once on itself and continuous with a pair of funnels opening into two of the four larger body cavities. The walls of the funnels tend to be much folded and are heavily ciliated. The activity of the cilia probably creates a current in the body cavities which carries fluid waste into the funnels and eventually to the outside via the nephridial pores.

The body wall consists of an outer layer of epithelial cells and two layers of muscle fibres: the outer circular and the inner longitudinal. Many of the epithelial cells secrete a fluid which is used by the animal to build the tightly fitting chitinous tube in which it lives. The freshly secreted fluid is transparent and sticky, but on contact with water it gradually hardens. In some species the secreted tube becomes encrusted with tiny grains of sand, mud or shell which adhere to the surface. In many such cases the cemented particles are arranged to form a very even and beautiful mosaic. The tube is in most cases closed at the proximal end; from the distal open end the body may be extended a rather long distance. Most phoronids can shorten or lengthen the body considerably; this is accomplished by the muscles in the body wall contracting against the fluid in the body cavity.

The nervous system is also located in the body wall and consists chiefly of a nerve net lying immediately beneath the epithelial cells. This nerve net is continuous with a more dense concentration of nervous tissue in the horizontal mesentery. Extending from this region and running along, in or beneath the epidermis are one or two giant nerve fibres which taper and end near the proximal end of the body. The giant nerve fibres are known in all but one species and are probably related to the animal's ability to withdraw the body into the tube with great rapidity.

Reproduction and Natural History. — Reproductive tissue is formed from cells located on the thin walls of the short, blind blood vessels in the proximal part of the body. The phylum includes species in which individual animals are either male or female and other species in which each animal is a hermaphrodite and carries both male and female organs. As the reproductive

tissue grows along the walls of the blood vessels it displaces the surrounding vasoperitoneal tissue which shrinks proportionately. When the ova and spermatozoa are ripe, they are shed into the body cavity, find their way to the nephridial funnels and pass through these organs to the outside. In some species the sex cells simply pass out into the surrounding water where early development takes place. In others the ova are retained in the tentacular crown of the adult until each has developed into a tiny, transparent, free-swimming larva. The type of larva characteristic of the phylum Phoronida, an actinotroch larva, is distinguished chiefly by a ring of ciliated tentacles and a flap of tissue over the mouth.

The actinotroch larva may spend over a month swimming freely, feeding on plankton and increasing considerably in size. Eventually, it settles on the bottom and undergoes a metamorphosis whereby it is rapidly and drastically changed into a tiny adult phoronid. All phoronids can reproduce sexually. and in most cases the life history includes an actinotroch larva. Some species are known to reproduce asexually as well. by the apparently simple process of dividing the body into a number of segments, each of which then breaks off and develops into a new adult.

Many phoronids occur in vertical tubes placed just below the surface in intertidal or subtidal mud or sand flats. Other species form dense feltlike masses of intertwined tubes attached to rocks. pilings or logs in shallow water. In both these cases the tubes are encrusted with small particles of sand or shell. A third living habit concerns those phoronids which are found living inside closely fitting channels in limestone rock or in the discarded shells of bivalve mollusks. Phoronids appear to be widely distributed in temperate and tropical seas, but there are no records from polar regions.

See L. H. Hyman, *The Invertebrates:* vol. *5* (1959). (J. R. **Ma.)**

PHORORHACOS, a genus of extinct flightless birds of large size, known from Tertiary formations in southern South America. They appear to have been remotely related to the living seriema *(q.v.; Cariama cristata)* of that region. *Phororhacos* (family Phororhacidae) is included in the order Gruiformes, to which the living cranes (Gruidae) and rails (Rallidae) belong. Numerous parts of specimens have been found, and the most complete fossil specimen is P. *inflatus,* of which head: pelvis, limb bones and some of the vertebrae are recorded.

BY COURTESY OF BRITISH MUSEUM (NATURAL HISTORY)

RESTORATION DRAWING OF PHORORHACOS, AN EXTINCT BIRD

The skull in this bird is about 13 in. long, with the maxilla high in profile, much compressed laterally and terminating in a strong hook; the heavy mandible is curved upward at the tip. The long legs are strong though slender. the tibia being 15–16 in. long. The small size of the wing elements, the form of the shoulder girdle and the skeleton as a whole indicate a cursorial species unable to fly. From the form of the bill, the bird was apparently a formidable predator. It is estimated to have stood about three feet high at the shoulder.

The skull of another species, P. *longissimus,* is about *24* in, long with the beak 10 in. high. indicating a bird of gigantic size. An allied genus, *Andrewsornis,* described by *B.* Patterson from an incomplete skull and other fragments, had a slender 15-in.-long mandible and indications of a stronger wing. Another genus, *Mesembriornis,* has been recognized from Pliocene deposits (about 10,000,000 years ago). Several workers have described a dozen or more species from fragmentary bones in addition to those mentioned, but the relationships of several of these are doubtful. The family, the earliest known representative of which appeared in the latter part of the Oligocene epoch (more than 30,000,000 years ago), continued into the early Pliocene.

See Karman Lambrecht, *Handbuch der Palaeornithologie,* pp. 494–516, fig. 147–154 (1933) ; Bryan Patterson, "A New Phororhacoid Bird From the Deseado Formation of Patagonia," *Field Museum of Natural History Geological Series,* vol. *8,* no. 8, pp. 49–54 (1941). (A. Wt.)

PHOSGENE or CARBONYL CHLORIDE is a colourless, extremely poisonous gas. about three and one-half times heavier than air. having a stifling, nauseating odour resembling sour green corn or musty hay. It is primarily a lung injurant and even in small amounts may prove to be very harmful. It may act slowly, its full effects sometimes developing several hours after inhalation. It first came into prominence in World War I (1914–18), being used as an offensive poison gas either alone or mixed with chlorine. Phosgene was first synthesized in 1812 by John Davy. the ,British chemist. hy the reaction of carbon monoxide and chlorine in the presence of sunlight; hence the derivation of its name from the Greek *Phos* (light) and *genes* (born). It is manufactured by passing the two gases over a specially prepared charcoal catalyst *(see* CATALYSIS). The reaction is expressed chemically by the equation ($CO + Cl_2 = COCl_2$). It has also been manufactured by the reaction of oleum (fuming sulfuric acid) on carbon tetrachloride. By 1900. phosgene was being manufactured on an extensive scale by the Germans for use as an intermediate in the preparation of dyestuffs, its chief use at mid-20th century. A number of pharmaceutical preparations and industrial chemicals also involve its use. Phosgene is active chemically; it fumes in moist air and reacts with water to form hydrogen chloride (hydrochloric or muriatic acid) and. carbon dioxide: $COCl_2 + H_2O = 2HCl + CO_2$. Phosgene gas can be readily condensed to a liquid which boils at 8.2° C. (46.8° F.) at atmospheric pressure. It is ordinarily stored and transported under slight pressure in steel cylinders. although under certain circumstances, it is stored and transported as a solution in toluene. (A. V. C.)

PHOSPHATE ROCK, a sedimentary formation of marine phosphorite usually interbedded with shales or limestones. It occurs in many parts of the world and is mined in North Africa, Germany. the U.S.S.R., the Cnited States and several other countries. The name collophane is sometimes given to the massive. seemingly noncrystalline apatite *(q.v.)* that is the essential constituent of phosphate rock. It is composed largely of calcium phosphate. an important ingredient of bones. teeth and many shells. Other components include lime, silica. fluorine and carbonaceous (carbonate) matter. Phosphate rock is used in the preparation of fertilizers and as a source of phosphorus for matches and of phosphoric acids used in the chemical industries. It originated on the sea floor during several geologic periods at times and under conditions that favoured precipitation of the apatite from solution but retarded the addition of much land waste. For uses, occurrences. production, etc. *see* FERTILIZERS AND MANURES. *See* also MINERAL PHOSPHATES: PHOSPHORUS. (J. T. P.; X.)

PHOSPHATES: *see* PHOSPHORIC ACIDS AND PHOSPHATES.

PHOSPHORESCENCE: *see* BIOLUMINESCENCE; LUMINESCENCE.

PHOSPHORIC ACIDS AND PHOSPHATES. Phosphates are salts of phosphoric acid. Phosphoric oxide. P_2O_5 or P_4O_{10}, combines with water in three proportions to form $H_2O.P_2O_5$ or HPO_3, metaphosphoric acid: $2H_2O.P_2O_5$ or $H_4P_2O_7$, pyrophosphoric acid; and $3H_2O.P_2O_5$ or H_3PO_4, orthophosphoric or ordinary phosphoric acid. These acids each give origin to several series of salts. those of ordinary phosphoric acid being the most important. *See* also PHOSPHORUS: *The Oxyacids of Phosphorus.*

Orthophosphoric acid, H_3PO_4, a tribasic acid. is obtained by boiling a solution of the pentoxide in water; by oxidizing red phosphorus with nitric acid. or white phosphorus under the surface of water by bromine or iodine: and also by decomposing a mineral phosphate with sulfuric acid. It usually forms a thin syrup which on concentration in a vacuum over sulfuric acid deposits hard. transparent, rhombic prisms which melt at 41.7° C. After long heating the syrup is partially converted into pyrophosphoric and metaphosphoric acids. but on addition of water and boiling the ortho-acid is reformed. It gives origin to three classes of salts: $M'H_2PO_4$ or $M''(H_2PO_4)_2$; M'_2HPO_4 or $M''HPO_4$; and M'_3PO_4 $M''_3(PO_4)_2$ or $M'''PO_4$, wherein M', hl", M''' denote

a univalent, bivalent and trivalent metal. These correspond to H_3PO_4 in which one, two or three atoms of hydrogen, respectively, have been replaced by a metal. The three principal groups differ remarkably in their behaviour toward indicators. Those of the first type are strongly acid, the second are neutral or faintly alkaline, while the third are strongly alkaline and are decomposed by carbon dioxide: $Na_3PO_4 + CO_2 + H_2O = NaHCO_3 + Na_2HPO_4$. The salts of the types NaH_2PO_4 and $CaH_4P_2O_8$ may be obtained in crystal form, but those of the heavy metals are stable only when in solution. All soluble orthophosphates give with silver nitrate a characteristic yellow precipitate of silver phosphate, Ag_3PO_4, soluble in ammonia and in nitric acid. Since the reaction with the acid salts is attended by liberation of nitric acid: $NaH_2PO_4 + 3AgNO_3 = Ag_3PO_4 + NaNO_3 + 2HNO_3$, $Na_2HPO_4 + 3AgNO_3 = Ag_3PO_4 + 2NaNO_3 + HNO_3$, it is necessary to neutralize the nitric acid if the complete precipitation of the phosphoric acid is desired.

The three series also differ when heated: the trimetallic salts containing fixed bases are unaltered, while the monometallic and dimetallic salts yield metaphosphates and pyrophosphztes, respectively. Other common precipitants of phosphoric acid or its salts in solution are: ammonium molybdate in nitric acid, which on heating gives a canary-yellow precipitate of ammonium phosphomolybdate, $12[MoO_3] (NH_4)_3PO_4$, insoluble in acids but readily soluble in ammonia; magnesium chloride, ammonium chloride and ammonia. which on standing in a warm place give a white crystalline precipitate of magnesium ammonium phosphate, $Mg(NH_4)PO_4.6H_2O$, which is soluble in acids but highly insoluble in ammonia solutions, and on heating to redness gives magnesium pyrophosphate, $Mg_2P_2O_7$.

Of the organic phosphates, triphenyl phosphate, $(C_6H_5)_3PO_4$, is important, acting as a filler or "dope," and as a plasticizer. It is a colourless solid of m.p. 53° C. and b.p. 245° C.

Pyrophosphoric acid, $H_4P_2O_7$, is a tetrabasic acid which may be regarded as derived by eliminating a molecule of water between two molecules of ordinary phosphoric acid; its constitution may therefore be written $(HO)_2OP.O.PO(OH)_2$. It may be obtained as a glassy mass. indistinguishable from metaphosphoric acid, by heating phosphoric acid to 215° C. When boiled with water it forms the ortho-acid. and when heated to redness, the meta-acid. After neutrrilization, it gives a white precipitate with silver nitrate. Being a tetrabasic acid it can form four classes of salts; for example. the four sodium salts $Na_4P_2O_7$, $Na_3HP_2O_7$, $Na_2H_2P_2O_7$ and $NaH_3P_2O_7$ are known. The most important is the normal salt, $Na_4P_2O_7$, which is readily obtained by heating disodium orthophosphate. Na_2HPO_4. It forms monoclinic prisms (with $10H_2O$) which are permanent in air.

All soluble pyrophosphates when boiled with water are converted into orthophosphates.

Metaphosphoric acid, HPO_3, or more correctly $H_2P_2O_6$ as determined by vapour density, is a monobasic acid which may be regarded as derived from orthophosphoric acid by the abstraction of one molecule of water, thus $H_3PO_4 - H_2O = HPO_3$; its constitution is therefore $(HO)PO_2$. The acid is formed by dissolving phosphorus pentoxide in cold water, or by strongly heating orthophosphoric acid. It forms a colourless vitreous mass, hence its name "glacial phosphoric acid." It is readily soluble in water, the solution being gradually transformed into the ortho-acid, a reaction which proceeds much more rapidly on boiling. Although the acid is monobasic, salts of polymeric forms exist of the types $(MPO_3)_n$, where *n* may be 1, 2, 3, 4 or 6. They may be obtained by heating a monometallic orthophosphate of a fixed base, or a dimetallic orthophosphate of one fixed and one volatile base; *e.g.*, microcosmic salt. $MH_2PO_4 = MPO_3 + H_2O$; $(NH_4)NaHPO_4 = NaPO_3 + NH_3 + H_2O$. The salts are usually noncrystalline and fusible. Their solutions on boiling yield orthophosphates, while those of heavy metals give a trimetallic orthophosphate and orthophosphoric acid $3AgPO_3 + 3H_2O = Ag_3PO_4 + 2H_3PO_4$. Metaphosphoric acid can be distinguished from the other two acids by its power of coagulating albumen, and by not being precipitated by magnesium and ammonium chlorides in the presence of ammonia.

For perphosphoric acids, see PHOSPHORUS.

PHOSPHORITE, the name given to impure massive apatite (*q.v.*), or phosphate rock (q v.).

See also FERTILIZERS AND MANURES.

PHOSPHORUS. Phosphorus was first prepared in elemental form in 1669 by the alchemist Hennig Brand of Hamburg, who used the residue from evaporated urine as the source of the element. News of the discovery soon spread over Germany. Brand did not disclose to the public his method of producing phosphorus but he sold the secret to Johann Krafft of Dresden. The chemist Johann Kunkel sought to learn from Brand the method used, but found only that urine had been used as the source of the phosphorus. With this information Kunkel was able, after many trials, to duplicate Brand's accomplishment. Kunkel likewise attempted to keep the process a secret and, like Brand and Krafft, tried at various times to sell it.

Krafft exhibited samples of phosphorus in many countries; in 1677 he performed experiments with it before members of the Royal society in England. A few years later the British chemist Robert Boyle devised a method of preparing the element, and deposited with the secretary of the Royal society a description of his method which, however, was not published at the time. Boyle had little or no interest in alchemy. In Europe, however, many alchemists sought the philosopher's stone, and it was thought that such an unusual material as phosphorus might lead to the long-sought goal. It is of interest to note that Gottfried Leibnitz, the German mathematician, then librarian for Duke Johann Friedrich at Hanover, arranged a contract between Brand and the duke, under nhich Brand was to demonstrate his process and reveal his method.

It is easy to understand the widespread interest that was aroused in the 17th century by the discovery of such a remarkable substance as phosphorus. A substance which glowed in the dark and took fire spontaneously upon exposure to the air was something startlingly new and mysterious. It is indeed notable that an element so difficult to isolate should have been discovered through the unguided fumbling of an alchemist.

In the decades that followed 1680, methods for the preparation of phosphorus from various animal and vegetable materials were developed and, in some instances, published. It was not until 1775, more than a hundred years after Brand's discovery, that Karl Scheele published the much easier method of preparing the element from bones, which then became the chief raw material used as a source of phosphorus.

The Phosphorus Atom. — The chemical atomic weight of phosphorus is 30.975, and its atomic number of 15 indicates that there are 15 positive charges on the nucleus of the atom. Since the atomic mass number is 31, the nucleus is composed of 15 protons and 16 neutrons. The 15 electrons which revolve about the nucleus are arranged at three major quantum levels, usually referred to as the K-shell. the L-shell and the M-shell. There are two electrons at the first quantum level or K-shell. eight electrons in the L-shell, and five electrons in the M-shell.

In the nomenclature commonly used, the arrangement of the electrons about the nucleus of the phosphorus atom may be expressed as $1\ s^2,\ 2\ s^2\ p^6,\ 3\ s^2\ p^3$. In this expression the 1, 2, 3 refer to the major quantum levels or shells, the s and p to sublevels within the principal quantum levels. and the exponentially written numbers refer to the numbers of electrons at each sublevel.

The only stable isotope of phosphorus is P^{31}. Six unstable, radioactive isotopes have been produced: P^{28}, half life 0.28 sec.; P^{29}, half life 4.5 sec.; P^{30}, half life 2.5 min.; P^{32}, half life 14.3 days; P^{33}, half life 25 days; and P^{34}, half life 12.4 sec. Of these, only P^{32} is useful as a tracer element. Because of the important role that phosphorus compounds play in the chemistry of organic life. it is unfortunate that the only useful radioactive isotope has so short a half life in relation to the normal life cycle of higher plants and animals.

Occurrence. — Phosphorus does not occur free in nature. but its compounds are widely distributed and are found in many rocks and minerals. It ranks 11th in abundance in the lithosphere, of which the average content of phosphorus is about 0.12%. Some

of the common minerals of phosphorus are apatite [$Ca_{10}F_2(PO_4)_6$], a avellite [$Al_6(PO_4)_4(OH)_6.9H_2O$] and vivianite [$Fe_3(PO_4)_2.8H_2O$].

Large deposits of rock phosphate are found in many localities. These deposits are of great economic value as a source of phosphate in the manufacture of fertilizers. In the United States the deposits of Florida and Tennessee have been exploited extensively, and exploitation of the deposits of Utah. Wyoming, Idaho and Montana is increasing rapidly. In Africa the deposits of Algeria, Tunisia and Egypt are also mined on a large scale. All these deposits mere laid on the floor of shallow seas and are mostly the remains of myriads of aquatic microorganisms. The phosphate beds of the western United States are primary deposits nhich lie conformably with the shales, limestones and other formations of the region. whereas the main deposits of Florida. Tennessee and North Africa are secondary, being the residues from the leaching of phosphatic limestone.

Many textbooks of chemistry and technical articles erroneously refer to rock phosphate as tricalcium phosphate. $Ca_3(PO_4)_2$, although the phosphatic material present is actually a calcium fluorphosphate, or possibly hydroxyfluorphosphate, which gives the same X-ray pattern as the mineral apatite.

Phosphorus is one of about 20 elements essential to the growth and development of plants and animals. and the supply of phosphoric compounds in agricultural soils must he maintained. Where crops are removed, the supply of phosphorus ccmpounds in the soil may become the limiting factor in crop production. Large quantities of phosphorus compounds are used as a fertilizer and an extensive deposit of rock phosphate therefore represents a great natural resource.

Preparation. — Phosphorus may be prepared readily by heating metaphosphoric acid with carbon, or by heating a calcium phosphate mith carbon and sand. Carbon monoxide and phosphorus vapour are evolved in both processes.

In the modern industrial method for the production of phosphorus. rock phosphate, coke and silica pebble are charged continuously into a three-phase electric furnace. The electric energy serves only to heat the charge. which melts and reacts chemically with the coke and silica to produce phosphorus vapour and carbon monoxide which pass out of the furnace. while a molten calcium silicate slag accumulates in the furnace. Any iron compounds present as impurities in the furnace charge are reduced and the molten metallic iron then absorbs phosphorus to form ferrophosphorus which is heavier than the slag and therefore sinks to the floor of the furnace.

From time to time the furnace is tapped and the ferrophosphorus is cast into pigs. while the slag is granulated by means of jets of water. The granulated slag is composed chiefly of calcium silicate. The ferrophosphorus is used in making iron alloys but the market does not utilize all the by-product ferrophosphorus produced. Several methods were developed for the recovery of the valuable phosphorus from the ferrophosphorus but none was in commercial use at mid-20th century.

The stream of gas from the electric furnace consists principally of phosphorus vapour and carbon monoxide. After the gas is freed of dust and then cooled the phosphorus condenses to the liquid and eventually to the solid form. Because it ignites spontaneously when exposed to air, the usual practice is to store the phosphorus under water.

Physical Properties. — Phosphorus exists in several allotropic forms nhich will be discussed later. The ordinary variety, when pure, is a colourless. semitransparent, waxy solid at room temperature. but is usually slightly yellow because of impurities present

Although virtually insoluble in water, nhite phosphorus is slightly soluble in many organic liquids. in phosphorus trichloride. liquefied ammonia. and liquefied sulfur dioxide, and is extremely soluble in carbon disulfide. Its molecular weight in solvents. and in the vapour state, corresponds to a P_4 molecule. The atoms in the molecule are in a tetrahedral arrangement. the edge of the tetrahedron being 2.21 angstrom units.

When phosphorus vapour is heated, the dissociation of P_4 molecules into P, molecules becomes measurable at about 800° C. Spectrographic examination of hot phosphorus vapour indicates that P_4, P_2 and P molecules are present, but even at 1,200° C. the proportion of monatomic molecules is exceedingly small.

Some of the other physical properties of white phosphorus are given in the following table:

Specific gravity	1.83
Melting point	44.14° C. at 1 atm.
Boiling point	280.5° C. at 1 atm.
Heat of fusion	630 cal. ± 2 cal. per Pa mol.
Critical temperature	720.6° C.
Heat of sublimation	14,066 cal. per P_4 mol.
Hardness	0.5 on Mohs' scale
Atomic heat capacity	5.69 cal. per gram atom
Atomic volume	16.9 c.c. per gram atom
Surface tension	43.09 at 78.3° C. 35.56 at 132.1° C.
Index of refraction	1.8244 for the D line at 29.2° C.
Parachor	37.7
Entropy $S°_{298}$ (solid)	9.80 ± 0.02 cal. per gram atom per °C.

C_p, cal./mole P_4/° C., vnpour = $19.25 + 0.510 \times 10^{-3}T - 2.980 \times 10^{5}T^{-2}$

Allotropic Forms. — The data accumulated from the many investigations of the allotropic forms of phosphorus are voluminous, confusing and contradictory. In the present summary the statements are those for which the experimental evidence seems most consistent and convincing.

White phosphorus exists in at least two allotropic forms. The one that occurs under ordinary conditions of temperature and pressure is called the α form. It has a density of 1.83. At −77.8° C. the α form changes to a β form which has a density of 1.88. The crystal habit of the α form is cubic whereas that of the β form is hexagonal.

The β form is strongly doubly refractive and this makes it possible to observe the transition from the one form to the other by means of a polarizing microscope.

Red phosphorus can be prepared by heating the white variety at 250° to 300° C. in a closed container. The conversion is accelerated by a trace of iodine. Red phosphorus may be obtained also by exposure of phosphorus vapour to an electric glow discharge, to a spark discharge, or to a heated tungsten filament.

Red phosphorus does not ignite in air at ordinary temperature and is not dissolved by the usual solvents for white phosphorus. The red form melts in the range 590° to 600° C. and, as ordinarily prepared, is amorphous or microcrystalline. Its colour, density and other physical properties: as well as its chemical activity. are governed by the conditions under which it is formed. Upon prolonged heating, the ordinary amorphous form of red phosphorus undergoes progressive. exothermic, irreversible transitions to crystalline modifications. Thermal analyses, X-ray diffraction measurements and microscopic observations lead to the conclusion that there are certainly three and possibly five forms of red phosphorus. At one end of this series of transitional forms stands the variety obtained by the methods ordinarily used for the conversion of white phosphorus to the red form. The density of that variety may be as low as 1.9, and its X-ray pattern is diffuse, which establishes the absence of structural regularity. As the change progresses from one form to the nest, the X-ray pattern sharpens and becomes progressively more complex. The most highly crystalline modification obtained by the thermal aging of ordinary red phosphorus is probably at least monoclinic but the symmetry is usually distorted so that its optical properties are those of a triclinic crystal. This form has been called violet or metallic phosphorus. It seems best, however, not to increase the confusion with regard to red phosphorus by giving special names to any of the modifications.

Black phosphorus is deemed another distinct allotropic form of phosphorus and is obtained by subjecting white phosphorus to a pressure of 35,000 atmospheres at ordinary temperature or to 12,000 atmospheres at 200° C. This allotropic form is a flaky, crystalline inaterial that resembles graphite and has a density of 2.699. It is a conductor of electricity with a resistivity of 0.711 ohms per centimetre cube, and is not dissolved by any of the liquids that dissolve white phosphorus. Black phosphorus changes irreversibly into the red allotrope at about 550° C. under ordinary pressure.

Chemical Properties. — Phosphorus is a nonmetallic element and belongs in Group V of the periodic table. The subgroup to which it belongs includes the elements nitrogen? phosphorus,

arsenic, antimony and bismuth. The transition from nonmetallic to metallic elements as atomic weights increase is unusually sharp in this subgroup. It is also characteristic of the subgroup that corresponding compounds of the five elements do not resemble each other as closely as might be expected, even when the formulas are alike. Probability of resemblance is greatest in the hydrides, less in the halides, and least in the oxides. Even in the hydrides, however, the correlation of properties for corresponding formulas is poor.

The usual valencies of phosphorus are three and five. It would be expected from the arrangement of electrons in the phosphorus atom, that the valency due to exchange of electrons would be plus five when the outer shell is stripped of electrons, and minus three when the outer shell is filled by the capture of three electrons. The chemistry of phosphorus is complex, however, and the element forms many compounds wherein its valency is other than the simple kind due to loss or gain of electrons in the outer shell of the atom.

White phosphorus is relatively active. It glows in the dark and ignites spontaneously to form dense white fumes of the oxide P_4O_{10}.

It precipitates copper and lead from their solutions at ordinary temperatures and reacts with most metals to form phosphides at elevated temperatures.

Hydrides.—There are two well-known hydrides of phosphorus, namely PH_3 and P_2H_4. Phosphine, PH,, is a colourless, poisonous gas of characteristic odour. It can be produced by heating white phosphorus in a solution of potassium hydroxide, or by the hydrolysis of a solid phosphide such as Ca_3P_2. Phosphine solidifies at $-134°$ C. under its own vapour pressure of 27.3 mm., and there are at least four allotropic forms of the solid.

The hydrogen atoms of the phosphine molecule are replaceable by metals with the formation of unstable compounds such as PH_2K, PK_3, etc.

The hydride P_2H_4 is a liquid which boils at 52° C., solidifies at $-99°$ C. and ignites spontaneously. Other solid hydrides such as $P_{12}H_6$ and P_9H_3 have been reported, but X-ray studies of these solids indicate that they are probably solid solutions of PH_3 in phosphorus.

The monovalent phosphonium radical PH_4^+ is analogous to, although much less stable than, the ammonium radical NH_4^+. Phosphonium iodide is a colourless, crystalline solid formed by the interaction of phosphine and hydrogen iodide; the corresponding chloride and bromide are gases.

Halides and *Oxyhalides.*—The halogen compounds of phosphorus are numerous. In addition to simple halides such as PCl_3 and PCl_5, there are many mixed halides such as $PFCl_2$, PF_3Cl_2, etc. Theoretically there are 20 simple and mixed halides of trivalent phosphorus and 56 such halides of pentavalent phosphorus. In addition to these halides, not all of which have been prepared, there are phosphorus halides of the type P_2I_4 which is analogous to the hydride P_2H_4.

There are also many oxyhalides of phosphorus, of formulas POF,, $POCl_3$, $POFCl_2$, etc.; and for each oxyhalide there exists the corresponding sulfohalide, such as PSF_3, $PSFCl_2$, etc.

Oxides.—The three best-known oxides are: P_4O_6, usually called phosphorus trioxide and expressed as P_2O_3; P_nO_{2n}, sometimes written as P_2O_4 and called phosphorus tetroxide; P_4O_{10}, nearly always written P_2O_5 and called phosphorus pentoxide.

In addition to these three oxides. existence of an oxide P_2O_6 is indicated by considerable evidence, and some doubtful evidence suggests the possibility of P_4O and P_2O.

The oxide P_4O_6, phosphorus trioxide, is a colourless, crystalline substance which melts at 23.8" C. and boils at 175.4° C. It forms phosphorous acid in cold water and therefore may be said to be the acid anhydride of this acid, but it yields phosphorus, phosphine, phosphoric acid and other compounds when treated with hot water. The vapour density, the Raman spectrum and the electron diffraction pattern of phosphorus trioxide indicate P_4O_6 molecules and the molecular formula of the trioxide when dissolved in molten naphthalene is also P_4O_6.

Its heat of vapourization is 9,400 cal. per mole at the boiling point.

The oxide P_nO_{2n} is a lustrous, crystalline substance of density 2.537 at 22.6" C. The vapour at 1,400° C. has a density corresponding to molecules of P_7O_{14}. Phosphorus tetroxide reacts slowly in water with some evolution of phosphine but the principal products are phosphorous acid, H_3PO_3, and metaphosphoric acid, $(HPO_3)_n$.

The oxide P_4O_{10}, usually expressed as P_2O_5 and designated phosphorus pentoxide, is the main product obtained when phosphorus is burned in an excess of air. The vapour density, Raman spectrum and electron diffraction pattern agree in indicating a P_4O_{10} molecule of the T_d point group with a symmetry number of 12. This oxide exists in several forms which vary in appearance. The white, amorphous powder is the one most common but there is a vitreous, glasslike form and also a silky white form. The most volatile is a crystalline variety obtained by the sublimation of the ordinary white form in *vacuo*. The vapour pressure of this crystalline variety is one atmosphere at about 358° C.

Phosphorus pentoxide, P_4O_{10}, is an unusually effective agent for the drying of air. It hydrolyzes first to metaphosphoric acid. The water vapour pressure over this P_4O_{10}-acid mixture is not more than 10^{-5} mm. of mercury at room temperature. Its capacity for water absorption is low, however, since one gram of water will convert nearly eight grams of P_4O_{10} to metaphosphoric acid.

Sulfides.—The sulfides of phosphorus are not as closely analogous to the oxides as is usually the case with elements other than phosphorus. The sulfides P_4S_3, P_4S_5, P_4S_7 and P_4S_{10} are well known and there is some evidence for the existence of P_3S_6.

The **Oxyacids of** Phosphorus.—There are six well-known oxyacids of phosphorus, namely: hypophosphorous acid, H_3PO_2; phosphorous acid, H_3PO_3; hypophosphoric acid, $H_4P_2O_6$; metaphosphoric acid, (HPO,),; orthophosphoric acid, H_3PO_4; and pyrophosphoric acid, $H_4P_2O_7$.

The barium salt of hypophosphorous acid can be formed through the prolonged boiling of phosphorus with an excess of barium hydroxide. The over-all equation is:

$$8P + 3Ba(OH)_2 + 6H_2O = 2PH_3 + 3Ba(H_2PO_2)_2$$

The excess of $Ba(OH)_2$ is precipitated by means of CO_2 and the resultant $BaCO_3$ filtered off. Sulfuric acid then is added to the solution to free the hypophosphorous acid and to precipitate barium sulfate which then is removed. When the solution is evaporated, colourless crystals of hypophosphorous acid, H_3PO_2, appear. The acid is monobasic, and the Raman spectrum indicates that two of the hydrogen atoms in the molecule are linked directly to the phosphorus atom while the third hydrogen is in a P-O-H linkage. As written for organic acids. the formula would be H_2POOH. The acid and its salts are powerful reducing agents although they often react slowly.

Phosphorous acid, H_3PO_3, is a colourless, deliquescent solid which melts at about 72° C. It is a dibasic acid and is a strong reducing agent. It is prepared easily by drawing a stream of air through PCl_3 and then through cold water. The equation is:

$$PCl_3 + 3H_2O = H_3PO_3 + 3HCl$$

Hypophosphoric acid, $H_4P_2O_6$, is formed by the slow oxidation of moist phosphorus under special conditions. Although the formula may be written as $P_4O_6.2H_2O$, the acid is not formed when P_4O_6 is brought into contact with water. The dihydrogen, disodium salt. $Na_2H_2P_2O_6.6H_2O$ can be prepared through the slow addition of red phosphorus to a cooled, alkaline solution of sodium hypochlorite. Hypophosphoric acid is a colourless, deliquescent solid which decomposes when heated. It is a tetrabasic acid, with one, two, three or four replaceable hydrogens.

Theoretically, metaphosphoric, pyrophosphoric and orthophosphoric acids can each be obtained by the reaction of P_4O_{10} vapour with the appropriate amount of water; *i.e.*,

$P_4O_{10} + 2H_2O \rightarrow$ metaphosphoric acid
$P_4O_{10} + 4H_2O \rightarrow$ pyrophosphoric acid
$P_4O_{10} + 6H_2O \rightarrow$ orthophosphoric acid

Likewise, orthophosphoric acid can theoretically be dehydrated to pyrophosphoric and to metaphosphoric acid in succession.

However, phosphoric acids with compositions corresponding to these acids are not pure. simple acids, but are complex mixtures of several polymeric acids, the proportions of which depend upon the over-all concentration.

Metaphosphoric acid exists in several polymerized forms indicated by the general formula $(HPO_3)_n$. The salts of several of what were supposed to be the individual polymers are known by such names as Pascal's salt. Madrell's salt. Knorre's salt. Graham's salt, Kurrol's salt, etc. It has been found. however, that these supposed salts of individual polymers of metaphosphoric acid are mixtures of different complex polymers, the degrees of complexity of which have not been determined with certainty. The sodium salt of so-called hexametaphosphoric acid is formed by the heating of NaH_2PO_4 and is important industrially for the treatment of boiler feed water. In hard water this complex sodium phosphate forms soluble complexes with calcium ions and thereby prevents the formation of the usual insoluble calcium compounds responsible for boiler scale.

Pyrophosphoric acid, $H_4P_2O_7$, is a colourless solid. It is tetrabasic and, so far as the first replaceable hydrogen is involved, is a stronger acid than orthophosphoric acid. In aqueous solution it hydrolyzes slowly to orthophosphoric acid.

Orthophosphoric acid. H_3PO_4, is commercially the most important of the oxyacids of phosphorus. The acid and many of its salts find extensive industrial applications. Some of the most widely used salts of both metaphosphoric and pyrophosphoric acid are prepared most readily through dehydration of the appropriate orthophosphoric salt. Thus when the monosodium. dihydrogen salt of orthophosphoric acid is heated, sodium metaphosphate is formed:

$$n NaH_2PO_4 \rightarrow (NaPO_3)_n + n H_2O$$

And, likewise. when the disodium, monohydrogen salt of orthophosphoric acid is heated, the corresponding sodium pyrophosphate is formed:

$$2Na_2HPO_4 \rightarrow Na_4P_2O_7 + H_2O$$

Orthophosphoric acid is a tribasic acid and at ordinary temperatures anhydrous H_3PO_4 is a colourless, crystalline solid which melts at 42.3° C. to a syrupy liquid. It forms a hemihydrate $2H_3PO_4.H_2O$, which melts at 29.3° C.

Two methods are in common use for the manufacture of orthophosphoric acid. In the older method. rock phosphate is treated with sulfuric acid solution and the engendered calcium sulfate and other insoluble material filtered off. The impure solution of orthophosphoric acid can then be purified and concentrated. Because of the difficulties encountered in the removal of impurities and in the step of concentration, the phosphoric acid obtained by this so-called "wet method" is utilized almost exclusively in the manufacture of fertilizer superphosphate, for which purpose the impurities need not be removed from the acid. The modern method for the manufacture of orthophosphoric acid consists in the burning of white phosphorus in an excess of air to form P_4O_{10} which is cooled and the vapour hydrated to orthophosphoric acid mist, which is collected by means of an electrostatic precipitator. Acid of any desired concentration can be prepared by this method. The usual product contains about 80% H_3PO_4 and is relatively free from impurities. As produced in large industrial plants the acid usually carries some solid impurities in suspension and traces of dissolved impurities, the most objectionable of which is hydrogen fluoride. The suspension can be removed by filtration or settling. and most of the hydrogen fluoride by blowing air through the acid.

It will be noted that in the case of several of the oxyacids discussed above, not all of the hydrogen atoms that appear in the formula are replaceable by metals. Inasmuch as the most common co-ordination number of phosphorus is 4, it is instructive to consider the following co-ordination formulas:

$$[PO_4]H_3; \quad [P^{O_3}_{H}]H_2; \quad [P^{O_2}_{H_2}]H; \quad [P^{}_{H_3}]; \quad [PH_4]X$$

These formulas lead to the expectation that the hydrogens replaceable by a basic element would be three in the case of the orthophosphoric acid molecule, two in the case of the phosphorous acid molecule, and one in the case of the hypophosphorous acid molecule. The co-ordination formulas are in agreement with the observed facts in each case.

The fourth member in the above-listed series is known only through its organic derivatives and the fifth member is represented in phosphonium compounds.

Two other oxyacids of phosphorus have been described in technical writing, namely permonophosphoric acid, H_3PO_5, and perdiphosphoric acid. $H_4P_2O_8$. It is known that a double oxygen (peroxide) group can replace one of the co-ordination elements. Thus, permonophosphoric acid would be:

$$[P^{O-O}_{O_3}]H_3$$

and perdiphosphoric acid would be $H_2[O_3\,P\,O\text{-}O\,PO_3]H_2$.

The oxide P_4O_{10} is miscible with water in all proportions. Orthophosphoric acid contains 72.4% of P_4O_{10} equivalent, pyrophosphoric acid contains 79.8%, and metaphosphoric acid contains 88.75%. Compositions corresponding to these acids are solids under ordinary conditions. Compositions containing 75% to 76% of P_4O_{10} equivalent are liquid at room temperature. With small shift of the P_4O_{10} equivalent in either direction, solutions are obtained which will yield crystals when seeded at room temperature.

In the absence of seed crystals, however, the solutions can be strongly supercooled. Little is known about melting points in the composition range between pyrophosphoric and metaphosphoric acids.

Some Industrial Uses of Phosphorus and Its Compounds. --White phosphorus, as such, has but few industrial uses. In warfare it is used in incendiary bombs and for the generation of smoke screens. Red phosphorus finds its main use in the match industry, as does the sulfide P_4S_5.

The trichloride and the pentachloride of phosphorus are employed in the manufacture of organic chemicals.

Phosphorus pentoxide, P_4O_{10}, is used widely as a drying reagent in laboratories, but the oxide costs too much to permit its use for this purpose in industry.

Of the several oxyacids of phosphorus the one most widely used as such is orthophosphoric acid. This acid is used in dental cements, in the preparation of albumin derivatives, in the sugar and textile industries, and it serves as a substitute for the more costly tartaric and citric acids in the manufacture of food products such as jellies and essences.

Phosphoric acids are used as reactants in the manufacture of a large variety of phosphates of industrial importance. Of the sodium salts, the tripolyphosphate, $Na_5P_3O_{10}$, is used in the largest amounts.

Several other sodium salts also find wide uses.

When ground rock phosphate is treated with phosphoric acid a fertilizer known as superphosphate (sometimes called double or treble or triple superphosphate) is formed. The main reaction involved is indicated by the equation:

$$Ca_{10}F_2(PO_4)_6 + 12H_3PO_4 = 9CaH_4(PO_4)_2 + CaF_2$$

Monocalcium phosphate, $CaH_4(PO_4)_2$, has a P_4O_{10} (or P_2O_5) equivalent of more than 60% but the concentrated superphosphate made from ground rock phosphate carries only 48% to 50% of P_4O_{10} equivalent. Hundreds of thousands of tons of this superphosphate are made annually, but several million tons of a much lower grade superphosphate are made annually through the acidulation of ground rock phosphate with sulfuric acid according to the equation:

$$Ca_{10}F_2(PO_4)_6 + 6H_2SO_4 = 3CaH_4(PO_4)_2 + 6CaSO_4 + CaF_2$$

In this case the generated calcium sulfate is a diluent and the superphosphate made by this process contains 16% to 20% of P_4O_{10} equivalent.

Considerable tonnages of other phosphates such as $(NH_4)H_2PO$, and $(NH_4)_2HPO_4$ are also used in the fertilizer industry. The Tennessee Valley authority developed a process for the manufacture of a calcium metaphosphate fertilizer by the direct reaction between rock phosphate and P_4O_{10} vapour at about 1,100° C. This fertilizer carries 60% to 62% of P_4O_{10} equivalent.

Several of the phosphates of sodium, notably the so-called hexametaphosphate, tetrasodium pyrophosphate, $Na_4P_2O_7$, and trisodium phosphate, Na_3PO_4, are useful as water softeners. Disodium pyrophosphate, $Na_2H_2P_2O_7$, is used in electroplating baths and in tinning. Dicalcium orthophosphate. $Ca_2H_2(PO_4)_2$ (or $CaHPO_4$), is used as a supplement to animal and poultry food. It is also an excellent fertilizer but costs more than superphosphate upon the basis of P_4O_{10} equivalence.

Besides such inorganic phosphates as those mentioned above, several organic phosphates have industrial importance.

(H A Cs.)

PHOTIUS (c. 820–891), patriarch of Constantinople (858–867 and 878–886). The way to public life was probably opened for him by the marriage of his brother Sergius to the princess Irene, sister of Theodora, who, upon the death of her husband Theophilus in 842, had assumed the regency of the empire. Photius became captain of the guard and subsequently first imperial secretary. The dissensions between the patriarch Ignatius and Bardas, the uncle of the youthful Emperor Michael III, brought promotion to Photius. Ignatius was arrested and imprisoned (Nov. 858), and upon refusing to resign his office was illegally deposed, while Photius. although a layman, received all the necessary sacerdotal orders within six days, and was installed as patriarch in his place. Ignatius, continuing to refuse the abdication which could alone have given Photius' elevation a semblance of legality, was treated with extreme severity. His cause was subsequently espoused by Pope Nicholas in a manner highly offensive to the independent feeling of the Eastern Church, Photius felt himself the champion of Eastern Christianity against Latin pretensions; and when in 863 Nicholas finally anathematized and deposed him, he replied by a counterexcommunication. Meanwhile, the situation was suddenly changed by the murder of Photius' patron, Bardas, by order of the emperor Michael, who was himself assassinated by his colleague Basil in the following year (867). The fall of Photius immediately ensued; he was removed from his office and banished about the end of Sept. 867, a few days after the accession of Basil, and Ignatius was reinstated on Nov. 23.

About 876 Photius was suddenly recalled to Constantinople and entrusted with the education of Basil's children. On the death of Ignatius, probably in Oct. 878, Photius again became patriarch. In 879 the legates of Pope John VIII attended a synod convened at Constantinople, prepared to acknowledge Photius as legitimate patriarch, a concession for which John was much censured by Latin opinion. But John stood firm on outstanding points of difference, disowned his legates and again excommunicated Photius. Photius ignored John's action, but a palace revolution caused his banishment (886) to Bordi in Armenia. He is said to have died there on Feb. 6, 891.

Photius shows to no little advantage as an ecclesiastical statesman. His firmness was heroic, his sagacity profound and far-seeing; he supported good and evil fortune with equal dignity; and his fall was on both occasions caused by revolutions beyond his control. In erudition, literary power and force and versatility of intellect he far surpassed every contemporary.

The most important of the works of Photius is his renowned *Bibliotheca* or *Myriobiblon* (ed. I, Bekker, 1824–25), a collection of extracts from and abridgments of 280 volumes of classical authors (usually cited as *Codices),* the originals of which are now to a great extent lost. To Photius we are indebted for almost all we possess of Ctesias, Memnon, Conon, the lost books of Diodorus Siculus and the lost writings of Arrian.

The *Lexicon* (*Lexeon Sunagog*) was probably in the main the work of some of his pupils. The only manuscript of the *Lexicon* is the Codex Galeanus, at Trinity college, Cambridge (edited by S. A. Naber, 1864, with introduction on the authorities, critical commentary and valuable indexes) The *Amphilochia* is a collection of about 300 questions and answers on difficult points in scripture, addressed to Amphilochius, archbishop of Cyzicus (edited by Sophocles Oeconomus, 1858) Other similar works are his treatise in four books against the Manichaeans and Paulicians, and his controversy with the Latins on the Procession of the Holy Spirit His *Epistles* were edited by J Valettas (1864) A large number of his speeches and homilies were edited by S. Aristarches (1900) The only complete edition is Bishop Malou's in Migne's Patrologia graeca, ci–cv. R Reifzenstein in Der *Anfang* des Lexikons des *Photius* (1907) published a hitherto unedited manuscript containing numerous fragments from various verse and prose authors

See Cardinal Hergenrother, Photius, Patriarch von Constantinopel (1867–69).

PHOTOCHEMISTRY is the study of chemical reactions which are initiated (or otherwise influenced) by the absorption of light. Light in this context means a portion of the electromagnetic spectrum considerably more extensive than that occupied by visible light *(see* LIGHT) The visible spectrum embraces wave lengths between about 4.000 A (violet) and 7,200 Å (red), one angstrom unit (Å) being 10^{-8} cm. Radiations in the infrared, having wave lengths greater than 7,200 A, are only rarely of photochemical consequence: of far more importance is the ultraviolet region, extending downward from 4,000 A to below 1,500 Å.

The significance of photochemistry in research arises chiefly from its power as a tool in exploring the mechanisms of chemical reactions By the insight it provides into the intermediate stages of fleeting existence in chemical transformations, it contributes most significantly to the understanding of the kinetics of reactions. In some instances, moreover, the results of photochemical experiments can be made to provide information on the nature of the process of light absorption itself. On the practical side, photochemistry plays a role in many familiar phenomena. The most important application of a photochemical reaction is photography. The practical use of light simply as an agent for effecting chemical change is of less consequence and is confined to a relatively small number of reactions; among the few commercial applications may be mentioned the formation of vitamin D by ultraviolet irradiation of certain food materials, for example, milk, and the bleaching of linen by exposure to sunlight. Among biological photochemical reactions is one of supreme importance — photosynthesis, the production of carbohydrates from carbon dioxide and water by plants; this process is solely responsible for the synthesis of organic matter from inorganic and therefore ultimately for the maintenance of life on the earth.

Photochemical reactions are of many types, including synthesis and decomposition, oxidation and reduction, polymerization and depolymerization, hydrolysis, isomerization and even such not truly chemical transformations as phase (allotropic) changes. A more significant classification specifies whether the free energy is increased or decreased by the reaction. Thermodynamics (q *v.)* shows that chemical reactions which are spontaneous, *i.e.,* which proceed without external influence, must always result in a decrease of free energy. Most photochemical reactions are also of this type; in them the absorption of light merely accelerates a transformation which otherwise would proceed very slowly. In some cases the effect of light is that of a trigger: the illumination initiates a reaction which then runs to completion without the assistance of light. Thus a gaseous mixture of hydrogen and chlorine is ordinarily quite stable, but it will react with explosive violence when irradiated with light of appropriate wave length. Some photochemical reactions, however, actually effect an increase in free energy, the additional amount deriving from the energy of the light. All such reactions, of which examples are the formation of ozone from oxygen, the polymerization of anthracene, the decomposition of water and of ammonia, and photosynthesis, tend to reverse themselves after the irradiation has ceased, although some may do so extremely slowly. An instance is the oxidation of carbohydrates in the respiration of plants and animals; this is the biological reversal of photosynthesis. A historical and cardinal objective of photochemistry, not yet realized, is the efficient utilization on an industrial scale of solar energy incident on the surface of the earth, by conversion of the energy to chemical free

energy in a photochemical reaction of this second type.

The Equivalence Principle. — The foundation of the modern interpretation of photochemistry is the quantum theory (see QUANTUM MECHANICS), which has demonstrated that light is emitted and absorbed by matter, not in arbitrary amount, but in small but definite "packets" of energy. These units or quanta of light are called photons.

The energy of such quanta depends only upon the frequency of the light which they constitute; if ν is this frequency, the energy of a single quantum is:

$$\mathbf{E} = h\nu$$

In this, the fundamental relation of the quantum theory of radiation, h is a constant of nature called Planck's constant after the originator of the theory. The relation may alternatively be written in terms of the wave length λ of the light (this being related to the frequency by the formula $\lambda = c/\nu$, where c is the velocity of light):

$$\mathbf{E} = hc/\lambda = 12{,}400/\lambda \text{ when } \begin{cases} \lambda \text{ is expressed in Å} \\ \text{E is expressed in ev per photon} \end{cases}$$

Here the numerical value of the constant hc is given, since it is more useful than that of h in discussions of photochemical processes. The electron volt (ev) is the energy unit most commonly used in atomic physics. One electron volt is equal to 1.602×10^{-12} ergs. Thus a photon of green light, with a wave length of about 5,000 Å, has an energy of about 2.5 ev. Often, instead of a single photon, a number N of them is considered ($N = 6.02 \times 10^{23}$ is called Avogadro's number and is the number of molecules in a gram molecular weight, or mole, of any substance). This number of photons is called an einstein. For an einstein of photons the above formula becomes:

$$E = Nhc/\lambda = 286{,}000/\lambda \text{ when } \begin{cases} \lambda \text{ is expressed in Å} \\ \text{E is expressed in kg.cal. per einstein} \end{cases}$$

Thus an einstein of photons of green light has an energy of about 57 kg.cal. These energy units — electron volt for a single photon and kilocalorie (kg.cal.) for an einstein — are those most commonly employed in photochemical work.

The greatest single event for the interpretation of photochemical reactions was the enunciation by Albert Einstein, in a series of papers appearing shortly after the advent of the quantum theory (1905, 1912, 1916), of the principle of photochemical equivalence. It had then been known for almost a century that of the light impinging on a system only that part which is absorbed by the components of the system can be effective in causing photochemical transformation. This had been discovered by T. von Grotthus in 1817 and later rediscovered by J. W. Draper in 1843. Einstein's principle forged the link between photochemistry and the quantum theory of light by asserting that the initial or primary process is always the absorption of a single photon of light by one of the molecules participating in the reaction. The relation between the number of affected molecules and the quantity of absorbed light is thus one of remarkable simplicity. This simplicity may be obscured, however, by various secondary processes. Indeed, absorption of a photon does not ensure that a molecule will react at all. For a given molecule, photons of some wave lengths may be effective and those of others not. The mechanism of a photochemical reaction is therefore best described in two stages: interpretation first of the absorption act, or primary process, and then of the more or less clearly separable ensuing secondary processes, which are essentially chemical in nature. Except in rare cases the latter are quite uninfluenced by the light and would be the same if the primary products mere formed in some fashion other than by its action. The former step is a matter of pure physics. belonging to the province of the theory of spectra (see SPECTROSCOPY).

The effectiveness of light absorption in provoking chemical reaction can be readily understood on the basis of the quantum theory. Chemical kinetics (see REACTION KINETICS), the study of the speed of "dark" or nonphotochemical reactions, has shown that of all factors which affect the rates of chemical reactions, the most important one is usually the activation energy, which is the amount of energy that must be communicated to the primary reactants before reaction can occur. These reactions are also called thermal reactions because without external influence the only source of such activation energy is the heat energy of the molecules (see KINETIC THEORY OF MATTER).

Many thermal reactions are slow at ordinary temperatures, because for them the activation energy is many times greater than the average thermal energy at such temperatures, and it requires a relatively long time before a molecule will by chance acquire such an energy greatly in excess of the average. Thus for most thermal reactions that proceed at measurable speeds the activation energy is between 10 kg.cal. and 80 kg.cal. per mole, whereas the average thermal energy of a molecule at 20° C. is approximately 1 kg.cal. per mole. But an einstein of photons of visible light has an energy between 40 kg.cal. and 75 kg.cal., and an einstein of ultraviolet up to 200 kg.cal. or even more. Hence, absorption of light provides more than enough energy to initiate most chemical reactions. (In a sense, activated reactants in a photochemical reaction are so highly excited that they may be regarded as extremely hot entities reacting in a cold environment.) This simple consideration is generally valid, but it should not be inferred that light absorption will always accelerate a slow thermal reaction, or that if it does the reaction mechanism or even the products will be the same. Light absorption not infrequently leads to an entirely different sequence of events. (In such cases comparison of the thermal and photochemical reactions may afford valuable insight into both mechanisms.)

It should be emphasized, finally, that light absorption is not only a more powerful way to initiate reactions than thermal activation; it is also a way more susceptible of exact study, for it substitutes for the chaotic activation by collisions between molecules an activation that is qualitatively and quantitatively well defined and controllable.

The quantum yield, often called the quantum efficiency, of a photochemical reaction is defined as the ratio of the number of molecules of reactant chemically transformed to the number of light quanta absorbed. The equivalence principle implies that this quantity must always be equal to 1, but in reality such can be the case only for the efficiency of the primary process (which in general cannot be measured directly). Because of the secondary processes and their complexities, the over-all quantum yield usually differs from 1. This distinction was first clearly stated by M. Bodenstein (1913).

The Photochemical Primary Process. — The absorption of a photon by an atom must result either in excitation of its electronic system or in the removal of one of its electrons, a process called ionization. The absorption spectrum (see SPECTROSCOPY) of an atom shows at once whether absorption of a particular wave length of light leads to excitation or to ionization; in the latter case the wave length must lie in a broad region of continuous absorption, whereas in the former it must coincide with one of a number of sharply defined wave lengths at which absorption also occurs (discrete absorption — the individual regions are called absorption lines). Ionization is only rarely involved in photochemical reactions, since only for a few exceptional atoms has a photon in the visible or near ultraviolet region enough energy to remove an electron. In the case of excitation the atom has its energy increased by an amount exactly equal to the energy $h\nu$ of the absorbed photon. This energy can be subsequently lost in only two ways: by transfer in a collision to another atom or molecule or by the emission of a photon of light. Re-emission of the absorbed light is called fluorescence. Although the exception rather than the rule, it has great importance when it does occur. for observations of its spectrum. duration and intensity provide insight into the length of time during which the absorbed energy (or part of it) is retained by the activated atom and is thus photochemically available. *See* LUMINESCENCE.

Absorption of a photon by a molecule is a more complicated matter. As in the case of atoms, the energy may be retained for a short time and then re-emitted as fluorescence. or it may be completely or partially transferred to another molecule during a collision (after which the absorbing molecule may be left either

in the original or in a chemically altered state). But there are other possibilities. The first is photochemical dissociation. It was shown first by J. Franck (1925) that light absorption can dissociate a molecule into smaller fragments, and that for gases of diatomic or polyatomic molecules this occurs when the absorbed light has a wave length lying in a region of continuous absorption. (This type of continuous absorption must be distinguished from that giving rise to ionization; the latter occurs for molecules as well as atoms but is almost always confined to the extreme ultraviolet spectral region.) These fragments may be stable molecules, but usually they are free atoms or radicals which are very reactive chemically. Their presence may on occasion be shown directly: for example. a gas containing even a minute amount of CH_3 (methyl) radicals will remove a thin metallic film (lead: zinc, arsenic. etc.) when allowed to flow past it, and hydrogen atoms will strongly catalyze the interconversion of orthohydrogen and para-hydrogen. It is also possible to detect and measure the transient concentrations of certain free radicals by means of their own characteristic light absorption.

In addition to regions of continuous absorption, molecules also possess absorption bands, which are simply groups of closely spaced absorption lines. The immediate effect of absorption in such a band is excitation. just as for an atom; but, if the absorbed energy is greater than the bond energy, spontaneous dissociation of the excited molecule may nevertheless ensue. This may occur within 10^{-10} sec. after the absorption act; if it does the individual lines of the band will be diffuse, and the behaviour is called predissociation. If the components of the ahsorption band are sharp, this spontaneous dissociation usually does not occur; but even here, if the excitation energy is sufficient, dissociation can often be induced by collisions of the excited molecules with other atoms or molecules (this may be brought about by increasing the density of the reacting gas or by admixing a foreign gas) (O. Stern and M. Volmer, 1920).

Dissociation into radicals or atoms is the most common primary photochemical process, particularly in the case of gases irradiated with ultraviolet light. In this respect photochemical reactions differ from thermal reactions. which usually proceed by molecular rearrangements during or subsequent to collisions (because these require less energy than dissociation and therefore occur faster under thermal activation). However: in reactions induced by visible light (for example. photochemical reactions of organic dyestuffs) the absorbed energy is usually insufficient for dissociation, and the only explanation for the photochemical action is that excited molecules collide with appropriate reaction partners before their energy has been lost by fluorescence. At first sight this might seem inefficient. in view of the short period (normally of order of magnitude 10^{-8} sec.) which usually elapses between the absorption of a photon and its re-emission. However, in the case of a molecule containing many atoms, an excited molecule may undergo internal alterations of varied and complex nature. Thus, excitation of the electronic system by light may lead to an internal chemical (structural) transformation (formation of an isomer or tautomer of high energy). After a time which is long compared with 10^{-8} sec., the molecule may revert to its original state, often with the emission of light (called delayed fluorescence or phosphorescence). But by this temporary storage of activation energy the secondary photochemical process will have been separated by a considerable interval of time from the primary process of light absorption. and opportunity thus given for new modes of chemical interaction.

Secondary **Processes.**—As previously indicated, the action of light ends with the formation of the primary products (free atoms. radicals. excited atoms or molecules), and the further course of the reaction depends upon the interaction of these with each other and with additional entities present (original reactants. reaction products. impurities). These secondary processes present a great array of possibilities, the unraveling of which is the task of the investigator of each particular photochemical reaction. Some insight is attained from study of measurements of the quantum yield and its dependence on various variables. Whether the quantum yield is less than. equal to or greater than 1 is itself very illuminating. If it is less than 1, some of the absorbed quanta were ineffective. This may stem either from loss of energy by fluorescence or from deactivating collisions in which energy is dissipated into heat before it has had time to render photochemical action; in large molecules degradation of excitation energy into heat may even occur by conversion into vibrational energy within the molecule itself (internal conversion). If the primary process is a dissociation, the quantum yield may also be reduced by recombination of dissociation products. Back reactions are also possible; for example, reduction products may be reoxidized if air is present. (It is worthy of note that a small quantum yield does not imply that more than one photon must be absorbed by one and the same molecule before it will dissociate. For a given molecule the probability of absorbing a photon is very small, and the chance that, if it has absorbed one, a second will be encountered before the first is disposed of is infinitesimal. All known photochemical changes are in this sense single photon processes.)

If the quantum yield is somewhat but not greatly in excess of 1, the reaction of a fragment with another primary molecule is suggested. In this way more than one molecule can be altered by the single photon. An example is the photolysis (a general designation given to photochemical decompositions) of hydrogen iodide. This reaction is one of many studied by E. Warburg, whose classical researches on the equivalence principle (1911–21) form the foundation of modern quantitative photochemistry. Warburg obtained the following data:

Wave length A	Moles decomposed per kg.cal. absorbed	Quantum yield
2,070	0.0114	2.0
2,530	0.018	2.1
2,820	0.021	2.1

The yield, if expressed in moles of HI decomposed per kilocalorie of radiant energy absorbed (centre column), varies as the wave length is altered. But the quantum yield is constant within the accuracy of the experiments and, moreover, has the very simple value 2. The interpretation of this result is summarized by the following equations:

$$HI + h\nu \longrightarrow H + I \qquad (1)$$
$$H + HI \longrightarrow H_2 + I \qquad (2)$$
$$I + I \longrightarrow I_2 \qquad (3)$$

Reaction (1), the primary process, is the dissociation of the hydrogen iodide molecule; this part of the mechanism follows from the fact that the absorption in the spectral region used is continuous. Reaction (2) occurs much more often than would the reaction between two hydrogen atoms to give a hydrogen molecule, because the concentration of HI is very much greater than that of H. The analogous reaction for I:

$$I + HI \longrightarrow H + I_2$$

cannot take place because it requires energy (about 32 kg.cal. per mole, whereas reaction [2] evolves 35 kg.cal. per mole). Hence, reaction (3) is the only possible fate for iodine atoms. (That reaction is oversimplified as written. because recombination of two atoms has a quite negligible probability in a simple collision. It is necessary that they collide together with a third body—another molecule or the wall of the containing vessel—which acquires the energy liberated in the recombination; otherwise this energy must be retained in the diatomic molecule. dissociating it almost immediately.) The over-all result of reactions (1), (2) and (3) is the decomposition of two molecules of HI for each photon absorbed The photolysis of hydrogen bromide also occurs after a primary dissociation and with a quantum yield of 2. It is of interest to compare the photochemical decomposition of hydrogen iodide with the thermal decomposition. The latter is a bimolecular reaction nith an activation energy of 44 kg.cal. per mole. The mechanism is simple:

$$HI + HI \longrightarrow H_2 + I_2$$

It is to be noted that the photochemical primary process (1), in which an H—I bond must be broken, requires 71 kg.cal. per mole.

This explains why the thermal reaction proceeds by the energetically less demanding direct rearrangement.

If the quantum yield is much greater than 1, a chain reaction is indicated. In a chain reaction the initial impetus is passed on and on in a series of identical steps. so that one photon can be ultimately responsible for the transformation of many molecules. Thus. a fragment may decompose a stable molecule to form both a product molecule and another reactive fragment, which latter in turn undergoes a similar cycle.

Such chains may be very long. They are possible, of course, only in exothermal reactions. Chain mechanisms were first introduced in chemical kinetics by J. A. Christiansen and H. A. Kramers (1923), but their role in several photochemical reactions was demonstrated earlier by Bodenstein (1913) and by W. Nernst (1918). It was, indeed, the unequivocal evidence provided by large quantum yields that first established the correctness of chain mechanisms and pointed to the role of free atoms and radicals as active intermediates in chemical reactions. This has been perhaps the greatest contribution of photochemistry to the understanding of chemical kinetics.

The most familiar photochemical chain reaction is the union of hydrogen and chlorine to form hydrogen chloride. The reaction

$$H_2 + Cl_2 \longrightarrow 2HCl + 44 \text{ kg.cal.}$$

has negligible speed in the dark at low temperatures. When mixtures of the two gases are irradiated (with light of wave length less than about 5,000 Å), a chlorine molecule absorbs a photon and is dissociated into two chlorine atoms. There then ensues a chain reaction, one link of which is the pair of processes (Nernst, 1918):

$$Cl + H_2 \longrightarrow HCl + H$$
$$H + Cl_2 \longrightarrow HCl + Cl$$

That the chain may be extremely long has been known since 1913, when quantum yields as great as 10^5 were found by Bodenstein and W. Dux. The chains are broken by removal of either hydrogen or chlorine atoms. which may occur by recombination at a wall or in a three-body collision in the gas or by reaction with a variety of possible impurities or inhibiting substances added for that purpose. By taking extreme precaution to eliminate such chain-breaking substances, quantum yields as great as 4×10^6 have been achieved. At the start of the reaction the quantum yield is often observed to be small, only to rise after a certain induction period has elapsed. This effect mas discovered by Draper (1841) and was further explored by R. W. von Bunsen and H. E. Roscoe in their classical investigations of this reaction (1855–60). It is known to arise from the removal of free atoms by reactions with impurities present in the gas or residing in the vessel walls; the chains lengthen and the quantum yield becomes large as soon as the walls have been "cleaned" and the impurities destroyed. If the walls are initially clean and the gases pure, no such induction period is observed. (The effect of chain-breaking impurities is forcefully illustrated by some experiments on the photolysis of acetaldehyde: the quantum yield, normally several hundred, is reduced to about 1 by the addition of a small amount of nitric oxide. which is known to break chains in analogous thermal reactions.) The above mechanism has been verified by initiating the reaction with chlorine atoms formed otherwise than by photodissociation (for example. in electrical discharges or by the reaction 'of chlorine with sodium vapour) or by means of atomic hydrogen from a standard source. The most carefully studied inhibitor is gaseous oxygen. which breaks chains chiefly by collisions with hydrogen atoms and a third body, the radical HO, being formed in these collisions. The details of this, possibly the most extensively investigated of all photochemical reactions. are exceedingly intricate; the elucidation of many minor features, particularly as regards the various chain-breaking processes, remains to be accomplished.

Experimental Techniques. — Early experimenters employed sources of light emitting many wave lengths (for example, the continuous spectrum of the sun's radiation), but contemporary work usually demands the more informative results given by the use of monochromatic light. The most nidely used light sources are the arcs with iron or graphite electrodes and the mercury-vapour discharge. The first two provide intense radiation throughout the entire visible and near ultraviolet regions. The particular region of wave length desired must be isolated with a prism or grating monochromator (see SPECTROSCOPY), and the ultimate intensity is therefore comparatively low. The mercury spectrum consists of a number of well-separated lines, and many of these can be isolated for photochemical use by the interposition of appropriate filters of coloured glass or of certain solutions or gases which remove the undesired lines. If the mercury discharge tube is constructed of quartz, several strong lines in the ultraviolet become available. Among these is the intense resonance line at 2,537 A, the most widely employed source for photochemistry in the ultraviolet. Another resonance line at 1,849 A is also useful. For special purposes still other sources are available. The sodium-vapour lamp is a powerful source of the yellow line of sodium (a doublet of wave lengths 5,890 A and 5.896 A). Resonance lamps filled with other vapours can be made to yield monochromatic light at a variety of wave lengths in the visible and ultraviolet. Neon discharge tubes produce many intense lines in the yellow and orange parts of the spectrum. For the far ultraviolet, namely for wave lengths less than about 2,000 Å, high-voltage sparks between metal electrodes (*e.g.*, magnesium, aluminum, zinc) are commonly used. For work in the ultraviolet all optical parts (*i.e.*, portions of the equipment through which the radiation will pass) must be made of quartz or fluorite. Glass absorbs wave lengths below about 3,500 A; fused quartz, those below about 2,100 A; crystal quartz, those below 1,800 A; and fluorite, those below 1,350 A. At wave lengths less than about 2,000 Å the entire system must be made free of air, since in this region oxygen loses its transparency. For photochemical studies very intense sources of light are generally required. Since an illumination of one foot-candle of light of wave length 5,550 A entails 4.8×10^{12} photons falling on one square centimetre each second, it corresponds to only 8×10^{-12} einsteins per square centimetre per second. With a quantum yield of 1, this means that 8×10^{-12} moles or 2×10^{-7} c.c. of a gas (at room temperature and atmospheric pressure) will be transformed each second per square centimetre of illuminated surface. Therefore, unless the quantum yield is extremely large, intense sources with illuminations of hundreds or thousands of foot-candles are required if the chemical effect is to be measurably great within a conveniently short time.

The reacting substance is usually contained in a vessel in which a pair of opposite sides are made of thin sections of transparent material, in accurate parallel alignment. For visible light, glass is a satisfactory material for these windows; in the ultraviolet one of the three transparent substances mentioned above must be used. The light enters the vessel through one of these windows, and such of it as is not absorbed leaves through the other. If possible this reaction cell is maintained at a constant temperature by immersion in a thermostat. Should this be impossible, special precautions must be taken to ensure that the temperature of the reacting system does not vary during the exposure. In particular, care must be exercised to prevent any strong infrared radiation, which has a strong heating effect, from reaching the cell.

Measurement of the quantum yield devolves upon two distinct steps: determination of the number of molecules that have reacted in a certain interval of time and of the number of photons that have been absorbed in the same period. The first step is common to many branches of chemistry, and the appropriate method depends upon the special character of each case. Standard chemical analysis is a common one. For many gaseous reactions simple measurement of the variation in pressure is practicable. Analysis of a reactant or product can often be achieved by spectrophotometry, that is, by measurement of its light absorption at some nave length (not necessarily or usually the exciting one); this may be feasible not only for solutions but also occasionally for gaseous systems Other, more specialized analytical methods are applicable in some cases. In any event, the analysis must be quite sensitive, since as explained above the actual extent of chemical change is very small (and should be small, so that the reaction products do not interfere with the study by reacting with intermediates or by absorbing part of the incident light). But it need not be highly

accurate, for the second stage in the measurement can be made so only with greatest effort.

This second stage — determination of the number of photons that have been absorbed — often presents the most difficulty. When feasible, the reactants are made to absorb all of the incident radiation, so that only the absolute intensity of the latter will have to be established. (If this should not be possible, the fraction of the entering radiation which is absorbed by the reacting substance must be ascertained.) Instruments such as photoelectric cells, radiation thermopiles or bolometers provide the best means, but their accurate use requires considerable skill and patience. Photocells are the most sensitive and are easy to operate, but their sensitivity is strongly dependent on wave length, and they can therefore be used for intensity measurements only in strictly monochromatic light. Thermopiles and bolometers, aith surfaces blackened so as to absorb all incident radiation. respond equally to the light of all wave lengths and are therefore preferable for absolute measurements or for experiments in nonmonochromatic light, An alternative method occasionally preferred by photochemists is chemical actinometry. An actinometer makes use of a photochemical reaction, the quantum yield of which is already known; determination of the intensity of a light source requires simply the measurement of the rate at which the reaction proceeds with this source. The principle seems to have been applied first by H. de Saussure (1790), who employed the action of light on chlorine water. Draper (1843) utilized the photochemical union of hydrogen and chlorine. The most important actinometers in contemporary use are based on the photolyses of gaseous hydrogen iodide and of oxalate solutions sensitized by uranyl ions. Relative values of the light intensity may also be measured photographically. This method, which is in fact also actinometric, is convenient because the photochemical yield can be immensely increased by chemical development of the latent image, but is unfortunately not of great accuracy.

Determination of the Mechanism of Photochemical Reactions. — The initial stage in the investigation must evidently be the identification of the reaction products and determination of the conditions, such as wave lengths of exciting light, under which the reaction proceeds. The second stage may be the correlation of the reaction with the absorption spectrum of the absorbing reactant, and elucidation of the primary process. We have seen that this is more or less a matter of pure physics, although the photochemical results themselves may be of aid in complex cases, particularly for polyatomic molecules, for which the understanding of the spectroscopic processes has not progressed very far. But a third stage, in which the principal effort is almost invariably required, is the unraveling of the nature of the intermediate stages between initial reactants and final products. These intermediate reactions, although occasionally simple. are for most photochemical transformations more or less intricate and often involve (in minute concentrations) radicals, free atoms, or excited atoms or molecules which are quite unknown in ordinary chemistry and the existence of which must usually be inferred indirectly. Many of these intermediates are also encountered in analogous considerations of the mechanisms of thermal reactions, and others are known from physical studies of the interaction of light and matter.

The photochemist must correlate his deductions with knowledge gleaned from these related fields.

The experimental data from which the mechanism is determined should embrace values of the quantum yield for all significant variations in the following factors: concentration (or in the gaseous phase, partial pressure) of the reacting substances; concentration of the products; concentration of any added substance that is found to influence the reaction; presence and nature of impurities; temperature; wave length of the light; condition and available surface area of the walls of the reaction vessel (for a gaseous reaction); and nature of the solvent (for a solution). Not all of these variables need be studied for any given reaction, but the more extensively they are, and the more completely the results can be correlated with the mechanism, the more surely can the latter be considered to have been established.

The effects of varying the concentration in a photochemical reaction are utilized in deductions on the mechanism in the same way as for thermal reactions. Adding a foreign substance can lead to very useful information if one is found which has a specific influence. It is significant that most photochemical reactions are dependent on the temperature to only a slight extent (E. Goldberg, 1903). This is in marked contrast nith ordinary chemical reactions, the overwhelming majority of which are greatly accelerated by even a slight temperature rise. This difference arises from the fact that whereas activation in photochemical reactions is achieved by the absorption of light quanta. in thermal reactions it is brought about by rare molecular collisions in which much more than the average thermal energy is available, and the number of such collisions increases rapidly with rise in temperature. In certain instances, honever, photochemical reactions show a more or less pronounced temperature dependence; this will be the case when a secondary process has an appreciable activation energy. Changes in quantum yield when the wave length is varied may be very significant. Sometimes the primary process will be quite different in two different spectral regions. In the same spectral region, say in a band of continuous absorption, photons with the shorter of two different wave lengths mill have greater energy and will therefore cause the fragments to fly apart faster. This greater kinetic energy may have photochemical consequences; for example, it may serve as activation energy and make possible certain secondary processes or it may decrease the probability of recombination, especially in liquid systems (see below). The quantum yield of many photochemical reactions is independent of the intensity of the light (*i.e.,* the rate of photochemical change is proportional to light intensity), as it should be for processes initiated independently by single photons. When there is a dependence. however, valuable inferences concerning the mechanism can be made.

Finally, study of effects of the vessel walls (and of addition of an inert gas) provides information on the role and mechanism of the recombination of fragments.

Sensitized Photochemical Reactions. — In a sensitized photochemical reaction the light is absorbed not by one of the reacting substances but by an extraneous substance (called a sensitizer or photocatalyst) often added just for that purpose. The absorbed energy is subsequently transferred to or otherwise utilized for the transformation of the active material. One of the virtues of most photosensitizing substances chosen for laboratory research is that the absorption process is one that is familiar and fully understood. By means of photosensitization, reactions often can be effected by light to which the reacting substances are transparent. Photosynthesis. for example, is a reaction of two transparent substances, carbon dioxide and nater, which can occur in visible light because of sensitization by the green plant pigment, chlorophyll.

Simple photosensitized reactions were first studied by F. Weigert (1907), who found that irradiated chlorine accomplished a number of transformations, such as decomposition of ozone and oxidation of sulfur dioxide, without being itself altered. Important sensitizers in common use are various metal vapours. uranyl ion (in aqueous solution) and organic dyestuffs (for photography and photosynthesis). Mercury vapour, under illumination by the resonance line at 2,537 Å, is the one most commonly used for gaseous reactions. This radiation has an energy of 112 kg.cal. per einstein, so that an excited mercury atom can. for example, dissociate a hydrogen molecule (dissociation energy 103 kg.cal. per mole) in a collision (G. Cario and Franck, 1922). Atomic hydrogen is very reactive, and mixtures of hydrogen and various vapours containing a trace of mercury undergo interesting reactions when illuminated with the 2,537 Å line. Examples are the formation of ethane from ethylene (some decomposition and polymerization also occur), the formation of formaldehyde from carbon monoxide and the synthesis of water (and hydrogen peroxide). A few of the many other reactions sensitized by mercury when irradiated with this line are the formation of ozone from oxygen and the decomposition of nitric oxide and of ammonia. The cadmium resonance line. with wave length 3.262 A, has an energy of 88 kg.cal. per einstein; this sensitizer has not

enough energy to dissociate hydrogen, but it can form an excited hydrogen molecule which is reactive. For example, illumination of a mixture of ethylene and hydrogen containing a trace of cadmium vapour results in polymerizatiop (but does not lead to the formation of ethane, which would occur if the hydrogen were dissociated).

Liquid Systems.—A photochemical transformation may, like any chemical reaction, be profoundly modified when it occurs in the liquid state. The complicating factors arise chiefly from two circumstances: a molecule in a liquid may be considered to exist in a more or less continual state of collision with surrounding molecules; and the reacting, intermediate or product molecules may exhibit strong chemical interactions with the environment. A generalization deriving from the first of these was advanced by Franck and E. Rabinowitch in 1934. If the primary process is a dissociation, the two fragments will be compelled by the surrounding molecules of the liquid to stay in each other's neighbourhood for an appreciably long time and in this period will make numerous collisions. During such collisions recombination will be possible, because in the liquid system (in contrast with a gaseous one) the environment can function as a third body and take up the recombination energy.

The Franck-Rabinowitch principle thus asserts that in the liquid state the effective quantum efficiency of the primary process may be less than 1. Exceptions can occur. If the fragments react with surrounding molecules, for example, they could be removed before recombining; or, if the dissociated molecule is very complex, the chance that the fragments collide with the proper orientation may be small. But the principle is supported by many instances in which the quantum yield of a reaction is smaller in the liquid than in the gaseous state. An example is the photolysis of hydrogen iodide, which, as stated above, has the quantum yield 2 as a gaseous reaction; for solutions of HI in hexane, the quantum yield depends somewhat on the concentration and wave length but is always less than 2; for liquid HI it is 1.84. It should be mentioned that the principle does not apply if the primary process is not a dissociation. If it is an excitation, and dissociation follows only when induced by a collision, the yield of fragments may be greater in the liquid.

The individual nature of chemical interactions does not permit generalizations concerning interaction of photochemical reactants or products with neighbouring molecules. On the whole, chemical reactions in liquids present many perplexing impediments to their interpretation, and the present state of knowledge concerning them is far from satisfactory. This is particularly true for aqueous solutions containing ions.

In many cases the same reaction may be studied both in gaseous and in liquid systems, the latter being either a pure liquid or a solution. From such studies the influence of the liquid phase may be revealed. (When a solution is used it is essential that the light be absorbed by the reacting substance and not by the solvent. In the case of aqueous solutions, for example. this requirement restricts the wave length to values longer than 1,850 A; water is opaque to shorter wave lengths.)

Photochemical reactions in liquids present as great a variety as do gaseous reactions, and again only a few examples can be cited here. The isomerization of fumaric to maleic acid, and vice versa, is effected in aqueous solution by exposure to ultraviolet light. Absorption of a photon occurs at the double bond, so weakening it that rotation about the bond can occasionally take place. The quantum yield is low, indicating deactivating collisions in which energy is removed by the solvent before rotation can occur. Oxalic acid in aqueous solution is decomposed by ultraviolet light to a mixture of formic acid, carbon dioxide, carbon monoxide and water; the quantum yield is small, being 0 01 or less. This reaction can be sensitized by uranyl ion, in which case it proceeds in visible light as well, the quantum yield between 2.000 A and 5,000 Å being about 0.5. Another interesting reaction is the oxidation of aqueous solutions of sulfite ion. This takes place both thermally and photochemically by a chain mechanism. The reaction rate is very sensitive to the presence of minute amounts of certain inhibitors and accelerating agents, and the quantum yield of the photochemical reaction may exceed 50.000.

Solid Systems.—The photographic process is by far the most important photochemical reaction in a solid system. Although in practical use for more than a century, it has been investigated carefully from the viewpoint of photochemistry only since the 1920s (see PHOTOGRAPHY: Theory of Photography) and was not yet fully understood in the mid-1950s. The sensitive surface of a photographic plate or film consists of tiny particles of a silver halide (chloride or bromide) embedded in an emulsion of gelatin. Under the influence of light some of the molecules in certain particles are transformed into metallic silver, the halogen being taken up by the gelatin. The totality of these neutral silver atoms distributed throughout the emulsion constitutes the latent image, the latter being transformed and stabilized by chemical processing into the ultimate photographic image. Pure silver halides are almost insensitive to visible light, so that the emulsion must play an important role even in the primary process.

Photographic emulsions vary greatly, according to the method of preparation, in their sensitivity and in their colour response. The sensitivity to a particular spectral region often can be considerably augmented by adsorbing an appropriate sensitizing dye on the emulsion; the dye molecules absorb light quanta and transfer the energy to silver-halide particles. Appropriately sensitized photographic emulsions are among the very few photochemical systems that respond to infrared light.

Alkali-halide crystals are also photosensitive: they are coloured by ultraviolet light (E. Goldstein, 1896). The underlying primary process is closely related to that of photography; and because of this fact and of its great intrinsic interest, it has been studied extensively (R. W. Pohl and R. Hilsch and others). The absorption of a photon removes an electron. from a halide ion to form a halogen atom; this electron is either transferred to an adjacent, or more remote, positive ion, thus neutralizing it, or wanders through the crystal until it meets some sort of irregularity that attracts it.

It is the electrons in these irregularities, and the neutral alkali atoms, which absorb visible light and hence give the irradiated crystal its colour.

Photochemistry of the Atmosphere.—One of the most interesting photochemical systems in nature is the upper atmosphere of the earth. The photochemical reactions which occur there determine many details of the composition of the atmosphere and have an important influence on weather, on magnetic phenomena and on the direct transfer of radiation from the sun to the surface of the earth. The atmosphere is composed of nitrogen, oxygen, the rare gases (argon, neon. etc.), small amounts of water vapour and carbon dioxide and traces of a number of other substances. Under the influence of solar radiation two main effects occur. At very high levels, between about 100 km. and 300 km. above the ground, many atoms and molecules absorb light quanta of very short wave length (extreme ultraviolet) and are ionized. It is the large density of free electrons in this region, called the ionosphere (*q.v.*), that is responsible for the reflection of radio waves and thus makes ordinary radio communication possible. Of more relevance to familiar photochemistry, however, are the photoprocesses which cause part of the oxygen to exist as free atoms and ozone (*q.v.*).

The chief facts may be summarized as follows: most of the ozone is concentrated at a certain level in the stratosphere, the ozone content decreasing at higher and at lower altitudes. The maximum ozone density occurs at about 20 km.–25 km., the maximum concentration (approximately 0.001%) at about 40 km. The layerlike structure of the ozone region (and of the ionized regions) is a simple consequence of the exponential absorption of radiation in a medium in which, as in the atmosphere. the density declines approximately exponentially with height. The total amount of ozone, although roughly constant (to within about 10% of its average value), varies diurnally, seasonally and with latitude, with various less regular fluctuations superposed. This ozone, although present in relatively small amount, is of the utmost importance, for it completely absorbs the ultraviolet radia-

tion of the sun in the region from about 3.000 Å to 2,200 Å. (Oxygen itself, and nitrogen. absorb the shorter wave lengths.) Without such a protective covering life would be impossible on the earth's surface, for ultraviolet radiation of these wave lengths readily destroys most organic substances. (The presence, in the atmosphere. of oxygen, and hence also of ozone, is believed by some to be itself a result of processes of life—namely, of photosynthesis. In the early stages of the earth's history the atmosphere is supposed to have consisted chiefly of nitrogen, and the ultraviolet light, therefore, to have penetrated to the ground.)

Atomic oxygen is present in the upper atmosphere during the day in amounts which, relative to O_2, increase steadily with altitude. predominating over O_2 above about 100 km. The density of atomic oxygen attains a maximum at about noon but virtually vanishes shortly after sunset. The presence of O and of O_3 can be proved directly: of O_3, by chemical analysis of air near the surface and by spectroscopic analysis at altitudes up to 30 km.; and of O, by the spectral lines of oxygen atoms emitted by the sky and observed on a moonless night. Photochemistry provides indirect evidence of their presence by correlating results of many diverse observations with data from known laboratory reactions (S. Chapman. O. R. Wulf and others).

Of all the atmospheric constituents, only O_2 and O_3 absorb appreciably in the ultraviolet above about 1,450 Å. The primary processes, which show the sources of oxygen atoms, are:

$$O_2 + h\nu \longrightarrow O_2^* \ (\lambda \text{ between 2,400 A and 2,600 A})$$
$$O_2 + h\nu \longrightarrow O + O \ (\text{A shorter than 2,100 A})$$
$$\text{and } O_3 + h\nu \longrightarrow O_2 + O \ (\text{A shorter than 11,800 A})$$

The first of these processes leads to an excited molecule (indicated by the asterisk). because the absorbed energy is insufficient for dissociation. Dissociation. the second process, occurs either directly (continuoui absorption—wave length less than 1,750 Å) or following a collision.

Oxygen atoms may also be formed from an excited molecule by the reaction.

$$O_2^* + O_2 \longrightarrow O_3 + O$$

This is not an important source of atomic oxygen, because most of the radiation which can form excited oxygen molecules is absorbed by the ozone in more elevated regions. Oxygen atoms are removed by the processes:

$$O + O_2 + M \longrightarrow O_3 + M$$
$$O + O + M \longrightarrow O_2 + M$$

(Here M represents an atom or molecule which functions as a third body.) The first of these explains the quantum yield of 3 obierved in the laboratory formation of ozone from oxygen by wave lengths betneen 1 700 4 and 1,900 Å a photon dissociates one oxygen molecule, and each of the tno atoms so formed reacts with another oxygen molecule

The decomposition of ozone occurs by the reactions:

$$O_3 + O \longrightarrow O_2 + O_2$$
$$\text{and } O_3 + O_3 \longrightarrow O_2 + O_2 + O_2$$

and in daytime also by light absorption. The second of these is the thermal decomposition; laboratory experiments show it to have negligible velocity at the temperature of the stratosphere, which averages about −50° C. Lahoratary experiments on the photolysis of ozone give a quantum yield which may be as high as 7. This result is explained by a chain reaction, based largely on elementary processes given above. The precise mechanism, however, is not yet established. It is interesting to note that. as is usually the case, the laboratory experiments are complicated by reactions at the walls of the containing vessels.

Atmospheric photochemistry is unique in that there are no walls!

Photochemical Reactions of Biological Importance. — The energy which provides the motivating force for the functioning of life of all kinds reaches the earth from the sun and is transferred in the form of light quanta. Most of the ultraviolet radiation is removed by the upper atmosphere, so that it is the visible and infrared regions in which the surface of the earth is bathed. In the course of evolution many biological systems on all levels of complexity have acquired the ability to react with this light in very special ways.

Among such interactions the cardinal position is held by the process known as photosynthesis — the conversion of radiant energy into stored chemical energy by green plants. But there are others, interesting if less important; among them are the formation of vitamin D from ergosterol in the skin tissues of man by ultraviolet light, and sunburn and its physiological effects *(see* LIGHT AND RADIATION IN RELATION TO HEALTH). Doubtless there exist many more subtle interactions that are still unknown.

Photosynthesis, in its purely photochemical aspects. is still only partially understood, and its myriad complexities have been at once the despair and inspiration of investigators for more than a century.

The over-all chemical reaction

$$112 \text{ kg.cal.} + CO_2 + H_2O \longrightarrow \tfrac{1}{6} C_6H_{12}O_6 + O_2$$

is sensitized by the dye chlorophyll, the green pigment to which plants owe their characteristic colour. One of the remarkable aspects of this reaction is its large energy requirement. Since photosynthesis will proceed in red light, the photons of which have an energy of 35 kg.cal. per einstein, at least four photons are required to reduce each CO_2 molecule. (In reality the plants are less efficient; the smallest number with which they can contrive is not less than eight.)

Such a situation is unique in photochemistry. In all other known endothermal reactions a single photon has sufficient energy to give a net heat evolution. In the case of plant photosynthesis there must exist a mechanism of extraordinary delicacy and complexity to ensure that the energy. which is absorbed over an extended interval of time, is concentrated into the proper channels. (For further discussion *see* PHOTOSYNTHESIS.)

The mechanism of vision involves another photochemical reaction of fundamental importance in biology. The primary process is the absorption of a photon by a molecule of a dye located in the cells of the retina of the eye *(see* VISION). That this primary process is sensitive to changes in wave length is evidenced by the perception of colour. The mechanism of the intermediate processes whereby this absorption event engenders a nerve impulse is still unknown. Measurement of a quantum yield for light perception has shown this phenomenon to be almost incredibly sensitive: an impulse of only 100 photons can be detected by the human eye when properly conditioned, and it can be shown that about 90% of these are lost by refection, scattering and absorption in outer regions. Thus the eye is one of the most sensitive mechanisms for the detection of visible light known.

Radiation Chemistry. — Radiation chemistry is the study of chemical transformations caused by absorption of radiations of high energy. These include X-rays, which are electromagnetic radiations, the photons of which have an energy of many thousands of electron volts, and the radiations emitted by radioactive substances. The latter embrace not only electromagnetic radiations (γ-rays) but corpuscular (α- and β-) rays as well, and each particle or photon has an energy which may exceed 1,000,000 electron volts *(see* X-RAYS; RADIOACTIVITY, NATURAL). Various artificially produced radiations. such as fast neutrons, protons. deuterons and electrons, should also be included. Chemical reactions caused by such radiations have been studied from the time of their discovery; indeed. their effects on photographic emulsions were the first and are still an important means of detecting them.

Radiation chemistry is in a sense a larger field of which photochemistry is a subdivision. Interpretation of the reactions of radiation chemistry has not progressed far, however,. the major reason being that the primary process is always extremely complex. In the photochemical primary process a single photon is absorbed by a single molecule to produce a specific excited state; that is possible because the actual excitation energies of atoms and molecules lie in the same energy region — several electron volts — as the energies of light quanta in the visible and ultra-

violet spectral region. Quanta of X-rays and nuclear radiations have thousands to millions of times this energy, and each forms not one excited or ionized atom or molecule but a very great number of them. Moreover, a mixture of all possible excited and ionized atoms or molecules is produced by a single ray. For this and other reasons, an understanding of the mechanisms in radiation chemistry can be expected to come only slowly and with great difficulty Nevertheless, the subject is of great importance, particularly since the success in achieving nuclear chain reactors has made radioactive materials available in unprecedented variety and strength. Some of the more important applications are in the interpretation of radiation action on biological materials (cells, tissues, genes, etc.) on the basis of knowledge of radiation action on the cell constituents. A pre-eminent goal of radiation chemistry is the discovery of a way to utilize the vast amounts of energy now being largely wasted in nuclear reactors (by degradation of the energy of the various radiations into heat) by conversion of this energy into chemical free energy. This promises a technological significance which may transcend that of any artificial photochemical reaction.

PHOTOELECTRICITY (literally, "light electricity") is the study of certain changes of an electrical nature induced in matter by light and other forms of radiation. When the primary result of the absorption of electromagnetic radiation by matter is the dissociation of the matter into electrically charged particles, the process is designated a photoelectric effect As commonly investigated, with radiation lying between the X-ray and infrared limits of the electromagnetic spectrum, the photoelectric effect results in the ejection of electrons from the atoms of which matter is composed. The γ rays whose energy exceeds 1 Mev (million electron volts) may create pairs of positive and negative electrons The γ rays whose energy is very large (~ 300 Mev) may create π mesons.

The study of the photoelectric effect was of major importance for the development of physical theory during the first two decades of the 20th century. The role played by the photoelectric effect during this period was largely due to the unambiguous manner in which it displayed the quantum properties of radiation which are not describable by the electromagnetic wave theory of James Clerk Maxwell. (See ELECTRICITY; ELECTROMAGNETIC WAVES)

In addition, observation of the behaviour of photoelectrons was of the greatest aid in solving the riddle of atomic structure. For these reasons a brief survey will be given of the early history of the photoelectric effect, after which the photoelectric effect of high-frequency radiation and of low-frequency radiation, applications of the photoelectric effect, and nuclear photoeffects are discussed.

This article, therefore, is divided into the following sections:

I. Historical Survey
II. Photoelectric Effect of High-Frequency Radiation
  1. Direction of Emission
  2. Compton Effect
  3. Auger Effect
III. Photoelectric Effect of Low-Frequency Radiation
  1. Metals
  2. Insulators
  3. Gases
  4. Photovoltaic Effects
IV. Applications of the Photoelectric Effect
V. Nuclear Photoeffects

I. HISTORICAL SURVEY

E. Becquerel, in 1839 reported that the illumination of one of a pair of metal plates immersed in a dilute acid solution altered the electromotive force of the cell. The decrease in the electrical resistance of selenium on illumination was discovered by Willoughby Smith in 1873 These photoelectric phenomena attracted great interest at the time of their announcement but remained unexplained and isolated observations.

In 1887 Heinrich Hertz observed that the behaviour of a spark gap was affected by illumination of the electrodes. W. Hallwachs investigated Hertz' observation and in the following year reported that a clean, insulated zinc plate acquired a positive charge on illumination with ultraviolet light. A negatively charged plate could be made to lose its charge by illumination. The effect was found to persist if the metal was placed in a vacuum.

In 1900, three years after the discovery of the fundamental particle of negative electricity. the electron, Philipp Lenard proved that the effects observed by Hallwachs were due to the ejection of electrons from the metal under the stimulus of radiation. It was quickly found that the effect was a common property of metals but that only a few (*i.e.*, the alkali and some of alkaline earth metals) were sensitive to visible light. In general, it was necessary to use ultraviolet radiation to provoke the effect.

J. Elster and H. Geitel discovered in 1900 that the number of photoelectrons emitted per second from the surface of a metal is proportional to the intensity of the incident radiation. Lenard established in 1902 the important fact that the maximum kinetic energy of a photoelectron depends only on the frequency of the incident radiation and is independent of its intensity.

According to Maxwell's theory, radiation consists of an electric and a magnetic field propagated through space in the form of a transverse wave. The constant velocity, c, of propagation in a vacuum is the product of the wave length of the wave and the frequency of vibration of the electric and magnetic vectors The energy transferred by the wave across unit area perpendicular to the direction of propagation in unit time is the intensity of the radiation and is proportional to the square of the amplitude of the electric vector.

It was believed that the electric field of the radiation exerted a force upon the electron which freed it from the atom to which it was bound. It was difficult to understand from the theory of Maxwell how the kinetic energy of the electron can be independent of the intensity of the radiation, which is fixed by the magnitude of the electric field.

This difficulty was ascribed by A. Einstein to a fundamental incompleteness of the Maxwellian wave theory of radiant energy. Einstein proposed that radiation possessed many of the properties commonly associated with material particles. In particular, he suggested that in a beam of radiation of frequency ν, the energy exists in the form of units of magnitude hν The names photon and quantum are given interchangeably to these units of radiant energy. Einstein viened the photoelectric process as one in which an electron absorbs a photon. The kinetic energy of the free photoelectron is the difference between the energy it has absorbed and the work it has performed in its escape from the forces binding it to the atom. Einstein proposed in 1905 the simple relation

$$T = h\nu - w \qquad (1)$$

between the maximum kinetic energy, T, of the free photoelectron and the frequency. ν, of the radiation. The constant w is the minimum work which the electron must perform to escape from the material to which it is bound. Einstein predicted that the consant h would be found to be the same constant which Max Planck had previously introduced into theoretical physics in discussing the emission of radiation from matter.

The experimental data available in 1905 did no more than suggest the correctness of these conclusions, but by 1916 the validity of Einstein's relation between the maximum kinetic energy of a photoelectron and the frequency of the absorbed radiation had been fully confirmed. This was largely the result of the beautiful experimental work of Robert Millikan, whose measurements

also determined Planck's constant, h, with great precision.

Photoelectric phenomena present another major difficulty to Maxwell's theory of radiation. It was estimated by Lord Rayleigh in 1916 that according to Maxwell's theory it would take a time of the order of several hours for an electron to absorb sufficient energy from a beam of radiation to escape from an atom. But Elster and Geitel had noted that the appearance of photoelectrons occurred simultaneously with the illumination of a metal surface. In fact, E. O. Lawrence and J. W. Beams, in 1928, found that the time lag between the incidence of radiation and the appearance of photoelectrons was less than 3×10^{-9} seconds. If the photoelectric effect is initiated by the collision of two corpuscles, the electron and the photon, then there is no difficulty in understanding the instantaneous character of the emission.

The success of the photon hypothesis in yielding the Einstein equation (1) and in interpreting other photoelectric phenomena stands in sharp contrast to the successful application of the wave theory of radiation to the field of interference and diffraction effects. *(See* LIGHT.) It appears that a dual character must be ascribed to radiation and that a complete description of its interaction with matter cannot be obtained by the consistent use of either a wave or a corpuscular theory. *(See* QUANTUM MECHANICS.)

II. PHOTOELECTRIC EFFECT OF HIGH-FREQUENCY RADIATION

Radiations whose wave lengths lie between 100 and 0.01 angstroms are termed X-rays. The angstrom unit of length, named in honour of the Swedish spectroscopist A. Ångstrom, is equal to a hundred millionth of a centimetre (1×10^{-10} m.). X-rays are commonly produced by the impact of fast electrons upon matter *(see* X-RAYS); y rays are of even shorter wave length and are emitted by the nuclei of radioactive atoms.

The photoelectric effect of high-frequency radiation in gases is easily demonstrated with an instrument known as an ionization chamber. This consists of a closed box filled with the gas, A thin window of metal foil or mica allows entrance of the X-ray beam. Inside the chamber are a pair of metal electrodes. By connecting the electrodes to the terminals of a battery an electric field is established between them. A gas under normal conditions is a good electrical insulator and no current will pass between the electrodes.

When X-rays enter the chamber, the photoelectrons and the positive ions formed from the atoms which have lost electrons are swept by the electric field to the electrodes and an electric current may be readily detected. The fast photoelectrons collide with the atoms of the gas and dislodge electrons from them so that the total number of electrons and positive ions is many times the number produced photoelectrically.

The photoelectrons produced by X and γ radiation possess very large kinetic energies and, therefore, very high velocities. The velocities commonly approach the speed of light and necessitate the use of relativistic equations in the discussion of their motion. The kinetic energies correspond to those acquired by

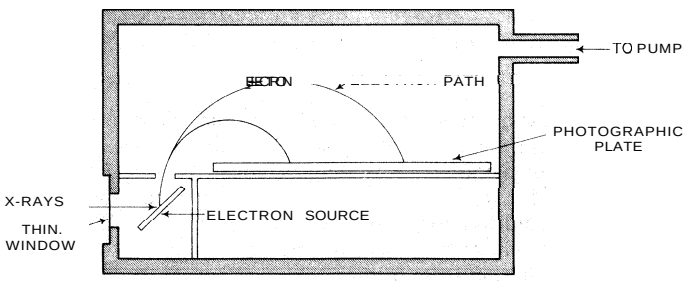

FIG. 1.—β-RAY SPECTROGRAPH. UNIFORM MAGNETIC FIELD PERPENDICULAR TO PLANE OF PAPER

electrons which have been accelerated by potentials of many thousands of volts.

With an instrument known as a β-ray spectrograph, H. Robinson and his coworkers performed some very informative experiments. This device, the use of which was introduced by O. Hahn, L. Meitner and C. D. Ellis, is illustrated in fig. 1. Robinson allowed X-rays of known frequency to impinge upon a solid placed in the position indicated. A fraction of the photoelectrons emitted by the solid pass through the slit and enter the evacuated chamber.

Here they are bent in arcs of circles by a uniform magnetic field of known magnitude. The photoelectrons then fall upon the photographic plate leaving developable traces. The position of the traces and the dimensions of the apparatus determine the radii of the circular arcs traversed by the electrons. A knowledge of these radii and of the magnitude of the magnetic field makes calculable the velocities of the electrons.

Robinson tested Einstein's equation with X-rays of known frequency. The energy lost by a photoelectron in escaping from an atom of a given chemical element (the quantity w) was found to assume several sharply defined values. This behaviour was direct evidence for the existence of atomic energy levels.

If radiation of unknown frequency is allowed to eject electrons from an element whose atomic energy levels have been determined. the unknown frequency may be determined by the use of Einstein's equation after measurement of the kinetic energies of the photoelectrons with the β-ray spectrograph. In this manner, Ellis and M. de Broglie examined the y rays emitted by many radioactive elements and established the very important fact that y-ray spectra are discontinuous as are the atomic spectra of the elements. This important work was the beginning of a spectroscopy of the nucleus and the establishment of nuclear energy levels.

1. Direction of **Emission.**—An important problem connected with the photoelectric effect is the direction of emission of the electron by the radiation. According to Maxwell's theory, radiation consists of a transverse wave. and the direction of emission should be the direction of the force exerted upon the electron by the electric vector which lies in a plane perpendicular to the direction of propagation of the radiation. This problem may be investigated by using the photoelectric effect of X-rays upon a gas in a Wilson cloud chamber. *(See* CLOUD CHAMBERS.)

The Wilson chamber is a vessel in which a gas may be supersaturated with water vapour by a sudden expansion. A fast electron ejected from an atom by the radiation strikes other atoms in its passage through the gas. In this manner it ejects electrons from the atoms of the gas leaving the atoms positively charged. Water droplets condense upon the ions thus formed and render visible the path of the high-energy photoelectron.

If X-rays of long wave length (*i.e.*, low frequency) are used to produce the photoelectrons it is found that the most probable direction of emission is in the plane perpendicular to the direction of propagation of the X-rays. As the frequency of the X-rays is increased, the majority of the photoelectrons are emitted in a direction which makes an angle less than 90° with the direction of propagation of the wave. This effect is explained by the fact that in the photoelectric process the electron receives not only the energy, hv, but also the momentum, $h\nu/c$, of the photon. It is only when the frequency of the radiation is greater than that of soft X-rays that the momentum of the quantum is large enough to have a discernible effect upon the direction of emission of the electron.

Neither Maxwell's theory nor the simple photon hypothesis of Einstein is entirely successful in its description of the experimental results. Maxwell's theory demands that all the electrons be ejected in the plane perpendicular to the direction of propagation of the radiation. The photon hypothesis predicts a definite angle between the perpendicular plane and the direction of emission which is approximately half that observed between the most probable direction of emission and the perpendicular plane. The quantum mechanical treatment of the problem has met with considerable success. The observed variation in the direction of emission is correctly described and the effect of the quantum momentum upon the direction of emission is greater than predicted by the photon hypothesis.

2. Compton Effect.—A most unusual type of photoelectric ef-

fect is that in which in the act of absorption of the photon its full energy is not given to the photoelectron but a fraction is scattered as a quantum of smaller energy. *(See* COMPTON EFFECT.)

This phenomenon was originally observed in experiments upon the scattering of monochromatic X-rays by solids. Among the scattered X-rays there is radiation of the same wave length as that of the primary X-rays and two types of modified X-rays of longer wave length. Atoms which have absorbed quanta may reradiate energy as fluorescent radiation.

This fluorescent radiation contains wave lengths which are characteristic of the absorbing atoms and independent of the wave length of the primary X-rays and of the angle of observation. There is also present a scattered radiation whose wave length is dependent upon the wave length of the incident radiation and upon the angle which the direction of observation makes with the direction of the primary radiation.

The existence of this last-mentioned type of scattered radiation was established and a simple explanation of its origin was given by A. H. Compton in 1923. Compton suggested that. if radiation has the corpuscular character ascribed to it by Einstein. a quantum of energy $h\nu$ and momentum $h\nu/c$ might be conceived as making an elastic collision with a free electron whose kinetic energy before the collision is negligible by comparison with that of the quantum. The laws of conservation of energy and momentum. uhen applied to the collision, give at once a relation between the energy of the scattered quantum and the angle at which it is scattered. Expressed in terms of the difference in wave length between the scattered and incident quanta the relation is

$$\Delta\lambda = \left(\frac{h}{mc}\right)(1 - \cos\theta), \qquad (2)$$

where $\Delta\lambda$ is the difference in wave length, and θ is the angle of scattering. The constants h, m and c which enter the equation are Planck's constant, the electron mass and the velocity of light, respectively.

This equation agrees very closely with the results of experiment. Observation with Wilson cloud chambers has made possible the detection of the recoil electrons. The simultaneous appearance of the scattered quantum and the recoil electron at the predicted angles has been observed by experiments in gases with Geiger counters.

3. Auger Effect.—It was observed by C. T. R. Wilson in 1923 that the absorption of an X-ray quantum by an atom is accompanied occasionally by the emission of two or more electrons. In such a case, only one of the electrons has a kinetic energy which depends upon the frequency of the quantum in the manner described by Einstein's equation. The kinetic energy of the other electrons is characteristic of the type of atom. These facts were established by P. Auger in an extensive investigation of the phenomenon.

The explanation of the Auger effect is as follows. A tightly bound electron is first ejected from the atom by the usual photoelectric process. Such an electron is one for which the constant w in Einstein's equation is large. After the act of photoelectric emission the atom is left with the excess energy, w. The atom can decrease its energy by transferring an electron from a higher energy level to the one vacated by the photoelectron. In the course of this transition the atom loses energy, usually by the emission of a quantum of radiation. Occasionally the energy freed by the transition is given to one of the electrons of the atom which is ejected.

Such an Auger electron will appear outside the atom with a kinetic energy which is the difference between that given to it by the atom and the energy lost in escaping from the atom. Since each of these energies is completely determined by the atom, the kinetic energy of the Auger electron is characteristic of the atomic species.

In stripping itself of its excess energy the atom may emit more than one quantum and several Auger electrons. The total energy so lost cannot be greater than w, the excess energy nith which the atom was left as a result of the initial photoelectric act.

III. PHOTOELECTRIC EFFECT OF LOW-FREQUENCY RADIATION

The wave-length region from 2,000 to 10.000 angstroms (A) is of primary importance for photoelectric studies. The opacity of air and most optical materials has severely limited work in the region below 2,000 A. The quanta of infrared radiation of wave lengths longer than 10,000 A possess so little energy that they produce photoelectric effects in few substances. Visible radiation, or light, includes the wave-length region from 4,000 to 7,000 Å.

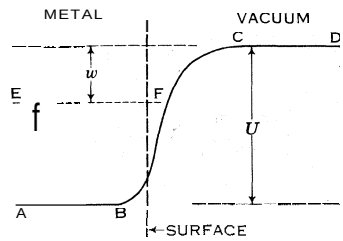

FIG 2.—ENERGY DIAGRAM FOR AN ELECTRON AT THE SURFACE OF A METAL

1. Metals.—The most important topic of investigation with low-frequency radiation has been emission from the surfaces of metals. In this case, the constant w of Einstein's equation is known as the work function of the metallic surface. A brief discussion of the structure of a metal is necessary in order to understand the significance of the work function.

The large electrical conductivity of metals is attributed to the presence of electrons which are not bound to particular atoms but are free to roam the interior of the metal. At the surface the electrons are subject to forces which prevent them from leaving the metal. The number of free electrons is of the same order of magnitude as the number of atoms. The minimum work which must be performed against the surface forces to extract an electron from the metal is the work function.

This discussion may be amplified by reference to fig. 2. The heavy solid line, ABCD, represents the potential energy of an electron in the neighbourhood of the surface. It is assumed that inside the metal the potential is constant as indicated by the horizontal part, AB, of the line. In passing through the surface the potential energy increases suddenly as shown by the portion, BC, of the line.

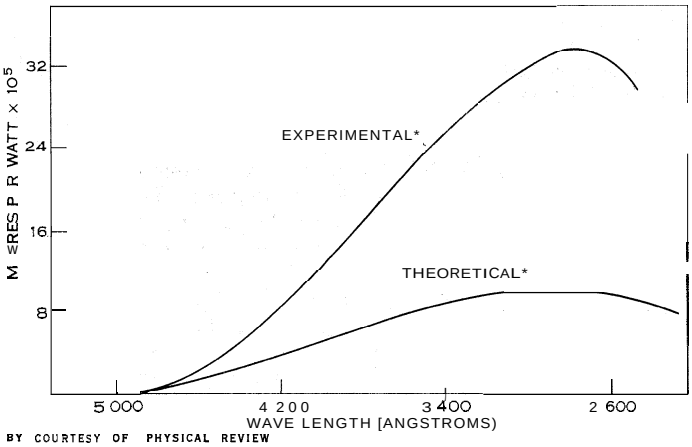
Outside the metal the potential energy is again constant along the line CD. To extract an electron, initially at rest inside the metal, would demand the work U. The electrons in the metal, however, have kinetic as well as potential energy. The kinetic energies vary between zero and a maximum value as indicated by the horizontal line, EF. The maximum kinetic energy of an electron inside the metal is K. The work necessary to extract the fastest electron and leave it with zero kinetic energy outside the metal is the difference between U and K, or w, the work function. The equation

$$h\nu = w \qquad (3)$$

determines the photoelectric threshold frequency. Radiation of smaller frequency is incapable of ejecting electrons. Equation (3) is the Einstein equation (1) with the kinetic energy T of the photoelectron set equal to zero. For most metals the photoelectric threshold is in the ultraviolet. Tungsten has a work function of 4.53 electron volts (ev) which corresponds to a threshold wave length of 2,730 A. This is well into the ultraviolet. Sodium has a work function of 2.28 ev or a threshold wave length of 5.400 A, which is in the green of the visible spectrum. The electron volt is a common unit of work or energy in photoelectric studies and is the work necessary to move an electron through a potential difference of one volt.

It has been found that the work function is extremely sensitive to the presence of traces of impurities upon the surface of the metal. If the characteristic work function of a metal is to be measured it is necessary to remove all traces of absorbed gas from the surface, preferably by prolonged heating at as high a temperature as possible in a very good vacuum.

If monochromatic radiation is incident upon the surface of a metal, the photoelectric yield (i *e.*, the number of electrons emitted for each quantum absorbed) is zero when the wave length of the radiation is longer than the threshold wave length. As the wave length of the incident radiation is made less than the thresh-



BY COURTESY OF PHYSICAL REVIEW

FIG 3 —PHOTOELECTRIC YIELD OF BARIUM AS A FUNCTION OF WAVE LENGTH EXPRESSED IN AMPERES PER WATT OF INCIDENT RADIATION THE EFFECT OF REFLECTION IS INCLUDED IN THE THEORETICAL CURVE

old wave length, emission begins and the photoelectric yield increases with decreasing wave length. There exists a wave length for which the yield is a maximum and for shorter wave lengths than this the yield decreases. This behaviour is illustrated by the experimental curve of fig. 3 for the metal barium. As the wave length of the incident radiation decreases, its quantum energy increases and a greater fraction of the photoelectrons are able to escape from the metal. The existence of a maximum in the yield curve is not so immediately understandable. It results from the fact that the probability of absorption of a quantum by an electron decreases rapidly with increase of the frequency or decrease of wave length. This is a general feature of photoelectric absorption by electrons under all conditions.

The maximum in the photoelectric yield curve is then the result of a superposition of two effects. The shorter the wave length of the radiation the greater is the fraction of the electrons which will escape from the metal after the act of absorption. But the shorter the wave length. the smaller is the probability that any individual electron will absorb a quantum. For wave lengths less than that which corresponds to the maximum in the yield curve, the second effect is more important than the first.

Radiation incident upon the surface of a metal and not reflected is absorbed in a thin layer approximately a hundred thousandth of a centimetre in depth The photoelectrons must come from this layer. I. Tamm and S. Schubin suggested that the majority of the photoelectrons are produced in a much thinner layer at the immediate surface of the metal. If the potential energy of an electron inside a metal is constant as drawn in fig. 2, it is easily demonstrated that only at the surface can photoelectric absorption occur. In the act of absorption the electron increases its energy by the amount hv but its momentum increases by the negligible amount hv/c.

As a result, a free electron, which is one moving in a region of constant potential, cannot satisfy simultaneously the laws of conservation of energy and momentum during the act of photoelectric absorption of a quantum. The surface of the metal where the potential is rapidly changing may act as a third body and enable the conservation laws to be obeyed.

In actuality, the potential energy of an electron inside a metal is not constant and the possibility of photoelectric absorption by the electrons in the interior exists. Only photoelectrons produced in a thin layer approximately a ten millionth of a centimetre thick will have an appreciable probability of escape. however, since this is the order of magnitude of the distance traveled by an excited electron before making a collision with another electron in which it loses a substantial fraction of its energy.

Tamm and Schubin pointed out, however, that the threshold wave length for the emission of photoelectrons produced in the interior will be shorter than the threshold of the surface photoelectrons. Electrons at the surface can absorb quanta of any frequency and the work function of the metal determines the threshold. Selection rules, determined by momentum considerations, set a lower limit to the frequency of the quanta which may be absorbed by interior electrons. This lower limit of frequency varies from metal to metal but is always greater than the threshold frequency set by the work functionfor the surface photoelectric effect.

The theoretical curve of fig. 3 for barium was calculated according to the quantum mechanical theory of K. Mitchell, who assumed that photoelectrons are produced only at the surface of the metal. It is not known to what extent the neglect of photoelectrons from the interior of the metal affects the divergence betneen the calculated and experimental curves. It is probable that the discrepancies are primarily due to an inadequate treatment of the behaviour of the radiation near the surface of the metal, where it is reflected and refracted.

The work function depends slightly upon the temperature of the metal. The most important reason for this effect is the variation of the kinetic energies of the electrons in the metal with temperature At the absolute zero of temperature there is a definite upper limit to the kinetic energy of an electron as indicated in fig. 2.

At any finite temperature, the upper limit is not sharply defined but the probability that any electron possesses more than a definite amount of kinetic energy is small. An effect of this indefiniteness in the upper limit of the kinetic energy is that the photoelectric threshold is not well defined. R. Fowler and L. A. DuBridge developed approximate theories of the photoelectric effect which permit the determination of the work function that the metal would possess if the electrons were at the absolute zero of temperature. It is this fictitious work function which is usually tabulated and discussed.

If a metal is heated to a high temperature, an observable number of electrons obtain sufficient kinetic energy to escape. This is known as the thermionic effect. From the variation in the number of thermionic electrons with the temperature it is possible to determine the work function w. It is highly gratifying that work functions measured in this manner agree with the photoelectric work functions. This is especially true in so far as it affords a confirmation of the theory of Tamm and Schubin that, at least near the threshold, the photoelectrons are produced at the immediate surface of the metal.

It has been mentioned that the photoelectrons produced by a given wave length of radiation emerge with a distribution of kinetic energies and velocities. At one time it was thought that the electrons inside a metal were practically at rest and that the distribution of energies among the photoelectrons was the result of collisions of the electrons with atoms of the solid in their escape. If the photoelectrons originate at the surface, another reason for their distribution of kinetic energies must be found.

According to the model pictured in fig. 2 the reason for a distribution of energies is the fact that before photoelectric absorption takes place the electrons possess different kinetic energies. If all electrons absorb the same energy, hv, and if all suffer the same energy loss, w, in escaping from the metal, then the distribution of kinetic energies of the photoelectrons is an accurate replica of the distribution of kinetic energies of the electrons in the metal.

FIG. 4.— ENERGY DISTRIBUTION OF THE PHOTOELECTRONS FROM SODIUM. THE WAVE LENGTH OF THE RADIATION 3,650 A; TEMPERATURE OF THE SURFACE. 25° C.

A comparison of the theoretical and experimental energy distributions of the photoelectrons from a sodium surface is shown in fig. 4. The agreement between the curves is particularly good for the most energetic electrons and provides a direct test of the Fermi-Dirac distribution function which is used to describe the variation with temperature of the kinetic energy of the electrons

in metals. The differences between the experimental and theoretical curves at low energies may be due to a slight velocity dependent reflection of the escaping electrons by the surface potential.

The photoelectric effect of contaminated metal surfaces has been studied in great detail. Many of these surfaces have high yields and very low work functions. They are, therefore. of great importance in the manufacture of commercial photocells. The properties of a surface which is widely used, known as the cesium-on-silver oxide surface, are almost entirely unexplained. The threshold is in the infrared near 12,000 Å and the yield is extremely large over the visible and near ultraviolet regions of the spectrum.

2. Insulators. — The topics of interest in the investigation of the photoelectric effect with dielectric solids are somewhat different from those with metals. Little work has been done upon the emission of photoelectrons from surfaces of insulators. The loss of electrons leaves the surface with a positive charge which prevents the establishment of a steady photocurrent.

Whereas the photoelectrons produced in the interior of a metal cause an unobservable change in its conductivity, the decrease in resistance of an insulator due to the presence of photoelectrons is readily detected. This phenomenon is referred to as photoconduction.

Typical insulating crystals, such as the alkali halides and the oxides of the light metals are quite transparent to visible and near ultraviolet radiation. Absorption by the electrons starts somewhere in the ultraviolet. The typical absorption spectrum begins mith a series of overlapping bands which are absorption lines broadened by the interaction of the electrons with the vibrating ions of the crystal lattice. Following these bands and overlapping them is a region of continuous absorption resulting from the photoelectric production of free electrons. In this region of the spectrum the absorption is so large that the radiation penetrates only a thin layer of material as in a metal. Experiments with photoconduction are usually performed with radiation absorbed in the long wave-length tail of the first absorption band.

In this case one cannot predict unambiguously whether photoconduction will result.

The reason for this statement is that absorption in the bands which precede the region of continuous absorption does not lead directly to the production of a free electron in the interior of the solid.

The electron is raised by the absorbed quantum to an excited state in which it is still bound to the positive charge left on the atom from which the electron originated. The electron and positive "hole" are not bound to an individual atom of the crystal but may move as a pair throughout the volume of the solid. The movement of this pair, or exciton, as it has been called, cannot lead to a shift of electrical charge and photoconduction. The exciton may obtain sufficient energy from the vibrating ions of the lattice, however, to enable it to dissociate into a free electron and a free positive charge.

In an electric field they may then move in opposite directions giving rise to a photocurrent. The temperature of the crystal determines the average energy of the vibrating ions and it is to be expected that if photoconductivity occurs because of thermal dissociation of excitons, it will disappear at a sufficiently low temperature.

Absorption of radiation in the long wave-length tail of the absorption band of an alkali halide crystal such as sodium chloride does not produce photoconductivity. Presumably the excitons are not thermally dissociated. Under the same conditions, photoconductivity is produced in the silver and thallous halides. In this case the question has been raised as to whether the absorption is not due to foreign impurity atoms.

Large quantum yields, approaching one electron freed for each quantum absorbed, are quite common. In the region of true continuous absorption and the direct production of photoelectrons, the measured yield becomes small. In the cases of diamond and zinc sulfide the photoconductivity disappears entirely. The reason for this is not understood but may, in some cases, be due to the two following effects. When the absorption coefficient becomes large the reflectivity of the crystal surface becomes large. The major fraction of the radiation does not enter the crystal, an effect which has been commonly overlooked. In addition, since the radiation is absorbed in a very thin layer at the surface, the concentration of photoelectrons is large and recombination is promoted.

The fate of a photoelectron in a crystal is a matter of interest. Through collisions with the lattice ions it rapidly loses the energy gained from the absorbed quantum and comes into thermal equilibrium mith the lattice. Finally, it will recombine with an atom which has lost an electron or will be trapped at an impurity atom, a crack, or other imperfection of the lattice.

It appears to be the rule rather than the exception that the photoelectrons in the interior of the crystal initiate secondary reactions. These may be of the most diverse types and have complicated enormously the study of the primary photoeffect. It is commonly observed that the primary photocurrent produces a more or less permanent decrease in the resistance of the crystal. In a few cases it has been possible to study this secondary current independently of the photocurrent proper.

The problem is further increased in complexity by the unavoidable presence of minute amounts of impurities. Concentrations of impurities of a few parts per 1,000,000 may determine completely the observed effects, either by acting as sources of photoelectrons or by trapping them and giving rise to secondary reactions.

An example of the last-mentioned effect is found in the silver halides. The formation of the latent image in photographic emulsions is the result of the production of photoelectrons in the interior of the small crystals of silver halide which are dispersed throughout the gelatin of the emulsion. The photoelectrons are trapped at specks of silver sulfide which are present as impurities on the surfaces of the crystals. The silver halide has a small number of positively charged silver ions wandering throughout the interstices of the crystal lattice and these are attracted to the trapped electrons.

The electrons and silver ions unite to form silver atoms. Submicroscopic clumps of silver atoms form the latent image which makes the silver salt susceptible to development by the proper chemical reagents.

Photoconductivity is a genera1 property of semiconducting solids. Semiconductors have a feeble. temperature-dependent, electronic conductivity which disappears at low temperatures where they become good insulators. The photoconductive properties of selenium and cuprous oxide have been known and used for many years. The pure elements silicon and germanium are semiconductors that exhibit photoconductivity when exposed to radiation whose wave length is less than 1.2 microns *(p)* and 2 *p,* respectively. One micron equals 10,000 Å. These threshold wave lengths correspond to the onset of strong optical absorption by the elements. The semiconducting compounds lead sulfide, lead selenide and lead telluride are extraordinarily sensitive to near infrared radiation when properly prepared in the form of thin films. Lead sulfide films are formed by vacuum evaporation followed by sensitization with oxygen or by chemical deposition from solution. Lead sulfide is a useful photoconductor for wave lengths less than about four microns. while the threshold wave lengths of lead telluride and lead selenide are near six microns and eight microns, respectively. Lead sulfide cells are commercially available and have numerous industrial and military applications. The military applications include not only infrared signaling but also the location of vehicles.

Trucks, tanks. ships, planes and missiles can be detected at long ranges by means of the infrared radiation emitted by heated parts or exhaust gases. Infrared search systems offer better optical resolution and less susceptibility to enemy "jamming" than do radar systems.

3. Gases. — The photoelectric effect in gases is of particular interest because the ejection of an electron from a free atom represents the simplest photoelectric process. Unfortunately, experimentation in this field is very difficult. The work necessary for the removal of the most weakly bound electron from the atoms or

molecules of the simple gases is large enough to place the photoelectric threshold in the neighbourhood of 1,000 Å. In this region of the spectrum there are available neither convenient high intensity radiation sources nor simple optical instruments. Common difficulties are the emission of electrons from the walls of the reaction vessel by scattered radiation and the occurrence of secondary chemical reactions which are induced by the primary photoelectric effect.

The photoelectric threshold frequency can be predicted very precisely from spectroscopic observations. Photoelectric emission of electrons from atoms or molecules which have been previously excited by absorption of a quantum frequently gives an apparent threshold at a lower frequency than the predicted one. While the available data are in qualitative agreement with the theoretical prediction that one electron is emitted for each quantum absorbed, a precision test of this point is lacking because of the experimental difficulties.

4. Photovoltaic Effects.—The photovoltaic effect consists in the generation of an electromotive force in a material on illumination. An electromotive force (e.m.f.) is the source of the electric field which produces a current in a closed circuit of conductors. The discovery of the phenomenon by Becquerel is mentioned in the *Historical Survey* section of this article. A similar effect was noted in 1876 by W. Adams and R. Day, who observed the generation of an e.m.f. on illumination of a junction of selenium and platinum.

The junctions of semiconductors and metals which exhibit a photovoltaic effect usually possess the property of being rectifiers. That is, the resistance of the junction depends upon the direction in which current is passed through the junction. Two of the most important junctions of this type are the selenium-metal junction and that between cuprous oxide and copper.

A theory of the photovoltaic effect at such junctions given by N. Mott appears to be at least qualitatively successful. In the case of the cuprous oxide unit there is a film, termed the blocking layer, of pure oxide of the order of a ten thousandth of a centimetre in thickness separating the copper and the impure bulk oxide.

The bulk oxide owes its semiconducting properties to the presence of an impurity which is an excess of oxygen. When radiation is absorbed in the oxide near the blocking layer, electrons are ejected from the oxide into the blocking layer. Within the blocking layer, there exists an electric field which drives the electrons to the metal. This results, in a closed circuit, in the production of a steady current. The field in the blocking layer exists because of the trapping of electrons from the copper by the impurities of the cuprous oxide, giving the oxide a negative charge with respect to the metal.

The cuprous oxide-copper photocell has a threshold in the neighbourhood of 14,000 Å and a maximum sensitivity near 6,000 Å. Another commercially important photovoltaic cell is that formed from the junction of a metal and selenium. Its characteristics are much like those of the cuprous oxide cell.

These cells are extremely convenient for many applications since they generate their own power and operate without the use of batteries or power supplies. The electromotive force generated by moderate illumination is sufficient to operate a low-resistance microammeter. Their stability is inferior to that of vacuum photocells. In addition, when amplification of the small e.m.f.'s is necessary it is an extremely difficult matter. The response to changes in illumination is slow so that they cannot be used for many applications.

The chief field of application is the qualitative detection of radiation and measurements where high precision is unnecessary as in light metres for photographic work. In photometric work of this type, the fact that the relative sensitivity of these cells to light of different colours is similar to that of the human eye is of particular importance.

A photovoltaic effect is produced when radiation is absorbed near a P-N junction (*see* TRANSISTOR) in a semiconductor Excellent photovoltaic cells have been constructed with silicon, germanium or indium antimonide as the semiconductor. The P-N junction is formed by adding to the pure semiconductor carefully selected impurities with the proper spatial distribution. Arsenic and boron are typical impurities used with silicon. The silicon crystal is prepared so that there is an abrupt transition from a region in which boron is the dominant impurity to an adjacent region in which arsenic is the dominant impurity. At the junction of the two regions there is a large electric field that accelerates free electrons produced by absorption of radiatibn. Silicon photovoltaic cells have an output voltage of approximately 0.5 and a threshold wave length near 1.2 μ. They are efficient converters of solar energy to electrical energy. The conversion efficiency of cells available in the late 1950s was about 10%, which is approximately half their theoretical efficiency. The earth satellite launched by the United States on March 17, 1958, with a Vanguard rocket utilized solar energy and silicon photovoltaic cells to power one of its radio transmitters.

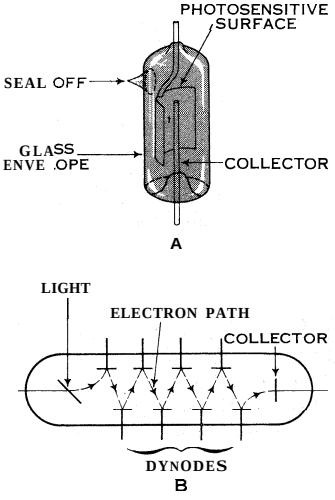

FIG. 5.—(A) PHOTOCELL. (B) DIAGRAMMATIC SKETCH OF PHOTOMULTIPLIER TUBE

IV. APPLICATIONS OF THE PHOTOELECTRIC EFFECT

The applications of the photoelectric effect are numerous and diverse. The ionization chamber which has been described is a standard instrument for the determination of X- and y-ray intensities. The determination of X-ray dosage in medical therapeutic work is performed in this manner.

The photoelectric cell illustrated in fig. 5 (4) makes use of the emission from a metal surface. Frequently the metal surface is present in the form of a thin film which is deposited upon a portion of the inner surface of the glass envelope. The photoelectrons are drawn to the collector by an electric field and the resulting electric current measured with a galvanometer. Some photocells are not evacuated but are filled with an inert gas such as argon. The photoelectrons on being accelerated to the collector dislodge electrons from the argon atoms. In this manner the total current set up in the photocell may be 10 to 100 times the initial photocurrent. Since the photoelectric cell is inherently a high-resistance device, it is adapted for use with vacuum tube amplifying circuits. This is a fortunate fact since the maximum current obtainable from a typical photocell is only of the order of a microampere.

To avoid the use of amplifying circuits the photomultiplier tube has been developed. This tube is illustrated in fig. 5 (B). In this device the photoelectrons are accelerated to the first of a set of auxiliary electrodes called the dynodes. The surfaces of the dynodes have the property of liberating several electrons for each electron which strikes them. In this manner the initial photocurrent is amplified as it passes from dynode to dynode. Such a device may have as many as ten dynodes and the current to the collector may be 100,000 times the primary photocurrent. The photomultiplier tube is manufactured in a size no larger than the ordinary photocell.

The scintillation counter is a device for the detection of y rays or high-energy nuclear particles. A y-ray photon or particle strikes a luminescent crystal and produces a brief flash of luminescence. A typical crystal is sodium iodide containing a trace of thallium as impurity. The photons of the luminescent radiation strike the cathode of a photomultiplier tube and eject photoelectrons that are amplified by the tube. If, as is commonly the case, the nuclear particle loses all its energy within the luminescent crystal, the number of luminescent photons and the magnitude of the output pulse of charge from the photomultiplier is a measure of the energy of the particle. The scintillation counter not only

can detect and measure the energy of individual nuclear particles and y-ray photons but does so in an incredibly short time. The speed of response of the counter is usually less than a microsecond and with crystals such as trans-stilbene may be as short as 0.006 microseconds.

The fundamental use of a photocell is to convert a change in the intensity of the incident radiation into a change in an electric current. This change in electric current may then be used to operate control or measuring devices. For example, a person approaching a doorway may interrupt a light beam which is incident upon a photocell. The abrupt decrease in photocurrent may be used to start a motor which opens the door or rings an alarm. The variations upon this usage are endless. In the manufacture or processing of materials photocells are used to detect imperfect articles and to actuate mechanisms which reject them. The speed and accuracy of such control is far greater than possible with a human operator.

In the production of sound motion pictures, a strip of variable density upon the photographic film is converted by a beam of light and a photocell into a fluctuating electric current which after amplification operates the loud-speakers. (See MOTION PICTURES.)

In television production the photoelectric effect is used to convert the light reflected from the object to be televised into an electric current. The electric current is reconverted by the radio transmitter into the long wave-length radiation termed radio waves. These are picked up by the receiver, transformed into electrical impulses and finally appear as a picture upon the fluorescent screen of a cathode-ray tube. (*See* TELEVISION.)

In scientific work photocells are used whenever it is desired to measure the intensity of a light beam with precision. They are, therefore, much used in the construction of photometric instruments. (*See* PHOTOMETRY.)

Finally, it should be noted that the photographic film, whose importance need not be reviewed, owes its light-sensitive properties to the production of photoelectrons by light in the interior of the silver halide crystals of the emulsion (see PHOTOGRAPHY).

V. NUCLEAR PHOTOEFFECTS

J. Chadwick and M. Goldhaber discovered in 1934 that the deuteron, the nucleus of the deuterium atom, will absorb a y-ray quantum and disintegrate. The disintegration products are a proton and a neutron. The proton is the nucleus of the hydrogen atom of which deuterium is an isotope. The neutron is an uncharged particle of approximately the same mass as the proton. A minimum quantum energy of 2,170,000 ev (2.17 Mev) is necessary to produce the photoelectric disintegration of the deuteron. The nuclei of many other atoms have been shown to exhibit a similar reaction. In all cases the photoelectric effect results in the ejection of a neutron.

A second important nuclear photoeffect is pair production. A y-ray quantum in traversing the neighbourhood of a nucleus may be annihilated and a positive and a negative electron created. This is a direct conversion of radiant energy into matter. In such a conversion, energy and mass are related by an equation due to Einstein:

$$E = mc^2, \qquad (4)$$

where E represents the energy converted into the mass m, and c is the velocity of light. With m taken as the sum of the masses of the positive and negative electrons, the minimum quantum energy E which is necessary for pair production is calculated as 1,020,000 ev. A quantum of greater energy will impart kinetic energy to the created electrons. This process is one of the most important mechanisms by which high-energy quanta interact with matter. The positive electron is unstable and soon after its creation combines with a negative electron, the pair being annihilated with the creation of one or two y-ray quanta.

The y-ray photons whose energy exceeds 150 Mev interact with protons and neutrons to create positively charged (a'), negatively charged (a−) and neutral (a^0) mesons. The charged a mesons have the same charge as that of an electron but have a mass that is 273 times that of the electron mass. They are unstable particles that decay into μ mesons and neutrinos with a lifetime of 2.6×10^{-8} seconds. The neutral a meson has a mass that is 264 times the electron mass and disintegrates into a pair of y-ray photons in about 10^{-15} seconds.

The interaction of a y-ray photon with a proton may either transform the proton into a neutron with the creation of a π^+ meson or create a neutral π^0 meson and leave the proton unchanged. Similarly, the interaction of a y-ray photon with a neutron may produce a proton and a π^- meson or create a π^0 meson without transformation of the neutron into another particle.

Pairs of a mesons and of μ mesons are also created by the interaction of y-ray photons of sufficient energy with nuclear particles. Since it is believed that mesons are responsible for the forces between nuclear particles, they are the subject of intensive research.

PHOTO-ENGRAVING. One of the photomechanical processes, the generic term being applied chiefly to the making of etched metal printing plates or blocks (zinc, copper, brass, etc.), the design being in relief for typographical (letter-press) printing. Parts of the process are also used in the photo-lithographic and rotogravure processes for the production of plates and cylinders.

History.— The first specimens were produced, as far as can be ascertained, during the years 1859–1862 by Col. James in Southampton, by Gillot in Paris, Angerer in Vienna and Husnik in Prague. The name *Gillotype* was for many years applied in France and England to line etchings.

Photography was not originally used in their production, the image on metal being obtained either by manual design or by lithographic transfer. The introduction of the photographic negative permitted the reduction or enlargement of the original design for reproduction.

"Nature Autotypy," an early reproduction process, furnished copies of natural objects which, while imperfect reproductions in the sense of our present standards, were still good enough to convey the image in multiple editions. Leonardo da Vinci describes the method in his "Codex Atlanticus" (1490–1519): "This paper must be coated with lampblack mixed with sweet oil. The color of the leaves is thinned by applying white lead dissolved in oil, as printers do with typefaces and then it is printed as usual. The leaves (*i.e.* the impression) will appear dark in the depression and light in the raised parts. . . ." Several botanical publications of the late 17th and of the 18th Centuries were illustrated by this method and are still preserved.

Niepce's early attempts to etch photographic intaglio images on metal sensitized with asphaltum initiated but did not hasten progress in the photomechanical processes. As early as 1841 daguerreotypes were etched in galvanic baths for printing on gravure presses. Donné was the first to show proofs of etched daguerreotypes; Fizeau, Claudet, Berres in Vienna and Grove in England also etched them. Paul Pretsch in London etched them in 1856. He was the originator of the later spray or blast system employed today in etching and was also the first to discover the swelled gelatin process of which many splendid examples are still in existence. The negatives for his work were usually made by the photographer Roger Fenton, using the wet collodion process; the printing plates were electrotypes moulded from the hardened gelatin reliefs.

As early as 1862 Pretsch exhibited at the London Exhibition half-tone plates for letterpress printing. Poitevin, independent of Pretsch's work, pursued the same idea and produced relief electrotype printing plates from chromated gelatin originals. George Scamoni in Russia experimented and succeeded inde-

pendently in the same process. Swan and Woodbury in England produced the Woodburytype (1863).

In the development of reproduction processes, it was soon realized that the prime necessity for faithful reproduction consisted in finding a means for breaking up the continuous tones of photographs or drawings, reproducing in effect the quarter, half, and three-quarter tones of the subject. Graining and dusting of the printing surfaces, long employed, did not furnish the answer. Talbot recommended as early as 1852 in his gravure process the use of a gauze netting for breaking up the continuous tones into separate printing elements.

As in most inventions, the credit for the invention or discovery of the halftone process of photo-engraving cannot be awarded to any one man.

A one-line glass screen in which parallel lines were scratched on an opaque background is described in a French patent of December 14, 1857, by Berchtold. Burnett published a method of single- and cross-line screens for photography. Screens are mentioned in a patent of 1865 by the brothers Bullock. Egloffstein's patent of the same year can hardly be cited as his lines were engraved on steel and his process met with no success. Swan in 1866 also used line screens and so did Leggo in the United States in 1871, Jaffe in Vienna in 1877, Stephen H. Horgan in 1880. Meisenbach (1882) used a single-line screen which he turned at 90° after half the exposure was made.

To Frederic E. Ives of Philadelphia, Pa., U.S., is due the idea of the optical V which led to the present cross-line screen which he used in his halftone plates, the printing surface of which was a bichromated glue enamel coating.

To the brothers Louis F. and Max Levy, also of Philadelphia, must be accorded the perfected halftone screen (grating) which today is universally used and has not been excelled since 1888.

The Levy brothers coated selected plates of high quality optical glass with an etching ground, in which parallel lines were cut by means of a ruling machine.

The ruled lines were etched with hydrofluoric acid and filled in with Canadian balsam. The lines appeared in sharp contrast. The two diagonally ruled glass plates were faced at an angle of 90°, sealed and later bound together with aluminium frames.

One of the important contributions to the halftone process was the invention of the highlight process. F. J. M. Gerland patented such a method in 1883 and the Bassani Company a mechanical improvement in 1925. The outstanding difficulty in the early days of the process was its inability to meet the demands for printing in quantity, rapidity, and the danger of the ink filling up the spaces between dots. This required the use of highly coated, hard-surfaced and expensive paper. In the last twenty-five years, however, the process has been adapted to almost any kind of specification. Newspaper and poster plates are made through screens as coarse as 40 lines to the inch and pulp paper periodicals carry illustrations, sharp and full of colour, printed from plates up to 110 lines to the inch.

Colour Plates.—Photo-engraved colour plates are made to represent the subjects in the colours of the original colour photographs or coloured designs or from objects in their natural colours.

The early attempts to reproduce colour effects were the manual painting in of the different tints on black and white prints. Later stencils were used, but seldom for superimposed and colour combinations. The simplest form of colour reproduction followed the manual process and used photo-engraved key plates and different plates for each colour or shade. Later shadings and overlapping plates were used to achieve colour nuances and combinations by overprinting.

The three- and four-colour processes used in 1940 are based on a Latin Treatise of 1611 by Dominis who described the additive system of complementary colours. Isaac Newton described light in its colour spectrum (1666). The German Le Blon in 1722, living in Paris, was the first to use three-colour printing with red, yellow and blue printing plates. Clerk Maxwell, the English physicist, was the first to publish (1861) the theory of colour reproduction by means of three-colour light filters. Ducos du Hauron and Charles Cros, independently of each other, published in 1868 their three-colour processes. The discovery (1873) by H. W. Vogel of optical sensitization led to a great advance in the reproduction of colour copy in monochrome by the use of orthochromatic plates.

The brothers Lumière of Lyon, France, gave the craft the Autochrome which with other colour records by similar processes often serve as a colour guide when the original painting is not obtainable. Modern panchromatic plates are the result of the successive work of Vogel, Konig, Homolka, Eder, Miethe, Mees, Traube, Lehman, and other modern workers in the field of optical sensitizers. Colour separation negatives are made today on colour-sensitized gelatino-bromide dry plates or on colour-sensitized collodion emulsion. The old-fashioned hand-press in the engraver's shop is now replaced by power presses. Colour reigns and is in steady ascendancy.

Technique.—The accessories necessary for the production of photo-engravings are a camera, a corrected (process) lens with diaphragms, prism and screen. If the wet collodion process is used, properly cleansed glass and a silver bath are required; also the chemicals for development, fixing, and intensification, all of which are in the purely photographic department. The stripping department, where negatives are reversed unless made through a prism, requires stripping collodion and rubber solution, and $-inch thick glass upon which the negative films are reversed as to position, either singly or sometimes assembled in a combination form of line and halftone.

The photo-printing department is equipped with a mechanically operated whirler and vacuum printing frame, as well as a heating apparatus for the burning-in of the enamel image with which the polished copper has been coated.

The etching department is equipped with machines in which the plates are etched by hand, by mechanical rockers, by acid, spray, blast, or by electrolysis.

The routing department is equipped with routing machines, circular and jig-saws, planing, squaring, and mounting machines. Plates to be mounted on metal are usually sent to the electrotyper for that purpose.

The engraving room has heating and cooling devices, also small trays containing acid for re-etching small surfaces. Proofing presses range from the old-fashioned hand-press and special engraver's small power presses to large cylinder machines.

Line Plates.—When a negative of a line drawing which has to be made into a line plate has been obtained, a photographic print from it is made on to a piece of metal, usually zinc, which is first thoroughly cleansed. The plate is then coated with a bichromated ammonium solution, sensitive to light. The solution is poured over the plate which is then placed in a whirler in order to insure an even coating.

The negative is next placed with its film side to the coated zinc plate and put into a screw or vacuum printing frame with a plate glass front, in close contact. The printing frame is then exposed to light (usually electric arc), the time of exposure varying according to the density of the negative and the intensity of the light. The plate, after being slightly warmed, is rolled up with *a* greasy ink.

It is then placed in a tray of clean water and the surface gently rubbed over with absorbent cotton. Where the albumen coating has not been hardened by the action of light, it washes away, leaving those parts which have become insoluble by exposure to light on the plate.

The plate is dried by heat and defective lines retouched. The plate is then powdered with a finely ground topping powder which sticks to the ink providing an effective resist to the acid. The surplus resin is removed and the plate heated to melt the resin.

When the plate is cool, it is ready for etching, by placing in *a* diluted bath of nitric acid for the first etch; but before doing so, the margins and back of the plate are coated with a varnish which prevents the acid from etching away those parts which are to be left unetched.

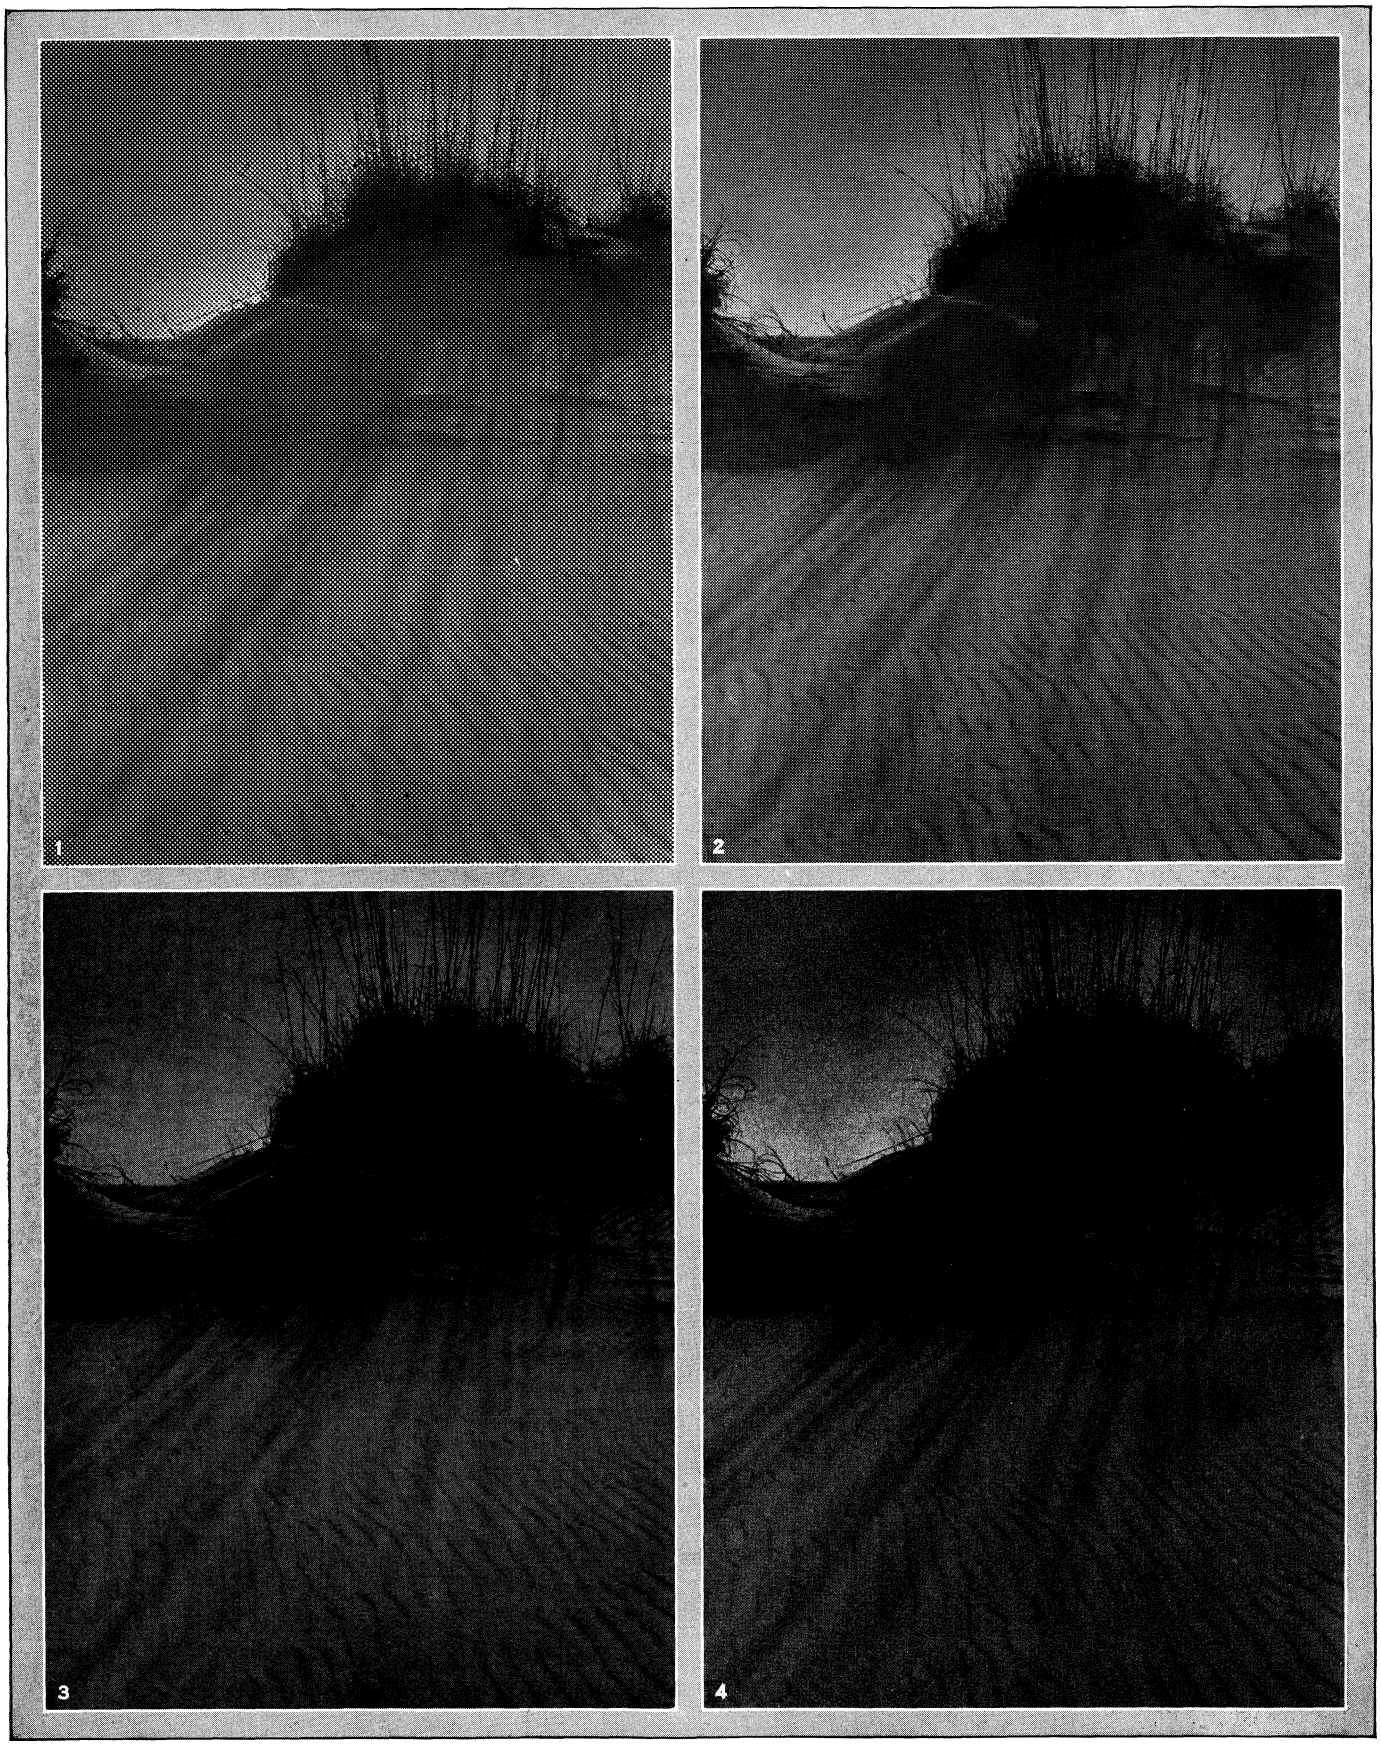
STAGES IN COLOUR PHOTO-ENGRAVING

1. Photographing a colour subject with a process camera. In the camera is a half-tone screen through which the image passes. The negative is thus divided into a great number of small "dots." In colour photo-engraving, four negatives are usually made, one for each of the primary colours (see Plate III)
2. The negatives are placed on sensitized metal, upon which the subject Is photographically printed
3. Etching the plates to subdue certain colours and bring others out, so that the final result will faithfully reproduce the original
4. Making further corrections in the colour values, by finishing and tooling the plates
5. Routing the plates, so that those parts which are not to be reproduced are removed from the printing surface
6. Pulling the colour proofs of the completed photo-engravings

PHOTO-ENGRAVING



PHOTOGRAPHS „A POEM IN SAND BY JOHN KABEL, BY COURTESY OF THE STERLING ENGRAVING COMPANY

EXAMPLES OF A SUBJECT REPRODUCED BY HALFTONE SCREENS OF DIFFERENT TEXTURES

1. 60 cross-line screen, used for printing on the cheaper grades of paper, such as newspapers and posters
2. 100 cross-line screen, used on machine-finished book paper
3. 133 cross-line screen, used on super-calendered and dull-coated papers
4. 175 cross-line screen, used when reproducing subjects containing fine detail printed on coated paper

COLOUR PRINTING
BY FOUR COLOUR PROCESS

PHOTOGRAPH, ENAT FROM THREE LIONS

Reproduction of a **painting,** a **photographic** transparency or **such** subjects as **wood** grain and **fabric is accomplished** by the halftone colour process. The early method of hand engraving has **been** replaced by a **photomechanical technique.** The reproduction may be **either** larger or smaller than the **original.** The **first** step in preparing four-colour printing plates from the Ektachrome shown above at the **left** is to make **colour-separation negatives** by means of filters on the **camera,** as **indicated** by the diagram. The transparency is **first** photographed through a blue-violet filter which **permits only its complementary** colour—yellow—to pass through the **lens** to the film. **Green, orange-red** and pale yellow filters are used to make negatives of the red, blue **and black values.** After metal printing **plates** are made, they are inked and **printed in the same** sequence shown above; *i.e.*, red on yellow, blue on yellow and **red,** and finally the black key plate for sharp detail.

The acid is agitated, either by rocking the bath by hand or by machines now generally used for this purpose, in which the acid is sprayed by means of air or mechanical action on to the surface of the plate. When the plate has been a short time in the bath, it is removed, washed and dried by heat, then powdered with "dragon's blood," applied in four directions so that all sides of the lines will be protected from the acid which is apt to "undercut" the lines. The plate is again heated, causing the resinous powder to melt and run down the sides of the etched lines, until the necessary depth is obtained.

A more recent practice which saves much time is flowing a zinc plate with a so-called "cold enamel" solution, eliminating the rolling up with ink. The plate is developed in alcohol and is then ready for etching.

The line process is occasionally used for colour work. The colours are generally made up of a number of "solid tints" or "stipple," the usual method being to take "key prints" from the etched "key plate," "stopping out" or painting in those parts required for the particular colour in which it will be printed. Where stipple or lines are to be introduced, shading mediums ("benday") are usually employed. These consist of gelatin or celluloid sheets with the design of the particular grain, dot, line or stipple in relief.

The film is rolled up with transfer ink and placed face downwards on the plate, which has been gummed over on those parts which are not required, pressure being applied by a roller or squeegee to those parts of the key plate which are to be printed in the particular colour.

Each colour requires a separate plate, which is rolled up, powdered and etched in the usual way.

Halftone Plates.—Halftone engraving is the process by which full-tone subjects in monochrome and colour are reproduced. The negative is made in the usual way, but to provide the necessary reticulated surface the exposure is made through a screen. This may be composed of grains (mezzograph), or what is most general, a series of lines running across each other at right angles. The cross-line screen consists of two sheets of thin plate glass, ruled with diagonal lines of mechanical exactitude. These are engraved into the glass, each piece of glass being ruled at right angles to the other. The lines are filled with a black pigment, leaving transparent spaces between. The two sheets of glass are placed face to face and sealed, the black lines crossing each other and leaving square transparent openings through which the light passes forming a halftone or dot image on the photographic plate or film.

Halftone screens are obtainable in various "gratings" or rulings, ranging from 40 to 400 lines to the inch, though for commercial use they rarely exceed 150 lines. The different rulings are used to suit the grade of work to be reproduced and the class of paper on which the illustration is to be printed. When printing on cheap, coarse paper, such as "news," a 60-line screen is usually employed.

Plates made with fine screens require printing on a highly finished or coated paper. For ordinary "black and white" commercial work, screens from 120 to 150 are used, and for fine colour reproductions, screens from 150 to 200.

The screen is secured in a holder and placed in the camera immediately in front of the photographic plate. The distance—an important factor—is governed by the particular ruling of the screen, the particular subject and the effect desired. When the negative is developed, the tones in the original are represented by a number of dots varying in area according to the tones of the original but of more or less uniform opacity.

The next operation is to make a print from the negative on to a metal plate, usually copper. The solution for coating plates is composed of water, fishglue and ammonium bichromate. The copper plate is polished to remove grease and foreign matter. The sensitive solution is poured on the plate which is then placed in a whirler to distribute the coating evenly.

After printing. the exposed halftone image is developed in water, after which the plate is sometimes placed in a bath of aniline dye, rendering it more visible. The margins and back of the plate are painted with asphalt or shellac to protect them from the acid.

The fishglue or enamel image, after being burned in, forms the acid resist. The plate is then placed in an etching bath of iron perchloride.

The plate is etched until the fine dots in the higher lights are as small as it is possible to etch them without undercutting the "dots."

The "re-etcher" or "finisher" then continues a series of fine etching by stopping out with an acid-resisting varnish those parts which have been rough-etched, and applying a series of local etchings for the purpose of recording the highest lights.

A proof is then pulled from the plate. compared with the original copy, and still further necessary alterations made. When approved, the plate is "finished" and mounted on wood or metal ready for the printer.

When a vignetted plate is required, the design and close surrounds are protected with varnish and the extreme edges are treated with acid so that the "dots" on the latter are reduced to the smallest point; gradually results are obtained until the dots merge into the white paper without showing a hard edge.

When pencil drawings are to be reproduced in halftone, it is usual to make a "high light" negative in which the high lights of the drawing and the paper on which it is made do not show a "screen." One of several methods may be employed.

(a) *direct,* when an over-exposed negative is made and certain stops used during the exposure, which tends to make the "dots" in the high lights overlap and become solid, the other tones being brought back to their correct relation by manipulative reduction of dot size;

(b) *the Bassani Apparatus,* which, attached to the camera, causes a slight circular movement of the halftone screen sufficient to veil the highlight dots and makes them disappear in the subsequent intensification of the negative;

(c) a patented diaphragm of the Waterhouse or Groesbeck type, used at one portion of the exposure to transpose the positions of the highlight dots and the spaces between them thus veiling the dots which disappear when intensified; and

(d) *the indirect method,* entailing the use of three photographic plates: first, a continuous tone negative is made of the original, which can be retouched; from this a positive is made through a screen; and from the positive a negative is obtained with the "dots" eliminated from the highest lights, which include the paper surface on which the drawing has been made.

Combination line and halftone plates are frequently made for commercial purposes, either by making two plates, and mounting finished line and halftone plates together; or by making two negatives, one in line and the other in halftone, stripping the films and combining them in their respective positions on one piece of glass which then forms the negative for printing on metal. In this way the combined design is etched on one plate and in one operation.

Halftone **Colour** Process.—When reproducing colour subjects by the halftone process, the plates are made in the same way as halftones, but the photographic plates must be colour-sensitive (panchromatic); when making the exposure the light not only passes through the prism, lens and screen but also is transmitted through what are known as "colour filters."

Generally considered, these are either dyed (coloured) films of gelatin cemented between two sheets of optical glass (and attachable to the lens by means of special holders), or they may be plain sheets of dyed gelatin, inserted in the barrel of the lens in a slot provided for Waterhouse stops.

The action of the filters is identical, in that the filter allows only rays of light of a certain colour to reach the photographic plate.

A special colour filter is used for each colour negative. Thus, a negative only records the colour and its component tints of one of the fundamental colours of the spectrum.

To make a negative for the yellow printing plate, a blue filter is used; for the red printing plate, a green filter, and for the blue printing plate, a red filter.

The light, passing through the respective filters, prevents the

colours and tints not complementary to the inks in which the printing plates are printed from being recorded on the special photographic plate.

As in the production of the halftone plate, the ruled screen is placed in front of the photographic plate, but for colour work, a circular screen, which can be turned at different angles, is used for each of the colour negatives.

The angles of the screen must be different for each colour to prevent a "pattern" or "moiré" effect when the three colours are superimposed in printing. For one colour, the screen angle is set at 45° from the vertical, and for the others at 75° and 15°, respectively.

The negatives are developed, printed on metal and etched in the same way as when making a monochrome halftone plate, but much fine etching, demanding great skill, has to be done in the reproduction of colour subjects.

The "fine etcher" must possess a good knowledge of colour and its analysis so that the final results will approximate the colour original. He must correct the deficiencies of the colour separations. This he does by a series of fine etchings, painting out certain parts and continuing the etching by local application of acid.

This operation may have to be repeated a number of times, and many proofs are pulled from the plates before final satisfactory results are obtained.

It is now usual to include a fourth colour plate when reproducing coloured subjects. This is usually printed in gray or black; the colour, however, is not dissected in the ordinary sense of the term, although a yellow filter is used. The fourth plate represents the whole of the tones in the original in their proper relation to each other, and becomes the key plate. The fourth printing allows for cleaner and more rapid working on the printing press, and at the same time provides a depth of colour and quality which, because of the scientific shortcomings of the process, are not always possible to obtain.

The plates are finished in the usual way, mounted usually on metal or sent unmounted to the printer along with progressive proofs which show the shades of colour used in the proofing and their sequence in printing.

Halftone colour negatives are made either by the direct or the indirect method. In the first instance, each colour negative is made in the same way as an ordinary halftone negative, but the exposure is made through a colour filter in addition to the screen, thus recording on the panchromatic plate one of the primary colours and its shades and constituting, when developed, one of the halftone negatives from which a plate will be made to print in a certain coloured ink.

The *indirect* method entails the use of three or four photographic plates for each colour. The first exposure provides a continuous tone colour-separation negative. It is obtained by making the exposure through a colour filter.

The full-tone negative can be retouched to assist in correcting colour values. From the full-tone negative a continuous tone positive is made and from it the screen negative.

This concludes an outline of the principles and processes of photo-engraving. The casual reader is warned against any attempt to use the chemicals and machinery mentioned. The necessary skill for their employment can be attained only after years of training and practical application of the process.

(E. EN.)

PHOTOGRAMMETRY, in simplest terms, means "picture measuring." At the point where we cease using the simple aerial photograph and start making a map from it, we enter the realm of photogrammetry. It was in 1851 that the Frenchman, A. Laussedat, first compiled map data based upon measurements from photographs. Handicapped by the narrow field and imperfections of the photographic lenses of his time, Laussedat, who is known as the father of photogrammetry, is credited with the first conception of the possibilities of photogrammetry, though his efforts and those of others for many years resulted in little practical progress.

It was nearly 50 years after Laussedat's original conception of photogrammetry that the first practical work was done by E. Deville, a Canadian. About the end of the 19th century Deville took a stereoscopic pair of phototheodolite pictures (phototheodolite pictures are those taken from tripods on the ground, as contrasted with aerial pictures), and devised a simple stereoscopic machine for drawing a map from these pictures.

With the beginning of the 20th century progress in photogrammetry became much more rapid. Strangely enough, for a period of many years after Deville's original work, very little photogrammetry was practised on the American continent, while many experimenters scattered throughout central Europe were working upon apparatus for automatic plotting from phototheodolite pictures.

Practically all of the development which took place prior to World War I contemplated the use of phototheodolite pictures. There were many machines of European origin made for this purpose. These machines, in the simplest language, use a pair of pictures taken from the extremities of a measured base line. They measure and plot through various mechanical arrangements the intersection of the rays which formed the common images of the two pictures.

The phototheodolite method was very successful and economical, especially in regions like the Alps where the steep terrain afforded camera stations overlooking an extensive area. The method was also employed by the U.S. engineers and the U.S. geological survey in Alaska.

The entire basis of photogrammetry changed abruptly as a result of the introduction of practical aerial photography in World War I. The aeroplane afforded a superlative camera platform and flew rapidly from one exposure station to the next. Large areas could be covered in a single overlapping pair of photographs and blind areas which had been a serious handicap to the terrestrial method were minimized.

Along with the many obvious advantages of aerial photography came a series of complications. Whereas in terrestrial photogrammetry the length of the base subtending the two pictures is known, it is an unknown in aerial photography. Other unknowns in aerial photography are the precise elevation from which the pictures are taken, and especially the difference in elevation between an overlapping pair of pictures and the angle of inclination of the camera at the instant of exposure. The stereoscopic plotting machines which had been so laboriously developed for terrestrial photography thus became obsolete. A new double trend became manifest, for a universal plotting machine, on the one hand, and for a simpler product, planimetric maps and mosaics,

on the other.

The universal plotting machine utilized either terrestrial or aerial photography, and this type of machine dominated most of the period between World War I and World War II.

By 1945 terrestrial photogrammetry was used very little. Even large-scale maps of dam sights, for example, at 1:240, were produced by aerial methods. The quality was excellent and the method proved very economical. We thus find emerging from World War II aerial stereophotogrammetric processes, mosaics and a widely used system of reconnaissance mapping known as the Tri-Metrogon system.

Ordinary aerial photographs, just as they come from the camera, have a wide variety of uses without the application of any photogrammetric processes whatsoever. Thus, we find the air-view, or oblique photograph, employed for many illustrative purposes. This is the simplest and most widely understood application of aerial photography.

Uncorrected vertical contact prints are extensively used, especially in petroleum geology. Hundreds of thousands of square miles of territory have been photographed for this purpose, with the end product consisting of a complete set of stereoscopic. overlapping vertical prints. Ordinarily, these are accompanied by an index map which shows the relationship of each individual print to the survey as a whole. In this type of work the photographic laboratory work is simple and standard and the only aspect of the undertaking requiring experience is the flying itself.

Geometry of the Picture. — Early users of aerial photography discovered that a picture taken with camera axis vertical was only truly a map if the ground was flat and horizontal. Aerial pictures in the early days were said to be distorted. Some of this distortion was caused by qualities of the early lenses although this was a very small part of it. The major cause of this trouble is more correctly termed displacement. The picture is actually a conic projection. Thus, vertical objects such as telegraph poles situated in any part of the picture except at its exact centre

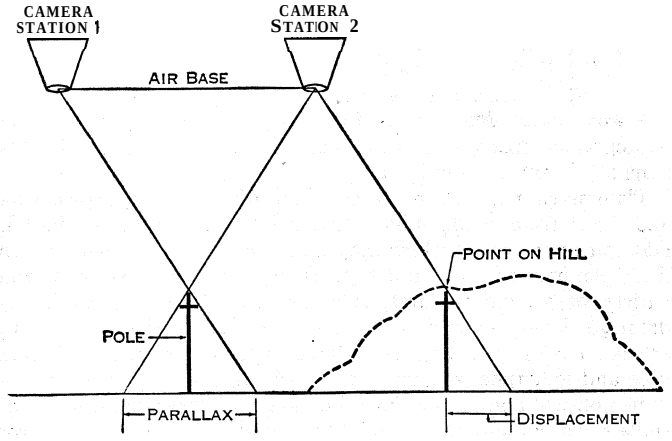

FIG. 1. — DISPLACEMENT BECAUSE OF DIFFERENCE IN THE HEIGHT OF OBJECTS AND PARALLAX. THE DISTANCE BETWEEN THE DISPLACED POINTS MEASURED PARALLEL TO THE AIR BASE. ARE HERE ILLUSTRATED

appear as radial images with the base of the poles toward the centre of the picture and the top displaced outward (fig. 1 and fig. 2). Another way of thinking of the picture is as a perspective with all vertical lines disappearing at a vanishing point at the centre of the picture. If, in place of the telegraph pole, we visualize a hill of the same height, the top of the hill will be radially displaced in relation to a lower datum just as the top of the telegraph pole was.

However, since these displacements lie along radial lines, the angle subtended by any two images at the centre of the picture, or, to be more accurate. at the nadir point. is a true angle.

While this displacement is very troublesome to the person trying to use an uncorrected contact print of mountainous terrain, it is the very essence of photogrammetry. Actually photogrammetry measures this displacement and all elevation data is derived from these measurements. The simplest form of stereoscopic plotting instrumehts measure the so-called parallax of the picture. This parallax is the measured difference between conjugate image points of objects lying at varying elevations. Thus, if the two overlapping images of the base of a telegraph pole are placed in registry the images of the tops will be in two radially disposed positions. Their separation, measured parallel to a line

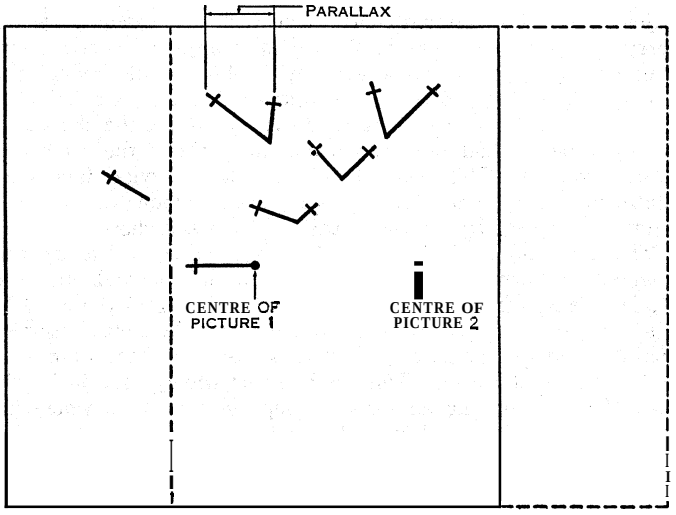

FIG. 2. — RADIAL IMAGES OF POLES OF SAME HEIGHT. PARALLAX THE SAME FOR THE SAME ELEVATION

connecting the picture centres, is the parallax of the top of the pole in relation to the base (fig. 2).

Systems of Control. — All photogrammetric processes depend upon control. Control is of two general kinds, viz., ground control and office control. By ground control we mean positions and/or elevations established by processes conducted independently of the aerial photography and the laboratory. Most ground control is established by conventional instrumental survey on the ground, or else uses a system of ground survey which has previously been established. We may thus say that the most common methods of ground control are astronomical determination of position, triangulation, traverse and levelling, either by spirit level or trigonometric levelling. These ground control operations are distinguished from office control operations which are done in the laboratory by radial control methods, aerial triangulation and similar processes.

Aerial Triangulation and Bridging. — Aerial triangulation consists of starting from some known ground control and extending by laboratory processes through a series of pictures. These processes are known as carrying forward control, or as bridging. Carrying forward of control is done in machines of the type of the stereoplanigraph and is accomplished by the successive adjustment of adjacent stereoscopic models upon each other. The stereoscopic model, for example, consisting of pictures 1 and 2, would be adjusted to known ground control. Picture 1 would then be replaced by picture 3, and while picture 2 remains unmoved in the plotting machine, picture 3 is adjusted to picture 2 until perfect stereoscopic correspondence is achieved. Then picture 2 is replaced by picture 4, and the process continues indefinitely.

The continental European schools are inclined to use this method extensively. Closure errors build up toward the end of a long series of pictures and have to be adjusted. A very long strip of pictures would not adjust so accurately as a short strip of pictures.

Another method of extending control in vogue on the continent of Europe is by the use of the radial triangulator, which is a machine performing the radial control operation more precisely (according to the users) than the graphical processes used almost universally by the Allies in World War II. In radial triangulation a pair of pictures which have been restituted is used (that is, the tilt has been minimized or eliminated, or provided for mathematically). Radial angles are measured at the nadir point to various image points. From a starting base of known length,

these angles are applied and the control thus extended by computation.

Bridging is a process of extending control between separated groups of ground control by means of the multiplex and similar instruments. The multiplex is set up with a plurality of projectors, sometimes as many as 20, each of which projects the image of one picture in the series. The first pair of projectors is adjusted to known ground control, and each subsequent projector carrying the next picture in the series is adjusted successively. This process goes on until control at the far end of the series is reached. The error existing at this point of closure is distributed by various formulae, which take into consideration the characteristics of the method, lens distortion, curvature of the earth and similar factors. This method was in 1946 in wide favour in continental Europe and had many supporters among users of the multiplex type of equipment in the U.S. and elsewhere.

The most universally used method of office control is the one originally known as the Arundel method in England, and the Bagley method in the U.S. The modern evolution of these methods. generally referred to as radial control, is the slotted templet method, widely practised both with slotted cardboard templets and slotted metal arms. This method was widely used in World War II for compiling all sorts of maps in territories where insufficient ground control existed.

The Slotted **Templet** Method. — The slotted templet method is a means of graphical triangulation. By this method a templet, most easily explained in the cardboard version, is made from each individual photograph. The principal point, or nadir point, and at least eight radial points around the edges are pricked through from the picture to the cardboard templet (fig. 3). A

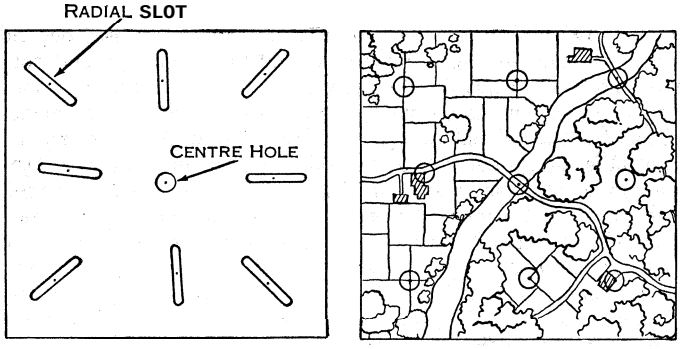

FIG. 3.— A SLOTTED TEMPLET IS MADE FROM EACH PHOTOGRAPH, AND THE SERIES OF OVERLAPPING TEMPLETS, WHEN ASSEMBLED, CONFORM THEMSELVES IN A GRAPHICAL TRIANGULATION NET

hole is punched at the centre prick mark of the templet, and through each of the outlying points a radial slot is cut. Because of the conventional 60%×30% overlap, each of these points is common to several pictures — sometimes as many as 6. The templets are then "buttoned up" with connecting posts through the intersecting slots, so that all the slots representing a given common point from the various pictures are assembled over a single post. These posts are like a flat-headed rivet with a hole through the stem. Previously, the known ground control points had been identified on the photographs and on the templets representing these photographs. The positions of these points are plotted on the assembly board and a post is secured immovably on these points. With these posts fixed and all others free at the intersection of the radial slots, the entire templet assembly expands or contracts to conform to the fixed ground control points, thus establishing a uniform scale throughout.

When the entire area is covered by the templets, each one of which represents one of the pictures, the posts at the various radial slot intersections represent the true position of a great many points. These points are then pricked through the hole in the post to the compilation board underneath the templet assembly thus affording an intensive control pattern from which subsequent processes may develop.

The slotted templet method affords excellent control for mosaics, planimetric maps and small-scale contour maps. In the case of large-scale contour maps with small vertical intervals, most photogrammetrists insist on ground control in each stereoscopic model. The slotted templet method is not quite accurate enough to control the setup of the plotting machine. Bridging and similar processes maintain accuracy by reducing the flight altitude, thus nullifying, in part at least, the theoretical advantage. Proponents maintain that bridging actually does result in control economies. This question is one of the most perplexing problems of photogrammetry.

Mosaics.—Mosaics have evolved from an uncontrolled and often misleading conglomerate assembly of pictures to a map of predictable accuracy and widely accepted usage. Most mosaics are compiled through the following steps:

(1) Scattered ground control.

(2) Nine points per picture, established by radial control (slotted templet).

(3) Comparison of the contact print with the control to determine what restitution is required.

(4) Restitution, consisting of the following:

(a) Enlargement or reduction of the picture as a whole, to compensate for varying altitude of the aeroplane and varying elevation of the ground.

(b) Tilt correction, to compensate for lack of verticality of the picture at the instant of exposure, and for average slope of the ground.

(c) Fractional treatment — the breaking up of the picture into small parts to compensate for irregular ground.

(d) Pyramiding — where the utmost in precision is required. This is a process of roughly contouring the picture and making a series of ratio prints, one for each tier of elevation, all from the same negative. The pictures are then cut on these approximate contours, and reassembled, with the picture for each higher contour being pasted over the lower one. Thus, the error may be reduced to plus or minus half the interval of the pyramiding.

(5) Stick-up and editing — this consists of superimposing on the mosaic: grids, geographical lines and names, marginal data, etc.

(6) Copying by quadrangles, on large plates or films.

(7) Reproducing by quadrangles,

(a) Photographically

(b) Lithographically, etc.

Planimetric Mapping. — Line maps as distinguished from photographic maps have two general classes: (1) planimetric maps; (2) topographic maps.

Planimetric maps delineate any kind of horizontal information and differ from topographic maps, which have contour lines in addition to the detail which may be shown on a planimetric map. Both planimetric maps and topographic maps may show a wide variety of ground features, such as roads, railroads, buildings, drainage, lakes, shore lines, swamps, cadastral data and many others. They may both show various types of grids, such as latitude and longitude, rectangular co-ordinates, etc. They can also show political and geographical boundaries, property lines and an endless variety of special data, such as land classification, crop classification, soil types, etc.

Planimetric maps are almost universally controlled on a slotted templet base. From this point on the methods of compilation differ depending upon the character of the aerial photography and the preferences of the compiler.

The soil conservation service of the United States department of agriculture, for example, compiles planimetric maps by projecting from a contact print onto a base compiled by slotted templet. The image is enlarged or reduced to conform to the control on the compilation board and the detail is then traced.

There are many other modifications of the system. Some organizations prefer, especially in country of steep relief, to establish radial intersections at intervals along all the principal features that are to be shown on the planimetric map. These intersections are then used to guide a draftsman, who fills in the features by hand, while looking at a photographic print.

Planimetric maps are also compiled from oblique photography. In instruments for this purpose, called photo alidades and similar names, a contact print or glass diapositive is observed in front of

a transit, the centre of rotation of which is placed in the position occupied by the rear node of the taking lens. Below the vertical axis of this transit and attached thereto is a blade similar to a conventional alidade, which plots the horizontal projection of the rays to the various points which are sighted through the telescope. The true position of these points is determined by intersections developed through observations on overlapping pictures.

Still another extensively used method of placing planimetric detail from the photograph onto the map is by means of the sketchmaster. This is a device on the camera lucida principle. Through a half-silvered mirror or split prism the picture and the compilation sheet are seen simultaneously. After establishing a good empirical registry between picture and compilation sheet, the detail is traced. Sketchmasters have been of three types, namely, vertical, oblique and universal. The first-class plots from vertical pictures only. The oblique sketchmaster, as its name implies, draws maps from oblique pictures such as the Tri-Metrogon wing pictures, while the universal sketchmasters will draw from either type of photography.

Tri-Metrogon System. — The Tri-Metrogon system derives its name from three K-17 cameras equipped with six-inch Metrogon lenses which are used as a unit. They are mounted with 1 axis vertical and the other 2 axes at 60° to the vertical and extending to the sides. Thus, the camera covers 7° or 8° above the horizon (fig. 4). This is an important factor since the position of the horizon in the pictures is used to determine the X tilt and the Y tilt. Since the horizon shows in each of the wing pictures and since each is subject to the same tilt conditions, there are two determinations which can be used as a check, one against the other. If one or both wing pictures show a clean-cut water horizon or a horizon on fairly flat, low land. the tilt can be determined with good accuracy. If the terrain is mountainous, a considerable amount of estimating enters into the determination.

The constants which should be known for satisfactory planimetric work from Tri-Metrogon photography are the focal length of each camera and the exact angular relationship among the three cameras.

In charting work the Tri-Metrogon photography is assembled by slotted templet processes. The templet of the vertical picture is made in conventional manner while the templets of the oblique pictures are made with the aid of a number of different kinds of equipment. Probably the photo alidade is the most accurate and satisfactory means of laying out the oblique templets although a number of types of simplified apparatus such as the rectoblique plotter, photoangulator, etc., are extensively used. The accuracy of the final result is to a large extent dependent upon the success in determining the title of the various pictures and the interlocking angles of the cameras.

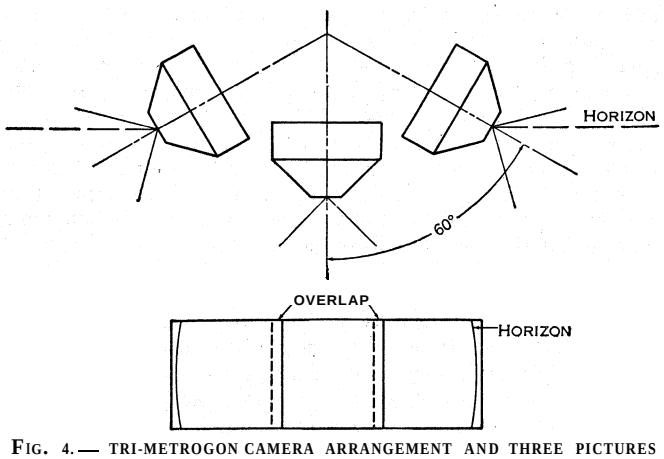

FIG. 4. — TRI-METROGON CAMERA ARRANGEMENT AND THREE PICTURES SHOWING VERTICAL AND TWO WING PICTURES

When the radial control plot has been completed by slotted templet the detail is put on the map with the aid of sketchmasters and other plotting devices of similar character. Small-scale charts have been made by this method covering a large part of the world.

Tri-Metrogon photography has also been used to some extent as the basis for topographic maps. For this use it presents many problems and few of the existing plotting machines get effective production from Tri-Metrogon photography. The depth of focus of the multiplex has proved inadequate for the great range of the oblique photographs and the excessive enlargement coupled with bad definition makes multiplex work fairly unsatisfactory. The stereoplanigraph has been fairly successful in mapping at scales for publishing at 1:25,000 from Tri-Netrogon photography. In this instrument also the enlarging factor becomes so great and definition so poor beyond the centres of the wing pictures (25°± below the horizon) that accuracy is seriously impaired. The stereoplanigraph has, however, done the most effective job of contouring from Tri-Metrogon photography.

Tri-Metrogon photography has been flown at various elevations up to 40.000 ft. The practical separation between flight strips depends upon many factors, the most important of which is atmospheric haze. Other factors are topographical relief and ground cover. Tri-Metrogon photography is generally usable to a total subtended angle of 110°. Under favourable conditions it can be used to a total subtended angle of 135° or 140°. Practically speaking, the principle point of the wing pictures is about the limit of successful coverage in terrain which contains considerable planimetric detail. Farther out than this, buildings, roads, etc.. become very indistinct.

Topography. — Topography is developed from aerial photography by two processes: (1) two-dimensional processes; (2) three-dimensional processes.

All stereoscopic measuring is accomplished through viewing a stereoscopic pair of pictures and measuring with a reference member known as a floating mark. The floating mark as used for measuring stereoscopically may be a single mark which is physically at the intersection of the two projected rays of a common image as in the multiplex, or it may be two marks which are fused into one just as the stereoscopic pictures are fused into one. When the two marks are superimposed on the pictures and correspond exactly with conjugate images of any point, they appear to touch the ground at that point. If the eyes must converge more to see the mark than to see the image, the mark will appear closer to the observer (higher) than the image of the ground. If the eyes diverge to see the mark in relation to the image, the mark appears to lie below the surface of the ground.

The floating mark, then, consists of a single reference point at the intersection of the rays of the multiplex or of two points

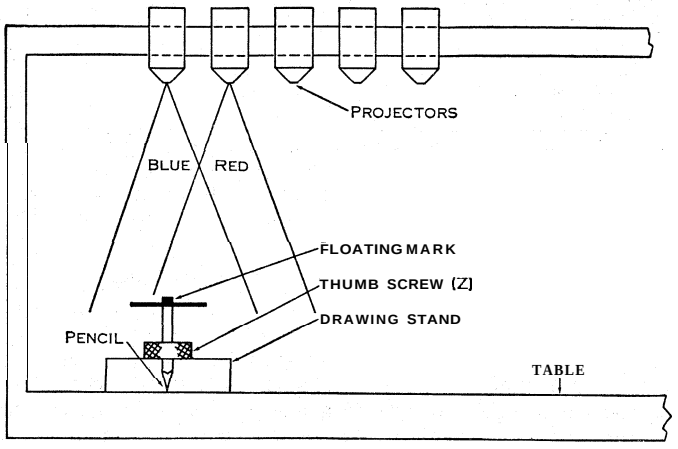

FIG. 5. — MULTIPLEX

The Multiplex projects an overlapping pair or series of pictures in correct three-dimensional relationship. .The images of complementary colours are viewed stereoscopically through spectacles with complementary coloured lenses. Drawing is accomplished by moving the drawing stand while keeping the floating mark in exact registry with the stereoscopic image

which the operator fuses into one on other types of equipment (figs. 5 and 6). The floating mark may be physically in contact with the pictures, or optically in contact with the image of the pictures in the more elaborate machines, and may be set for any desired ground elevation.

The above description of parallax measurement applies very aptly to the two-dimensional processes. In principle, it also applies to the three-dimensional processes but not quite so obviously.

Two-Dimensional Processes.—The two-dimensional processes are the simplest means of deriving elevation information from a stereoscopic pair of aerial photographs. The apparatus consists of

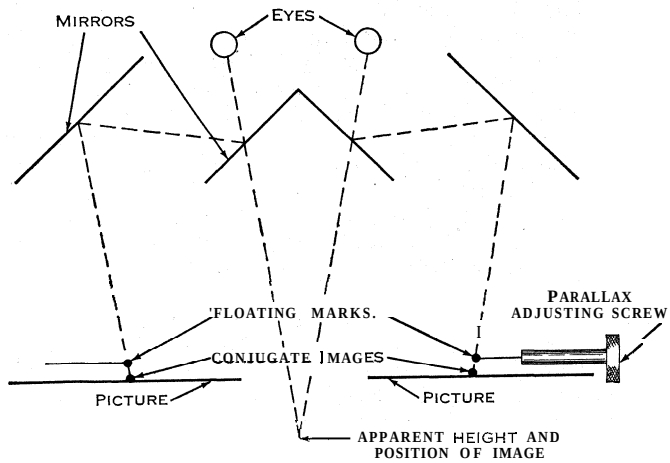

FIG. 6.— SIMPLE PARALLAX MEASURING STEREOSCOPE

a pair of stereoscopic pictures used in a stereoscope having a pair of marks in contact with the pictures. By setting the separation of the marks in accordance with the parallax of the desired elevation, and moving the mark along the exact ground surface of the stereoscopic image, a contour is drawn. All points of the same elevation have the same parallax in vertical photography. The parallax is set once only for each contour. In drawing planimetry a road may, for example, go up- and downhill requiring the parallax to be continuously changed. Maps drawn by the two-dimensional process emerge from the stereoscopic plotting instrument as a conic projection (fig. 7). It is a true conic projection only when the two pictures of the stereoscopic pair were rectified

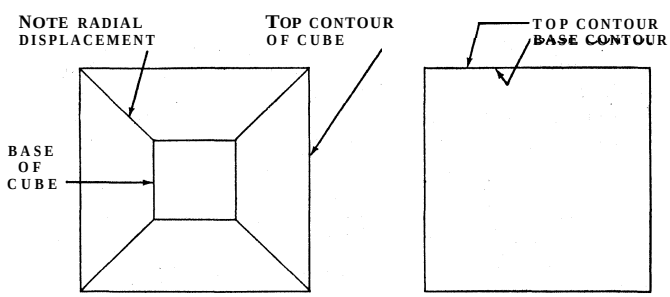

FIG. 7.— THE PHOTOGRAPH IS A CONIC PROJECTION AS ILLUSTRATED AT THE LEFT. THE MAP MUST BE ORTHOGRAPHIC. AS AT THE RIGHT. THIS CORRECTION IS MADE AUTOMATICALLY IN THE THREE-DIMENSIONAL PROCESSES, BUT IS AN ADDITIONAL OPERATION IN MOST TWO-DIMENSIONAL PROCESSES

(corrected for tilt) prior to their use. A great number of stereocomparagraphs, the best-known piece of equipment of this character, are in use. Acceptable maps can be made by this process even without using rectified photographs, providing a sufficient amount of ground control is available. Unrectified pictures will give reasonably good results with one point of known elevation for approximately every two square inches of photograph. The same pictures, if properly rectified, will give an excellent map with four known control points per stereoscopic model.

After the contours and planimetry have been traced off, the conic projection must be corrected. This means that each contour which is at a different scale in accordance with the distance from the taking camera to the ground and each planimetric detail which is similarly displaced must be proportionately corrected, elevation by elevation, in order to get a resulting orthographic map. This step may be accomplished by tracing the detail off by pantograph, or some similar device, changing the ratio for each change of contour; or it may be done in a projector by changing the projection ratio from contour to contour and tracing the orthographic map off on the projection screen.

Two-dimensional plotters go by such names as stereocomparagraph, contour finder, stereometer, parallaxer, etc.

Three-Dimensional *Processes*.—The three-dimensional process differs from the two-dimensional process in that the light rays which originally formed the image are reprojected from the image in miniature back to the ground (its mechanical representation).

If it can be imagined that the aerial camera remains in space in the same position in which the picture was taken and that the film after development is replaced in the camera and the camera used as a projector, each ray will return to the source from which it originated. Thus, if we now visualize two cameras retained in their spacial stereoscopic relationship, the conjugate rays from the two images of the common ground point when reprojected will fall back on that common ground point and intersect thereat. It also can be readily seen that if the cameras were moved together so that their separation was only half as great, that the rays now instead of intersecting at the true ground would intersect at a distance halfway between the cameras and the ground. In other words, we have cut the scale of the entire system in half. If now we move the cameras together so that they are only $\frac{1}{20,000}$ of the distance at which they were separated in the air, we can draw a map at precisely $\frac{1}{20,000}$ of the original scale. Similarly, the survey can be planned to produce a map at any desired scale.

The simplest example of the three-dimensional process is the multiplex. The original air pictures which may have been 9 in. x 9 in. are reduced for multiplex use to $\frac{1}{4}$ of their original size. This reduction permits very small projectors to be used which can be brought physically close enough together to get the desired scale. Full-scale projectors using a 9 in. x 9 in. picture could not be put close enough together. For example, if a scale of 1:10,000 is desired and the pictures were taken **3,000** ft. apart, the nodal points of the two projection lenses would be separated only $\frac{3,000}{10,000}$ **=.3** ft. or 3.6 in. Obviously, big projectors carrying 9 in. x 9 in. pictures could not be arranged this close together. But the multiplex with its $2\frac{1}{4}$ in. x $2\frac{1}{4}$ in. pictures can be so arranged.

The multiplex projectors will have lenses of perhaps 1.5-in. focal length, stopped down to a tiny aperture. Thus, at the focal plane of these lenses definition is sharp and for a considerable distance both sides of this plane the circle of confusion is small enough to be tolerable. In other words, the lenses have great depth of focus. This feature tends toward simplification of the multiplex system since the focus is sharp enough to draw a substantial band above and below the plane of most critical definition. Thus, without providing for any change of focus the multiplex operates effectively through a wide range of ground elevation.

Stereoscopic vision in the multiplex is by the anaglyph method. The two projectors or, in case more than two are used, alternate projectors carry filters of complementary colours, that is, red and blue. The observer wears spectacles with a red filter over one eye, a blue filter over the other. Thus, the two images are separated and sterescopic vision is made possible. The projected images are received on a drawing stand which is free to be moved around over the compilation sheet which is secured to a very flat table often made of slate or hand-scraped metal. The drawing stand carries a screen parallel to the surface of the paper which can be raised or lowered by a thumb screw. In the middle of this screen is a tiny point of light which serves as the floating mark and directly beneath is a pencil in contact with the compilation sheet, which draws as the stand is moved around. Thus, in drawing contours the screen is set at the desired elevation and the stand is then pushed around by hand. The operator observes the floating mark in relation to the plastic stereoscopic image and moves the stand so that the floating mark follows the surface of the ground without getting either above or below it. In drawing planimetry, the floating mark is caused to follow the feature, such as a road. The operator works the thumb screw of the screen, causing it and the floating mark to move up and down following the undulations of the feature.

Other three-dimensional processes use equipment of the stereo-

planigraph type. These machines include the Wild autograph, the Santoni stereocartograph and others.

All of these machines operate in a somewhat similar manner, the main difference being that the Porro principle is the basis of the stereoplanigraph whereas the other two machines mentioned have a mechanical representation of the nodal point and the light rays. The Porro system means that projection in the plotting machine is through a lens set at infinity focus and having identical optical characteristics with the lens of the aerial camera which took the pictures. Since projection through this lens is at infinity focus and the image on the stereoplanigraph must focus in the plane of the floating mark, an automatic focusing lens is interposed between the projection lens and the floating mark. This is a telephoto lens which is constantly accommodating for the changing distance between the projection lens of the picture holder and the floating mark.

The other type of machine such as the Wild autograph has a ray rod passing through the mechanical representation of the nodal point. This rod actuates an optical system which scans the photograph in such a manner that the point viewed is always the point which was formed by a ray of light passing through the lens at the same angle as the ray rod.

These machines have a mechanical base by means of which the scale is set. In the case of the stereoplanigraph (fig. 8), the distance between the two floating marks is varied by changing this base, and on other types of machines the distance between the ground extremities of the ray rods is determined by the base adjustment.

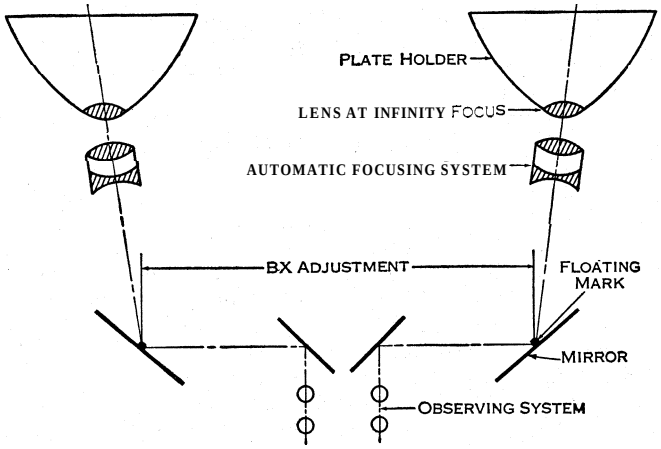

FIG. 8.— SCHEMATIC DIAGRAM OF STEREOPLANIGRAPH

In all machines of this general classification the picture holders, or plateholders as they are more frequently called, are arranged so that they can be given X tilt and Y tilt around the nodal point. After the stereoscopic model has been perfected the two plateholders together can be horizontalized by the application of common X tilt and common Y tilt. The bases of these machines also carry the BY and BZ adjustments. BY is an adjustment at right angles to the main base adjustment BX. BY is the equivalent of rotating the base in a horizontal plane. BZ is the adjustment for difference in the aeroplane elevation at the instant of exposure of the two pictures. Instead of lowering the camera, the floating mark or the base of the ray rod is raised in relation to the base, thus shortening the distance from nodal point to ground.

Stereoscopic pictures in a three-dimensional plotting machine can be put into perfect relative adjustment or correspondence without any reference whatever to the true horizontal. This is accomplished by a trial-and-error system which makes imperfections of adjustment manifest by vertical parallax. This is a splitting of the floating mark so that one mark appears above the other. When the adjustment is perfect no vertical parallax is present any place in the model. The subsequent process known as horizontalizing consists of moving the stereoscopic pair as a unit so that it bears the proper relationship to the base movements of the machine. Thus, before horizontalizing, the cameras (plateholders) will probably lie in some inclined plane relative to the X and Y tracks of the base. The scale will also generally need adjusting. Horizontalizing is accomplished by measuring the distance between known ground control points and adjusting BX to get the proper scale and by measuring the elevation of known points in the model and adjusting common X tilt and common Y tilt.

Drawing is accomplished by turning handwheels which actuate the X and Y movements and a footwheel controlling Z. The X and Y motion of the handwheels is transferred to a pencil on a plotting table.

This plotting table is connected to the stereoscopic machine through a gear box so that differential ratios may be established between machine and plotting table. It is not at all unusual to draw the map on the plotting table at six times the picture scale, and frequently the scale is enlarged as much as ten times horizontally.

This brings up one of the main criteria by means of which a stereoscopic survey is planned. There is very little relationship in most stereoscopic systems between the horizontal scale and the flight altitude, because the horizontal scale can be enlarged or reduced. The determining factor of the flight altitude is the accuracy required of the contours. Thus, plotting machines of the finest type can fly 2,500 or more times the permissible contour tolerance. From this elevation a map can be drawn in which at least 90% of all points tested will check out within ½ the contour interval.

The wide choice of plotting scales on the stereoplanigraph type of equipment gives it an advantage over the multiplex where the plotting scale is restricted by the depth of focus of the projectors.

One of the principal differences between the plotting machines of the stereoplanigraph type and the multiplex is the fact that with the multiplex drawing is accomplished by pushing the stand around over the compilation sheet, the elevation being changed by a thumbscrew. On the stereoplanigraph, drawing is accomplished by turning handwheels, the left hand controlling the X motion of the machine, and the right hand controlling the Y motion. On machines of the stereoplanigraph type the elevation of the floating mark is controlled by a footwheel. Thus, when drawing contours, the footwheel sets the proper elevation. At this setting the floating mark, like the floating mark of the multiplex, is restrained to movement in a given horizontal plane. For drawing planimetry with the stereoplanigraph, the operator looking through the stereoscope causes the handwheels to follow the ground feature and with the footwheel keeps the floating mark moving up and down to conform with the elevation of the surface of the ground.

Summary.— Aerial photography and photogrammetry augment but in no way eliminate ground surveying. In all photogrammetric processes a certain amount and often a considerable amount of ground surveying is required for control. There will often be areas to be mapped which are too small to justify the cost of flying an aeroplane to them or which are too remote to absorb this cost. There will also be areas obscured by vegetation. These areas will probably be mapped with a plane table just as they always have been.

There will also always be surveying on the ground actually to lay out projects which may have been designed from a photogrammetric map. It is not possible to drive a stake in the ground from an aeroplane and the construction project must therefore always be laid out by conventional survey processes.

Aerial photography greatly enriches the visual information obtainable about the surface of the ground. It frequently makes available a more complete visual inventory more rapidly and cheaply than could be obtained in any other manner.

Photogrammetry usually minimizes the more costly phases of conventional surveys by ground instruments. Whether a photogrammetric or a ground survey will be more practical involves a consideration of such factors as purpose of the survey, scale of map, contour interval, size of area, distance from operating base, character of ground cover, data to be shown on the map and character of the terrain. A study of the individual project will determine whether the survey should be by photogrammetric methods, by conventional ground methods or by a combination of both. (L. T. E.)

PHOTOGRAPHIC ART. Photography came into being through an artistic urge. Louis Jacques Mandé Daguerre was an artist, a scene painter whose illusionistic diorama was a landmark in Paris long before he announced, in 1839, his daguerreotype process. And William Henry Fox Talbot was led to make his simultaneous researches because he found it difficult to dram. It was not mere coincidence that photography came into being almost simultaneously with means of multiplying pictures in great quantities (lithography and wood engraving) and with semimechanical means of picturemaking (the silhouette and the physionotrace). The underlying chemical and optical principles had long been known, but the conception of using the light-sensitive property of silver salts to record the optical image of the camera did not occur until there was a demand for pictures following the rise of the bourgeoisie after the French Revolution.

The first criticism of photography was necessarily a comparison of it with painting or drawing, as no other standards of picturemaking existed. The Parisian painter Paul Delaroche. when questioned about the value of the daguerreotype to artists, went so far as to say that the "process completely satisfies art's every need." Photography's remarkable ability to record a seemingly inexhaustible amount of detail was marvelled at again and again. The critics regretted that. because of the great length of exposure, moving objects were not recorded. or were rendered blurry and indistinct. The inability of the first processes to record colours was disappointing, but as the critics were conditioned to black-and-white prints and drawings. this was not so serious a drawback as the harshness of the tonal scale. The technique of photography was at once recognized as a short cut to art. No longer was it necessary to spend years in art school drawing from the cast and from life, mastering the laws of linear perspective and chiaroscuro. As Daguerre boasted in a broadside announcement. "with this technique. without any knowledge of chemistry or physics, one will be able to make in a few minutes the most detailed views. . . ." But formal art education had a purpose over and above the mastery of technique. The discipline taught the student to observe. and it gave him a feeling for the significant moments of time and an intuitive sense of composition. Using photography as a short cut to picturemaking was dangerous, because it often led to superficial results. lacking in the qualities that distinguish a work of art from an illustration.

D. O. Hill and R. Adamson. — In the hands of artists, photography quickly showed its artistic possibilities. David Octavius Hill, a Scottish painter. became interested in Fox Talbot's calotype process. In 1843 he mas commissioned to make a group portrait of the disruption meeting of the Scottish churches. There were hundreds of figures to be painted. and in order to simplify this enormous task. Hill turned to photography. He enlisted the aid of Robert Adamson, a pioneer photographer: and together they made hundreds of portraits. They did not confine themselves to the members of the church meeting. but included people from all walks of life. Posing their sitters out-of-doors, in strong sunlight and with exposures measured in minutes of time, it is hard to understand how Hill and Adamson managed to retain that spontaneity which is so essential to the success of a photographic portrait. They photographed the fishermen and their wives at Newhaven, Scot., posing them in groups reminiscent of paintings, and some of their landscape photographs show a startling affinity to watercolour drawings. The work of Hill and Adamson was forgotten after the 186os and almost unknown when it was rediscovered in the early 189os by J. Craig Annan, who made modern prints from the original paper negatives.

Daguerreotypes in the U.S.—By universal consent, the United States led the world in the production of daguerreotypes. It has been claimed that the first portraits made by photography were produced in the United States. By the late 1840s, photography was a big business. Every city of size had its "daguerreian artist." and ingenuity led to the use of machinery and production-line processing. The work of the Boston, Mass., firm of Albert Sands Southworth and Josiah J. Hawes rivalled in artistic quality the best work of Hill and Adamson. The special quality of these two Boston daguerreotypists was their perception of the individual. Instead of the stereotyped lighting and posing formulas of the average daguerreotypist. they showed the greatest variety. and they did not hesitate to present their sitters unprettified and "as they were." Chief Justice Lemuel Shaw stands with crumpled coat and unruly locks of hair under a glare of sunshine; John Quincy Adams sits in his own living room; Lola Montez lolls over the back of a chair.

Formulation of an Aesthetic Theory. — In England the heyday of photography followed Scott Archer's invention of the wet collodion process in 1851. This new technique rapidly displaced and made obsolete the daguerreotype and calotype. Professionals had found the need of banding together; and the new process. which mas free from all patent restriction, attracted countless amateurs. Rallying points sprang up: in 1853 the Photographic society (renamed, in 189;. the Royal Photographic society) was formed in London; and in the next year the Société Française de Photographie was founded in Paris.

Up to this time there had been little conscious effort to impose artistic rules on the production of photographs. No particular distinction seems to have been made between photographs produced for an aesthetic intent and those made for documentary purposes. An exhibition of photographs. including examples of the work of Hill and Adamson, was shown at the Crystal Palace in London, 1851, in the section "Philosophical Instruments." In the preceding year Gustave Le Gray. a French professional. had sent eight photographs to a competitive art exhibition in Paris. They were accepted by the jury and catalogued as lithographs. When it became known that they were photographs, they were withdrawn by the organizing committee.

Photographic societies undertook to remedy this situation and began to examine the position of artistic photography in relation to scientific photography. At the first meeting of the Photographic society the president, Sir William Newton, who was a miniature painter by profession, read a paper "Upon Photography in an Artistic View" (*Journal of the Phot. Soc.*, i [1853]). His argument was that, except for scientific purposes. photography should depict natural objects "in accordance (as far as it is possible) with the acknowledged principles of Fine Art." One way in which the photographer could make his results "more like works of art," Sir William pointed out, was to throw the subject slightly out of focus. The extreme blue-sensitivity of wet collodion plates rendered the sky areas so dense that they appeared as blank paper on the print. To overcome this failure of the photographic process he recommended liberal retouching and free use of handwork on the negative.

Combination Printing. — An outcome of the urge to create photographs which would fit a priori concepts of art was the technique of making one print from several different negatives. The most iamous example was made by O. G. Rejlander, Swedish by birth, who had received an art education in Rome and was practising photography in England. It was a figure piece, 31 x 16 in. in size; printed from no fewer than 30 separate negatives. The picture was entitled "The Two Ways of Life." and showed, in allegory as obvious as it was sentimental, that the way of the blessed led through good works and the way of the damned through vice. The same models were used again and again. Rejlander, who described the technique in photographic journals, stated that his purpose was to show artists the possibilities of using photography, and for that reason chose a subject which enabled him to use nude models variously draped. The photograph was shown in the Manchester Art Treasures exhibition of 1857 and was purchased by Queen Victoria.

H. P. Robinson. — This technique stimulated Henry Peach Robinson! a professional photographer who had studied art as a young man. He became iamous with a five-negative combination print, "Fading Away," in 1858. The subject depicted a dying girl, and this was considered by critics as too painful a subject to be represented by art. .Perhaps the implied authenticity of photography bothered them, because painters had long presented subjects of far more painful nature. Robinson became a most articulate member of the Photographic society, and his teaching was even more influential than his photography. In 1869 appeared the

first of many editions and translations of his book, *Pictorial Effect in Photography*. Robinson went a step further than Newton; he offered photographers a set of rules. From a then outmoded handbook on painting, he borrowed compositional formulas the use of nhich, he claimed. would bring artistic success. The student was instructed to arrange his models in pyramidal compositions; and examples from the work of Sir David Wilkie, a popular painter of genre scenes, were given to show how this artist used the triangular form of composition. The importance of balance was stressed. and the opposition of light against dark was made clear. The fault of the book lay not only in the assumption that rules set up for one art form can be applied to another, but also in its intellectual and academic approach to art.

Robinson's work is, by modern standards of taste, weak and artificial. Not only did he practise combination printing. but he preferred to work in the studio, against painted backdrops and with props of natural objects, even foliage, mounted on casters. When he did photograph in the country, he took models with him, dressing them up to play the part of country girls, instead of turning to the genuine thing.

Mrs. Cameron. — Using. by accident or design, a lens of such poor quality that the image mas seldom sharp, Julia Margaret Cameron produced a remarkable series of portraits in 1864 and the following years. The success of these portraits, representing friends prominent in literary and artistic circles, cannot be laid to any technical trick, however because her genre studies, too obviously based on Pre-Raphaelite paintings, were weak and sentimental. The key to the success of the portraits lies in their intensity. "When I had these men before my camera," she related in her "Annals of My Glass House" (*Phot. J.*, lxvii, pp. 296–301 [1927]), "my whole soul has endeavoured to do its duty toward them in recording faithfully the greatness of the inner man as well as the features of the outer man. The photograph thus obtained has been almost the embodiment of a prayer."

Adam Salomon and Retouching. — An important influence came from France. The sculptor Adam Salomon introduced a new style of photographic portraiture. In place of the even and diffused lighting which was almost universal, he used a strong side light to give the so-called Rembrandt effect. He was a master of retouching. Arguments were frequent in the 1860s over the legitimacy of retouching, particularly of portraits. Some prints of Salomon were tested by the Edinburgh Photographic society in 1868 to ascertain "whether they were pure photographs or indebted to retouching for their beauty." It was found that they were retouched.

O. W. Holmes on Photography. — There was one form of photography in which retouching or any other form of handwork was virtually excluded, and that was stereographic work. The paired images which, when viewed properly, produce the most astonishing illusion of three dimensions, depend upon the most minute and exact differences in detail to render their startling effect, and this precision cannot be imitated manually. Love of stereographs led the C.S. physician and writer Oliver Wendell Holmes to write three articles in the *Atlantic Monthly* in which he put down the basis of a functional aesthetic which was almost diametrically opposed to what Newton had recommended in London. To Holmes the photograph had characteristics which no other art could rival. Far from regretting that the camera had not been used in accordance with the accepted rules of art, Holmes praised what appeared to some the defects of the process. "The very things which an artist would leave out, or render imperfectly, the photograph takes infinite care with, and so renders its illusions perfect. What is the picture of a drum without the marks on its head where the beating of the sticks has darkened the parchment?" (*Atlantic Monthly*, iii, p. 746 [1859]). "In a perfect photograph," he added, "there will be as many beauties lurking, unobserved, as there are flowers that blush unseen in forests and meadows." Holmes was but one voice against the many. The aesthetic value of straight photography was not generally recognized, and the work of those who recorded the battlefields of the Crimean and Civil Wars and who travelled throughout the world was overlooked by the aestheticians.

Naturalistic Photography. — The introduction of the dry plate in the 1880s attracted an increasing number of amateurs to photography. In comparison with the messy and awkward wet plates, even the uncertain dry emulsions were revolutionary. The photographer could buy ready-made plates and process them at his convenience. Soon he would be freed of his tripod.

Peter Henry Emerson felt the artificiality of the Robinson school, and he set against the latter's theories another viewpoint which he named naturalism, and which he described in his *Naturalistic Photography for Sfudents of the Art*, first published in 1889. He believed that photography was potentially a great creative art, and that it did not need to be bound down to rules set up for painting. "Naturalism," he wrote, "is an impersonal method of expression, a more or less correct reflection of nature wherein (1) truth of sentiment, (2) illusion of truth of appearance (so far as is possible) and (3) decoration are of first and supreme importance."

Emerson sought a scientific basis for pictorial photography. He analyzed the physiology of vision in order to find out how the camera can simulate human perception. He reasoned that since the eye sees distinctly only a small part of what lies before it, while the surrounding area appears indistinct, it should be possible to reproduce this phenomenon by control of focusing. Only a small part of the photograph should be sharp; the rest should be just slightly out of focus. Today we recognize that this theory of vision is fallacious, because the eye. unlike the lens of a camera, is a living organism, which scans the field of view constantly so that the mind receives a composite report and the impression of full detail. The naturalistic theory was an advance over Newton's. for Emerson believed that the photographer should rely entirely on controls which were themselves part of the photographic process. In addition to control through differential focusing, he advised the careful use of developing and printing methods.

Most especially, however, he took the camera out of the studio and into the fields and fens. He made several series of photographs of the strange amphibious life of the pheasants on the marshes, which were far removed from the artificial genre studies of Robinson. These he published in handsome folio volumes as original platinum prints or as superb photogravures.

In 1891 Emerson renounced his theory. He said that he had been led to take this step because the researches of F. Hurter and V. C. Driffield had proved to him that control could not be exercised by development. A great artist, he went on. had shown him that the mere reproduction or translation of nature was not art. Humbly he confessed that photography was not art and never could be. The fallacy of this argument lay, of course, in the definition of art. It appears that "art" and "painting" were almost synonymous to Emerson when he wrote his retraction. But he could not take back his words. Even the dramatic publication of a black-bordered pamphlet *The Death of Naturalistic Photography* was ineffectual.

The Linked Ring. — In his book Emerson had a good deal to say about photographic exhibitions. He felt that they were poorly organized. He recommended that photographs be framed in simple white moulding and that they be exhibited on one line in galleries, not plastered over the wall with the frames practically touching. And he felt that pictorial photographs should be isolated. instead of being lumped together nith work done for scientific, technical and other nonaesthetic purposes.

This issue caused a split in the Photographic society in 1892. A group of pictorially minded members. under the leadership of H. P. Robinson and George Davison, formed a society for the exclusive purpose of furthering "the development of the highest form of art of which photography is capable." (*Camera Notes*, 1901, p. 119, *The Camera Club of New York.*) The society was named the Linked Ring. They held annual exhibitions which they referred to as salons, a name borrowed from the painting world, and nhich demonstrated their artistic motivation. By 1901 it was their proud boast that "through the Salon the Linked Ring has clearly demonstrated that pictorial photography is able to stand alone and that it has a future quite apart from that which

is purely mechanical." *(Camera Notes,* 1901, p. 119, The Camera Club of New York.)

Stieglitz and the U.S. School.—In 1887 Emerson, judging a competition for the *Amateur Photographer,* awarded a prize to Alfred Stieglitz, a young American who was studying in Germany. It was the first award which Stieglitz had received; the first recognition of one nho was to carry pictorial photography to a high level, not only with his own work. but in his constant championship of all that has been progressive in photography and other forms of modern art.

When Stieglitz returned to the U.S. he found that photography was a fad, and that the New York Society of Amateur Photographers threatened to change their organization into a bicycling club. After serving as editor of the *American Amateur Photographer* for a number of years he organized a sympathetic group in the Camera club. New York city, and founded a handsome periodical. *Camera Notes,* nhich. devoted exclusively to pictorial photography. was outstanding for the unusually high quality of its illustrations. Stieglitz was one of the first to demonstrate the pictorial possibilities of the hand camera. He made photographs by night and under all conditions of weather. He showed that the lantern slide was a splendid form of pictorial presentation, and organized competitions, offering a prize cup to the Camera club.

In 1900 F. Holland Day brought to England a collection of the work of the new photographers who had emerged largely because of the guidance and the example of Stieglitz. The showing, although not fully representative, included the work of A. L. Coburn, Frank Eugene. Gertrude Kasebier, Edward Steichen and Clarence White. It was characterized by an emphasis upon aesthetic intent, by a variety of printing techniques and by subtle presentation. Day, addressing the Royal Photographic society, where the exhibition was held, referred to the exhibitors as the new school which "holds tenaciously that photography may be, if it is not yet, a fine art." (F. Holland Day, *The Photographic Journal* [Oct., 1900], Royal Photographic Society.)

The Photo-Secession.—Stieglitz and his friends, disturbed by the lack of standards and the general conduct of photographic exhibitions in the U.S.. formed in 1902 the Photo-Secession. They chose the word "secession" to show their split with the *status quo,* just as the German and Austrian painters had used the same word to make manifest their independence of officialdom. The record of the Photo-Secession is contained in the 50 issues of *Camera Work* which were published by Stieglitz between 1903 and 1917. The society had a gallery. known as "291" from the street number on Fifth avenue, New York city. where it was located. and there the group showed not only pictorial photographs. but other works of art as uell. *Camera Work* contains reviews of these exhibitions, photogravures and other reproductions of the highest quality. and stimulating essays.

The Photo-Secessionists were much concerned over the recognition of photography as a fine art. The independence of pictorial photography had been proved, but as yet little interest had been shown officially by art museums. In 1910 the group organized an exhibition of about 500 prints by leading pictorial photographers from all over the world in the Albright Art gallery, Buffalo, N.Y. The show created a sensation. Some of the exhibited prints were purchased by the gallery; for the first time photographs were admitted to an art museum on an equal footing with paintings and drawings.

Transition.— The last issues of *Camera Work* contained photographs by Paul Strand which showed a new approach. There were views looking down from unusual angles; there were bowls in quasi-abstract arrangement; there were striking unposed open-air portraits of a type which 20 years later were to be called candid. One of the first Photo-Secessionists, A. L. Coburn, made a series of photographs looking down irom a tall building, which he published as *New York From Its Pinnacles,* noteworthy for the way in which emphasis was thrown on form. He also made photographs devoid of subject matter. T'ortographs, which he contributed to *Photogranzs of the Year* in 1917.

There mas other evidence that new trends were coming to the surface at the close of World War **I.** Edward Steichen renounced both his painting and his prewar style of photography. which had been characterized by broad, simple effects often rendered by gum prints, a process nhich was readily adaptable to manipulation. He turned to a precise, clean-cut may of working, which he applied to illustration work. Charles Sheeler, a painter used the camera to record the stark beauty of Pennsylvania barns and the forms of industrial structures. Edward Weston gave up the soft-focus, often sentimental landscapes and figure pieces which had brought him fame and discovered the beauty of close-up details and isolated form, which he recorded in full detail and with brilliant contrasts. Alfred Stieglitz carried his work further; in 1924 he began the "Equivalents" series in which the ability of the camera to record nature gives may to its use as a creative instrument, capable of imparting the most intense emotional reactions. He found in the photographic series a ponerful means of expression A portrait, for example, consisted of many separate yet mutually related photographs.

Influence of Abstract Art.—In Europe. a similar revaluation of the photographic medium took place, largely under the influence of the Bauhaus, an experimental art school u-here much of the modern idiom of architecture and industrial design originated. A change in point of view led these experimenters to find out what they could learn irom photography, rather than be concerned about photography in relation to the other arts. They discovered that there was a photographic vision which in itself was aesthetically stimulating. Instead of deploring the distortions caused by the use of lenses of abnormally short or long focal length, they delighted in the new forms thus created. They tipped the camera up and pointed it donn. Around 1920 L. Moholy-Nagy, a painter residing in Germany, and Man Ray an American living in Paris, Fr., simultaneously and nithout knowledge of the other's work, made highly complex abstract compositions by placing objects directly on sensitized paper, which was then exposed to light. The objects not only left negative images of their profiles, but also, if they were translucent, gradations of light modulated by them. Aesthetically, these "photograms" or "rayographs" were the photographic equivalents of abstract paintings of the period; technically, they were revivals of Talbot's photogenic drawing process.

Later Photographic Art.—The experimental work of the 1920s served to break down the barriers of conservatism and to reveal that photography is an artistic medium with its own special characteristics. After 1930, two closely related trends became of increasing importance. On the one hand. there were those nho found the greatest challenge in using large cameras, from which to make contact prints, rich in detail and brilliant in tonal gradations. These photographers sought to produce prints which, like etchings or lithographs, would be of value as independent works of art, to be framed or kept in portfolios. On the other hand, there were those who wished to exploit to the utmost new technological developments in lenses, films and lighting equipment to capture the fleeting moment and to photograph things and places which could never before be recorded on film. These photographers tended to consider their prints only the means to the end of reproduction in books, magazines and newspapers.

The masters of the first group were largely American—Alfred Stieglitz, Paul Strand, Edward Weston and Ansel Adams. Their work was distinguished by an impeccable technique and by a rich pictorial imagination. They preferred in general to photograph by natural light, and they found their richest subject matter in the natural scene and architecture.

The miniature camera. which came to a state of perfection in 1932, found its greatest exponent in Henri Cartier-Bresson. This French photographer found that the poaerful lenses which can be used with this camera and the high-speed film made for it give him the opportunity to photograph "on the run" and to find compositions which exist for the briefest interval of time. To him the camera was "an extension of the eye," and his photographs—mostly of people—were characterized by their immediacy and by their unusual form. Light advances—the development of electric flash and the even more powerful electronic flash—gave the photographer yet another creative medium. Steichen pioneered in the use of electric light in his portraits of celebrities; Barbara Morgan

captured the very essence of the dance in her remarkable action photographs. Photographers who are primarily journalists, such as W. Eugene Smith, pushed their work beyond documentation.

Collections.—In comparison with the collecting of other forms of art. the building up of depositories of art photographs was noticeably sporadic. Both the Royal Photographic society in Great Britain and the Societé Française de Photographie in France have notable collections. In the United States the Smithsonian Institution, Washington, D.C.. was one of the first to build up a collection. It has a sizable representation of the work of the Photo-Secession. The most important collection of this influential group, however, is in the Metropolitan Museum of Art. New York city. The Museum of Modern Art. New York city. following the success of a large retrospective exhibition in 1937, formed a department of photography for the express purpose of collecting and exhibiting examples of artistic photography. The museum held important one-man shows, notably of D. O. Hill. Walker Evans, Paul Strand, Edward Weston and Henri Cartier-Bresson; illustrated monographs on these workers have been published. The National Gallery of Art. Washington. D.C.. acquired an extensive collection of Stieglitz photographs. The Brooklyn (N.Y.) museum also founded a department of photography, and in 1945 the Santa Barbara (Calif.) Museum of Art opened a gallery dedicated exclusively to photography. The George Eastman House in Rochester, N.Y.. has an important group of art photographs, and the holdings of the American Museum of Photography in Philadelphia, Pa.. include many art prints.

TECHNIQUES OF PHOTOGRAPHIC ART

Anyone who has mastered a few simple instructions can make printable negatives with a pocket camera. Because it is impossible for the untrained beginner to achieve such acceptable results in any other medium. photography has sometimes been called the easy art. But to bridge the gulf between the taking of such casual snapshots and the production of photographs that can be classed as art is certainly no easy task. To the mastering of his tools and the perfecting of his technique, the photographer must devote just as much time and effort as does the musician or the painter. Since the nature of the photographic process determines the artist's approach, we must have some knowledge of the inherent characteristics of the medium in order to understand what constitutes the aesthetic basis of photographic art.

Photography must always deal with things—it can not record abstract ideas—but far from being restricted to copying nature, as many suppose, the photographer has ample facilities for presenting his subject in any manner he chooses. First, an infinite number of compositions can be achieved with a single stationary subject by varying the position of the camera. the camera angle or the focal length of the lens. Second. any or all values can be altered by change of light on the subject. or the use of a colour filter. Third, the registering of relative values in the negative can be controlled by length of exposure, kind of emulsion used and method of developing. And finally, the relative values in the negative can be further modified by allowing more or less light to affect certain parts of the image in printing. The photographer is restricted to representing objects of the real world, but in the manner of portraying those objects he has vast discretionary powers; he can depart from literal recording to whatever extent he chooses without resorting to any method of control that is not of a photographic (*i.e.*, optical or chemical) nature.

But the artist's use of these controlling powers must be conditioned by two factors: (1) the nature of his recording process and (2) the nature of his image. There is a frequent cause of mistaken understanding in the belief that the camera's image reproduces nature as the human eye sees it. On the contrary, its ability to record things as the unaided human eye can never see them is one of the most important attributes of photography. The human eye can focus on but one small area at a time: consequently, we observe an object or a scene only by letting our eyes rove over it in a series of short jumps. The assortment of images thus recorded are flashed to the brain which sorts and edits them, automatically discarding some as of no importance and emphasizing others. according to its individual conditioning. The impersonal camera eye makes no such distinctions; every detail within its field of vision can be recorded instantly and with great clarity. In the time the eye takes to report an impression of houses and a street the camera can record them completely. from their structure. spacing and relative sizes, to the grain of the mood. the mortar betneen the bricks, the dents in the pavement. The image that is thus registered has certain characteristics that at once distinguish it from the products of all other graphic processes. In its ability to register fine detail and in its ability to render an unbroken sequence of infinitely subtle gradations, the photograph cannot be equalled by any work of the human hand. For this reason any manual interference with the image at once destroys those very qualities that give the true photograph value as an art form. From these two facts we may draw an obvious' deduction: if the recording process is instantaneous and the nature of the image such that it cannot survive corrective handwork, then it is clear that the artist must be able to visualize his final result in advance. His finished print must be created in full before he makes his exposure, and the controlling powers enumerated above must be used. not as correctives. but as predetermined means of carrying out that original visualization. As in the mastery of any other graphic form. years of experience are necessary in photography before technical considerations can be made entirely subordinate to pictorial aims. The ability to prevision the finished print is the photographer's most important qualification and in order to attain it he must concentrate on learning to see in terms of his tools and processes. Having chosen the simplest possible equipment (so as not to complicate his task needlessly) he first learns by experiment the potentialities and limitations of each instrument and process. He must learn the field of his lens, the scale of his film and paper emulsions; he must learn to judge the strength and quality of light; he must learn to translate colours into their relative monochrome values and know how those values are affected by the use of different filters.

He must learn the kind of negative necessary to produce a given kind of print. and then learn what kind of exposure and development will produce that negative; then, having learned how those needs are fulfilled for one kind of print. he must discover how to vary the process to get other kinds of prints. Gradually. with experience. this knowledge becomes intuitive; the photographer sees a scene or object in terms of his finished print without having to think of these processes any more than a musician playing a piece thinks of the whereabouts of the next note he will sound or how much pressure he will use in sounding it.

The Print.—The value of the photograph as a work of art depends primarily on the photographer's seeing before exposure, but its artistic value can be determined only by an examination of the finished print.

Exposure records the photographer's seeing; developing and printing execute it; so no matter how fine the original vision, if it has not been faithfully carried out in subsequent procedures. the resulting print will suffer. The clarity of image and delicacy of gradation that characterize a fine photograph demand a special kind of surface for their best presentation. A rough surface destroys the integrity of the image; a smooth surface retains it. A shiny or reflecting surface enhances the beauty of image quality, while a dull or absorbing surface tends to obscure it.

For beautiful image quality. the best of the old daguerreotypes have never been equalled. The positives were made directly on the metal base and the small pictures were esteemed for their exquisite rendering of fine detail. The photo-painters, who did away with all things characteristically photographic, often used

papers of independently beautiful surface texture for their prints. The result of such a combination is that the paper competes with the image instead of becoming a part of it.

Among modern processes the nearest approach to the fine image quality of daguerreotypes is a waxed or glossy print. Unfortunately. glossy paper is still held in general disfavour among artist photographers. It is said to be harsh and cold and only suitable for commercial work.

These erroneous beliefs are partly a hangover from the heyday of photo-painting and partly a result of the difficulty of making good glossy prints. The glossy surface reveals the image with such clarity that minor blunders, which might escape detection on the more veiled, dull-surface papers, are at once exposed. However, the glossy surface has the advantage of a longer scale which makes it possible to reproduce more of the negative and allows a greater latitude in reproducing extremes of tone from the strongest to the most subtle and delicate. When a photographer speaks of the warm or cold tone of a print, he is usually referring to its colour—a cold blue-black as opposed to a warm green-black. But to use such variations of colour to emphasize the feeling of his picture is to misuse his medium. If he prints a snow scene blue-black so that it will look cold and a forest scene green-black so that it will appear warm, he is introducing a foreign element into his monochromatic process just as surely as if he coloured the print by hand. In black-and-white photography the effect of warmth or coldness should be communicated by the values in the print, whose colour should—at the extremes of the scale—be as nearly pure black and pure white as possible (use of obvious colour tone belongs in the province of colour photography). Obviously then, the longer scale of glossy paper gives greater opportunity of producing through the values in the print whatever effect is desired. And lastly, the luminous surface of the glossy paper, by making the image light-giving, comes nearer to rendering the effect of the original scene and so heightens the illusion of reality. A good glossy print reveals the delicacy of subtle gradation, the lucidity of tone and the brilliant clarity of image that are unique characteristics of the photographic process.

Subject Matter.—It is impossible to make any sharp distinction between the subject matter appropriate to one graphic medium and that more suitable to another. But in the case of photography we can at least draw a few general conclusions, based on an examination of the work of the past and our knowledge of the special properties of the medium. From the wet plate era we may draw two contrasting examples that serve to indicate a field of endeavour in which the photographer is least likely to be successful. On the one hand is the work of O. G. Rejlander and Henry Peach Robinson, two men who achieved prominence for their photographic work in England during the '50s and '60s. In their best-known pictures (Rejlander's Two Ways of *Life,* and Robinson's *Fading* **Away)** they attempted to depict allegorical and dramatic situations by combining a number of negatives of posed and costumed figures into composite prints. On the other hand is the work of Mathew Brady, Alexander Gardner and many anonymous photographers who documented the American Civil War. These men were bound by no artistic purpose; their sole aim was to record to the best of their ability every phase and aspect of the hostilities that their clumsy and limited equipment could encompass. Yet it is in these straightforward records that we perceive true photographic quality: here is the tremendous power and appeal of the camera's realism, the intensity of its vision undiluted; and these documents of the past still move us profoundly with their clear, objective picture of the horror and pathos of war. Beside these photographs the artistic efforts of Rejlander and Robinson appear self-conscious, stilted and artificial. Their carefully posed and costumed figures look absurd and unreal.

Now this comparison makes one fact apparent: the camera lens sees too clearly to be used successfully for recording the superficial aspects of a subject. It searches out the actor behind the make-up and exposes the contrived, the trivial, the artificial for what they really are.

But if the camera's innate honesty works any hardship on the photographer by limiting his subject matter in one direction, the loss is slight when weighed against the advantages it provides. For it is that quality that makes the camera expressly fitted for examining deeply into the meaning of things. The discriminating photographer can direct its penetrating vision so as to present his subject—whatever it may be—in terms of its basic reality. He can reveal the essence of what lies before his lens with such clear insight that the beholder will find the recreated image more real and comprehensible than the actual object.

The photograph isolates and perpetuates a moment of time: an important and revealing moment, or an unimportant and meaningless one, depending upon the photographer's understanding of his subject and mastery of his process. The lens does not reveal a subject significantly of its own accord. On the contrary, its vision is completely impartial and undiscriminating. It makes no distinction between important detail and meaningless detail Selection, emphasis and meaning must be provided by the photographer in his composition. Nowhere has the painter's influence had a more lasting hold on photography than in the field of composition. Photographers who have put to use every other resource of their medium still try to emulate the work of painters in this respect They consider composition as a thing apart, having no relation to a specific medium, but consisting of a set of tested rules and conventions that must not be contravened. To compose a subject well means no more than to see and present it in the strongest manner possible. The painter and the photographer will have two different ways of doing this because of the basic differences between their mediums. Its capacity for rendering fine detail and tone makes photography excel in recording form and texture. Its subtlety of gradation makes it admirably suited to recording qualities of light or shadow, and its ability to record sharply everything within the angle of lens vision from the immediate foreground to the distant horizon carries it far beyond the painter's province. The photographer cannot depend on rules deduced from finished work in another medium. He must learn to see things through his own eyes and his own camera; only then can he present his subject in a way that will transmit his feeling for it to others.

An intuitive knowledge of composition in terms of the capacities of his process enables the photographer to record his subject at the moment of deepest perception; to capture the fleeting instant when the light on a landscape, the form of a cloud, the gesture of a hand or the expression of a face momentarily presents a profound revelation of life.

The appeal to our emotions manifest in such a record is largely due to the quality of authenticity in the photograph. The spectator accepts its authority and, in viewing it, perforce believes that he would have seen that scene or object exactly so if he had been there. We know that the human eye is capable of no such feat, and furthermore that the photographer has not reproduced the scene exactly; quite possibly we would not even be able to identify the original scene from having seen the photograph. Yet it is this belief in the reality of the photograph that calls up a strong response in the spectator and enables him to participate directly in the artist's experience.

Conception and execution so nearly coincide in this direct medium that an artist with unlimited vision can produce a tremendous volume of work without sacrifice of quality. But the camera demands for its successful use a trained eye, a sure, disciplined technique, keen perception and swift creative judgment. The artist who would use his photographic powers to the full must have all these, plus the first requisite for the artist in any medium—something to say. (E. WN.)

PHOTOGRAPHY, the science and art of producing pictures by the action of light on chemically prepared (sensitized) materials (Gr. $\phi\omega s$, light, and $\gamma\rho\alpha\phi\epsilon\iota\nu$, to write).

The practice of photography depends upon the sensitiveness of silver compounds to light. When silver bromide, dispersed in a medium such as gelatin, is exposed to light, it undergoes a change as a result of which it becomes developable. When, after exposure, it is treated with a solution having reducing properties, termed a developer, the exposed bromide is reduced to metallic silver and forms an image corresponding to the intensity of light to which it was exposed. (See fig. 1.)

After development, the unexposed silver bromide is removed by a solvent which does not attack silver but dissolves the bromide, and the picture is then permanent and is said to be fixed. The picture thus obtained is a negative; that is, the light parts of the object are the blackest in the picture and the dark parts appear the brightest.

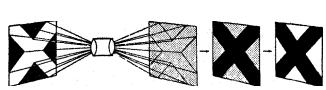

FIG. 1.—THE PRODUCTION OF A PHOTOGRAPH

In order to obtain a positive picture, in which the light and shade correspond to that of the original subject, the negative is printed. It is placed in contact with another piece of sensitive material which is exposed to light through the negative, and this gives in turn a positive image after development.

The operations required to produce a photograph are:

1. Preparation of the sensitive negative material.
2. Exposure in a camera.
3. Development; with the after processes, fixation, washing and drying.
4. Preparation of the sensitive positive material.

5. Printing.
6. Development, fixation, washing and drying of the print.

In the early days of photography all, of these operations were carried out by the photographer, but at the present time the sensitive materials. both negative and positive, are almost always made by manufacturing companies.

A wide variety of negative materials, cameras and printing processes are used in photographic operations. their selection depending upon the particular branch of photography under consideration. The chief branches are:

Amateur Photography, including both the casual taking of photographs for record or amusement and the serious pursuit of pictorial photography as an art.

Professional Photography, which may be subdivided into *Portraiture, Commercial Photography* and *Press Photography.*

Motion-Picture Photography (see MOTION PICTURES: *Motion-Picture Technology)* both professional and amateur.

Radiography, photography by means of X-rays, for medical, scientific and industrial purposes.

Applied Photography, including many uses of photography in connection with the arts and sciences, such as aerial photography, photomicrography, astronomical photography, medical photography, documentary photography, etc.

MATERIAL PHOTOGRAPHY

Negative materials are made by preparing a precipitate of silver bromide containing a small amount of silver iodide in a medium containing enough gelatin to enable it to be set to a jelly when cooled. This suspension is termed the *emulsion.* The melted emulsion is coated upon a support which may either consist of glass, in which case *plates* are produced or may be a flexible cellulose compound, in which case the product is termed *film.* After the emulsion is set by chilling and then dried, the material is cut to suitable sizes and packed in light-tight containers. Films are packed as sheet films, for use in holders similar to those used for glass plates, roll films protected mith paper in special cassettes to make them suitable for loading in daylight, film packs and as long rolls for use in taking motion pictures.

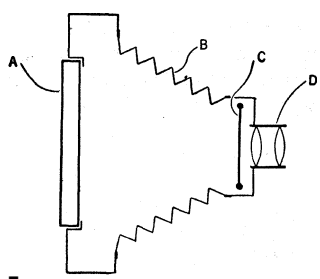

FIG. 2.—DIAGRAM OF A CAMERA

Cameras are of many varieties, the essentials being a *lens* (D) to form the image, a *shutter* (C) to regulate the duration of the exposure, a *material holder* (A) to carry sensitive plates or film and a *connecting shield* (B) to protect the sensitive material from light other than that which comes through the lens. This is generally extensible and then takes the form of a *bellows. (See* fig. 2.)

The cameras used for various purposes are discussed under the section *Apparatus.*

Positive matevials may be used for transparencies, in which case they are *lantern slides* on glass or *positive films* (especially for motion-picture photography). They are prepared in the same way as negative materials, the emulsion being modified to give the results desired. Usually, however, negatives are printed upon sensitized *paper.* Printing papers are generally coated with a sensitive emulsion prepared either with silver bromide, *bromide papers,* with silver chloride, giving *chloride papers,* or with a mixture of chloride and bromide to give *chlorobromide* papers.

Previously, most types of paper were prepared with an emulsion containing free soluble silver compounds and were printed under the negative in strong light until the image was visible—printing-*out papers.* No development was required with these papers, which are, however, almost obsolete now except for the preparation of *proofs* submitted by professional photographers to customers.

Many other varieties of printing processes are known and some are used to a large extent in the reproduction of drawings, *e.g.,* the blueprint, diazotype and Vandyke processes. Others use specially sensitized gelatin or other colloid layers containing pigments, *e.g.,* the carbon and Carbro processes, or to which pigments may be applied, *e.g.,* bromoil.

HISTORY

Photography was discovered by no one man. It was the outcome of the early observations of the alchemists and chemists on the action of light, a subject that belongs strictly to the domain of photochemistry (*q.v.*). Although the blackening of silver salts was known in 1565, it was not until 1727, when J. H. Schulze used a mixture of silver nitrate and chalk under stencilled letters, that it was definitely recognized that this darkening action was caused by light and not by heat. The experiments were also done by W. Lewis in 1763. These experiments were important in that, in conjunction with those of K. W. Scheele, 1777, they led to the experiments of T. Wedgwood with silver nitrate on paper and leather in 1802. It was also suggested that silver chloride was more sensitive These were practically failures because of the very long exposures required, and no means were kno n of removing the unaffected material and thus stabilizing or "fixing" the image against light.

Camera.—Leaving for the time being the question of the sensitive salts, we may turn to the evolution of the camera. This was the outcome of the old camera obscura, the invention of which is usually ascribed to Giovanni Battista della Porta. 1553, though its principle had been indefinitely described by Xlhazen, 1100, Roger Bacon. 1267, and others. Leonardo da Vinci, who died in 1519, described and pictured a camera obscura in an unpublished manuscript. In 1 jjo J. Cardan suggested the use of a speculum or concave mirror in front of the instrument, and D. Barbaro, 1568, proposed convex lenses and the use of a diaphragm to secure greater sharpness of the images. E. Danti, 1573, corrected the reversed image by means of a mirror behind the lens, a device still in use. F. Risner, who died in 1580, described in his works published in 1606 the methods of enlarging and reducing, and a portable box in lieu of the cumbrous fixed hut in use until then. Porta in his second edition, 1589, of which an English translation was published in 1658, was the first to introduce the use of the convex lens in the camera. Johann Kepler in his work on optical astronomy, 1604–11, described the use of a concave lens behind the convex to obtain larger images, and thus anticipated the telephoto lenses of the present day. In J. Zahn's book, 1665, there was described a portable camera obscura with two or three lenses, to secure greater brilliancy of the image, and side wings to shield it from extraneous light. At the beginning of the 18th century the portable camera obscura had become a regular article of commerce and was used to obtain sketches from nature. It was encouraged by the growth of amateur artists.

The Beginnings of Photography.—Toward the end of the 18th century there grew a demand for pictures. Wood engraving was revived and lithography was invented. A simple way of producing pictures was the silhouette, made by tracing the outline of a projected image of the face and filling it in with black. In 1786 G. L. Chrétien invented the physionotrace in which the projected image of a head was traced by a stylus, and by a pantograph arrangement an engraving tool cut a copper plate which could be inked and printed. A. Senefelder discovered lithography in 1796; but, though it was introduced in Paris in 1802, it was not until 1813 that it became a success and a fashionable hobby. From that date until 1817 J. Nicéphore Niepce was engaged in an examination of natural stones to find one suitable for the process. Since he was unable to draw, his son Isidore, undertook this work. and when the latter was called for military service. Niepce was impelled to produce the images automatically In conjunction with his brother Claude. Niepce first tried photography with silver chloride on paper. The light-sensitiveness of iron, manganese, acids and other compounds was tested. stone, metal and paper being used as supports. Finally, guaiacum resin was tried and then asphaltum. or bitumen of Judea, which had been in common use as an etching ground since the days of Rembrandt van Rijn. This, becoming insoluble in its usual solvents by the action of light, gave not only a resist for the etching of metal plates but also transparent images on glass A successful result was obtained in 1822, and thus it may be said that the first permanent photo-

graph was made in that year by Niepce. Prior to this, in 1816, Niepce had obtained a positive on paper, probably in silver chloride, which he could not fix.

Three years were required to perfect the process of heliography, as it was called, and in 1836 an etched metal plate was sent to G. Lemaître, of Paris, to be printed. In order that the pictures should be more distinct, they were exposed to the vapours of iodine. The high lights of the plates consisted of hardened bitumen; the shadows, of the bare metal; thus, the contrasts were very poor, which led to the use of tin instead of copper. Lemaître suggested silvering copper plates.

Daguerreotype. — In 1826 L. J. M. Daguerre, a painter who had experimented with silver salts, heard of Niepce's work and approached him to form a partnership. This was consummated in 1829. The work which Daguerre had done with Niepce had drawn their attention to the light-sensitiveness of silver iodide, and Daguerre discovered accidentally that the effect produced by exposing an iodized silver plate in a camera would result in an image if the plate were fumed with mercury vapour. The inventions of Niepce and of Daguerre were published to the world simultaneously by the French home minister in a bill presented to the house of deputies proposing a national reward to the inventors. A full description of their methods was presented by François Arago on Aug. 19, 1839, at a meeting of the Academy of Sciences.

The daguerreotype process was a complete success. In its operation, a silvered copper plate was buffed and burnished to a high polish. It was then iodized by fuming with iodine, and later (1840) resensitized with bromine and then exposed in a camera. At first, exposures of minutes in bright sunlight were necessary; but later, exposures were secured in a few seconds under favourable conditions. The development was effected by placing the exposed plate over a cup of mercury heated to about 75° C. The image was then fixed with a solution of thiosulphate of soda and toned by treatment with gold chloride. The results obtained were excellent when all the operations had been carried out correctly; and the process flourished, especially for portraiture, until it was superseded by the wet collodion process in 1851.

Calotype.—A preliminary notice of Daguerre's success was made by Arago on Jan. 7, 1839. This caused Fox Talbot, an Englishman, to claim priority in obtaining a picture in the camera, and rendering it permanent. Talbot began his experiments in 1834, using the camera obscura with silver chloride and common salt or potassium iodide as fixing agents. A communication was made to the Royal society on Jan. 31, 1839. But not until a month later did he disclose his working method, which then involved silver iodide with excess of the nitrate, and fixation with sodium thiosulphate. The solvent action of this for silver salts had been discovered by Sir J. W. F. Herschel in 1819. Talbot's process was called "calotype," and the image was developed with gallic acid, the action of which seems to have been discovered independently by the Rev. J. B. Reade.

The developed image on calotype paper was the exact reverse, as far as light and shade were concerned, of the original image. Such a picture was termed by Herschel in 1841 a "negative." The transparency of paper can be increased by waxing or oiling, and so Talbot was able to obtain true copies or positives of any negative by simple contact printing upon another piece of sensitized paper. Talbot's process is the first stage in the real line of photographic development, the inventions of Daguerre and Niepce being bypaths whose chief importance was the stimulus they gave to photographic evolution. The disadvantages of calotype were the somewhat long time required for printing and the structure of the paper.

Herschel suggested the use of glass plates and the deposition of silver chloride thereon. In 1848 Niepce de Saint-Victor suggested albumen as the vehicle for silver iodide. This process, called "Niepceotype," held its own until 1851, when Scott Archer, an English architect, published his wet collodion process.

Collodion Process. — To a solution of pyroxylin in ether and alcohol, Archer added a soluble iodide, usually with the addition of a little bromide, and coated a clean glass plate with it. In the darkroom, the iodized colodion was sensitized by immersion in a bath of silver nitrate and formed silver iodide with excess of silver nitrate. The plate was exposed wet in the camera, developed by pouring on a solution of pyrogallol containing acetic acid, and fixed with a strong solution of thiosulphate of soda for which cyanide of potassium was later substituted. Archer's collodion process was not patented, and in three or four years it displaced both calotype and daguerreotype.

The necessity for preparing the plates immediately before exposure and developing them immediately after considerably limited the practice of photography. J. Spiller and W. Crookes suggested bathing the prepared plates in a solution of a hygroscopic salt, so that they could be kept some time both before and after exposure. This was followed by the use of hygroscopic substances of all kinds.

Collodion Emulsion. — In 1864 B. J. Sayce and W. B. Bolton described the preparation of an emulsion of silver bromide in collodion. In 1874 Bolton washed the emulsion in bulk to remove the soluble salts formed in precipitating the silver bromide, and his methods are still followed.

Collodion emulsion was a practical advance on wet collodion, but it was no more sensitive. A considerable increase of sensitiveness was obtained when C. Russell introduced alkaline development in 1862, but the full fruit of this was reaped only with the introduction of gelatino-silver bromide dry plates.

Gelatin Emulsion. — In 1871 R. L. Maddox made an emulsion of silver bromide in essentially the same manner as that used for making collodion emulsions but he replaced collodion by gelatin. The matter was followed up by other experimenters, among whom may be mentioned J. Burgess and J. Kennett. Kennett placed on the market a dry, washed emulsion which photographers could dissolve in warm water and use as a coating on glass and thus produce their own plates.

A great amount of experimental work was at once commenced on gelatin emulsions, the records of which filled the photographic journals between 1873 and 1885. The by-product salts were removed by washing. Sir William Abney recommended the use of iodide in small quantity with the bromide and found that this made it possible to obtain faster emulsions with less fog. Digestion, or "ripening," as it was called, came into use — long digestion at low temperatures being suggested by C. Bennett — in 1878, and digestion with ammonia was used in 1876 by J. Johnson and in 1879 by D. B. van Monckhoven, who employed precipitation in ammoniacal solution as the basis of a process of manufacturing dry plates.

In 1877 the commercial plates of the Liverpool Dry Plate company, Wratten and Wainwright and B. J. Edwards were introduced; and by 1879 comparatively rapid dry plates were available on the market similar in type to the slower varieties of plates used today.

After this period, amateurs gradually ceased their researches, and mass manufacture became general. Considerable increases in sensitiveness were made between 1890 and 1900, and after 1930 improved emulsion-making techniques resulted in further advance in sensitivity without the undesirable qualities which previously accompanied attempts to increase speed.

It is interesting at this point to record the advance made in photography in terms of the relative sensitivity of the process.

Progress in Speed Represented by the Exposure Required to Give a Good Negative at f/11 in Sunlight	
Original daguerreotype, 1839	4,000 sec.
Bromized daguerreotype, 1840	80 "
Wet plates, 1864	8 "
Early dry plates, 1880	1/2 "
Dry plates of 1885	1/10 "
Dry plates of 1900	1/50 "
Dry plates of 1931	1/100 "
Modern fast film	1/500 "

Colour Sensitivity. — The silver halides are sensitive chiefly to the blue, violet and ultra-violet rays; hence, all other colours are reproduced as dark grays or blacks. In 1873 H. W. Vogel discov-

ered that the addition of certain dyes to the emulsion, or immersion of the coated plates in a solution of dye, increased the sensitiveness to the less refrangible colours.

Following this, J. Waterhouse found that eosin sensitized collodion emulsion, and shortly afterward J. Clayton and P. A. Tailfer found that eosin would sensitize gelatin emulsions. They obtained a patent for its use in England and France, and their plates were placed on the market under the name of "isochromatic" plates. In **1884** eosin was replaced by erythrosine, which was found by Joseph M. Eder to be a better sensitizer, and for 50 years erythrosine was used almost exclusively for the use of the so-called "isochromatic" or "orthochromatic" materials. In 1902 A. Miethe and A. Traube found that ethyl red, an isocyanine dye, gave strong colour sensitiveness as far as the orange of the spectrum, and in 1905 B. Homolka discovered Pinacyanol, a dye of structure somewhat similar to ethyl red but which sensitizes very powerfully throughout the red.

It was now possible to make "panchromatic" plates, which would photograph the entire spectrum without difficulty, and such plates were placed on the market in 1906.

The early dyes were largely of the cyanine and isocyanine types. In **1920** W. H. Mills and F. M. Hamer found Pinacyanol to be a carbocyanine dye. After that time there was great activity in the study of sensitizing dyes, resulting in the present great variety which permit high sensitivity in all parts of the visible spectrum and out into the infra-red. Most of the new dyes were found after 1929 in England, Germany and the United States, and the most important types are modifications of the carbocyanines and the merocyanines.

The first panchromatic film was made by the Eastman Kodak company in **1914,** but it was not generally used for motion-picture work until 1925. In 1931 a new super-sensitive type of panchromatic film was introduced. The progress in sensitizing dyes made possible the great advance in colour photography since about 1930 and the introduction of plates and films of high speed and low graininess.

Film.—The weight and fragility of the glass support led to attempts to replace it by lighter and flexible substitutes. In **1884** the roll film system of photography was developed by George Eastman and W. H. Walker, the emulsion being coated on paper, and a machine for continuously coating photographic paper in long rolls was patented by them in **1884.** The sensitized paper was loaded into a roll holder which could be attached to the back of a camera in the same position as a plateholder. At first, the paper was greased to reduce the printing time, but later a stripping film was used, this consisting of a temporary paper base coated with soluble gelatin, which in turn was coated with a gelatin emulsion.

This stripping film was used in the first portable roll film camera, the No. 1 Kodak, marketed in **1888.** The pictures were circular, about two and one-half inches in diameter. When the film was used up, the camera was returned to the manufacturing company, which developed and printed the pictures and reloaded the camera. This was the origin of modern photofinishing.

Eastman made experiments to produce a flexible film from collodion, but the ether-alcohol solutions would give only films which were too thin to be of practical use. Finally, the use of wood alcohol as a solvent for nitrocellulose was discovered, and a flexible film was marketed in rolls in **1889.** In the same year J. Carbutt introduced emulsion coated on sheets of plastic nitrocellulose cut from blocks. The new flexible Eastman film was applied at once by Thomas A. Edison to making motion pictures.

In **1891** daylight loading film was made. The film was wound on a wooden core inside a light-tight box and black cloth leaders were attached to the ends of the film. Later, the film was wound inside a protective sheet of black paper leaving sufficient overlength to permit loading of the camera without fogging the sensitive film. This was further modified in 1903, when a noncurling film was produced by coating the back of the film with plain gelatin.

In **1895** positive film was introduced for printing motion pictures, the film used previously being of the negative variety. In 1909 slow burning motion-picture film was first made by the substitution of cellulose acetate for cellulose nitrate as the plastic used in the preparation of the base.

A method of packing films, invented in 1903, was introduced on the market under the name of "film packs." These are now used mostly in cameras of the type originally designed for dry plates. They have the advantage of not requiring a special roll film back. Flat sheet films have taken the place of plates to a considerable extent, especially in professional photography.

In 1917 X-ray films coated on both sides with emulsion were introduced. Because of the transparency of the material to the X-rays, this enables double the density to be obtained.

In 1923 motion-picture film **16** mm. wide on cellulose acetate base was introduced packed in such a manner that it could be loaded into small motion-picture cameras without the use of a darkroom. This film was designed for finishing by a reversal process, in which the first negative is removed by a bleaching bath and a positive is then developed in the remaining silver bromide. In 1932 a similar film **8** mm. wide was introduced.

The use of these films led to a great advance in amateur cinematography.

Developing Agents.—In the calotype process gallic acid was used as the developer, but in 1851 H. V. Regnault of Paris and Justus Liebig simultaneously discovered the more energetic pyrogallol, which actually allowed shorter exposures to be given. This was used also at first for wet collodion, though it was later replaced by an iron salt, and for dry collodion plates. Until **1861** free silver nitrate was an important ingredient of developers; but in that year G. Wardley proved that pyrogallol alone could be used. C. Russell and J. Leahy independently announced alkaline pyrogallol development, the former suggesting also an alkaline bromide as restrainer. Even after the introduction of the gelatin plate, pyro-ammonia was the only developer used until **1884,** when the alkaline carbonates became general. In 1880 Abney discovered the developing properties of hydroquinone. C. Egli and Arnold Spiller recommended the use of hydroxylamine in 1884. In **1888** M. Andresen of Berlin patented the use of paraphenylene diamine, paratoluidine diamine and xylidene diamine as developers. In **1891** he patented the use of paraminophenol and its derivatives, especially monomethyl-paraminophenol, known under the trade name of metol.

Printing Processes.—The first printing process was with silver chloride and excess of silver nitrate on plain paper, which gave prints with a rather sunken appearance, the image being more or less buried in the fibres of the paper, and daylight was essential for printing. Louis-Désiré Blanquart-Evrard, in **1847,** suggested the use of albumen to keep the sensitive salt more on the surface. In the same year Romieu proposed salting with a mixture of alkaline bromides and chlorides containing gelatin and subsequent floating on silver nitrate solution. A few years later the first coat of albumen was coagulated and a second applied, which gave a more brilliant glossy surface. The colour of prints obtained on these papers was foxy, and to darken this an acid was added to the fixing bath, causing sulphur toning. G. Le Gray, in **1850,** proposed the use of a gold salt to improve the colour, and an alkaline gold bath was recommended by Waterhouse in 1858. E. De Caranza, 1856, recommended the use of platinum in lieu of gold. Albumenized paper made in this way and toned with gold remained the standard photographic printing medium until 1890.

A. Gaudin had suggested an emulsion of silver chloride in collodion for printing-out. This was revived by Wharton Simpson in **1865.** Paper thus prepared was introduced commercially by J. B. Obernetter three years later. Humbert de Molard, 185**j,** proposed to precipitate silver chloride, wash and suspend it in solution of starch or gelatin and paint the mixture onto paper. The same process was revived by W. H. Smith and J. E. Palmer in **1865** and by Abney in **1882.** From that date gelatinochloride or printing-out paper came into general use and eventually completely displaced albumen. Printing-out papers are little used now except for proofs.

Silver bromide with excess silver nitrate was used by Fox Talbot, and J. W. Swan in **1879** patented the use of paper coated with silver bromide emulsion not containing excess silver for

development. It did not, however, come into general use until marketed by Eastman and by E. Just in *1883.* J. M. Eder and G. Pizzighelli published, *1881,* an exhaustive paper on gelatinochloride of silver with development, and the former, two years later, described a chlorobromide emulsion. Chloride developing paper was introduced by A. Marion in England under the name of Alpha in 1889, and by Leo Baekeland in America as Velox. Since then the use of this paper has increased, special types, including a great variety of surfaces, being used for amateur and professional work. Modern papers are of the chloride type for contact printing, and of the bromide and chlorobromide types mainly for enlargements.

Nonsilver Printing Processes. — Robert Hunt was the first to utilize the light-sensitiveness of ferric oxalate in combination with a platinum salt in the hopes of obtaining images in that metal. But the process was a failure because he did not recognize that the ferrous salt, formed by the action of light, must form a complex salt in order to reduce the platinum salt to the metallic state. W. Willis in *1878* introduced the first workable platinum process. The advantage of this process is that the pictures are permanent. The high cost of platinum and the ease with which development papers are worked has resulted in disuse of the process.

Louis Vauquelin in *1798* had discovered the light-sensitiveness of silver chromate; G. I. Suckow in *1832* observed that the bichromates were reduced by light in the presence of organic matter. Mungo Ponton, *1839,* used paper treated with potassium bichromate. Edmond Becquerel, *1840,* and R. Hunt, *1843,* made improvements; but Fox Talbot first pointed out, 1852, that bichromated gelatin became insoluble in light, and this was patented as a resist for photogravure, for which it is still used.

P. Pretsch, Alphonse Poitevin, Testud de Beauregard, H. Garnier and A. Salmon and John Pouncy, *1859,* devised carbon processes, in which carbon itself in a finely divided state was used as the pigment in bichromated gelatin. But they failed to recognize the important point that, as the light acted first on the outer surface of the gelatin, those parts underlying the half tones and high lights would still be soluble; hence, on developing with warm water, they would have no anchorage to the support and would be washed away. J. W. Swan in *1864* patented the production of carbon or pigment prints by transfer of the exposed pigmented tissue to a temporary support, on which it was developed from the back. His process is in use today, and its long scale of gradation, the possibility of using pigments of any colour and the stability of the pictures are much in its favour, though the necessity of day- or arc-light for printing is against it.

T. Manly, 1905, patented a pigment process in which a developed silver print was squeegeed into contact with pigmented tissue saturated with potassium ferricyanide and bichromate. These salts migrated to the silver image, bleached it, and the reduction products wandered back to the tissue, rendering it insoluble in ratio to the amount of silver in the picture, as though the tissue had been exposed to light under the negative. A modification of this, known as Carbro, was introduced later.

In 1905 G. E. Rawlins reverted to an old process suggested by E. Mariot in *1866.* Gelatinized paper is sensitized with bichromate. dried, exposed under a negative, freed from excess salt and inked up with a greasy ink, which adheres only to the light-affected parts. Somewhat similar is the bromoil process first suggested in 1907 by E. J. Wall and worked out by Welborne Piper. This utilizes the principle stated by Howard Farmer in *1889* that finely divided silver imbedded in gelatin reacts with bichromates and renders the contiguous colloid insoluble. A bromide print is treated with a hardening and bleaching solution, fixed, washed and dried, then soaked in water and inked up with a greasy ink, which takes only on those parts where there was silver.

A number of printing processes have depended upon the light sensitivity of salts of iron. The most used is the blueprint process for copying drawings, introduced by Herschel in *1842.* Paper is sensitized with a mixture of potassium ferricyanide and ferric ammonium citrate. On exposure to light the latter is changed to the ferrous compound which, on wetting the paper, combines with the ferricyanide to form Prussian Blue. In the ferrogallic process the exposed iron salts are developed in gallic acid to give a positive image in dark ink. The ferrous salts formed by exposure to light of ferric compounds can reduce other metal salts to the metal. Platinotype depends essentially on this reaction, but in the argentotype (Herschel, *1842)* and kallitype *(1889)* and the more recent Vandyke processes, a silver image is formed by reduction of silver nitrate by the ferrous salt. In the ferrogelatin process (A. Tellkampf and *A.* Traube, 1905; also known as fotol, Ordoverax, fulgar) an unwashed blueprint is squeegeed in contact with a moist gelatin surface, then removed and the surface rolled up with greasy ink which gives a positive image which can be transferred to paper.

Light-sensitive organic compounds have formed the basis of many printing processes, the most used being the diazotype process for copying drawings (G. Kogel, 1917, *1920).* In it, paper is coated with diazo compounds which are destroyed on exposure to light, development being with a "coupler" which combines with the diazo compound not exposed to form a dye.

(C. E. K. M.: W. Cк.)

THE BRANCHES OF PHOTOGRAPHY

Amateur Photography. — In the 19th century, amateur photographers were responsible for many of the major advances, particularly in the days when the photographer had to make his own materials. Nowadays, however, the making of photographic materials is in the hands of manufacturers who can supply ready-to-use products in large quantities and of uniform quality. The amateur is now essentially a user and his opportunities for making basic advances are limited. He can and does, however, contribute much to advance practical techniques and pictorial qualities. The amateurs range from the millions who want personal photographic records with the minimum of effort, skill and expense, to the group to whom photography is an extremely serious matter, and who will spare no pains to achieve the technical quality and aesthetic effect they personally desire. (See *Pictorial Photography.)*

In general, however, photography did not become a popular amateur interest until the roll film camera was introduced in *1888.* It then became the means by which uninstructed amateurs could record scenes from their o n experience easily and faithfully. The first such cameras, to which George Eastman gave the name of Kodak, were preloaded at the factory with a roll of film sufficient for 100 pictures, each of which was round in shape and about 24 in. in diameter. After the roll was exposed. the loaded camera was returned to the factory, where the film was developed. With contact prints from all printable negatives and with a fresh loading of film, the camera was then returned to its owner.

The mass production of negatives and prints which this procedure involved constituted the beginning of the business of photofinishing, which was later developed by independent concerns all over the world. Some of the largest of these do immense volumes of work on a mail-order basis.

Almost from the start, amateur photography became extremely popular. Picturemaking came within the grasp and capacity of practically everyone. The necessary financial outlay was small, and the production of satisfactory pictures of personal interest required neither great skill nor intensive training. Before long, of course, strata developed within the great mass of camera users. Because of personal aptitude, perception and persistence, some individuals and groups took up photography in a serious way. They preferred to control the processes of development and printing; thus was formed the beginnings of the great body of advanced amateurs to whom photography is a consuming interest and an intense avocation.

Cameras and general photographic equipment for the amateur have evolved rapidly since the turn of the century. The simple, fixed-focus, fixed-exposure, roll film camera of the "box" type appeared in 1900. Thereafter, the box camera maintained its great popularity and has changed very little. It is basic; any attempt to equip it with faster shutters, faster lenses or adjustments of any complexity whatever have tended to cancel its fundamental usefulness and appeal. Various box-camera formats

have appeared, but the most popular is that which permits eight $2\frac{1}{4}$x$3\frac{1}{4}$-in. images per roll of film. Box cameras are made in metal, fibreboard and plastics. The lenses, of simple meniscus formulae, are generally about *f*/13 in relative aperture.

While the box camera remains an amateur photographic staple instrument, many other types of cameras have developed out of it. There are folding or snap-out cameras which afford box-camera simplicity of operation, yet attain greater compactness when not in use. Folding cameras are available in many varieties, some of which incorporate wide-aperture anastigmat lenses, shutters which can be adjusted for exposure ranging from "Time" to 1/500 sec. plus means for synchronization with flash lighting, accurate range finders and focusing adjustments and a host of small features of greater or lesser importance to suit the interests of the individual amateurs.

In the 1920s, the miniature camera appeared. Originally designed as a means of testing 35-mm. film made for professional motion-picture photography. the miniature camera soon assumed importance as a means of making small but excellent "still" negatives. Considerable precision was necessary to produce a clean, sharp, enlargeable image on an area about 1x1½ in. in size; this precision was implicit in the lens, in the adjustments for focusing, for exposure and for film movement. Lenses for the miniature camera were, as a rule, considerably faster than lenses for larger cameras; lens ratings of *f*/1.9, *f*/2 and *f*/3.5 are common among miniature cameras, whereas larger cameras are seldom equipped with lenses rated at faster than *f*/4.5.

Its fast lenses, highly sensitive films and inconspicuous size threatened, for a time, to characterize the miniature as primarily a candid camera, but it survived this threat as serious-minded amateurs appreciated the wide capability of miniature equipment. These amateurs soon constituted a large and influential group. They organized themselves, forming enthusiastic and articulate units. They required, and ultimately received, improved equipment of all kinds—finer cameras, specialized lenses and films, processing tanks and enlargers capable of producing clear and crisp enlargements of 10 or 20 diameter magnification.

In the late 1930s, reversal colour film became available. Again, as at the start of amateur photography, the processing was done by the film manufacturer, and without added cost. The colour transparencies thus made were mounted as 2x2-in. slides for projection, and many optical projectors were made available for use with them. They were also used for making several varieties of colour prints, some of which could be produced by the amateurs themselves.

Techniques developed for the miniature enthusiasts were ultimately reflected in refinements of equipment and processes for conventional-format photography. Mechanical and optical precision of high degree became characteristic of larger as well as smaller cameras. Films that once were primarily for the miniature cameras were made available in larger sizes; and fine-grain developers, often necessary in miniature work, came into general use.

Essential to the maintenance of photography as a popular amateur activity is the easy availability of film, and amateur roll film in standard sizes can be found in thousands of general merchandise shops as well as in those primarily concerned with photographic and optical goods.

Film for the box camera usually permits 8 or 12 exposures and is provided in a variety of types. For general outdoor pictures there is orthochromatic film; for work by artificial or low-level light there are fast panchromatic films; for pictures destined for considerable enlargement there are fine-grain films and there are negative and reversal colour films from which colour prints can be obtained.

While roll film is by far the most commonly used sensitive material among amateurs, many serious workers prefer sheet film (for which special film holders must be used) or film packs. Most of the types of film which are put up in rolls are also provided in sheets or packs, with a number of special types available in sheet film for the specialized requirements of many amateurs as well as professionals. Colour films are made in sheet and roll form.

The great majority of amateurs have their finishing (developing and printing) done for them by commercial photofinishers. Prints by contact are made on the so-called contact printing papers on special printers, while enlargements are made on bromide paper, in a variety of equipment.

For the amateurs who do their o n developing and printing, there is a wide range of simple and inexpensive apparatus; and chemicals are put up in packaged form to eliminate the need for measuring out quantities. Papers are provided in a great variety of surface and contrast either for enlarging or contact printing.

With the introduction of the sensitive panchromatic films, especially following 1931, it became possible for the amateur to take photographs indoors with simple artificial lighting equipment. This was aided considerably by the introduction of the overvolted Photoflood types of lamps and simple stands and reflectors, and later by the flash bulbs and synchronizers which could be attached to amateur cameras. Nowadays many amateur cameras are provided with flash attachments or at least with special shutters having electrical contacts which permit their use with flash bulbs. Colour films are made to give good quality photographs with artificial lighting. (See *Apparatus.*)

Estimates of the number of amateur cameras in more or less active use at any given time cannot be accurate; obviously they run into many millions.

However, the steady increase in the number of camera clubs and public participation in them, colour transparency clubs, exhibitions and salons is ample evidence of a great and increasing interest in photography as a hobby, as an avocation and as a means of recording individual and family histories.

Professional Photography. — From the era of the daguerreotypes—the 1840s and early 1850s—down through the collodion and dry plate eras to the first or second decade of the 20th century, the professional photographer mas almost invariably a portrait photographer. Indeed, photography was popularly accepted as primarily a means to personal portraits.

This was, in part, because of the rise of the bourgeoisie and the eager assumption—on a cheapened or mechanized basis—of those things which had formerly been limited to the aristocracy. Before photography, few but the wealthy could afford to have a good portrait made.

The photographic portrait establishments attempted to maintain something of the grand style. Furnishings and decoration were lavish, and the backgrounds against which patrons were posed were elaborate counterfeits of grandeur.

Because the common use of electricity came only in the 20th century, most early portrait studios used daylight, provided by large banks of windows facing north, or away from direct rays of the sun. By the ingenious use of reflectors, diffuse light was used with considerable effect, but the intensity was relatively low. This fact, coupled with the slowness of the photographic plates then available, necessitated long exposures. To assure the rigidity of the sitter during exposure a head clamp was commonly used; such a device tended inevitably also to induce rigid facial expressions. However, because naturalness and informality were almost foreign to the manners of the late 19th century, portrait photographers flourished and few respectable homes were without their albums in which portraits of the caste de *visite* size (2x3 in.) were elaborately presented, along with some of the larger "Cabinet" size (about 3x5 in.). By the 1860s, portrait photography had become so popular that cameras taking several portraits on one plate were used in order to speed up taking and developing.

In the United States particularly, the vogue of portrait photography was immense. "Artists of the lens" were established in every town, and itinerant portrait photographers toured the fringes of the frontier. The camera was invariably a bulky mechanism mounted on a heavy stand which was sometimes carved to comply with the standards of contemporary elegance. From beneath a black focusing cloth, at the back of the camera, the photographer watched the ground glass image of his sitter, suggesting, cajoling, pleading for a pleasant expression.

Early in the 20th century, public taste turned from the formality and the artificiality of conventional portraiture. Thanks to

the constant improvement in plates and to the growing use of artificial light. it became possible to make studio portraits with the sitter far more nearly at ease. Exposures were shortened. the head clamp disappeared and the rococo motif in furnishings and backgrounds gave way to simplicity, with all the interest falling on the sitter.

Modern professional portraiture is done almost exclusively on sheet film of the orthochromatic or panchromatic variety, one or the other being used according to the nature of the sitter. The negative sizes tend to be smaller than in earlier years, and modern types of long focus lens and modern shutters are used. The lighting is almost exclusively artificial, largely by tungsten filament electric lamps in special reflectors or as spotlights. Some fluorescent lighting is used for general lighting, and there is a growing use of the flash bulb.

Proofs of portraits are usually provided the sitter, and they are made on print-out paper or special slow types of enlarging paper. Contact and enlarging papers are made for portraits, frequently giving somewhat warmer tones.

Mass production methods have been introduced into portraiture, especially in automatic or semiautomatic "studios," and in coin-operated machines. The best portrait quality is, however, attained by the photographers who undertake each appointment seriously and carefully apply their time and skill to making good studies of the subjects. In recent years, colour photography has been introduced into portraiture.

Commercial Photography. — Photography is used very widely for commercial illustration and advertising, for technical illustration and for a wide variety of special purposes. When the photographs are made by professional photographers on a commercial basis, the subject is called commercial photography and it is a very important branch of photography. The photographers are usually highly skilled in the art of lighting and the use of special techniques, particularly as advertising agencies demand much in the way of unusual subjects and dramatic effects. There is some tendency to specialization in commercial photography, one man doing primarily fashion photography with live models, another still photography of food subjects, another sporting events and so on.

The apparatus of the commercial photographer is varied and flexible, to suit the wide range of subject matter. The studios are arranged so that all kinds of sets can be constructed, and many of the photographers are equipped with portable lighting equipment, even portable generators, so that they can make photographs on location.

Sheet film is generally used, but some photographers use roll film in miniature or twin lens reflex cameras. The prints are generally of such a quality that they can be used for reproduction by the graphic arts processes.

Colour photography is much used by commercial photographers. For still subjects, colour separation negatives may be made in succession through three separate filters, or in three-colour, one-exposure cameras, where the three negatives are exposed simultaneously. Living subjects are also photographed in these cameras. The integral tripack or monopack sheet colour films came rapidly into use for all work. (See *Colour Photography.*)

(W. B. BT.)

Press Photography. — Wood engravings were the earliest practical means of disseminating picture news. Economical to produce in comparison with engravings on copper, steel etchings, etc., the wood engraving could also be printed with type matter—a decided advantage. They are found in the ancient ballad sheets and broadsides, which, like the modern newspaper, had their origins in "tragedy and violence." National calamities, floods, storms and significant battles brought forth illustrated tracts and, with the beginning of regular newspapers, crude wood engravings for the press.

The modern illustrated press can trace its origin to the year 1842 and the founding of the *Illustrated London News*. The Mexican, Civil and border wars stimulated magazine and newspaper illustration in the United States. F. Gleason's *Pictorial Drawing-Room Companion,* patterned after the *Illustrated London News,* was established in Boston, Mass., in 1851, and lasted until 1859. P. T. Barnum and H. D. Beach started the *New York Illustrated News* Jan. 1, 1853, and sold it to Gleason a year later. Some of the most notable work produced in the United States during that period is to be found in *Frank Leslie's Illustrated Newspaper* and in *Harper's Weekly*. Leslie's publication began Dec. 1 j, 1855, and *Harper's Weekly* Jan. *3,* 1857.

Although the camera came into commercial use on both sides of the Atlantic about 1840, it received little recognition by the press until a number of years later. In spite of his great photographic coverage of the American Civil War, Mathew Brady was credited with but few of the pictures which appeared in the illustrated publications of his day, although his photographs must have served as "copy" for many illustrations. *Harper's, Leslie's* and the *Southern Illustrated* (published in Richmond, Va.) all had their sketch artists, among them Al Waud and Winslow Homer. Sketches drawn in the field were redrawn on wood blocks and carved by hand. Even with the advent of "photography on wood," which preserved the original work of the artist, the process was slow when judged by later standards. Line cuts, zincographs and chalk plates had been used before 1900, but few halftones — which would reproduce the tonal range of a photograph — had appeared.

The first halftone direct from nature, the now famous "Shantytown" reproduction credited to Stephen H. Horgan, appeared March 4, 1880, in the *New York Daily Graphic.* The halftone screen consisted of a set of parallel lines, rather than the cross-screen developed later by Frederic Eugene Ives and others and perfected by the Levy brothers.

The halftone process, although not in universal use at the time, did help to give visual reportage to the Spanish-American War. Jimmy Hare, for *Colliers Weekly,* and J. C. Hemment, for William Randolph Hearst, were among the combat photographers in 1898.

Sketch artists (among them Frederic Remington) also served in Cuba.

Although photo reportage was greatly stimulated by the Spanish-American War, it unfortunately was typed as a tool of the "yellow press." Conservative publishers looked upon it as an interloper —a sensational device used by Joseph Pulitzer and Hearst in their circulation war.

The reputation of press photography was further damaged in the 1920s when the *Daily Graphic, Daily Mirror* and *Daily News* staged a three-way battle for readership in New York. playing up the Hall-Mills and Snyder-Gray murder cases, the "Daddy" Browning-"Peaches" episode. etc. It brought forth use of the "composograph," a form of photographic fakery.

Another, but less violent, period came in the 1930s with the advent in the United States of the miniature camera and the candid camera craze. In the hands of such men as Eric Salomon, the miniature was a sensitive and valuable instrument. Many, however, imbued with the new power which the fast lens imparted, went beyond good taste in the snatching of unposed and unflattering pictures.

World War I was a stimulant to the illustrated press. With an increased interest in foreign lands, the reading public wanted to see pictures of the battlefields and armies in action. Thanks to more versatile and less cumbersome photographic equipment, improved lenses and sensitive material, the best photo documentation to date was possible. Visual education — movies and pictures as a training device for soldiers — and photographic propaganda for soldier and civilian consumption came into prominence. The work of the combat photographer became more involved, however, as war techniques increased in complexity. Not able to operate without restrictions as he had done in the Spanish-American War and the Russo-Japanese conflict, the aging Jimmy Hare gave way to younger men.

Photo Syndicates. — With the realization that pictures are news came a general demand for news-picture syndicates. Bain's and the American Press had made previous attempts at syndicated picture coverage and were followed in the 1920s by the *New York Times* Wide World, Hearst's International News Photos and Scripps Howard's Ne spaper Enterprise association (later Acme;

Acme Newspictures was sold Jan. 1, 1952, to the United Press), the Pacific and Atlantic (P and A), owned by the *Chicago Tribune* and the *New York Daily News*.

The Associated Press began its picture service in 1926. On Jan. 1, 1935, the Associated Press Wirephoto 10,000-mi. network was inaugurated. All major syndicates acquired photo networks.

The syndicates, in addition to radio and mire transmission, dispatch photographic prints and mats made from master engravings to publications not equipped to handle telephoto, wirephoto, etc. Larger papers utilize the mat services, too, for feature pictures and "time" copy, keeping the faster wire network for more urgent news breaks.

Pictures naturally fall into various classifications: spot news, feature, sports, picture stories (picture sets and picture sequences) and colour. Newspaper staff photographers provide the greatest number, with syndicates coming second.

Free-lance workers, or "stringers," also shoot a considerable number. on assignment and on speculation.

Other sources of pictures in the news include studios, amateurs and publicity bureaus. Local and national government bureaus and industrial organizations spend huge sums each year for pictures nhich are sent gratuitously to publishers.

Magazines in the decade 1920–30 greatly influenced newspaper illustrative trends. In Europe, and especially in Germany, a new publishing technique—the picture weekly with fast miniature camera illustrations—had come into being.

The picture publications, offspring of the new streamlined journalism which followed World War I and advancements in photography, were popular from the start.

Later, with the rise of Adolf Hitler, many German picture specialists went to England and the United States, where their influence was profound. *Picture Post*, London, one of the most successful of British picture magazines, was a result of this exodus. Among those from Europe who exerted a great influence in photojournalism in the United States were Kurt Safranski, Eric Salomon, Alfred Eisenstaedt, Eric Schaal and others.

Significant developments in U.S. photojournalism were: sale of the first flash bulb in the U.S. (1930); invention of the electronic light (1931); establishment of the AP Wirephoto network (1935); establishment of *Life* magazine (1936) and *Look* magazine (1937). Even before *Life*, the Cowles brothers had carried on extensive surveys in picture usage. The *Des Moines Register-Tribune* and other Cowles publications were pioneers in photojournalism. Many examples of photojournalism had appeared before *Life*—*the New York Times Mid-Week Pictorial, Roto, Panorama* and others—but it was not until *Life* appeared that a U.S. magazine based on photo reportage became entirely successful. *Look*, in Jan. 1937, and a host of others such as *Click, Pic, Focus*, etc. quickly followed.

The *New York Times* established the first Sunday rotogravure supplement in the U.S. in 1914. By 1930 the number had reached 80, but it dropped to 65 in 1940. Only ten newspapers produced their own supplements. The others had the work done by commercial gravure plants.

The earlier rotogravure sections were poorly designed and from many points of view inadequate. Profiting from the picture magazines, rotogravure supplements eventually became functional, enlightening and inviting. With a balanced offering of black-and-white and colour reproductions the roto sections became in effect small picture magazines tuned to local and world happenings.

Many editors considered the large picture magazines their strongest competition. This belief undoubtedly influenced the great circulation of such "inserts" as *Parade* and *This Week*.

Opposition to the newspicture weeklies helped bring about formation of the Metropolitan Group, the National Newspaper Network, an alliance of rotogravure papers throughout the nation. One of the purposes was to permit the group to bid on a more even footing for the services of top-flight free-lance cameramen—something they could not justifiably do as individual publications.

Sociological Aspects.—Photojournalists learned that pictures can document and report the happenings of the day. They also can and do editorialize.

"The backbone of photo-journalism," said Frank Luther Mott, "is 'the recording of fires, wrecks, tragedies." Yet, he adds: "The camera has a devastating effectiveness in portraying evils. It is the best crusader of our times. Think of any abuse—social, economic, political—and sound and honest pictures which will bring the evils to our eyes suggest themselves immediately."

Among the first to use pictures as an editorial influence was Jacob Riis, a great police reporter, who in 1888 used his camera to help bring about social reform in New York slum areas. Line drawings from his famous photographs appeared in newspapers, magazines and books *(How the Other Half Lives*, etc.). Lewis Hine's pictures of the Pennsylvania coal miners in the early 1900s, and his work which graphically portrayed the evils of child labour, became classics of their kind.

A later example was the work emanating from the Farm Security administration under the direction of Roy E. Stryker in the 1930s. Stryker's photographers—Walker Evans, Arnold Rothstein. Dorothy Lange, Russell W. Lee, Edward Rosskam and others (nucleus for the so-called documentary school)—photographed depression bread lines and the dust bowl with all their qualms and heartbreaks. Several FSA photographers as free-lancers or regular staff members were employed by the newly born photo publications. Their keen perception and austere style greatly influenced photojournalism.

Still other examples of "camera crusades" were those for slum clearance by the *St. Louis Post-Dispatch* (Mo.) and the campaigns against "Skid Row" in Detroit, Mich., and Chicago, Ill., by the Knight newspapers.

Press photography was advanced in the United States by the formation of two important organizations—the National Press Photographers association, founded at Atlantic City, N.J., in 1946, and the American Society of Magazine Photographers. Another factor contributing to the advancement of U.S. photojournalism was recognition by universities and accredited journalism schools, which introduced courses of training in the field. Regional short courses throughout the nation, such as those sponsored by the National Press Photographers association and the *Encyclopædia Britannica*, and the annual Photo Workshop conducted by the University of Missouri school of journalism also aided. Yearly photo competitions were also credited with furthering the cause of photojournalism.

World War II and After.—Wars and rumours of wars had long acted as stimulants to the publishing industry. Between World Wars I and II, photojournalism had gained in favour, and many significant developments had been made. The photo news magazines were accepted, flash bulbs and electronic tubes were invented. colour work had improved, wire and radio transmission of photographs became commonplace.

The reading public had learned to rely to a great extent upon visual presentation of the news. It was during this period that the picture magazines attained huge circulation figures, and the *Daily News*, "New York's Picture Newspaper," founded in 1919, became the largest daily in the country.

When World War II broke out, the stage was set for the greatest use of photojournalism the world had known. Press syndicates, newsreel companies, magazines and newspapers promised a coverage which would have been impossible at any previous date.

To assure an equitable photographic coverage of the far-flung battle fronts of World War II the U.S. photographic pool was organized in 1942. Principal participants in this enterprise were the Associated Press, Acme Newspictures, International News Photos, *Life* and the U.S. army and navy.

The combat photographer, whether a member of the pool or of the Allied services, served with distinction. Longer focal length lenses, high-speed equipment, sequence cameras and many other developments made it possible to photograph the war in all its phases.

At the war's end, many publications which had ceased to exist because of the manpower and material shortage were reactivated. During the postwar period a number of small daily and weekly publications installed photographic and photoengraving equipment. Some turned to the photoelectric engraver, while still

others installed photo-offset (lithography). (C. C. E.)

SCIENTIFIC AND APPLIED PHOTOGRAPHY

The advantages of photography for scientific and technical recording are that it can record visible images in black-and-white or colour; it can record radiations which are of wave length invisible to the eye; it can integrate faint radiation and build up a record which can be seen, whereas the eye does not possess this property; it can be used to measure the intensity of radiation and it can give glimpses of actions which are too fast to be studied in detail by the eye. Moreover, it gives a reasonably permanent record which can be studied at leisure, or filed for future reference.

Photomicrography. — Photography through the microscope is very important in biology, metallography and petrography. Apparatus for photomicrography consists essentially of a camera arranged at the eyepiece end of the microscope so that the image is focused on a film or plate. Photomicrographs are made by transmitted or reflected light. Low-power photomicrographs can be made with single short-focus lenses, while for the highest magnifications high-aperture objectives and high-magnification eyepieces are employed. Special supports are used for the apparatus, to ensure freedom from vibration and ease of centring the optical system.

In the case of stained specimens, such as biological sections or bacteria, maximum contrast is obtained in the photograph by using light filters which transmit light of the colour complimentary to that of the stain. If maximum detail rendering is required, the filter is selected to transmit light of the colour of the stain. The resolving power of a lens is higher, the shorter the wave length; and, therefore, the ultra-violet is frequently used to give the maximum rendering of detail. The infra-red is sometimes used because certain materials which are dense or opaque to visible light are transparent to the infra-red. Polarized light is frequently used in the photomicrography of rock sections and etched metal specimens. Colour photography is also important, especially when used in metallography, polarized light photomicrography and photography of stained sections. Many high-magnification motion pictures have been made by using a motion-picture camera in conjunction with the microscope.

Spectrography.—The bulk of spectroscopic observation is done by attaching a camera to the spectroscope and photographing the spectrum. The visual spectrum can be photographed on panchromatic materials. and the near ultra-violet on ordinary blue sensitive plates or films. For wave lengths shorter than 2,800A the absorption by the gelatin of the emulsion is too strong to permit photographs to be made, and in this region spectrography is done by coating the normal plate with a thin layer of material which fluoresces in the short wave length ultra-violet, the fluorescent light being used to make the photograph. In the Schumann method the emulsion has practically all of its gelatin removed. For the infra-red, emulsions containing special infra-red sensitizing dyes are used and photographic records have been obtained to beyond 12,000A. Plates are available having especially high sensitivity in rather narrow wave-length bands spaced all through the visible and near infra-red.

In spectrographic analysis, photographs of spectra are used to detect the presence of elements and to obtain an estimate of the proportions in which they are present. The analyses, qualitative and quantitative, are based upon measurements of the positions and relative intensities of the spectral lines. The method is particularly useful for identifying materials and for determining very small percentages which might be missed entirely or measured inaccurately by the normal chemical methods.

The spectrograph has been particularly useful in astronomy since it provides the only means of determining the composition of the celestial bodies. (See *Astronomical Photography*, below.)

Infra-Red Photography. — Films and plates can be sensitized to the invisible near infra-red to permit photography in that region. The optical properties of many materials in the infra-red are quite different from those in the visible region of the spectrum. Atmospheric haze is more readily penetrated by the infra-red than visible light, which tends to be scattered, and infra-red photography thus permits haze penetration over long distances and from high altitudes. Chlorophyll is transparent to infra-red and foliage appears white in infra-red photographs. Many green paints which match foliage in colour absorb the infra-red strongly, and infra-red photography can therefore be used in camouflage detection. The skin is somewhat transparent to infra-red and infra-red photography is sometimes of value in medicine in showing the appearance of veins just beneath the skin. It is also of use in dermatology, ophthalmology and the photography of gross specimens and biological sections. Other applications include photography in total darkness, determination of temperature distribution at the surface of heated bodies, deciphering of altered documents, study of falsified or deteriorated works of art and of textiles, particularly where dark dyes interfere with visual examination, and many applications in botany, palaeontology, the graphic arts field and technology.

Ultra-Violet Photography. — Ultra-violet photography is used in the examination of altered documents, restorations of works of art, detection of invisible writing and fingerprints and other instances where advantage can be taken of the fluorescence of materials. There are two different methods of ultra-violet photography: (1) The reflected ultra-violet method which is analogous to ordinary photography except that a filter is used allowing only ultra-violet to reach the film; (2) the fluorescence method in which the subject is illuminated by ultra-violet and the camera is provided with a filter which absorbs ultra-violet and allows only the visible fluorescent light to reach the film.

High-Speed Photography. — Photographs made at high speed are very important in science and technology, because they record a phase of a fast event, or photograph a rapid sequence of events which can be slowed down for study. It is necessary to use a very bright light and very short exposure times so that sharp records can be obtained.

The first high-speed photograph was taken by Fox Talbot, using a spark from a Leyden jar. In 1882 and following years, Eadweard Muybridge published photographs of moving animals, successive exposures of short duration being obtained in 24 cameras. E. J. Marey, in 1882, perfected a "photographic rifle" in which 12 photographs were taken in 1 sec. on a revolving plate. This was called chronophotography, and in 1890 he devised the photochronograph, using film. Similar experiments were made by O. Anschiitz in the 1880s.

The earliest photographs of projectiles in flight were attempted about the middle of the 19th century at Woolwich arsenal in England, by Marey in Paris and by Anschiitz in Germany. A cannonball in flight was photographed at Woolwich in 1866, but the best ballistic pictures were obtained after 1884, when E. Mach, in Prague, introduced the electric spark as light source. The spark was released by allowing the projectile to cut a wire. L. Bull, Marey's successor in Paris, applied Mach's principle in such a way that he obtained a rate of 2,000 pictures per second. In 1909 C. Cranz made a ballistic cinematograph giving exposures at time intervals of one five-thousandth of a second, for a total time of one-tenth of a second.

Among the early studies of extremely high-speed photography are the photographs of ripples by J. H. Vincent, of splashes by A. M. Worthington, the shadow photography of bullets in flight by C. V. Boys, the analysis of the propagation of flame by Mallard and Henry le Châtelier and T. E. Stanton's studies of the pressure of gases ejected from nozzles. P. P. Quayle later made improved studies of the flight of projectiles and R. W. Wood of sound waves, outlines of which had accompanied the ballistic pictures of Boys. With a high-speed camera devised by W. Heape and H. B. Grylls, and taking 10,000 pictures a second, studies were made of the penetration of shells into hardened steel targets. Other cameras designed by C. F. Jenkins and Baron Shiba, and the Eastman Kodak and the Bell Telephone laboratories, have yielded results of much value in the study of high-speed phenomena. During World War II, high-speed photography was very much developed and applied to a wide range of studies of military interest.

The modern methods of high-speed photography may be

broadly classed as follows:

A. Single, Instantaneous *Photographs.*—(1) Steady illumination and short shutter exposure: the best mechanical shutter will not permit of shorter exposures than about one-thousandth of a second.

(2) Light flash of short duration, (a) shadow or silhouette, (b) reflected light, (c) stroboscopic.

(a) In shadow photography, used for objects moving as fast as bullets, the shadow of the object may be cast directly on the film or plate. An electric spark is generally the source, since it is bright, of short duration and small, so permitting sharp shadows on a film at a fair distance from the spark, if the subject is near the film. Exposures of the order of one-millionth of a second may be obtained. Alternatively, a condenser may be used between the spark and the object, the photograph being made in a camera with a lens. A development of this is the Schlieren method, originally by Jean Foucault and applied by August Toepler, which depends on slight differences of refractive index in the air, or inhomogeneities in glass and other transparent solids. It will show sound waves accompanying the flight of projectiles, convection streams from heated bodies, vortex rings formed in warm air or vapours of different densities.

(b) In the reflected light method, the source is a spark or preferably a lamp of the type of the Edgerton gaseous discharge lamp, the latter with its large area source being preferred from the point of illumination. A camera is used, as in normal photography. This method requires more energy and longer exposure time than the shadow method, but exposures as short as 1/50,000 sec. can be attained, which is satisfactory for practically everything other than ballistics photography (See BALLISTICS).

(c) In the stroboscope, a series of light flashes is made to agree with the speed of rotation of a steadily rotating object, so producing a stationary appearance of the object. This can be photographed in an ordinary still camera with long exposures if necessary to record the aspect of the object at any part of its cycle.

B. Series *Photographs.*—(1) Motion pictures: The normal slow-motion camera takes photographs at 64 frames per second, and some at 128 frames per second. These cameras have intermittent motion of the film. For higher speeds, up to 5,000 or more per second, the film moves continuously and there is compensation for image movement by some optical device, such as a rotating plane parallel glass block, or rings of lenses or prisms. If films made in this way are projected at normal speed, the movement is slowed down to the extent of the ratio of the taking to the projection speeds. The Eastman Type III High Speed camera and the Bell laboratories Fastex are examples.

(2) Series of photographs can be made of short duration and at closely successive intervals. In one method, developed particularly by Gjon Mili, successive photographs are made on one sheet of film by using a rapid series of flashes from a gaseous condenser discharge lamp, or from a series of flash bulbs. In the early studies of animal locomotion by Muybridge, 24 separate cameras, operated in rapid succession, were used.

(3) A special high-speed camera was developed by the Bell laboratories as the ribbon-frame camera, primarily to study the behaviour of rockets in the early part of their flight. The shutter consists of two concentric drums, the outer of which has five slots and the inner four. Both are rotated in the same direction, but the outer at 24 and the inner at 30 r.p.s. Glass plates are used to compensate for image movement, and the photograph appears as a series of narrow adjacent strips across the film.

(4) In some cases, as in explosions, the subject is self-luminous, moving fast and of short duration, and a rapid sequence of photographs of it permits a study of its development. Two methods were in use in 1947 for the study of flame in explosions. In one, short snapshots are made through a rapidly rotating shutter onto a stationary film or plate. If the flame is moving along a transparent tube, a series of such photographs in rapid succession shows the consecutive phases of its propagation. In the second method, the film or plate is moved. If the explosion occurs in a horizontal glass tube, and it is photographed by a lens on a plate falling vertically, or on a film wrapped about a rotating drum, an envelope showing the changing shape of the flame will be obtained, and its velocity can be calculated. In some cameras, rapidly rotating mirrors are used in the moving film camera to give what amounts to a series of separate snapshots, or the film is held still and a single rotating mirror is used. Exposures shorter than 1/50,000 sec. can be obtained in this way. Continuous trace photographs on continuously moving film were used in the study of the initial stages of the explosion of the atomic bombs.

Astronomical **Photography.**—(*See* PHOTOGRAPHY, CELESTIAL; SPECTROSCOPY, ASTRONOMICAL.) Visual observation in astronomy has been replaced almost entirely by photography through the telescope, because it has many advantages. By giving long exposures, stars may be photographed which are much fainter than those which can be seen. Many stars may be photographed simultaneously, so providing a record of relative positions which may be compared with records made later. Wave lengths not visible to the eye may be used in photography, and careful choice of wave-length band may reduce the limitations imposed on penetration into space by the luminosity of the earth's atmosphere. In order to photograph extended areas of the sky, lenses of the type used in normal photography are employed, or Schmidt lenses. In these, high apertures and short focal lengths are obtained by using a correcting plate in conjunction with a spherical mirror. The small-scale photographs so obtained are valuable for position measurements and surveys, and if the aperture is high enough, faint nebulae, the Milky Way and meteors may be recorded.

For photographing positions more precisely, or for separating close stars, objectives of longer focal length are used. They are either refractors or reflectors. Refractors suffer from chromatic aberration and are corrected to give their best focus in the green, and the best photographic focus is therefore obtained by using orthochromatic plates and yellow filters. Reflectors do not have this disadvantage. The fastest available photographic plates are used, and the lower definition given by plates of highest speed is not serious, since "seeing" limits the sharpness of image the telescope will give. The plates are made to have the minimum reciprocity failure for long exposure times.

In addition to direct photography, the other great branch of astronomical photography is spectrography. The chemical and physical constitution of the stars may be determined by the light they emit. Spectra may be recorded, simultaneously, of many stars by placing a prism or grating over the camera objective. Spectral types of many stars may thus be determined in a short time. For more detailed study, the image of the star produced by the telescope is directed to the slit of a spectrograph, and long exposures may be given.

The nearer planets are bright and exposures are relatively short, although really fixed by the short time of good seeing. Short focal-length telescopes give small bright images, and slow plates may be used. In long-focus telescopes the image is larger but less bright and fast plates must be used. Information about the atmospheres of the planets has been obtained by using plates of different colour sensitivities, relying on the different opacities of the atmospheres to different wave lengths.

Detail of the surface of the sun, the nearest star, is much studied. Direct photography records the positions and areas of sunspots, and the prominences and the corona during eclipses. In times when there is no eclipse, the corona can be photographed by means of the coronagraph. Much information about the sun is obtained from instruments which enable phptographs to be made with narrow wave-length bands, in particular the spectroheliograph (*q.v.*), which uses the red light of the Ha line of hydrogen, or the blue light of the H and K lines of calcium. Birefringent filters transmitting extremely narrow bands of radiation were in 1947 being developed for the same purpose. Motion pictures, speeding up motion, have been made of the moon and the planets, and are regularly made of the sun.

Great advances in astronomy are attributable to improvements in speed and colour sensitizing of photographic plates, and the improvement in fine grain, resolution and reciprocity failure characteristics.

Criminology.— Photography plays an important part in identification records, fingerprint photography, photographs in crimes of violence, automobile accidents, arson cases, burglaries and forgeries; ultra-violet and infra-red photography aid in detecting stains, invisible writing and alterations on documents; spectrographic analysis of traces of evidence, radiographic analysis and cinematography in recording criminal operations. Comparison photomicrographs are important in the examination of bullets.

Photoelastic Analysis.— A study may be made of the stresses in structures by making models of them in transparent plastics which are isotropic and have large optical stress coefficients. If a stressed model is photographed in polarized monochromatic light, a pattern of light and dark bands results, and from these the distribution of stress may be calculated. The method has been sucressfully applied to such things as test bars, hooks and chain links, structural foundations, bridge trusses, expansion joints, machine details and the action of cutting tools. (See **LIGHT**: Polarization and Electromagnetic Theory.)

Recording in Physical Measuring Instruments can be done by photography where an external spot of light is deflected, for instance, by a galvanometer mirror and falls on a dropping photographic plate or on a moving band of paper or film and records a trace of its path. There are many such devices, *e.g.*, oscillographs, electrocardiographs, seismographs, magnetometers, optical gas-engine indicators and other devices recording variations in pressure, electrical characteristics, optical transmission and reflectance, thickness variations and so forth. The most-used photographic recording of this type is sound recording, by variable density or variable width trace, on motion-picture film. A somewhat more difficult type of recording is photography of the trace on a cathode ray tube, particularly if it is in the form of a rapid transient which does not repeat, or if the image does not persist. Fast materials specially sensitized to the green or inherently fast to blue light are needed for this. During World War II, a special adaptation of this was to photograph the images on the tubes of radar equipment.

Photo-Layout. — Special photographic methods are available for transferring drawings to metal or other sheets for making templates, precision dials, scales and wiring diagrams, and for laying out designs on metal for the engineering, aircraft and shipbuilding industries. Bichromated colloids may be coated on the sheet and developed in the manner used in photomechanical reproduction, and the final lines darkened by ink or dye. A later variation of this, called Transfax, uses a sensitive colloid containing the pigment, but gives a direct positive image from a positive. In the strictly photographic method, the sheet on which the drawing is to be printed is sensitized by a silver halide emulsion applied by spraying, or by a stripping layer transferred from a temporary support. The drawings from which copies are made on the sensitized metal by contact printing can be prepared on sheet material coated with a white layer which fluoresces or phosphoresces in ultra-violet or under influence of X-rays. The glowing sheet on which the glow is obscured where there are opaque lines drawn, is used to print on the sensitized sheet. Alternately, the fluorescent layer may be overcoated by a photographically opaque layer through which the drawing is scribed, exposing the lines in white fluorescent pigment which can be excited and printed. Copies can also be made by reflex copying to give negatives for contact printing, or in a camera to give reduced negatives which can be printed by enlargement onto the sensitized sheet.

Underwater Photography. — Photographs can be taken of underwater objects such as swimmers and divers, fish, the bottom of the sea, ship's bottoms and the corrosion of structures. Water absorbs red and blue light strongly, and the dominant colour is blue-green. At depths to 15–20 ft., pictures can be taken with reasonable exposures, using the light penetrating from outside. At greater depths, special lighting equipment has to be lowered into the water. Strong lights are required, particularly for study of the behaviour of fast missiles dropped into water, or launched under it. Special cameras in water- and pressure-proof cases have been designed for still and motion-picture photography, with flat glass pressure plates in front of the lens. Some attempts have been made to design lenses which can be used with the front surface in contact with the water. There are few special problems involved in photographing underwater from outside through windows, provided the water is clear, the light intensity is adequate and proper account is taken of reflections and refractions. Surface reflections must be avoided by shielding. Colour photographs will tend to appear blue-green, but compensation at moderate depths may be achieved with daylight-type film with the appropriate colour-correcting filter. During World War II, black-and-white and colour photographs were obtained from aircraft to permit depth of water determinations off enemy coast lines.

Medical Photography. — Among the most important applications of photography in medicine are radiography and photomicrography, ahich are dealt with as special subdivisions of photography. There are many other uses. It has largely replaced drawings and diagrams in publications and lectures. In the form of the motion picture it is important in surgery for recording and teaching. In still photography its scope has three main aspects, *i.e.*, photography of the living person, photography of surgical operations or methods of treatment and photography of pathological specimens. Special lighting techniques may be necessary in some cases, but in general the technique is that which would be used in good ordinary photography, but under the supervision of the medical expert. Colour photography is of increasing value. Special techniques used include infra-red and ultra-violet photography, use of special equipment for photographing the eye and studying body cavities by endoscopic photography in which pictures can be made of the interior of the stomach, larynx, bladder, thorax and nearly all other body cavities.

Some special instruments, such as the electrocardiograph, which record minute electrical charges generated in the body, use rolls of photographic paper or film for recording the galvanometer traces.

Photography of Documents. — The copying of documents by photography has assumed great importance. There are two main aspects. In one, copies of printed material and notes for research, musical scores and parts, drawings, letters, business records, insurance policies and such are made on paper at the same size as the original, or only slightly reduced. They may appear as positives, dark on a light ground, or as negatives, in light copy on a dark ground. In the other group, copies of the documents are made on film, usually of 16-mm. or 35-mm. motion-picture type. They are stored in this form to save storage space by substituting films for paper, to safeguard valuable records by having a copy of them stored away from the original, to record transient documents which might be destroyed and of which a record might be required, to facilitate shipment of copies of documents to other places and to provide duplicates of files and indexes for libraries. They can be preserved as negatives or positives, and prints on paper can be prepared from them if required.

Copies of the first type can be made by contact printing through onto sensitized photographic paper, if the original is printed only on one side, to give a negative from which further prints can be made, or if a single print is required, a negative in which the type is not reversed, by putting the support of the material to be copied in contact with the emulsion. In the case of double-sided or opaque originals, reflex copy negatives can be made and prints obtained from them. If large production is involved, or if the copy is to be reduced in size, special cameras for photographing onto paper are used, the best known being the Photostat, Rectigraph and Rutherstat. Alternatively, the documents may be made on film to reduced size in Microfile and similar cameras and the negatives enlarged to give paper prints.

An important microfilming procedure was introduced in England in 1941 as Airgraph and later in the United States as V-mail, and was used for distributing mail to and from the armed services overseas. Letters were written on special forms, copied onto 16-mm. film which was flown to centres abroad where enlargements on paper were made and distributed to the addressee.

In the drawing office, copies of tracings are made by blueprint, iron-silver and diazo processes and by special types of papers which give normal silver images, but which can be handled in ordinary room light.

Recording Cameras. — Among the uses of cameras for special recording purposes may be mentioned: gun cameras, used for training in aerial gunnery and for recording the effectiveness of gunfire in combat; phototheodolites for survey from the ground, and for plotting the position of shell-bursts; submarine periscope cameras for photographing through the periscope the results of torpedo fire, and enemy coast lines; cameras provided with enclosed lights for photographing fingerprints and instrument panels; special cameras frequently using invisible rays for photographing aircraft instrument panels; cameras for photographing inside tubular cavities such as gun barrels and oil well bore holes.

Photographic Photometry. — The intensity of radiation can be measured by photography. The radiation whose intensity is to be measured is compared with that from a standard source by matching the densities of photographic images produced by both. A number of conditions have to be met, and they are described

in the publications on the subject, especially by G. R. Harrison and L. A. Jones.

Phototopography.—(*See* SURVEYING; PHOTOGRAMMETRY; also Aerial Photography.) Col. Aimé Laussedat of the French army pioneered the application of photography to surveying, especially in the Alpine regions, and it was applied extensively in Canada, especially by E. Deville. Practically all photographic survey by the 1940s was done from the air. In ground phototopography, special cameras (phototheodolites) are used after the manner of theodolites, and photographs are taken in pairs from the ends of measured base lines, in such a way that the same object can be identified in both photographs. The cameras have means for orienting them precisely in relation to the subject, levels for setting them true to the perpendicular and means for properly orienting the image inside the camera. Plates are usually used rather than film, unless easy portability is important; and exposures may be long, so the plates may be relatively slow and of high resolving power. Special phototheodolites have been used for determining the position of anti-aircraft shell bursts and similar inaccessible objects.

Aerial Photography.— The first aerial photographs were made from captive balloons (Nadar, 1858, S. A. King and J. W. Black, 1860) using wet collodion plates. The principal early development of aerial photography came after the advent of the aeroplane, and particularly during World War I, when thousands of photographs were taken each day for military intelligence purposes. During World War II, millions of photographs were made from the air and more than 80% of knowledge of the enemy was derived from them; the same mas true during the Korean war.

The chief uses of aerial photography are: in military intelligence, for recording troop movements, positions, defenses, supply facilities, bridges, railways, docks, industrial establishments, shipping, etc., orientation of bombers and bomb damage assessment; in mapping, military and civilian, to provide the basis for making new maps and filling in detail or revising existing maps; for mosaics, which are composite aerial photographs made by joining together a number of separate photographs of the ground; making survey photographs for purposes of forestry, oil. geology, crops, soil erosion, archaeology, traffic distribution, real estate, exploration and such studies.

Aerial photographs are made in cameras specially mounted in aeroplanes to minimize vibration, and are called vertical or oblique according to the orientation of the camera to the ground. Early aerial cameras were modifications of existing plate cameras, but provided with magazines permitting exposure of a number of plates in rapid succession. With the exception of a few special survey cameras which still use plates, aerial cameras use long rolls of film which can be moved intermittently by hand or by an electric motor controlled by an intervalometer, in order to make series of photographs of the ground along the line of flight. These photographs are usually arranged to overlap about 60% so that they can be viewed stereoscopically when maps are being plotted from them, or when it is desired to study ground detail.

Film for general aerial photography is of the high-speed panchromatic type, with extra red sensitivity to permit short exposures through filters. Infra-red film is used for long distance and high altitude photography, for camouflage detection and for forestry survey. Colour film was first used extensively in aerial photography in World War II. The colour contrasts aid identification of objects, show up underwater features, and permit night photography of coloured flares. Aerial films range in width up to 20 in. and up to 400 ft. in length

The film support for aerial photography is mainly of the topographic variety, which undergoes little dimensional change in processing or with change in humidity, and so reduces the errors which must be corrected in plotting maps from the photographs.

A wide variety of lenses is used, ranging in focal length from about 3 in. to 100 in., and in apertures from f/8 to f/1.5. (See Photographic Lenses.)

In aerial photography the camera is moving in relation to the subject photographed, and exposure times must be very short or the picture will be blurred. High-speed shutters are therefore used. They are of the focal plane, louvre and between-the-lens types, the first two being favoured by the British and the last by the Americans. For night photography using flash bombs, special shutters were developed to be operated by a photocell circuit activated by the light of the flash.

Instead of, or in addition to, using high-speed shutters, compensation for movement of the image can be effected by moving the lens during exposure, moving the film continuously through its magazine at the same rate that the image moves, the exposure being made continuously through a narrow slit in the focal plane, or moving the film in its magazine but exposing the full picture area intermittently as in normal operation.

In order to photograph large areas of ground at one time, wide-angle and short-focus lenses, or multiple-lens cameras, or groups of separate cameras may be used. Multiple-lens cameras having three, four, five and nine lenses have been developed, the most popular being that with five lenses. In the Tri-Metrogon system developed for rapid survey during World War II, three cameras are used, one vertically and two obliquely, one on each side of it, the photographs being made to overlap somewhat to cover the entire ground from horizon to horizon on each side.

Atmospheric haze presents a serious problem for aerial photography since it tends to lower the contrast of or obscure ground detail. Haze scatters blue light preferentially and transmits the longer wave lengths. Its effects can, therefore, be largely eliminated by using panchromatic film and filters which absorb blue light. The commonly used filters are yellow, but for better haze penetration it is sometimes necessary to use red filters, or in extreme cases to use infra-red-sensitive film and a deep red filter. Special filters are used for particular purposes, for instance, green filters for distinguishing certain kinds of vegetation.

Film for aerial photography is developed in the roll on special machines in which it moves continuously through a series of tanks, or back and forth from one reel to another in single tanks, or on spiral reels or racks which can be immersed in the solutions for the desired times.

Special instruments and techniques are used for plotting maps from aerial photographs. (See SURVEYING; PHOTOGRAMMETRY.)

Radiography.— (See RADIOLOGY; X-RAYS, NATURE OF.) In this branch of photography, photographs are produced on film by the passage of X-rays or gamma-rays through an object. There are several aspects: medical and *dental* radiography which is by far the widest used; industrial *radiography* for examination of the interior condition of solid objects, especially castings, welds and structures, usually of metal; gamma radiography, for examination of the interior state of solid objects, but using the gamma-rays from radium; X-ray *diffraction* for the analysis of the atomic and molecular structure of materials.

Radiographs, other than diffraction photographs, are shadow photographs obtained by passing a beam of the rays directly through the object, which absorbs them to an extent depending on its nature (especially the atomic number of its elements) and thickness. Photographic films are sensitive to X-rays and gamma-rays, as they are to light, and when the exposed film is developed, the image varies in density according to the extent to which the rays were absorbed. The invisible internal structure is thus revealed.

The earliest radiographs were made in 1896, the year in which Wilhelm Rontgen discovered X-rays, and the glass plates then available were used. Modern radiography is done on film coated with a special emulsion, and usually on both sides to give maximum speed and contrast. Only a very small percentage of the X-ray beam is absorbed by the emulsion, and in order to increase the effectiveness of the exposure, therefore, the film is usually put between two "intensifying screens" which are coated with a layer of material such as calcium tungstate which fluoresces under the action of the X-rays and the fluorescent light augments the exposure caused by the X-rays. For some classes of industrial radiography, thin lead foil screens are used to improve the contrast and clarity of the photograph. For dental radiography and some industrial work, no intensifying screens are used.

The penetrating power of X-rays depends on the voltage between the filament and target in the X-ray tube; the higher this voltage, the "harder" or more penetrating are the rays. For general medical radiography 40–80 kv. may be used, the higher values being for the thicker body parts. For industrial radiography, voltages ranging up to several million may be employed. X-rays generated at high voltage for radiography of metals are so penetrating that materials such as cloth, paper and leather appear quite transparent to them, and low voltages of 4–20 kv. must be used with them.

When X-rays strike an object, a considerable percentage of them is scattered, in much the same way light is scattered by fog. The scattered rays tend to cause a veil over the radiograph and so reduce contrast and detail. This effect can be offset by using a Potter-Bucky diaphragm, which consists of a grid of alternate strips of lead and wood which is moved between the object and the film during the exposure. The direct X-rays pass through the wooden strips, while the lead strips absorb those scattered sideways. The grid is moved to prevent its casting a shadow, but sometimes a stationary Lysholm grid of thin, closely spaced lead strips is used.

Medical uses of radiography include location of foreign bodies and cavities, fractures, diagnosis of tuberculosis and abnormal conditions of the digestive and urinary tracts, the heart, the spinal column and the sinuses; and in the case of dental radiography, cavities, abscesses, unerupted teeth, pyorrhea and many other conditions.

The widest use of industrial radiography is in examination of interior structures for hidden faults, without involving damage to the object, for instance, in castings and welds, assembled mechanisms, moulded plastics, munitions and a vast range of manufactured products.

Among special radiographic techniques may be mentioned: *body-section radiography,* in which only one plane of the body gives a distinct image, nearer and farther parts being blurred, the result being obtained by moving film and X-ray tube in opposite directions about a pivot point in the plane which is to appear sharp; *roentgenkymography,* used for study of moving parts, such as the heart, by moving between the patient and the film during exposure a lead plate with a series of horizontal slits; *microradiography,* usually for thin specimens of low X-ray absorption, with very fine detail, in which the radiograph is made on fine-grain film and subsequently enlarged; *high-speed radiographs* have been made in one-millionth of a second for ballistic and other high-speed studies.

There developed, particularly during World War II, a need for radiography on a grand scale, particularly for making X-ray photographs of the chests of people being examined for induction in the armies. *Mass miniature radiography* was introduced. In Europe, photographs of the fluorescent screen image were made on 35-mm. film, using lenses of very high aperture. In the United States, the preferred size was 4 x 5 in., stereo pairs being made on film 4 x 10 in. in size. In motion-picture- or *cineradiography,* motion pictures are made of the image on the fluorescent screen, or, less frequently, series of natural-size radiographs are made in quick succession. Usually one cycle of movement of a part is photographed, and in projection it is viewed in repeated succession. The chief limitation in this work is that extremely high aperture lenses are required in order to keep the X-ray dosage to the patient at the minimum. In *gamma radiography,* the gamma-rays from radium are used. They are of shorter wave length than X-rays and thus have greater penetrating power. They are specially used in the radiography of thick metal specimens.

Radiographs are usually examined as the negatives, and in order to give the impression of depth they are frequently made in pairs, using two positions of the X-ray tube, and viewed in the stereoscope. In *X-ray diffraction* methods, the internal structure of crystals may he determined by the diffraction pattern photographed on passing a beam of X-rays through a single crystal or a sample of the material in powder form. Autoradiography is a procedure that originated with the ready availability of radioactive isotopes. It is known that when isotopes are introduced into an organism, they localize in certain tissues and, in some cases, in specific portions of the living cell. These concentrations of the radioactive substances can be detected by placing thin sections of the tissues in close contact with special photographic plates. Upon development of the plate, black specks identify the location of the concentrations of the radioactive materials. By using fine-grain materials and magnifying the resultant image microstudies are possible. (*See* CRYSTALLOGRAPHY: *Diffraction of Crystals;* X-RAYS.)

COLOUR PHOTOGRAPHY

In 1810 J. T. Seebeck, in 1840 Sir J. Herschel and later E Becquerel and Claude Niepce de Saint-Victor, observed that silver chloride darkened by exposure can record the spectrum of the sun by its direct action, in colours similar to those of the spectrum itself. The colours can not be fixed and the method has no practical value.

The first fixed colour photographs from nature were made by G Lippmann in 1891, using the interference principle, the possibility of which had been pointed out by W. Zenker (1868), Lord Rayleigh (1887) and O. Wiener (1890). In the method, a transparent grainless panchromatic emulsion is coated on glass and exposed with the emulsion in contact with a reflecting surface, usually of mercury. The reflected light gives an interference effect, setting up standing waves in the emulsion. The exposed and developed silver is thus arranged in laminae half a wave length apart, and reflects light of double the separation, giving bright colours. Beautiful colour reproductions can be obtained, but the plates are insensitive and the viewing is not convenient.

The basic principles of modern colour photography are derived from an experiment made in 1861 by James Clerk Maxwell in a study of the theory of colour vision. He photographed coloured ribbons through red, green and blue filters, from the negatives made three positive black-and-white transparencies and projected these in register onto a screen using three lanterns, each transparency being projected by light of the colour by which its negative was taken. The image on the screen was a colour reproduction of the ribbons.

In 1869 Ducos du Hauron published a book in which he laid down the principles which provide the basis for all modern processes of three-colour photography. At about the same time C. Cros published an article with much the same conclusions. Du Hauron's book gives a clear account of the two fundamental processes of colour photography, the *addztive* and the *subtractzve,* with suggestions for carrying them out. The practical development of the processes was delayed for many years until panchromatic plates became available through the introduction of colour sensitizing by Vogel in 1873 and the introduction of isocyanine and carbocyanine sensitizers early in the 20th century.

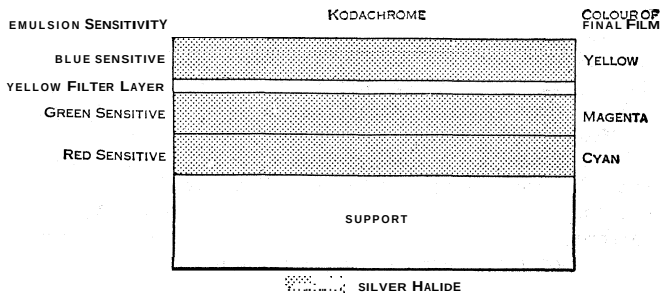
FIG. 3.— PROGRESS IN COLOUR SENSITIZING PHOTOGRAPHIC MATERIAL

Modern colour processes are divided into the additive process, which is used only for transparencies for projection and direct viewing, and the subtractive processes which can be used for transparencies and also for paper prints to be viewed by reflected light. In both cases the first step is to make three separation negatives of the subject by the red, green and blue light from it. It is also possible to make colour photographs by the two-colour process, in which the separation negatives are made by half the spectrum, blue-green and orange, but the best colour rendering is obtained by the three-colour process.

Additive Processes.—In the additive processes, the colours are produced by adding together varying amounts of red, green and blue light. There are three main processes of additive colour photography: *triple projection, screen unit* and *lenticular film.*

In the *triple projection* process, black-and-white positives made from negatives exposed through red, green and blue filters are projected through similar filters in register on a screen. This was

the original Maxwell experiment. Special equipment for making the three separation negatives in succession or simultaneously were put on the market, together with triple lanterns for projection. Du Hauron, Cros and F. E. Ives invented devices for viewing the three pictures directly rather than by projection. In the photography of stationary objects, the three negatives can be exposed in succession. In the case of moving objects, however, the three negatives must be made simultaneously, otherwise colour fringing will occur. For simultaneous exposure of the three negatives, groups of lenses have been used, as in the Gaumont motion-picture camera of 1912, or beam splitters consisting of a group of mirrors or prisms. Another system of making these three negatives, originally invented by Du Hauron, is the so-called tri-pack in which three separate films are arranged behind each other, with filters to ensure that the red, blue and green records are obtained separately, one on each film.



BY COURTESY OF KODAK RESEARCH LABORATORIES

FIG. 4.—CROSS SECTION OF INTEGRAL TRIPACK FILM

In the triple projection process extremely good colour quality can be obtained, but the system is complicated and up to 1947 had never been a commercial success.

The Screen Unit Process.—The first commercially successful colour process, the Lumière Autochrome, brought out in 1907, utilized the screen unit process. This was a modification of one form of additive process first suggested by Ducos du Hauron. Instead of making three separate negatives through filters, a single plate was covered with minute blue, green and red filter elements. A panchromatic emulsion was coated over this layer. The exposure was made through the filter layer so that the image obtained was broken up into tiny units representing blue, red and green components of the colours of the subject. The emulsion was developed by the *reversal process* (originally by *R.* Namias) to give a direct positive in black-and-white, which, on direct viewing or projection through the layer of minute filters, gives a reproduction of the subject in colour. Alternatively, if the filter elements are uniformly arranged, the plate or film can be developed to a negative and printed to give a positive transparency which can be registered in contact with a plate carrying minute filter elements to give a positive colour transparency.

The first successful use of the screen unit process was made by J. Joly and by J. W. MacDonough in 1892, the filter elements being on a separate plate from the negative. This arrangement was later employed in the Finlay plate, which was used commercially for many years. In the Lumière Autochrome process, the filter layer consisted of dyed starch grains with the spaces between filled with carbon black. The plates gave good colour quality, and were on the market as plates and later as films for 30 years. Other screen unit processes were later introduced, in particular, the Finlay process mentioned above, in which the screen was printed in bichromated colloids, the Agfacolor plates and film in which the filter layer consisted of dyed resin particles rolled flat and the Dufaycolor process, in which the emulsion was coated on a regular dyed screen pattern prepared on the film support. The Agfacolor and Dufaycolor materials were developed by reversal, and were sold as roll, sheet and motion-picture film.

The screen unit process gave transparencies of good colour quality, but the plates and films were difficult and costly to manufacture. They were dense, so that it was difficult to get enough light in projection, and the screen pattern was frequently very evident.

The Lenticular Film Process.—This was invented by R. Berthon in 1908 and developed by A. Keller-Dorian and particularly by J. G. Capstaff and the Eastman Kodak company, who made it commercially available in 1928 as the Kodacolor process for amateur motion-picture photography in colour. In this process, the film support is embossed mith minute cylindrical lenses on the side opposite the emulsion. A three-colour banded filter is used over the lens; and in taking, the embossed side of the film faces the lens. Somewhat as in the screen unit process, the lens forms a full image of the subject on the film, but it is broken up into minute elements which are images of the banded filter formed by the embossed lenses on the film. The film is developed by the reversal method and projected through a three-colour banded filter.

The quality of the results given by the lenticular film was excellent, but disadvantages were encountered in projection. which involved a great loss of light because of the filters, so requiring special projection optical systems, and the lenticular pattern was often very much in evidence.

Subtractive Processes.—The subtractive processes are the most important of the practical processes of colour photography. They were first described by Ducos du Hauron, and are now practically exclusively used for colour prints on paper and transparencies for still and motion-picture projection. In the subtractive process, three separation negatives are first made by red, green and blue light. From these, positives are made in colours which are complementary to those by which the negatives were made, and the three are superimposed in register, on white paper to give a colour print, or on film to give a transparency.

The negative made by red light is printed to give a cyan (blue-green) picture; that made by blue light is used to give a yellow picture, while that exposed by green light is printed in magenta. When these partial images are superimposed, a good colour reproduction can result.

The three separation negatives can be made: (a) separately by successive exposures through the three filters on three plates or films; (b) simultaneously on three plates or films using a one-exposure (one-shot) three-colour camera provided mith a beam-splitter of partially reflecting prisms or thin pellicles or split lenses; (c) simultaneously on a tripack of three films or plates superimposed and so sensitized and provided with filter layers that each records only one of the primary colours; (d) simultaneously on an integral tripack or monopack.

In the first three cases the three negatives are generally used to print three positives which can be superimposed on paper or film. Various processes have been used, in particular carbon, Ozobrome or Carbro, bromoil and dye-mordant methods and differential tanning of a gelatin layer. There are two principal forms of the last-named—the Pinatype process in which dye is taken up in an amount dependent on the softness of the gelatin, and allowed to stay in the layer if a transparency is required, or transferred to gelatin-coated paper by imbibition if paper prints are required; and the wash-off relief or dye transfer process in which the soft parts of the differentially hardened gelatin layer are washed out leaving a relief image in hard gelatin which can be dyed and the dyes transferred to paper or film by imbibition.

The Technicolor motion-picture films are made by dye transfer from three gelatin relief films to a final gelatin-coated film.

Monopack or Integral **Tripacks.**—It is evident that better results would be obtained if the three layers were coated over each other on a single film support. This proposal was suggested in the early history of colour photography with the idea that the layers should be separated for development and printing, but the manipulation proved to be too difficult for practical handling.

It was next suggested, first by K. Schinzel in 1905, that the three superimposed layers should each be arranged to respond to a single primary colour, that the layers should be inseparable and that a coloured image should be developed in each. In Schinzel's proposal, dyes of colour complementary to the spectral region of sensitivity were incorporated in the layers, which were to be developed and then treated in such a way that the dyes were bleached by oxidation to an extent proportional to the amount of silver developed. C. Christensen in 1918 proposed a similar arrangement, in which the dyes in the layers mere destroyed by reduction

by hydrosulphite in the presence of the silver image. The silver-dye bleach method was applied commercially by B. Gaspar, in whose process the dyes were catalytically bleached in the presence of the silver.

Instead of bleaching the dyes in the layers to an extent depending on the silver developed, it is possible to form dyes in the layers to a degree depending on the amount of action of light and consequent development of silver. Processes based on this formation of dyes form the greater part of modern colour photographic processes. They depend on the discovery made by Homolka and worked out by R. Fischer that when a developer reacts with silver bromide to reduce it to silver, the oxidized developer resulting can react with certain compounds to form dyes. This is generally known as coupler development. The developers which are used are of the kind known as the diamines. The couplers are distinguished chemically by possessing a reactive group, usually methylene. The couplers which form cyan dyes are usually phenols; those giving magenta dyes are often nitriles or pyrazolones; those which form yellow dyes are typified by esters, ketones or amides. Substituents may be introduced into the developer or coupler to modify the colour.

In 1912 Fischer proposed a colour process which used a film with three layers of emulsion coated over each other, each layer containing couplers so that during development appropriate colours would be developed in them. Fischer was not able to make his process work, because he could not ensure that the dye couplers and the sensitizers would not wander from the layers to which they applied.

The first commercially successful colour process using coupler development was worked out by L. D. Mannes and L. Godowsky and the Eastman Kodak company and marketed in 1935 as the Kodachrome process. The image-forming dyes were introduced in processing, the couplers being in the developers rather than in the emulsions. About 1931 nonwandering sensitizing dyes had been developed. In Kodachrome, the film was coated with three emulsion layers, which would respond respectively to red, green and blue light, that responding to red being nearest the support. Below the blue-sensitive top layer was a yellow filter layer to prevent blue light's reaching the two lower layers. The process was designed to give direct positive pictures by reversal. After exposure, the film mas developed to give a negative in all three layers. This was then bleached out, the film exposed to light and then coupler-developed to give a cyan dye image in all three layers. By means of a bleach the penetration of which was controlled, the dye was removed from the top two layers, and the silver bromide regenerated in them. They were then developed in a coupler developer to give magenta images in them. The top layer was then bleached by controlled diffusion of a bleach, and developed in a developer containing a coupler which gave a yellow image. The silver resulting from the development of all layers was then bleached out, leaving the dyes alone to form the colour transparency *(see* fig. 4).

The processing of Kodachrome by controlled diffusion was clumsy, but commercially successful for three years. Toward the end of 1938, it was replaced by a selective method, in which the assigning of the dyes to their proper layers was determined by the sensitivity of the layers. In this, the film is first developed to give a negative in all three emulsion layers. It is then exposed through the base to red light, which affects the undeveloped parts of the bottom red-sensitive layer, and is then developed in a developer containing a cyan coupler, so that a positive cyan dye image is formed in the bottom layer. By exposing through the front to blue light, an image in yellow dye can be developed in the top layer, and the middle layer can then be made developable and give a magenta image. If the silver in all three layers is bleached out, the dyes alone remain to give the colour picture. The success of the Kodachrome processing depends largely upon using sensitizing dyes which will not wander from their appro. priate layers, and which will withstand processing solutions.

The Kodachrome types of coating applied to white cellulose acetate sheet instead of clear film permitted prints to be made from Kodachrome transparencies. They were first known as Minicolor and Kotavachrome prints, but later simply as Kodachrome prints.

The type of process suggested by Fischer, in which the couplers were incorporated in the emulsion layers, was introduced by Agfa in Germany, and later by Ansco in the United States. The couplers were associated with heavy molecules so that their tendency to wander from one layer to another was reduced. Films giving positive colour transparencies were introduced as Agfacolor-neu and later Anscocolor. Negative films, giving complementary colours, were also made available by Agfa and Ansco.

In 1940 the Eastman Kodak company made a colour film, Kodacolor Aero Reversal film, for aerial photography for the U.S. army air forces, which could be developed in the field to give direct positives by reversal. The film was of the integral tripack type, and the dye-forming couplers were incorporated in the emulsion layers, dissolved in minute droplets of insoluble organic compound dispersed in the emulsions. On development of the film, the oxidation products of the developer enter the nearest dispersed solvent-coupler droplets, and react with the coupler to form a dye. On bleaching, the silver is removed, leaving dye images in their appropriate layers. This process is known as a protected coupler process.

In 1942 a new Kodacolor film was made available. It used the protected coupler process to give negative colour pictures. Red, green and blue sensitive layers were coated on the film as in Kodachrome film, but each layer contained dispersed particles containing couplers. After exposure, the film is processed with a developer the oxidation products of which react with the couplers to give silver plus dye images in each layer. The silver is removed and a colour negative results, in which the image is not only negative in the normal photographic sense, but all the colours are complementary to those in the subject photographed. These negatives are printed onto paper coated with a similar set of emulsions, and processed in the same way, and paper prints are obtained in which the colours of the subject are reproduced. Soon after the introduction of this film, an extra layer was incorporated in it in which a black-and-white negative could also be developed to act as a mask to give improved colour quality in the print.

In 1946 a form of Kodacolor designed to give direct positive transparencies by reversal, similar to the earlier Kodacolor Aero Reversal film but of lower contrast and longer scale, was introduced by Eastman Kodak as Ektachrome, in sheet-film form. It was designed to be processed by the photographer, and an important aspect of it was that for the first time, coupler developers were used which produced no more effect on the skin of the user than the customary black-and-white developers. All the diamine developers previously used could give bad dermatitis.

Late in 1946 the important invention of coloured couplers was disclosed by Eastman Kodak. They were intended for use in the integral tripack negative process to correct for the unwanted blue and green absorption of the cyan dye and the unwanted blue absorption of the magenta dye, so giving improved colour quality in printing. Couplers are used which are actually red and yellow in colour, but the colours are destroyed where the dyes are developed. The final negative consists of the negative dye images combined with positive images in red and yellow, caused by the residual coloured couplers.

Colour-printing Processes. — Prints on paper have been made by the screen unit process, but they are unsatisfactory because of the high density of gray with which they must be associated. All satisfactory colour prints are made by subtractive processes, in which positive images in yellow, magenta and cyan pigment or dye are combined in register. The chief methods of obtaining the coloured pbsitives are: Chemical *toning,* in which the black-and-white silver images are converted into coloured compounds, for instance, lead chromate for yellow, nickel dimethyl-glyoxime for the magenta and an iron blue for the cyan (Chromatone of Defender Co., Snyder and Rimbach); *dye mordanting,* in which the silver images are converted into compounds known as mordants which have an affinity for basic dyes, among the best known being silver iodide (Traube's Diachrome), copper ferro-

cyanide (Traube's Uvachrome) and copper thiocyanate (Christensen); imbibition or transfer processes, in which differentially hardened gelatin layers are formed by tanning development or tanning bleach in the pattern of the positive image of the subject, and dyed directly to give a picture in which the dye is taken up to an extent depending on the hardness of the gelatin (Pinatype), or washed out with hot water to give a gelatin relief image, which can be dyed. In either case the dyes can be transferred to gelatin-coated paper to give a print on paper, and if the three-colour images are so transferred, a colour print results (Eastman Rash-off Relief and Dye Transfer processes).

Pigment Processes.—In the pigment processes, the gelatin contains pigments and can be differentially hardened by the direct action of light if bichromated, or indirectly by a tanning developer, or by indirect action from a bromide print and a special bleach, to give positives which can be washed out with hot water to give pigment-gelatin images. In the carbon process, originally devised in a practical form by Sir Joseph Swan in 1864, the gelatin containing the pigment is bichromated and exposed and developed in hot water, leaving an image of hardened gelatin containing pigment. In Carbro, which was developed from processes devised by A. Marion (1873) and T. Manly (1898), a bromide print treated with a special bleach is placed in contact with a pigmented gelatin and differential hardening of the gelatin occurs. The soft gelatin can be washed out in hot water, and three positives so prepared can be transferred to a common support to give a colour picture.

In the Duxachrome process, silver bromide emulsions containing pigments were coated on supports from which the images could later be stripped. The exposed layers were developed in tanning developers and washed out in hot water, the silver was bleached out and the remaining pigment images transferred in register to a final support.

In the dye-coupling printing processes, there are the equivalents of Kodachrome, Kodacolor and Agfacolor on white support. The printing processes are known as Minicolor, Kotavachrome, Kodacolor prints, Kodachrome prints and Printon.

The dye-destruction printing processes are typified by the Gasparcolor prints, in which the three superimposed layers of emulsion contain the subtractive pigments. On exposure and development a special solution is used to bleach the pigment image to a degree depending on the amount of silver developed.

The dye-bleaching processes were not yet of practical importance in 1947; but the Utocolor paper of J. H. Smith (1910), relying on direct bleaching of the dyes by light, was produced commercially. The sensitivity of the dyes to bleaching was enhanced by thiosinamine, and the stability of the image was determined mainly by rendering the sensitizer ineffective.

Colour Motion Pictures.—The earliest colour motion pictures were by the additive processes: Kinemacolor, a two-colour additive process using successive projection of the separate positives and a rotating pair of filters; the Friese-Green process of successive projection through filters, or with the frames on the film themselves dyed; the Gaumont process of simultaneous additive projection using three lenses in taking and projection. Variants of these are proposed periodically. Later, the Dufaycolor screen-unit process was used for motion pictures, and methods of printing the film for theatre release were worked out. The lenticular process, of which 16-mm. Kodacolor was commercially developed, was worked out, but not used to any extent in the theatres. The additive processes, although giving unsurpassed colour quality, give low screen brightness and difficulty of registration, or undesirable patterns, and are surpassed by the subtractive processes, from the practical point of view.

The earliest subtractive processes used chemical toning, dye toning or dye mordant methods, especially as two-colour processes, printing the separate colour positives on the opposite sides of a single support. The earliest Technicolor process was a two-colour relief process, but about 1928 it was changed to a two-colour, and later to a three-colour, imbibition process. For the three-colour process a special camera was used in which separation negatives were made on a single film and a bipack, using a special type of beam splitter. The three negatives were printed onto special films to give matrices from which prints were made by imbibition. Later, integral tripack or monopack films were used in the cameras, and separation negatives were made from them for printing by the normal imbibition process.

Particularly in Germany, some motion-picture films were made by the Agfacolor process using the Fischer type of film by the negative-positive, or the reversal methods. A great deal of experimental work has also been done with the Gaspar dye-bleaching process for motion-picture colour photography.

THEORY OF PHOTOGRAPHY

The Sensitive Material.—Under the high-power microscope, the image on a photographic negative is seen to be not continuous but to consist of large numbers of small, dark grains of silver. They are derived from the structure of the original emulsion, which consists of crystals of silver bromide distributed in the gelatin. These crystals are usually flat, triangular or hexagonal in shape, with an occasional rod shape, but there are emulsions in which they do not exhibit a crystalline appearance. They are of various sizes, ranging up to about 1/10,000 in. across, depending on the type of emulsion. In a normal film, there are several thousand million in a square inch. Examination by X-rays shows that the silver halide is all in the crystalline form, even though the separate particles may have a lumpy appearance.

If solutions of silver nitrate and potassium bromide in water are mixed, the silver bromide formed settles out in flocks; but if gelatin is present, the silver bromide remains suspended in a much finer form. Gelatin is present in emulsion making, so keeping the silver bromide suspended as fine crystals. In the ripening stage of emulsion making, the crystals grow in size, but they are of low sensitivity. After the addition of the bulk of the gelatin, washing and digestion, there is little increase in crystal size, but there is a growth of sensitivity to light, to an extent which depends largely on the kind of gelatin.

The sizes and distribution of sizes of the crystals or grains in the emulsion are determined by the way in which the emulsion was precipitated, and the sizes are related to the photographic properties of the emulsion. If they cover a wide range of sizes the emulsion usually has high speed and low contrast and is used for making negatives. If they are small and uniform, the emulsion has low speed and high contrast, and might be used for motion-picture printing film, or lantern slides.

When an emulsion is exposed to light an invisible change known as the latent image is produced in it, and the effect of the exposure is not apparent until the emulsion is developed by treating it in a chemical reducing solution, the properties of which will be discussed later. On development, the emulsion blackens to a degree which depends on the extent of development and on the exposure. In the case of a film exposed in a camera, a negative is produced, in which the brighter parts of the subject are reproduced as dark, and the darker parts as light. The degree of blackening of the film is called density (see Sensitometry). When a print is made from a negative, the light parts again appear dark and vice versa, so that in the print the tones are in the same order as in the subject.

The density in the negative is caused by the presence of the developed silver grains—the more silver in a particular area, the higher is the density. The silver grains have their origin in the silver halide crystals originally present, so that higher density means that a higher percentage of these crystals was made developable by exposure. On the average, the larger crystals in an emulsion are more sensitive to light than the smaller crystals. This is not only because they are bigger and therefore contribute more silver than a small grain, for it is possible by chemical treatment to make a fast emulsion practically insensitive without changing the size of grain,

When an exposed grain starts to develop, it does so at a limited number of isolated points on its surface. These points are distributed according to the laws of chance, and it appears that they coincide with points on the crystals which were preferentially affected by light, *i.e.*, the latent image is concentrated at certain

centres. This indicates that the crystals had extra high sensitivity at these centres; in other words, there are sensitivity centres on the original emulsion grains. Evidence indicates that they are specks of silver sulphide in the crystal surface. The most important support for this view comes from the study by S. E. Sheppard of the function of gelatin in determining emulsion sensitivity. He isolated the sensitivity-promoting substance from gelatin and found it to consist of sulphur compounds. especially allyl isothiocyanate. This material forms allyl thiocarbamide in presence of alkali, and this can form a complex compound with silver bromide. In presence of alkali, the complex can give rise to silver sulphide, and apparently this is the sequence of reactions occurring in the manufacture of a high-speed emulsion. In addition to the sensitizing material, gelatin can also contain desensitizing materials, and the net sensitivity will be the result of a balance of properties.

There have been mady theories as to how the sensitizing specks act during exposure to give rise to the latent image. After Sheppard found the specks to be silver sulphide, he and A. P. H. Trivelli and R. P. Loveland propounded the "concentration speck" theory. According to this, the silver-sulphide speck was able to cause the light energy absorbed by the crystal to be concentrated about a speck, and there to liberate silver by decomposition of the silver bromide. There is plenty of evidence that the latent image consists mainly of metallic silver. It is accumulated about the silver-sulphide specks. A silver speck can initiate development when it has grown to a certain size.

The concentration speck theory still forms the basis of latent image theory, but the mechanism by which the concentration is effected is now explained on the basis of atomic physics. Although it cannot be assumed that the whole mechanism of latent image formation is understood, the modern theory based on photoconductivity and electrolytic conductivity can correlate much existing data and predict new effects. When light is absorbed by silver bromide, the ability of the material to conduct electricity is much increased by certain electrons becoming available. J. H. Webb suggested that these electrons could move through the crystal freely, but that they would become trapped at the sensitivity specks of silver sulphide. In addition to this conductivity. there is also a small conductivity of silver bromide which is actually caused by the movement of some silver ions within the crystal R. W. Gurney and N. F. Mott visualized a combination of these two conductivity processes in explaining latent image formation as follows:

On exposure to light, the photoconductivity electrons are supposed to move freely in the crystal until they by chance impinge on the silver-sulphide specks where they are trapped and build up a negative charge. This negative charge will attract the positively charged free silver ions which will migrate to the speck where they will be neutralized by the electrons to form neutral silver atoms. The speck will thus grow by accumulation of silver atoms until it is big enough to act as a nucleus in the development process.

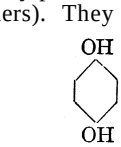
Development. — In development, the emulsion is treated with a solution which converts the exposed silver halide to black silver. The developer must act much more quickly on exposed than on unexposed grains. There are two kinds of development — physical and chemical. A physical developer contains chemical reducing agents and silver compounds in solution which deposit silver on the latent image from the solution. and not by changing the silver halide. It is of great importance for the theory of development, but not of much practical value. A chemical developer does not contain any silver, and is essentially a solution of chemical reducing agents which will distinguish between exposed and unexposed silver halide in an emulsion, and actually convert the exposed silver halide to metallic silver.

When a silver-halide crystal in an emulsion starts to develop, it does so at a limited number of points, from which development spreads outward, until the whole crystal is converted to silver. A giain develops completely or not at all. The development is initiated at the latent image centres where silver was deposited in the exposure, and the development of the silver bromide starts about these silver centres. It was felt by some for a long time that the latent image nuclei played no part in development except to act as a centre on which silver formed by reduction of dissolved silver halide could deposit. It is now clear that such a process does not play a major part in development, The more likely explanations involve a mechanism by which there is direct reduction of the silver halide at the boundary of the silver-sulphide latent-image speck, and that the speck itself in some way accelerates this.

Typical developed silver grains and the silver bromide crystals from which they were produced are shown in Plate V. The actual shape and size of the silver particles varies with the kind of developer and other factors. Studies made in the electron microscope show that the silver does not have a compact cokelike structure, as might appear from examining it in an ordinary microscope, but that it has a fibrillar, seaweedlike structure.

Only a limited number of types of chemical compounds are able to be used as developers. A few inorganic compounds. particularly ferrous oxalate, have been used, but the developers used in normal photographic practice are organic reducing agents of the classes known as phenols or amines. A rule established by A. and L. Lumière and by M. Andresen in 1891 stated that developers must contain at least two hydroxyl groups, or two amino groups or one hydroxyl and one amino group, attached to a benzene nucleus in the ortho- or para-position to each other. Meta compounds do not develop. It has also been pointed out that many developers form quinones or quininoid compounds when they are oxidized. J. D. Kendall formulated a rule which stated that hydroxy- and amino-compounds could be developers if they had the basic structure a-$(C=C)_n$-*b*, where C=C represents two cdrbon atoms joined by a double bond, *n* is zero or an integer and a and *b* are hydroxyl- or amino- or substituted-amino groups. There are, however, some developing agents which do not follow these rules.

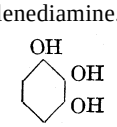
The most common developers are hydroquinone and monomethylparaminophenol (known by trade names Elon, Metol and others). They have the following structure:



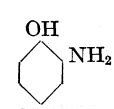
hydroquinone

monomethylparaminophenol (Elon, Metol)

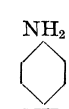
A popular developer in the past, but which is less used now, was pyrogallol. Amidol (2:4-diaminophenol) has been much used as a paper developer, and there is a wide range of developing agents on the market for special purposes, and under trade names. Fine grain and colour developers have been frequently based on paraphenylenediamine.



Pyrogallol (1:2:3-hydroxybenzene)



Amidol (2:4-diaminophenol)



paraphenylenediamine

The essential constituents of most practical developing solutions are: the developing agent; an alkali, sometimes called the accelerator; sodium sulphite, sometimes called the preservative, and potassium bromide, the restrainer.

The cotnmon alkalis are sodium carbonate, sodium hydroxide and some borates, particularly sodium metaborate (Kodalk) and tetraborate (borax). The function of the alkali is to make the developer active, and it does this by adjusting the alkalinity (or pH) to a suitable value and holding it there. This applies to developers containing hydroxyl groups, but the pH also seems to determine the activity of developers which do not contain such groups. Amidol does not require an alkali to make it effective.

Sulphite plays two important parts in a developer mixture. It acts as a preservative by decreasing the tendency of the developer to be oxidized by the oxygen of the air. It also combines with

the oxidation products of the developer which are formed when the developer reduces the silver bromide to silver, so preventing them from interfering with the progress of development, and from staining the photograph, for they may be highly coloured.

Potassium bromide is frequently added to a developer to restrain the growth of fog (*i.e.*, development of unexposed grains) and to control the uniformity of development. It usually slows down the rate of development, and may tend to make the photograph warm in colour. In addition to bromide, other antifoggants used in developers include benzotriazole and 6-nitrobenzimidazole.

Special developers for producing fine grain are either compounded with paraphenylenediamine as the developing agent, or of conventional developers adjusted to be of low activity, and containing a solvent for silver bromide, which may be an increase in the normal sulphite, or a special solvent added, *e.g.*, thiocyanates. Paraphenylenediamine probably acts by virtue of its own solvent action on silver halides.

The modern colour photography processes rely on so-called coupler development, in which the oxidation products of the developer combine with organic compounds known as couplers to form dyes. The couplers may be in the developer or in the emulsion.

Various developing agents differ in their behaviour. For instance in a plain elon developer the development starts much more quickly than in a plain hydroquinone developer. The elon gives detail first and slowly builds up density, while with hydroquinone the detail appears only after much density has been built up. In combination, the elon and hydroquinone form a very satisfactory developer.

The differences in activity are partly described by what is called the reduction potential of the developer. Three ways have been used for determining it: the ability of the developer to overcome the restraining action of bromide on the growth of density; the amount of silver bromide changed to silver by a certain amount of developing agent; measurement of the electrical potentials of the solution. The following table shows values obtained by the first method by A. H. Nietz. and by the third method by R. M. Evans and W. T. Hanson. The second method is little used.

Developing agent	*Reduction potential* Nietz	*Evans and Hanson*
Amidol	30–40	—0.434 *volts*
Bromhydroquinone	21	—0.327 "
Elon *(Metol)*	20	—0.308 "
Pyrogallol	16	—0.388 "
Chlorhydroquinone	7	—0.335 "
Paraminophenol (HCl)	6	—0.291 "
Toluhydroquinone	2.2	—0.390 "
Hydroquinone	1.0	—0.357 "

Practical developers are worked out for various special purposes, and they vary widely in their properties, depending not only on the material they are used to develop, but inherently among themselves. The developing rate increases with temperature but varies markedly with the nature of the developer. It also depends on the concentration of the components, and the effect of alkali in particular varies with the developing agent. Developers also vary in the way in which they keep when they are exposed to the air, in the rate at which they become exhausted in use, in the rate at which they will develop fog and in the effective emulsion speeds they produce,

When an exposed part of a film is developed, there is an initial period in which no visible effect appears, and this is known as the induction period. After this, the density increases, rapidly at first and then more slowly, and eventually further time in the developer produces no more density until fog starts. For the simplest case of a developer and emulsion in which there is no tendency to produce fog on prolonged development, and in absence of much free bromide, the relation between density and development time is

$$D = D_{\infty}(1 - e^{-kt})$$

in which D is the density which has been developed at a time t, Dm is the density ultimately developable and k is a constant—the velocity constant of development.

From this, the law of constant density ratios is deduced: if a film which has had a series of increasing exposures is developed, the ratio of the densities caused by any two exposures is constant and independent of development time. Other aspects of development are dealt with under Sensitometry.

After-Processes. — *Fixing.* — Afterdevelopment, the emulsion is "fixed" by dissolving out the unchanged silver halide. The commonest fixing baths are water solutions of sodium or ammonium thiosulphate (known respectively as hypo and ammonium hypo). Potassium cyanide is used in the wet collodion process in photomechanical reproduction, since it readily dissolves silver iodide, but it is extremely poisonous and is not desirable for bromide emulsions.

When a negative or print is transferred to the fixing bath, it carries some developer with it. This may oxidize and cause stain, which may be prevented by adding sulphite to the fixing bath. The alkali carried over in the developer may cause development to continue in the fixing bath and also tends to assist oxidation of the developer. Acid is therefore added to neutralize the alkali. Thiosulphate, however, is unstable in presence of acids and will deposit sulphur. This can be prevented by presence of sulphite. A simple acid-fixing bath, therefore, contains thiosulphate, sulphite and a weak acid, such as acetic.

In order to prevent softening of the gelatin, hardeners may be added, and the result is an acid-hardening fixing bath. The commonest hardeners are potassium and chrome alums, and their hardening ability is facilitated by the acidity of the bath. When the acidity of a potassium alum fixing bath becomes too low, a sludge of basic aluminum sulphite forms; but this tendency can be diminished by adding boric acid.

Stop baths or rinse baths are sometimes used between development and fixing, in order to neutralize the alkali carried over. A simple water rinse is better than nothing, but a weak acetic acid solution is preferred. Sometimes a hardening bath containing chrome alum is used prior to fixing, especially in hot weather. In order to depress swelling of the gelatin, sodium sulphate is sometimes added to the stop bath. As a special hardener for emulsions after fixing and before special later treatment, a bath containing formalin and carbonate is used.

The rate at which a fixing bath acts depends largely on the concentration of hypo and the temperature. It is most rapid at 20–40% concentration. The optimum temperature lies between 60° and 70° F. Agitation also increases the fixation rate somewhat. A practical rule for fixing is that it should be continued to twice the time taken for the film to clear, and still longer in the case of prints. Use of a second fresh bath is preferred.

Washing. — Negatives and prints are washed after fixing in order to remove products which might affect their appearance or stability, and in particular to eliminate the fixing salts and the compounds they formed in dissolving the silver halides. If the silver compounds are not removed, there will be stain in the highlights and unexposed areas, while if the thiosulphate and its products are not removed, there will be slow sulphurizing of the image on keeping.

In washing, the basic factor is the rate of diffusion of the hypo and other salts out of the film and into the water, provided the water in contact is continuously renewed. The removal is exponential. *i.e.*, the amount of salts remaining in the gelatin is halved for each equal period of' time. Removal of salts is more rapid the higher the temperature. but the temperature is limited by the danger of softening the gelatin, and 60°–70° F. is best. Washing is more rapid if no hardener is used than if a potassium alum hardening fixing bath is used, although chrome alum hardening has little eifect.

Washing of prints is slower than of negatives, because the paper fibres offer much resistance to the removal of the salts. It is very difficult to remove the last traces of hypo from paper by washing, and if in the interest of permanence the last traces must be eliminated, recourse must be had to chemical agents. Alkaline solutions will assist the removal, but it is preferable to use hypo-eliminators which convert the last traces of hypo to sulphate which does not affect the image. An effective solution contains

hydrogen peroxide and ammonia.

Drying.—After washing, negative materials are usually dried in moving, moderately warm air, after removal of surface moisture by blotting, wiping or squeegeeing. Prints on paper can be dried at higher temperatures, and in the case of large-scale photofinishing this is usually done on heated revolving metal drums, which may also give gloss to the prints if they are put emulsion side to the polished metal surface.

Reduction and Intensification.—"Reduction" in photography refers to methods of decreasing the density or contrast of an image by chemical means, while "intensification" involves processes for increasing density or contrast.

Photographic reducers are actually oxidizers in the chemical sense, and convert some of the silver into a soluble compound. They are divided into three classes according to the way in which they affect density and contrast:

(1) *Subtractive* or cutting reducers remove equal amounts of silver from all densities. The proportion of silver removed is thus greater the lower the density, and the effect is that of increasing image contrast. The reducers are used for overexposed negatives and for reducing fog density, and the most-used formulas contain potassium ferricyanide and hypo (Farmer's reducer), or potassium permanganate and sulphuric acid.

(2) Proportional or true-scale reducers remove silver in proportion to the amount present, thus reducing the contrast of the negative. They are used with correctly exposed but overdeveloped negatives, and a typical formula contains potassium permanganate, persulphate and sulphuric acid.

(3) Superproportional reducers remove a greater proportion of silver from the higher densities than from the lower, thus reducing the highlights without affecting the shadow detail. They are used with overdeveloped negatives of contrasty subjects. The formulas contain potassium or ammonium persulphate and sulphuric acid.

Photographic intensifiers increase the density of the image by deposition of some other substance such as chromium, silver or mercury compound on it, or by toning it. They may also be roughly divided into three classes according to the results they give:

(1) Proportional intensifiers are the most common and useful types. Best known are the chromium intensifier, in which the silver image is bleached in a solution of bichromate and hydrochloric acid and redeveloped in elon-hydroquinone, the silver being reinforced by a chromium compound; the silver intensifier, in which silver is deposited directly on the image from a solution containing silver nitrate, sulphite, hypo and elon, and Monckhoven's mercury intensifier in which the image is bleached with mercuric chloride and potassium bromide, and blackened with silver nitrate in cyanide solution.

(2) *Superproportional* intensifiers have a solvent or other inhibiting action which tends to prevent increase in the lower densities. Examples are the Monckhoven intensifier with a slight excess of cyanide in the redeveloper, or a mercury bromide bleach with a sodium sulphite redeveloper.

(3) Subproportional intensifiers do not fully intensify the intermediate and higher densities. Typical are the uranium toner containing uranium nitrate and potassium ferricyanide, and the chromium intensifier in which bleaching or redevelopment is incomplete.

A very effective intensifier which gives the greatest known degree of intensification of very weak images on fast negative films contains quinone and hypo.

Toning.—The colour of the photographic image can be modified by toning. The normal colour is black or gray, but by modifying the size of the silver particles by special development or other treatment, the colour can be changed, usually to brownish, olive-green, blue or purple. If fine-grain silver images tend to have a "warm" tone, it can frequently be made "cold" by adding certain organic chemicals called blue-black addition agents to the developer.

Toning can be effected by a change in the chemical composition of the silver image. In the days of print-out papers, it was customary to replace the silver of the image by gold by using a bath containing gold chloride and thiocyanate, and modern printing papers can be toned to brown by gold solutions.

Brown, purplish and reddish tones may be obtained by converting the silver into silver sulphide, selenide or telluride. sulphide toning may be direct, in which case the photograph is converted by direct bathing in a solution containing colloidal sulphur or polysulphide, or indirectly, in which case it is first bleached to silver chloride or bromide, which is then acted upon by sodium sulphide solution. Selenium or tellurium dissolved in sulphite or sulphide will tone directly, or the indirect method may be used.

Many coloured metallic salts will be precipitated by the silver image and tone it. In conjunction with ferricyanide, copper and uranium salts give red and brown tones, and iron compounds give blue.

Dye images may be obtained by the methods of coupler development used in colour photography, in which an image of silver halide (obtained by bleaching a silver image if necessary) is developed with the special developer in presence of a coupler (see Colour Photography). They may also be formed by the methods of dye toning in which the silver image is converted into a mordant, such as silver iodide, silver ferrocyanide or a mixture of silver and uranium ferrocyanides, to which the dyes attach themselves.

Sensitometry.—Sensitometry strictly refers to the measurement of the sensitivity of photographic materials, but in practice it includes the measurement of all the factors which go to making a photographic image. The first quantitative measurements of the action of light on photographic materials were made by W. de W. Abney in 1874. He measured the transparency of the image and demonstrated that within limits it varied inversely as the logarithm of the exposure.

In 1890 F. Hurter and V. C. Driffield published a paper, "Photo-Chemical Investigations and a New Method of Determination of the Sensitiveness of Photographic Plates," which laid the foundations of modern sensitometry. They studied the relation between exposure, development and the silver deposit resulting and defined density, D, as the logarithm of the opacity, O, which was defined as the reciprocal of the transparency, T. Thus, if a light of intensity I fails on a photographic deposit, and I is transmitted, then

$T=I'/I$; $O=1/T=I/I'$ and density D =log I/I' or $-\log I'/I$.

The following table shows the relation between a few values of transparency, opacity and density:

Transparency	Opacity	Density
1/2		0.301
1/4	4	0.602
1/8	8	0.903
1/10	10	1.0
1/100	100	2.0
1/1,000	1,000	3.0

The density of the silver deposit in many cases is approximately proportional to the amount of silver per unit area. A density of 1.0 is given by about $\frac{1}{10}$ mg. of silver per square centimetre of film area.

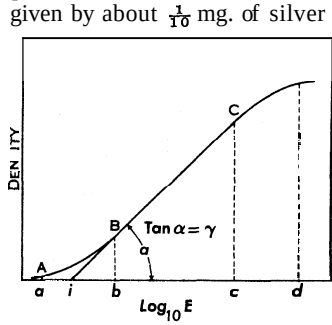


FIG. 5.—CHARACTERISTIC CURVE OF AN EMULSION

The relationship between density and the logarithm of exposure was first shown by Hurter and Driffield in what they called 'the characteristic curve. As light source they adopted first the standard candle and later the pentane lamp. Exposures were made in an increasing series of steps in a sensitometer using a rotating disk in which successively increasing angular apertures had been cut, and the density of the final plates was measured in a visual photometer. This curve is the basis of modern sensitometry. (See fig. 5.)

The characteristic curve has three fairly well-defined portions:

an appreciable part of the curve for most materials is a straight line, B to C, known as the region of correct exposure, because the exposure values rendered on it are directly proportional to the brightness values in the subject; in the lower and upper portions of the curve, this proportionality does not exist, and they are known respectively as the underexposure region or "toe" (A to B), and the overexposure region or "shoulder" (C to D).

The chief use of the characteristic curve is in determining the sensitivity or speed of a film, plate or paper, the contrast, the latitude of exposure and the manner in which tones will be reproduced. The curve must be made under carefully controlled conditions involving. a source of light giving radiation of known intensity and spectral quality; a modulator by which a series of graded exposures of known values are produced; standard development conditions; a means of accurately measuring density; a method of interpreting the results.

Many light sources have been proposed, but that adopted internationally in 1928 was a tungsten filament electric lamp operated at a colour temperature of 2,360° K., and screened with a filter (Davis-Gibson) of specified composition to give light having approximately the spectral quality of mean noon sunlight in Washington (5,400° K.).

The light source and the exposure modulator constitute the sensitometer. Exposures are made on a strip of the material either in a continuously increasing manner, or usually as a series of steps. The change in exposure through the series mag be made by changing the intensity of light or the time of exposure, and sensitometers are therefore either intensity-scale or time-scale instruments. A typical intensity-scale sensitometer is a step tablet or optical wedge consisting of a series of areas having precisely known light transmissions, or a continuously graded transmission. A typical time-scale sensitometer consists of a series of slots of known lengths, cut in a plate which falls past or is rotated in front of the material being exposed.

The exposure may be intermittent, *i.e.*, in a series of short times which add up to the desired total time, or continuous. The early sector wheel sensitometers gave intermittent exposures, for they were rapidly rotated in front of the material. Continuous exposures are to be preferred, however, because the photographic material does not add up the separate short exposures properly for normal frequency of intermittency. This is the so-called intermittency effect.

Since subjects photographed vary in brightness and negatives vary in transmission, and one time of exposure is given in the camera or in printing, the best sensitometers should be of the continuous-exposure intensity-scale type, and the exposure time should be roughly equal to that which would be given the material in use.

Development of the exposed strips is carried out in a standard developer or in the developer recommended for use with the particular material, for the desired time, at a standard temperature, usually 68° F., and under conditions of agitation which will ensure uniformity and reproducibility.

Density is measured in a densitometer, and in accordance with the definition established by Hurter and Driffield. The early densitometers were of the optical bench type using the inverse square law, but in more recent instruments the intensity is controlled by polarizing devices, as in the Martens photonieter, or by variable apertures. Some densitometers are comparators in which the density is compared with one which has already been calibrated on another instrument. Many instruments use photoelectric cells in place of the eye for the measurement.

When light passes through a negative, some of it is scattered or diffused, while some passes straight through and is said to be specular. If all the light, diffused and specular, which passes through is collected and used in the measurement, the density obtained is called the diffuse density. If only the light passing directly through is measured, the density is said to be specular density. The diffuse density is higher and is related to the other by Callier's Q factor, which increases as the density is lower. and also depends on the type of emulsion. The value may range from one to almost two. Most densitometers have a diffusing glass in contact with the negative and the readings are of diffuse density. The most satisfactory and reproducible diffusing medium is an integrating sphere.

Developed materials generally show a very slight density in parts which have not been exposed, and this is known as fog. Some fog is inherent in the emulsion, and some is caused by the development conditions and increases with time in the developer. Any density read also includes that caused by fog. In order to find the density caused by the exposure alone, it is customary to measure the density caused by fog on an unexposed area and subtract it, or make other correction for it.

In the case of prints on paper, the densities must be measured by reflected light, and the definition of reflection density is analogous to that for transmission density. If D_R is the reflection density, and R is the ratio of the light reflected by the paper to the light reflected by the image on it,

$$D_R = \log 1/R.$$

Characteristic curves are drawn by plotting the densities against the logarithms of the exposures which produced them (see fig. 5). If the straight line BC in the figure is produced to meet the exposure axis, it cuts it at a point i, which Hurter and Driffield called the inertia, and at an angle designated as α. This angle is of great importance; and its tangent, that is, the slope of the line BC, was called by Hurter and Driffield gamma (the Greek letter γ). It is frequently used as a means of expressing contrast, but it must be realized that it refers only to the straight-line portion of the curve.

The projection of the straight-line portion of the curve (BC) onto the exposure axis, at the points *b* and c, is called the latitude and is expressed in log E or exposure units. It represents the exposure range over which there is strict proportionality between density and log exposure. The total scale of a negative, on the other hand, represented roughly by the distance a to *d* on the log E axis of fig. j, denotes the whole exposure range within which the material can represent a brightness difference in the subject by a density difference in the negative. In most negative materials the total scale is much larger than the brightness range of most scenes.

As the time of development increases, the slope of the characteristic curve increases. Hurter and Driffield found that with a bromide-free developer, the inertia points for curves for different development times coincided. In other words, inertia was independent of development time and was therefore a very significant constant. Hurter and Driffield, therefore, used the inertia as a basis for a method of expressing speed. So-called "H. and D. speeds" were obtained by dividing the exposure corresponding to the inertia point into 34, a value which was arrived at empirically. Later, other people used other numerators, and the inertia method was used for many years. Unfortunately, it does not hold that with all emulsions and different developers the straight-line parts of the curves will intersect at the inertia, and the inertia method has fallen into disfavour.

Some methods proposed for estimating speeds did not rely on the characteristic curve, but on estimating the exposure which corresponded to a just perceptible density — the threshold density. Such methods included those which used the Eder-Hecht wedge, and the Scheiner method using a rotating sector wheel. A modification of the threshold method was the German DIN system, in which the speed was derived from the exposure required to give a density of 0.1 higher than the fog.

Since the function of the photograph is to reproduce brightness differences in the subject as density differences, it is logical to conclude that speed systems should not be based upon a single density. The idea that they should be based upon a gradient in the underexposure part of the curve, rather than upon a single point or density, was first proposed by R. Luther and later developed by L. A. Jones. It was applied first for Kodak speeds and later adopted by the British and Americans as standard. In the system, it is assumed that negative film speed should be based on the least exposure to give a negative from which prints of excellent quality can be made. On the basis of a statistical

study of print quality, the standard for measuring speeds was selected, based on the exposure, E, in the toe of the characteristic curve where the gradient is 0.3 of the average gradient over a log exposure range of 1.5. (See fig. 6.) Speed= 1/E.

FIG. 6.—ESTIMATION OF SPEED BY FRACTIONAL GRADIENT METHOD

The term speed actually refers to an inherent property of the film itself, whereas in practice the number used should take into account the exposure latitude, the type of exposure meter and the technique by which it is used and so on. Instead of film speeds, therefore exposure indexes based on the speeds have been worked out for practical use. Exposure index

It has already been mentioned that as development time is increased, the slope of the characteristic curve, or the gamma, increases. A typical series of curves is shown in fig. 7. Ultimately, further increase in development time results in no further increase in contrast, and the maximum obtainable is known as gamma infinity (γ_∞). If gamma is plotted against time of development, a rate-of-development curve or a time-gamma curve is obtained, similar to that in fig. 8. The curve describes the rate of change of development with time, showing that it increases rapidly at first and then gets slower until it reaches a limit. The limit reached depends on the developer and on the emulsion, being lowest for the high-speed materials and highest for the very slow materials used for photomechanical reproduction.

FIG. 7.— CHARACTERISTIC CURVES OF FILM FOR FOUR TIMES OF DEVELOPMENT. THE TIMES INCREASE IN THE ORDER 1, 2, 3, 4

The sensitometric characteristics of printing papers can be described by a series of figures parallel to those used for negatives, and derived from characteristic curves obtained by plotting reflection densities against the logarithms of the exposures. The most important constants of a paper are the *exposure scale*, which is determined by limiting exposures in the high and low density regions of the curve, the *density scale*, which is the difference between the densities corresponding to these two limiting exposures, and the *useful maximum density*, which is the density corresponding to the upper limiting exposure. The speed values of photographic papers are based on a gradient, as in the case of negatives, but it is at the limiting exposure in the high density part of the curve.

FIG. 8.—CURVE SHOWING INCREASE OF GAMMA WITH TIME OF DEVELOPMENT

The contrast of a printing paper is a difficult thing to define, since it involves both psychological and physical considerations, but it has been expressed in terms of sensitometric characteristics.

Increasing the development time of papers mainly increases the effective speed in the case of chloride and chlorobromide papers, since gamma infinity is reached very rapidly, but with bromide papers, increased development increases both average gradient and speed.

An important factor is the *failure of the reciprocity law*. The law itself was first enunciated for photochemical reactions, and stated that the result of the action of light depends on the product of the light intensity and the time of action, and not on the individual values of either. W. de W. Abney found that it does not hold in the case of photography that the density resulting from an exposure E is independent of the absolute values of I and t, where $E=It$. Generally, the curve relating density to intensity for constant It has a maximum, as shown in fig. 9. The extent of the failure varies with the emulsion, the sensitizing, the nature and extent of development and other factors. It may have much practical significance in the case of the very long exposures used in astronomy, or the very short bright exposures of some flash tubes. An effect closely associated with the reciprocity law failure is the *intermittency effect*.

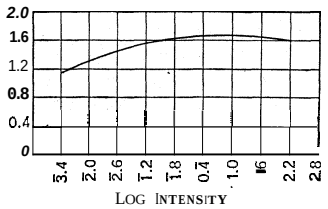

FIG. 9.—GRAPH SHOWING RELATION BETWEEN DENSITY AND INTENSITY " BEING CONSTANT

In addition to their sensitometric characteristics, photographic materials differ in *graininess* and *resolving power*. Graininess refers to the visual appearance of inhomogeneity in a developed photograph. Many methods have been proposed for measuring it, depending largely on visual observation of conditions under which it will just disappear, or comparing it with a set of standards. Measurements have also been made by physical means of *granularity*, which is the objective aspect not involving the psychophysical factors encountered in visually judging graininess. Graininess depends on a variety of factors. It is generally more noticeable in fast emulsions than in slow, it depends on the nature of the developer and it increases with time of development or contrast, and with the density of the image, reaching a maximum at a density of 0.6–0.8. In prints, graininess increases as the density of the negative increases.

Resolving power is defined by its ability to distinguish fine detail in the photograph. It is usually expressed as the number of lines per millimetre which can just be separately distinguished in the photograph. In general, the resolving power increases as the emulsions are of lower speed and higher contrast. The values range from 40–50 lines per millimetre for fast negative emulsions, through 80–100 lines for positive types of film, to several hundred lines for some special, slow, high-contrast materials. The values depend also on the contrast of the image photographed, the spectral quality of the exposing light, the density of the image, the turbidity of the emulsion and other factors. In practical photography, the combined resolving power of a lens and film combination is lower than that of either the lens or the film.

The simplest emulsions respond only to ultra-violet, violet and blue light, but by dye sensitizing they can be made to respond to other wave lengths. In measuring the *spectral sensitivity* of an emulsion it is customary to trace the curve showing its response to different wave lengths of a source of a particular spectral quality, or to an ideal source in which the energy is assumed to be the same at all wave lengths. The response to a particular source, such as a tungsten filament lamp, is frequently measured in a wedge spectrograph, which is a spectrograph in which the sample is exposed, and having an optical wedge over the slit, so that the photograph of the spectrum obtained will vary in height at any wave length according to the response of the material to the light source at that wave length. For equal-energy spectral sensitivity measurements, characteristic curves of the material are made for a series of narrow wave-length bands isolated in a spectroscope, and from the curves the sensitivity values for equal energies at all wave lengths are deduced and plotted against the wave lengths.

Tone Reproduction. — The basic problem of photography is to make a reproduction which will produce in the mind of the observer the same sensations as were produced by viewing the original scene. At least, it is important to represent satisfactorily the brightness aspects of the original on a paper surface. There are two major aspects of the problem. One of these is the objective phase, in which by physical methods it is possible to determine the fidelity with which the brightness and brightness differences in the original subject are rendered in the reproduction. On the other hand, the faithfulness with which the appearance of the original is reproduced involves psychological factors, and this is the subjective phase of the problem.

The quality of the reproduction of tone obtained in a two-stage negative-positive process depends on a variety of factors,

including the intensity of the light from the subject, flare light in the camera, the spectral sensitivity, exposure, development and shape of the characteristic curve of the negative material, the type of printer or enlarger and flare light in the enlarger, the exposure, development, shape of the curve and kind of positive printing material and the method of viewing the final photograph. The tone-reproduction problem has engaged the attention of many photographic workers, and complete studies have been made by L. A. Jones (see C. E. K. Mees, The Theory of *the Photographic Process*).

PHOTOGRAPHIC MANUFACTURE

Before the introduction of the dry plate, photographers made their own materials. In 1873 there appeared in England the first advertisement for a gelatin emulsion ready for use, and the first coated plates were placed on the market in England. In 1880 Eastman marketed plates in America and manufacture began on the continent.

The manufacture of photographic materials is now a large and specialized industry, and the distribution of its products is one of the world's big businesses. Until 1900 small factories under the control of their founders produced most of the sensitive products, but modern manufacture is largely organized in factories operating on a big scale.

The three chief photographic sensitive materials are plates, films and papers, and in each case three main manufacturing operations are involved — preparation of the base or support, manufacture of the sensitive emulsion and coating of the emulsion on the support. In addition, there is the cutting to shape and the packing.

Preparation of the Support. — Glass Plates. — The support of plates is glass sheets which are chosen from the higher grades of sheet glass made for various purposes. It is selected for reasonable optical flatness and freedom from blemishes. It is cleaned by brushing in alkaline solutions in special machines, and is then coated with a substratum, *e.g.*, of a weak solution of gelatin containing chrome alum, which will cause the gelatin emulsion to adhere to the glass. It is then dried, examined to reject defective sheets and passed to the coating room. The thickness of glass for plates increases with the size, and ranges from about 0.05 in. to 0.125 in.

Film Support. — Film support or base consists of a transparent, thin layer of cellulose nitrate, acetate or mixed esters, free from cloudiness or other optical defects. In general, it ranges in thickness from $3\frac{1}{4}$ thousandths of an inch for roll film, through $5\frac{1}{2}$ thousandths for motion-picture film, to $\frac{7}{8}$ thousandths for sheet and X-ray film. It is coated as a layer of viscous liquid called dope on a continuously moving smooth surface on which it sets and from which it is stripped and dried.

Cotton in the form of linters, which are the short fibres remaining on the cotton seed hull after the long fibres have been removed, is the source of cellulose for film base. It is first mechanically cleaned to free it from dust, mechanical particles, etc., and then degreased by heating under pressure with dilute alkali. It is then washed and bleached, treated with dilute acid to remove the last traces of bleaching solution and iron and washed again. The water is centrifuged off, and the cotton is conditioned to a low moisture content.

To form nitrocellulose with the correct properties, the cotton is nitrated with extreme care in a centrifuge, in a mixture of sulphuric acid, nitric acid and water, to give a product with about 12% nitrogen. It is then centrifuged thoroughly, washed extremely carefully and treated with dilute alkali to remove last traces of acid, bleached, washed again and dehydrated with alcohol.

To form cellulose acetate, the cotton is treated with acetic anhydride and acetic acid in the presence of a catalyst, usually sulphuric acid. The product is cellulose triacetate which can be precipitated out with water, and has an acetic acid content slightly under the theoretical value of 62.5%. To produce the variety for common safety film base with a lower acetic acid content, the product is hydrolyzed with water, sulphuric acid and other reagents. The acetate is thrown out of the solution by adding water, centrifuged, washed and dried. Nitroacetate, which has been used for film manufacture, is made by acetylating cellulose nitrate.

In order to convert the cellulose nitrate or acetate into film base, it is dissolved in suitable solvents. In the case of the nitrate, typical solvents may be methyl or ethyl alcohol and ether, or methyl alcohol and acetone, with a third material, such as amyl alcohol, to reduce the rate of evaporation of the solvent on drying. The solvents for cellulose acetate vary according to the method of preparation, but among those used are methyl acetate, methyl formate, methyl ethyl ketone, chlorohydrocarbons, amyl acetate and others. It is also common to add a nonsolvent for cellulose acetate, such as alcohol and water, to control evaporation of the solvent.

In addition to the solvents, softeners or plasticizers are added to give flexibility to the final film. For nitrate base, the softener is largely camphor, and for acetate base there is a large variety, *e.g.*, esters of phthalic acid, mono-, di- and triacetin, sulphones and sulphonic esters. The solutions are prepared in proportions suitable for coating, filtered and bubbles of air are removed. They have the appearance of clear honey and are called dope.

To form the film base, the dope is spread out into a thin layer by coating it onto a smooth travelling surface. In the United States, it is usually done on big wheels, approaching 20 ft. in diameter, with optically finished rims 4–6 ft. wide on which the dope is spread as the wheel rotates, and in Europe the coating is mostly made on endless metal bands about 26 in. wide and 40 ft. or more long, and sometimes coated with gelatin. After the band or drum has made almost one complete revolution, the film has set to such an extent that it can be continuously peeled off and passed over a series of heated drums until it is finally wound up in rolls of about 2,000 ft. The coating machines are completely enclosed so that the evaporated solvents may be drawn off and recovered. Special coatings or treatments may be applied to the film base, for instance, to modify its tendency to curl, to reduce the formation of electrical charges on handling, to change the colour, etc., and particularly to enable the emulsion to stick.

Cellulose acetate film is called safety film, since it is slow burning, presenting about the same fire hazard as common newspaper. It is used exclusively for amateur and educational motion-picture film, X-ray and portrait films and is coming into use for films for other purposes. Cellulose nitrate film is highly inflammable, but, at least until recently, it possessed a number of advantages over acetate film and was used where proper precautions against fire could be relied upon.

Paper Base. — Photographic paper base is generally made in mills which specialize in its manufacture. It is generally made from rag stock or specially prepared wood pulp. The methods of manufacture are similar in general to those used for other papers, but extreme care is taken to exclude traces of impurities, and especially of metals such as copper and iron from the paper stock. The composition of the paper and its treatment varies according to the purpose for which it is to be used. It is appropriately sized, and it must have high wet strength, for it has to undergo much handling while soaked with water and alkaline and acid solutions. It is generally made about 41 in. wide and 500–1,000 yd. long. It is calendered to give a closer texture or smoother surface or to give a special surface finish.

Before it is coated with the emulsion, photographic paper is usually baryta-coated, *i.e.*, a suspension of baryta (barium sulphate) in gelatin is coated over the surface; and if a high gloss is needed, the paper may be calendered after coating with baryta.

Emulsions. — Emulsions are of two main types, used for negative materials and for positive materials, generally printing papers. Negative emulsions consist of suspensions in gelatin of silver bromide containing a small amount of silver iodide, and the soluble salts which result from the precipitation of the silver halides are removed by washing. The emulsions for paper may also consist of silver bromide in gelatin and be washed, but usually printing paper emulsions consist of silver chloride or a chloride and bromide mixture in gelatin and not washed.

In making negative emulsions, silver nitrate is run into a solu-

tion of potassium bromide containing a small percentage of potassium iodide, and a low percentage of gelatin. The temperature, rate of addition and stirring are controlled, and the mixture is ripened in the presence of excess bromide at an elevated temperature, or of ammonia at a lower temperature, until the silver halide crystals have attained the required size and size distribution. More gelatin is then added, the emulsion is set to a jelly by cooling, cut into shreds and the shreds washed in cold water. The washed emulsion is then melted again, more gelatin added if necessary and the whole is digested by maintaining it at a moderate temperature during which period contrast and speed build up. Sensitizing dyes are added if required, and finally special additions to preserve the emulsion, to keep down fog and to aid in coating are included.

In making paper emulsions, chloride or a mixture of chloride and bromide are most used, most of the gelatin is added before precipitation and the emulsion is unwashed. Some of the high-sensitivity bromide papers used for enlarging are made with washed emulsions similar to those made for slow negatives or for motion-picture positive film or lantern slides.

There is one type of paper, which is now used only for making proofs by directly printing-out the image in sunlight or mercury light, which is also unwashed, and in which the silver salts are a mixture of chloride and citrate.

Coating.—Plates are coated with emulsion by passing the cleaned and prepared glass sheets, on a horizontally moving belt, under a device which permits the melted emulsion to spread out in a uniform layer on the glass. The coated plates pass to a cold moving belt or set of rollers where the emulsion sets, and at the end of the machine they are placed on racks and dried slowly and evenly in cabinets. When dry, they are cut to the required sizes by machines provided with diamonds, and packed with specially prepared interleaving paper in boxes for the market. Sometimes a special antihalation coating is applied to the back of the glass.

A great variety of plates in a wide range of sizes is made. For much photography there has been a tendency for sheet film to replace glass plates, but plates are much used in the graphic arts, commercial photography, for colour separation negatives, lantern slides, photomicrography, and in a great range of speeds, contrasts and spectral sensitivities for astronomy and spectroscopy.

Film and paper may be coated on the same type of machine. The roll of support, usually 42 in. wide and about 2,000 ft. long, is led over a series of rollers which keep it taut, into a coating trough or other device where a layer of emulsion is applied to it, the thickness depending an the temperature, viscosity and rate of travel. The coated base passes into a vertical run-up, where the emulsion coating evens itself out, or over a chill roll and then into a cold chamber where the emulsion is thoroughly set. The film or paper is then automatically looped into festoons varying from 5 to 20 ft. in length, and travels slowly through drying tunnels supplied with cleaned air of properly adjusted temperature and relative humidity. The dried film or paper is continuously reeled up into rolls of appropriate length and is then sent to the finishing departments.

In the case of many films, the back is coated with a layer containing dyes, which are destroyed or removed in processing, to prevent halation and sometimes to prevent curl. Special coatings may be applied over the emulsion in films and papers to prevent abrasion marks. Some motion-picture films are coated on a support carrying a nonremovable dye to reduce halation.

In modern films for colour photography, many separate coatings may have to be applied, for instance, there may be three emulsions responding to blue, green and red. with separating or filter coatings between them, and in addition antihalation coatings on the back.

Motion-picture film is slit from the roll in 35-mm. or 16-mm. width and is perforated for camera or projector use with standard perforations. It is edge printed with the maker's name and other marks in such a way that they become visible on development, and footage numbers are printed in the case of 35-mm. negative film, to aid in editing. Professional motion-picture film is packed in a variety of lengths, but mostly in 100-, 200-, 400- and 1,000-ft. lengths. The 16-mm. film is generally wound on metal spools in 100- or 50-ft. lengths and provided with leader for daylight loading, or in special magazines. Thirty-five-mm. film for miniature cameras is spooled in special cassettes in lengths for 18-, 20- or 36-exposures.

Roll films are slit from the full coated rolls in the required widths and lengths, usually for six or eight exposures, and wound on metal spools with light-impermeable backing paper so that they may be handled in daylight. Sheet films are cut in sizes comparable with plates and packed in a similar manner. In the case of film packs, the sheets are attached to black paper sheets carrying numbered tabs and inserted in groups of 12 in metal holders. For X-ray photography, film is usually coated on both sides with emulsion, and individual sheets are put into special light-tight envelopes.

Photographic paper is cut from the roll into sheets which are stacked and cut to the desired sizes by a guillotine, wrapped in black paper and boxed.

All plates, films and papers are carefully inspected at various stages during manufacture to ensure the minimum of defects, and all wrapping and packaging materials are carefully selected so that they will not have any adverse effect on the emulsion. For the tropics, special packaging methods are used which will not permit moisture to enter the containers.

APPARATUS

The most important piece of photographic apparatus is the camera, in which the photograph is made. Next is the equipment for printing and enlarging. The other important items are the apparatus for lighting the subject and that for handling the material in processing. There are large numbers of accessory apparatus. Of these may be mentioned the supports for the camera, filters, range finders, exposure meters, the special equipment for darkrooms and the devices for storing and viewing photographs. Lenses are dealt with later in this article. For detailed discussion of the historical development of photographic equipment, the reader should refer to some of the works listed in the bibliography of this article, particularly those by C. Fabre, J. M. Eder and K. Pritschow.

Cameras.—A camera consists of an image-forming device, which may be a pinhole but in practice is a lens; a shutter which permits light to enter the camera for a desired time; a holder for the sensitive material on which the photograph is to be made; a light-tight enclosure which carries the lens and material holder in their proper positions and prevents light not passing through the lens from falling on the material and a finder to show what is being photographed.

The camera is a direct descendant of the camera obscura, the principle of which was known to Aristotle, and was described by Leonardo da Vinci before 1519, and by Giovanni Battista della Porta in 1553. These were pinhole models, and the first description of the lens in the camera obscura must be accredited to Daniello Barbaro, in 1568. The early cameras were actually rooms, but later portable models were made and used for entertainment and as an aid to drawing. In 1826 Niepce made a photograph with a camera obscura equipped with a lens, and Fox Talbot and Daguerre established its use. The first commercially available cameras for photography were made by A. Giroux in Paris for Daguerre in 1839. They consisted of two wooden boxes sliding one in the other for focusing, a Chevalier simple achromatic lens, a pivoted metal cover to act as shutter, a ground glass back for focusing and a holder for the plates. Other models of cameras were quickly introduced, and the tripod was used in 1839 by Baron P. A. Séguier, who also introduced the collapsible bellows to make the camera more portable. To the same end, Peter Voigtlander made the camera conical in shape. The first panoramic camera was invented by F. von Martens in 1845.

Fox Talbot used simple cameras with telescopic boxes in his photography, and the construction was not much changed in the '50s when the wet collodion process was introduced, except that special holders were used for wet plates and the bellows was in common use. Wet plate cameras ranged in size from miniatures

taking plates about one inch square, to those taking very large plates of glass.

With the advent of the dry plates there was a demand for more portable cameras, because photography became easier for the general public. Plates for these were loaded into special single or double holders for use in the backs of the cameras. Sometimes 12 plates could be loaded in the back, a special device being provided for dropping them in the bottom of the camera after exposure, or magazines containing a number of plates could be used in the position of a single plateholder.

When paper roll film was introduced by Eastman in 1885, it was loaded into roll-holders which fitted on camera backs in place of the plateholders. In 1888 the Eastman company introduced the Kodak which was a simple box camera containing a roo-exposure roll of stripping film. This marked the introduction of modern amateur photography with roll film and the small hand camera. In 1889 the first transparent flexible roll film was marketed and many light-weight box and folding cameras were introduced for use with this type of film. In 1894 the roll film was packed with a roll of black paper to permit loading and unloading in daylight, and small cameras in box and folding form became popular. The first pocket Kodak was introduced in 1895 and the first of the collapsible cameras, the folding pocket Kodak, in 1898. The small cheap Brownie camera, originally intended for children, appeared in 1900. Later, sheet film instead of plates began to be popular in certain cameras of the plate type and the film pack was also introduced to provide a convenient magazine of sheet films for this type of apparatus.

Large studio portrait cameras were introduced in the wet collodion days. They had long focus lenses and from them were derived the later studio cameras taking dry plates and sheet film. Sturdy stands were used, adjustable for height and inclination and on casters to permit moving them easily. The cameras were generally of the square bellows type, with means for rapidly focusing by rack and pinion movements and with rising and falling fronts designed to carry heavy lenses.

The so-called field cameras were mainly intended for use outdoors on a tripod, for large groups, genre studies, landscape photographs and so on. The cameras were rigidly constructed, and had long bellows, rising and falling fronts and swing backs. Some had parallel instead of conical bellows, and they are still used in studios for copying.

With improvement in plates and films and facilities for enlargement, the use of large cameras tended to decrease. The small-sized pocket cameras increased in popularity, but there was developed an important group known as hand-or-stand or view cameras. They used relatively small plates, sheet films or film packs, had ground-glass focusing as well as focusing scales, long-extension bellows, rising, cross and swing movement for the front, swing, reversible and revolving backs and drop or swinging beds. They were the basic small cameras of great flexibility.

Small cameras were developed in the second half of the 19th century as instantaneous-hand-cameras or detective cameras, and in general they used lenses of short focal length with good depth of focus. Even in the wet collodion days, some were small enough to fall into the class now known as miniature cameras. Some of them were of the secret type, which could be concealed from the subject, *e.g.*, in the hat, vest or necktie, or had the form of some familiar object such as a book, satchel or pair of binoculars. Some cameras took the form of pistols or revolvers and used very small plates. The Skaife pistolgraph of 1360 was only $3\times1\frac{1}{2}$ in. in size over-all. These were the forerunners of the modern miniature cameras,

Early in the 20th century very small roll-film cameras, such as the Vest Pocket Kodak, were introduced and in 1914 there were brought out the first still cameras using 35-mm. motion-picture film. The new vogue in miniature photography did not develop until the '20s, however, being given a great boost by the introduction of the Leica in 1924. This camera had been designed by O. Barnack for testing motion-picture film. A wide variety of such cameras followed, and in general they used 3j-mm. film with pictures twice the normal motion-picture frame size, *i.e.*, 24×36 mm. in 18-, 20- or 36-exposure cassettes. The cameras were characterized by compactness. They had high aperture lenses of short focal length. and some had focal plane shutters and provision for interchanging lenses and coupled range finders. Special processing, printing and viewing equipment was made, films of fine grain permitted high enlargement of the small negatives and special colour films and projectors were made for use with the cameras.

Special cameras are used for press photography, many of them being based on the German Goerz-Anschiitz and the English Panros, which were introduced at the start of the 20th century. The most popular type in the United States in 1947 was the Speed Graphic. These cameras were designed for rapid use at eye level, and generally have focal plane shutters, large finders for rapidly viewing and composing the subject, means for rapidly opening and focusing them and, in modern models, range finders and flash lamp attachments.

In reflex cameras, it is possible to compose and focus the image to be photographed up to the moment of exposure. There are two forms. In that first developed (Sutton, 1860; Marco, 1883), a mirror inside the camera reflects the image to a ground glass on top, which is viewed through a collapsible vertical hood. The mirror is pivoted; and when the lever is pressed to make the exposure, the mirror is first urged out of the light path. The cameras usually have focal plane shutters, and folding types have been made. In the second type, called the twin-lens reflex camera, two similar cameras are in effect used, one above the other. The upper camera serves as the finder, while the lower carries the taking lens, shutter and film. In older forms of twin-lens camera the ground-glass focusing screen of the finder was in the rear, but in modern forms a reflex finder is used, a mirror reflecting the image to a focusing screen on top.

For panoramic photography, special cameras are used to cover the wide angles of view frequently involved. Panoramic photographs may be made with an ordinary camera by taking a series of pictures which slightly overlap, swinging the camera about the nodal point of the lens. In single cameras, the lens may be rotated about its optical centre while a curved film is scanned by a slit (Martens, 1845, Kodak), or the camera may be rotated about the centre point of the lens, the film being moved to compensate for the image movement. Such cameras are sometimes used for photographing large groups of people, or for wide landscape views.

Special cameras or attachments are used for stereoscopic photography. In principle, two photographs must be made from positions corresponding to the positions of the two eyes of an observer, and the prints must be viewed in such a manner that each eye sees only its appropriate view. Two successive views may be made from two camera positions, using a single-lens camera, but the most-used cameras are made with two lenses to make two photographs simultaneously. Alternatively, a single-lens camera may be provided with a beam splitter having two reflectors spaced at about the interocular distance apart, and giving two adjacent photographs on the normal picture area.

Shutters and Diaphragms. — The exposure in a camera is made by a shutter which is opened and closed to permit light to pass through the lens. The earliest shutters were hinged or pivoted metal plates by which the front of the lens could be uncovered and covered by hand. These, and the removable lens cap, could be used only where the exposures were rather long. With faster plates and shorter exposure times quicker-acting shutters were needed. The simplest was the guillotine or drop shutter which consisted of a wooden or metal plate with a hole in it, allowed to drop freely, or urged by a spring or rubber band, across the lens. In modifications of this, a second plate is provided to prevent light passing through the lens while the shutter is being set, or two plates with holes move in opposite directions, or the plates rotate rather than slide in a straight path. Modifications of some of these are still used on some cheap cameras. Varieties of flap shutter consisted of one or two hinged flaps opening outward. The roller-blind shutter has a blind with a fixed slit aperture, mounted in a frame and used behind or before the lens. The blind can be wound so that when it is released the slit passes rapidly across the lens, the speed being varied by changing the tension.

Two types of shutter were in common use in 1947: focal plane and diaphragm or between-lens shutters. In the focal plane type, a roller blind is used, having a single adjustable slit or a series of slits of different widths, one of which travels across the film to expose it. The tension on the blind and the setting of the slit are operated from outside the camera. The shutter operates just in front of the film—practically in the focal plane—and is capable of exposures as short as $\frac{1}{1,000}$ of a second. The common types of diaphragm or between-lens shutters have their blades arranged near the diaphragm between the lens elements. They usually consist of three or more thin blades which open out from and close into the centre of the lens. They are made to give a range of exposure times, in some cases from 1 sec. to a nominal $\frac{1}{500}$ sec., in addition to "bulb" in which the shutter stays open so long as the release is pressed, and "time" at which the shutter is opened when the release is pressed, and closed at any later time when it is again pressed. A spring provides the motive power to open and close the blades; and the time the shutter remains open is controlled pneumatically, or by gears and escapements.

Diaphragms, or stops, are apertures which control the amount of light admitted through the lens. They are arranged in front of the lens or between the elements, depending on the lens type. There are three main forms: Waterhouse stops, which consist of a metal plate carrying a single hole, and able to be inserted in a slot in the lens barrel; rotating stops, which are circular plates carrying a series of holes of different diameters, any one of which can be brought into position in the lens, and iris diaphragms, which consist of a series of overlapping leaves of metal associated with a rotatable ring to form an approximately circular aperture the size of which can be varied by turning the ring.

Finders.—Finders are important in that they show exactly what will be included in the photograph. In cameras which have a ground-glass focusing screen, the screen can be used to compose the picture as well as to focus it. In single-lens reflex cameras, in which the camera lens is used as the finder, the picture can be exactly composed on the ground glass to which the image is reflected. Most finders, however, are auxiliary to the camera. They are usually arranged on the top or side of the camera body, and view the subject from a slightly different angle from the lens. The errors introduced by this separation are reduced by putting the finder as close to the lens as possible, making the axes of the two intersect at about 15 ft. from the camera, and making the finder field smaller than the camera lens field. The errors will be apparent only in the case of very near subjects.

Finders can be divided into two general classes—reflecting finders and direct-vision finders. The simplest reflecting finder is a small camera with a simple lens, a mirror and a ground glass to which the image is reflected, reversed left to right. In the "brilliant" finders more commonly used the ground glass is replaced by a viewing lens. In twin-lens reflex cameras, the finder is essentially a duplicate of the camera, placed above it, and having a mirror which reflects the image to a ground glass where it can be composed and focused, the focusing mechanism being connected with that of the camera lens so that when the finder is in focus, the camera lens is in focus. Direct-vision finders are used close to the face. The simplest consists of a wire frame of the picture size arranged over the lens, and a peep sight behind in the plane of the film. In a more compact form, the aperture of the front frame is reduced in size and placed nearer the peep sight, the angle included remaining that of the camera lens. Direct-vision optical finders consist essentially of a reversed telescope, with a strong negative lens in front and a weak positive lens at the eye.

Range Finders.—Range finders are used in photography to measure accurately the distance of the subject from the lens. They may be separate from or attached to the camera and are small versions of those designed for military use. They are of the split-field and coincidence types. In coupled range finders, the range finder is mechanically coupled to the camera lens so that when a distance is determined in the range finder, the camera lens is automatically focused on that distance. The field of the range finder sometimes forms part of the full field of the view finder, so that it is only necessary to look through one eye lens to focus and compose.

Focusing Scales.—Cameras which do not rely on ground-glass focusing or coupled range finders are equipped with focusing scales. When the whole front of the camera moves in focusing, the scale is attached to the camera bed. If focusing is by rotating part of the lens, the scale is on the lens mount or shutter face.

Depth-of-Field Indicator.—Many cameras carry a table or circular slide rule which shows the distance range in focus for various distances on which the camera may be focused, and for various lens apertures.

Flash Attachments—In the early days, flash photographs were taken by burning magnesium ribbon, or by exploding a powder containing magnesium and an oxidizing agent, the camera shutter being opened before and closed after the burning time. Modern flash photographs are made by flash bulbs of glass containing wire or foil of magnesium and aluminum in an atmosphere of oxygen, or by condenser discharge lamps. They are fired electrically, and the circuit is closed when the camera shutter is operated. In one form, operating the shutter brings into play a solenoid which at the appropriate moment closes the battery circuit to the flash bulb. In the other form, the shutter itself is provided with a contact which closes the flash-bulb circuit as the shutter operates. Various settings are provided to be used according to the delay in the firing of the flash after the circuit is closed.

Exposure Estimation.—Experience gives photographers confidence in their unaided judgment of exposure, but for many people and in special circumstances, some guide is useful. *Exposure tables* are provided by most film manufacturers. They are reliable if carefully compiled. They usually give exposure times and lens apertures for the time of day, latitude, weather conditions, degree of light and shade and for various types of subjects. *Exposure calculators* are forms of slide rule in which the exposure can be calculated from the type of data given in exposure tables, the first important calculator being the Hurter and Driffield Xctinograph of 1888. A calculator was usually combined with the older chemical type of meter and is alnays included in the modern devices. *Chemical exposure nzeters or actinometers* depend on measuring the light value by a photochemical change, usually the time taken for a silver-chloride paper to darken to a standard tint, *e.g.*, in the Watkins and the Wynne meters, but the Hurter and Driffield Actinometer nas a form of differential thermometer which was used to provide the light values for the Actinograph. *Visual, optical* and *extinction exposure meters* are photometers in which (a) the brightness of a scene is compared with a calibrated lamp, the light from nhich can be modulated in a known way; (b) the scene is viewed through the instrument and a neutral density wedge is adjusted until shadow detail disappears or (c) a numbered or lettered step wedge is moved across the integrated light from the scene and the dimmest number or letter is taken as the basis for calculating the exposure. *Photoelectric exposure meters* measure the light by a barrier-layer type of photocell and a sensitive direct current meter. The meter readings are translated into exposures by using a calculator. These meters are used as illumination meters, which measure the light falling on the subject, and more generally as brightness meters, which measure the integrated light reflected by the scene, or the brightness of a particular part of it, the angle of view or acceptance angle being chosen to approximate that of the average camera lens. They are also used for determining exposures in contact printing and enlarging.

Light Filters.—(See also FILTERS, LIGHT). Filters are sheets of dyed gelatin or other plastic, coloured glass or other medium, specially designed to transmit particular regions of the spectrum and absorb others, or to absorb uniformly through the visible spectrum. There are many forms used in photography:

Correction (orthochromatic) filters are designed for use with panchromatic materials to ensure that the film-filter combination gives a photograph in which the tone values agree as closely as possible with those perceived by the eye. *Contrast filters* are used to enhance or subdue contrast in the reproduction of the subject, the principle being that to render a colour light in the print, a

filter is used which transmits that colour, and to render a colour dark in the print, a filter is used which absorbs that colour. *Colour compensating filters* are used with colour films to correct for variations in the colour of the light source or the colour response of tht film, to ensure good colour balance in the photograph. *Separation filters* are intended for use in two- and three-colour photography and in photomechanical reproduction in order to make the separation negatives for the printing process. *Monochromatic filters* transmit a narrow spectral band and are usually used in conjunction with a gaseous discharge light source. *Safelights* are filters designed for use with a specified lamp, to provide just enough light to see in handling plates, films and papers without fogging them. *Haze filters* decrease or eliminate the flattening influence of atmospheric haze. *Graduated filters* are made in such a way that the transmission varies over the area of the filter, the most used being the sky filter, which is yellow in the top part and graduates into clear in the lower part, and the neutral wedges or tablets, in which the light transmission varies along the length of the filter either stepwise or gradually. *Neutral density filters* reduce the photographic effectiveness equally at all wave lengths in the visible spectrum. *Special filters, e.g.,* for infra-red and ultra-violet photography. In addition to the normal types of filters there are special polarizing sheet materials (Pola-screens) which are used for subduing reflections and for special sky and other effects. Such filters are also made in combination with coloured filters.

Filters having the most precise spectral transmission and the best reproducibility are made from dyed gelatin sheet which may be used alone, coated with a transparent lacquer or cemented between glass or plastic sheets. Filters are also made of coloured glass, but they are not easily reproducible.

Most filters absorb some light, and in making photographs through them it is therefore necessary to increase the exposure by an amount which is known as the filter factor. In addition, filters can be made from coloured liquids or gases in special glass cells, but they are used only for special purposes.

Supports and Tripods.--When it is necessary to compose a photograph carefully, or when exposures longer than about $\frac{1}{25}$ sec. are to be given, it is necessary to use the camera on a rigid support. For commercial photography these supports may be of complex mechanical construction, permitting the camera to be used from near floor level to a great height above it, and to be tilted to any angle, and yet be quite steady. Portrait studio cameras are of sturdy pillar construction with means for rapidly raising and lowering the table on which the camera rests, and for moving rapidly about the studio floor. For general photography the tripod forms of stand are most used. They are made of wood, or preferably metal, and frequently have adjustable legs to permit folding or telescoping to increase portability and to allow them to be suited to uneven ground. The tripod top, or head, is generally flat and provided with a screw which attaches the camera by a special socket in its body: In flexible models, a second raised head can be used to give extra height, and there are means for rotating and tilting the head.

Auxiliary Camera Equipment.— Lens shades are used on the front of the lens to prevent as much light as possible not coming from the subject from reaching the front of the lens. Shutter operators with a pneumatic bulb or Bowden cable are used to operate the shutter at a distance. Changing bags are used to load plate- or film holders (or developing tanks) in daylight when a darkroom is not available.

Dark slides, or plate- and sheet-film holders, are used to carry plates or sheet films and to position them in the plane occupied by the focusing screen. They are provided with a draw-slide which makes them light-tight, but which can be withdrawn in the camera before the exposure is made. They take one or two plates or films, in the latter case back to back with a metal partition between. Film packs are used in special adapters which fit in the place otherwise used by dark slides, and are provided with draw slides. Roll-film adapters make it possible to use roll films in cameras made for plates and sheet film, and alternatively some roll-film cameras have plate or sheet-film adapters. Plate or sheet-film magazines contain 12 or 18 thin metal septums, each carrying a plate or sheet of film. After the front one has been exposed, it is transferred to the back of the group so revealing the next for exposure, the whole being done in the light-tight magazine.

Special Cameras.— Special cameras are designed for many of the particular applications of photography. They can not all be described here, but the following are a few of the important ones.

For photomicrography the cameras are of the conventional type using plates or sheet film, but they are arranged on special vertical stands or horizontal optical benches in conjunction with the microscope, filters, light source and a variety of attachments and adjustments for ensuring alignment.

For colour photography special cameras were devised to permit making three-colour separation negatives through three primary filters (see *Colour Photography).* In the simplest form, the negatives can be made by three successive exposures, changing the plateholder and filter three times. In repeating backs, the three filters mere placed in a row in front of a long plate or three separate plates in one holder which was moved through the camera back in three steps, one for each exposure. These are now obsolete and have given way to one-exposure three-colour cameras in which an arrangement of reflectors permits the three exposures to be made simultaneously. These cameras are used primarily for commercial colour photography but are being partly eliminated by the integral tripack films.

Cameras for copying in photomechanical reproduction may be large and complex. They may have to handle dry plates and film and wet collodion plates; provision is made for photographing through half-tone screens with means for varying the distance of the screen from the plate; precision lenses of long focal length are used and arrangements are made for changing filters. Some cameras have vacuum backs in which film is held flat by sucking it against a back-plate. Provision is made for accurately arranging parallelism of the plate or film and the copy, and special supports are used to eliminate effects of vibration. In copying cameras used for mapping, provision may also be made for correcting distortions by tilting the plate- or film-holder or the copy. Photocomposing cameras are available in which, through the operation of a keyboard, negatives of type face can be photographed on a roll of film in rapid succession, the material thus being actually composed photographically to give a negative from which a printing plate can be made directly. Composing backs are made in which a series of photographs of a number of pieces of copy can be made on one film or plate, properly arranged in relation to each other, thus composing a page of a variety of subject matter.

A wide range of cameras was made by 1947 for copying documents by microphotography on film. In the simple forms, negatives are made on 3j-mm. film in miniature cameras, but for work where large numbers of negatives of all kinds and sizes of subject matter are required, special cameras, with film and paper-feeding devices, special framing means and other refinements, are used. One of the most important developments in this field was the Recordak, originally brought out for the use of banks in copying checks on 16-mm. film, but later applied in both 16- and 35-mm. size to copying commercial documents, newspapers, drawings, large bound volumes and so on.

In cameras for photocopying, documents are photographed directly onto rolls of paper without using an intermediate negative, as in the Rectigraph and Photostat machines introduced in the first decade of the 20th century. Various scales of enlargement and reduction can be used, the lens carries a prism to invert the image and the photograph is white on a black ground. Automatic machines of this type are made in which the processing of the paper is also carried out. Automatic coin-operated portrait cameras are made, in which the subject is photographed on paper which is processed in the machine to give a direct positive picture.

Studio Arrangements and Lighting.— Photographic studios are provided with backgrounds, seats and properties to be selected according to the whim of the photographer and the nature of the subject. The most important studio materials, however, are those concerned with lighting the subject. In the earlier

days, daylight was used, controlled by drapes and reflectors. Mercury vapour lamps and carbon arcs were later employed; but since the introduction of fast panchromatic films, incandescent tungsten filament lamps are used in the main. Some carbon arcs are employed. and some fluorescent lamps for broad lighting, but the greatest flexibility is obtained with tungsten lamps. The lamps are used in special lamphouses or reflectors, which vary in the extent to which they concentrate the beam of light. Although good pictures may be made with one lamp, for flexibility several are needed. The number and arrangement of lights depends on the subject and the desired effect, but a typical arrangement for portraits consists of a key-light from the front, or partial front, a fill-light to illuminate the shadows, a backlight for use behind the subject and a background light to illuminate the background. Overvoltaged lamps of the Photoflood type came to be much used, especially by amateurs; for colour photography. lamps operating at a colour temperature of 3,200° K. are employed, and for general studio use high efficiency lamps of up to 5,000 watts are employed. The choice of reflector is very important.

For flash photography. flash bulbs are used in arrangements similar to the normal studio lights, although they are also much used at the camera position and on extensions from the camera synchronizer to other positions. Gaseous condenser discharge lamps, introduced by H. E. Edgerton, can be used in the same manner as flash bulbs. All have a shorter flash duration, and some have a much greater light output.

Printing and Enlarging.— Prints are made from negatives by contact, in which case they are the same size as the negative, or by enlargement or projection printing, to produce bigger pictures. Contact prints are made in (a) printing frames, which press the negative and paper in close contact against a sheet of glass through which exposure can be made to a lamp, and (b) printing boxes or machines, which contain the printing lamps as well as the means for holding negative and paper in contact. The simplest printers contain one lamp and are made for small negatives. The professional printers are designed for larger negatives. frequently have many lamps and means for dodging, or controlling the exposure of different parts of a negative. Printers for photofinishing are designed to permit a large number of prints to be made from single negatives or rolls of negatives in the minimum of time. In some the exposing platen is operated by a foot treadle to leave both hands free for manipulating the negative and paper, and there are means for stamping identification numbers on the prints. In the more advanced types, the printing time for the negative may be measured photoelectrically and the appropriate exposure given automatically.

A projection printer or enlarger has a means for illuminating a negative, and a lens for projecting an image of it onto a sheet of photographic paper on a board or easel. It resembles a lantern-slide projector, or a camera in which the negative is the subject and the paper corresponds to the film. The best enlarger lenses are designed to operate at magnifications of a few times, and are generally more satisfactory than camera lenses for enlargement.

Projection printers are distinguished mainly by the means by which the negative is illuminated, and are of three main types: (a) diffusion enlargers, in which there is a lamphouse or reflector containing a lamp, and in front of this, a sheet of ground or opal glass in front of which the negative is placed; (b) condenser enlargers, which contain a small light source, and a condensing lens behind the negative; (c) the modern type of condenser enlarger, in which a lamp with a diffusing bulb or having a large area, such as a fluorescent lamp, is frequently used to lessen the degree to which grain and dirt on the negative are shown sharply in the print. Condenser enlargers give prints of higher contrast than diffusion enlargers.

Enlargers are arranged horizontally or usually vertically. In the simplest forms, focusing is achieved by watching the projected image on a sheet of white paper which temporarily takes the place of the printing paper, and adjusting the lens until the image is sharp. Some enlargers. however, focus automatically, the image remaining in focus on the paper over a wide range of magnifica-

Darkrooms and Processing.— Rooms for handling films, plates and papers must be dark, or illuminated only by light to which the materials do not respond appreciably in a reasonable time. They are provided with running water, large sinks and benches on which operations can be carried out. Small darkrooms are used for loading, unloading and developing negatives and for printing and developing prints. In larger installations the negative and printing rooms are separate. Negative rooms for handling panchromatic materials are completely dark or illuminated by safelights green in colour, since the eye has its maximum sensitivity in the green, and a very low level of illumination may thus be used. For orthochromatic films, deep red safelights are used, while for slow noncolour-sensitized materials, such as positive or process films, orange or even deep yellow safelights can be used. In printing rooms, the lighting is yellow, orange or yellow-green, since most papers are not sensitive to red light.

Developing, fixing and washing are done in trays, tanks or special equipment; and all require sinks and plenty of water. Roll films are frequently developed in tanks on spiral reels on which they are wound, or hung vertically in tanks, and sheet films and plates are used in special frames or hangers, so that many can be handled together. Paper prints are developed in trays. Washing of negatives and prints must be done in such a way that there is frequent change of' water over the entire surface of all, and special washers are made for use where large quantities of films or prints are handled. Drying of negatives can be in the open air, or preferably in special drying cabinets through which warm air is blown. Prints can be dried flat in the open, on racks covered with muslin or between blotters or by passing automatically around heated drums which can also be used for glazing thé prints. Prints are commonly glazed by squeegeeing them onto metal plates with a lacquered or chromium-plated surface. Printing rooms contain the contact printers and enlargers.

Clocks are necessary in all darkrooms to time the steps of processing accurately, and thermometers must be used to control processing temperatures. Sections of the rooms are devoted to storage and mixing chemicals, and storing sensitive materials to be readily available for use. Adequate ventilation is important.

Special equipment is used in photofinishing establishments, especially for the automatic processing of large numbers of roll films. They are hung vertically on special hangers, and pass continuously into a deep tank of developer and then into each successive solution and washing tank and finally through a drying cabinet. In smaller installations, the film hangers are used in deep tanks but are transferred manually.

Similarly, special apparatus is made for large-scale printing operations, in which the exposed papers pass with the minimum of attention through the solutions, and are then dried, and glazed if necessary, on continuously rotating drum driers.

Finished prints are frequently mounted on cards. A number of adhesives may be used, the most satisfactory being dry mounting tissue, which is a sheet of tissue impregnated with shellac or other fusible plastic. If this is placed between the print and the mount and the whole is heated in a press, the shellac melts and sticks the print to the mount. (W. Ck.; X.)

PHOTOGRAPHIC LENSES

A photographic lens must give crisp definition over a relatively wide flat field, and in this respect it differs from all other types of lens. Moreover, for instantaneous photography the image must be bright, which implies a high relative aperture.

LENS TYPES

The Landscape Lens.—The first deliberately designed photographic objective was made in 1812, about 20 years prior to the introduction of photography. It was the simple meniscus landscape lens (see fig. 10a) proposed by the English physicist William Wollaston for use in the camera obscura. At first, a simple equiconvex lens was used, but it was found that the image was sharp in the middle and became blurred in the outer parts of the field. Wollaston's invention consisted in the use of a meniscus-shaped lens with a small stop on the front (concave) side, as in

fig. 10b, the mirror being mounted between the stop and the lens.

The effect of this change on the image quality is profound. In fig. 11 are shown a biconvex lens and a meniscus lens of the same focal length, each traversed by a number of light rays at an obliquity of 90° which may be supposed to emanate from an infinitely distant object point. In the upper figure, the oblique rays meet nicely almost at a point, but the point is not at all on the desired flat field. In the second case, the oblique rays through the whole lens do not meet at a point, but suffer from all the properties of spherical aberration. By placing a small stop (about f/11) at B we isolate a beam of light which comes to a focus exactly above the focus of the axial beam. We have thus produced a flat field by isolating only those rays which cross where we wish them to cross.

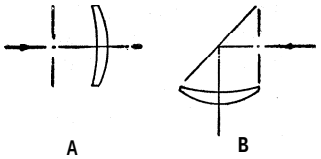

FIG. 10.—THE WOLLASTON LANDSCAPE LENS. A, IN A CAMERA, B, IN A CAMERA OBSCURA

Having introduced this type of lens, Wollaston also applied it to the small box type of camera obscura used by artists as an aid in drawing. This instrument was actually the original photographic camera, for the photographer merely had to replace the ground glass by a sheet of photosensitive material to make a record of a scene, the mirror being necessary to rectify the image. Landscape lenses of this simple type are still manufactured in large quantities for use in box cameras and in the cheaper types of folding cameras. At f/11 or f/16 they give satisfactory pictures over a half-field angle of 20° to 25°.

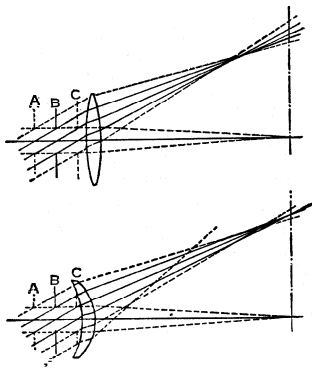

FIG. 11.—PATHS OF LIGHT RAYS THROUGH BICONVEX AND MENISCUS

The Defects of the Landscape Lens.—The Wollaston landscape lens suffers from many defects. These are:

(1.) The presence of chemical focus, which is a difference in image position between visual light and the photographically active rays. This was early regarded as very serious, especially as the necessary correction varies with the distance of the object, and thus can not be compensated in the construction of the camera.

(2.) The aperture is limited to f/11 or less, because of bad spherical aberration.

(3.) It possesses much lateral chromatic aberration, causing coloured fringes around images in the outer parts of the field. On black-and-white emulsions, these fringes appear as a blurring of the definition.

(4.) Beyond a semifield of about 20°, the astigmatism becomes bad. This implies that the image of a point object is no longer a point, but consists of a radial focal line, separated by a finite longitudinal distance from a similar tangential focal line.

(5.) It has bad distortion. When this aberration is present, a square object becomes imaged either as a pincushion-shaped or a barrel-shaped figure.

When photography appeared in 1839, with the daguerreotype and the calotype processes, the need arose to correct these defects and especially to increase the speed of the lens for portraiture. Historically, however, the problem of the chemical focus and lateral colour was solved first by achromatizing the lens. C. Chevalier in 1821 had combined a positive lens of crown glass (low refractive index and low dispersion) with a negative lens of flint glass (high index and high dispersion) as shown in fig. 12. This served to correct both of the chromatic aberrations perfectly, but the dispersive (or divergent) cemented face in the lens led to a backward curving field with much astigmatism in the outer parts. Also, the maximum speed remained around f / 15, so the new lens had limited application.

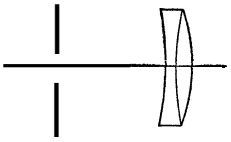

FIG. 12.—THE CHEVALIER ACHROMATIC LENS

The Petzval Portrait Lens.—Finding that the customary speed of landscape lenses (f/11) was slow for portraiture, J. Petzval of Vienna undertook the designing of a rapid lens. In 1841 he produced his famous Portrait lens, fig. 13, which had the remarkable speed of f/3.6 and covered a half-field of 10° to 12° in extent. Beyond that angle, the astigmatism and field curvature became so great as to soften the definition to a serious extent, but on the lens axis the definition was exceedingly sharp and clear-cut. The Petzval lens consists essentially of two modified telescope objectives spaced apart, each being achromatic and substantially spherically corrected. The lack of sharp definition in the outer parts of the field is not serious in portraiture; in fact, it is actually desirable to have the background somewhat out of focus.

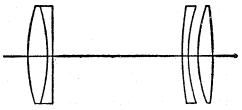

FIG. 13.—THE ORIGINAL PETZVAL PORTRAIT LENS (1841)

Because of its high relative aperture and excellent central definition, this type of construction, suitably modified, has been used extensively for motion-picture photography and projection. The definition is very sharp to about 5° from the axis even at apertures as high as f/1.6, after which it begins to fall off abruptly. The semi-field of projection lenses is often extended to 10° by means of a field flattener, a thin negative element close to the image plane which tends to overcorrect the astigmatism and thus flatten the field. This method of field flattening was first suggested by C. Piazzi Smythe, in 1863, who used it to make excellent miniature photographs in Egypt on one-inch square wet collodion plates.

Distortionless Landscape Lenses.—The landscape and the portrait lenses served photographers well for many years, but the distortion of the landscape lens became increasingly objectionable, especially after the introduction of the wet collodion process in 1850. The increased sensitivity of the collodion layer permitted photography indoors, and the distortion of the lens became evident on the vertical lines.

After 1850, therefore, opticians made great efforts to remove this distortion by variations in lens design. Early pioneers were J. T. Goddard and T. Sutton in England, who modified the arrangement of the Petzval portrait lens to widen the field at a much reduced aperture, the distortion being removed by arranging two positive components about a central negative component.

In 1860 a notable contribution was made by C. C. Harrison and J. Schnitzer of New York city in their Globe lens, so-called because the two outer faces formed parts of the same sphere (U.S. Patent 35,605). This lens was distortionless and covered a half-field of 30°, but only at an aperture of about 1/36. It was achromatic, but not spherically corrected. The same lens was made by T. Ross in England. A similar design was the Pantoskop, designed by E. Busch in 1865.

The Symmetrical Principle.—From these early attempts to correct the distortion of landscape lenses, it soon appeared that a lens which is symmetrical about the stop is automatically free not only from distortion, but also from lateral colour and coma. This is not entirely correct except at unit magnification, but the improvement in these three aberrations resulting from the symmetrical construction is so marked that symmetry in lenses became almost a universal rule from 1865 to about 1910.

The first to appreciate the advantage of the automatic coma-correction associated with symmetry were A. Steinheil in Munich and J. H. Dallmeyer in London about 1866. Prior to this time, landscape lenses had possessed spherical aberration; and, consequently, it was possible to choose a stop position which would simultaneously correct the coma and make the field as backward curving as possible. Dallmeyer and Steinheil realized that with the coma automatically eliminated by symmetry, it was no longer necessary to have a considerable residual of spherical aberration in the separate components. They, therefore, chose a symmetrical construction as indicated in fig. 14, in which the divergent cemented surfaces were used to correct the spherical aberration, and the outer shape of the lens was chosen so as to flatten the field. The coma of each component was bad, but it disappeared as a result of the

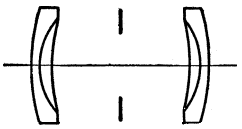

FIG. 14.—STEINHEIL'S APLANAT

symmetry. By this means, a simple, substantially distortionless lens could be constructed at an aperture of f/7 or f/8 with a flat field out to 25° half angle. There was some residual astigmatism at that obliquity, but the depth of focus at f/8 or f/11 covered it up to a considerable extent. This was fundamentally the construction of the Steinheil Aplanat and the Dallmeyer Rapid Rectilinear lens. This type immediately became popular, and it was imitated by almost every manufacturer for nearly 50 years. A number of variants of these designs mere tried, some of which were good, but no real progress was made until the introduction of barium glass in 1886, which brought about a revolution in the art of lens designing and ushered in a new era.

Barium Glasses, and the Anastigmat Lens.—In all the types so far discussed, the negative elements were of flint glass with a high refractive index and high dispersive power, while the positive elements were of crown glass with a low index and low dispersion. Thus, the cemented surfaces were generally divergent in action, and tended to overcorrect the spherical aberration and the astigmatism.

By 1880 E. Abbe and O. Schott in Jena were making experiments to try to develop a crown glass having a high refractive index combined with a low dispersion. If such could be found, it would be possible to make achromats in which the cemented surface would be convergent instead of divergent. Thus, it would be possible to stop and even reverse the drastic overcorrection of astigmatism which occurred in the outer parts of the field of all lenses up to that time. Their efforts were rewarded in 1888 when Schott announced the first barium crown glass having the desired properties.

By 1890 Paul Rudolph in the Zeiss company. working, no doubt. under Abbe's inspiration, had entirely redesigned the Rapid Rectilinear type of construction by replacing the divergent cemented surface in the rear component by a convergent surface (fig. 15). The new barium crown glass was used in one element of the rear component, thus rnaking an objective in which one of the cemented surfaces mas divergent and concave to the stop. lending to an increasingly overcorrected astigmatism and spherical aberration, while the other cemented surface was convergent and convex to the stop, leading to an increasingly undercorrected astigmatism. The result was a lens in nhich the astigmatism was everywhere small, and it actually became zero at one obliquity of the field. This lens was announced in 1890 as the Anastiginat, the name being changed to Protar after other firms took up the word Anastigmat to imply any lens having a node of zero astigmatism somewhere in the field. Early designs of this type up to f/9 were produced, and even an f/4.5 lens was made with a cemented triplet in the rear. The Protar was still manufactured in 1947, chiefly as an f/12 or f/18 extreme wide-angle lens.

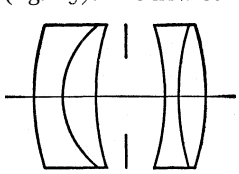

FIG. 15.— THE ZEISS PROTAR

The Dagor Type.——Within two or three years after Rudolph's design of the Protar, both he and Von Hoegh of Goerz announced almost identical designs of a symmetrical lens, each member consisting of a cemented triple lens (fig. 16). Rudolph called his the Triple-Protar, and Von Hoegh called his the Double Anastigmat Goerz, which was later contracted to Dagor by taking the initial letters of the name. In each half of this lens, the refractive indices rise steadily out from the stop, being in that order, 1.52, 1.57 and 1.61. Achromatism is secured as usual by choosing low-dispersion glasses for the convex elements and a higher dispersion for the concave element. Each component, therefore, contains a strong divergent cemented surface and a weaker convergent cemented surface, the convergent surface being convex toward the stop. Thus. the essential properties of the tno components of the original Protar design were combined in each half of the double lens.

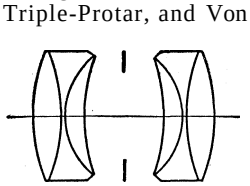

FIG. 16.—THE GOERZ DAGOR

Many variations of this lens were designed during the years 1893 to about 1905, the advantages being a wide field with a high degree of anastigmatic correction, but only at an aperture of f/6.3 or f/8. In 1930 A. W. Tronnier of the Schneider company revived this construction in his wide-angle Angulon, which is an f/6.3 lens covering satisfactorily to about 40° from the axis.

Convertible Lenses.—Most of the triple-cemented double lenses that have been designed are complete lenses corrected as a whole, but the two separate halves have too much coma to be used independently and the symmetry takes care of coma correction. However, the advantages of being able to double the focal length by removing the front component were so evident that Rudolph in 1894 designed his Double Protar or Quadruple Protar, which comprised both parts of the original Protar directly cemented together in each component (see fig. 17). The additional degrees of freedom made available to the designer by this construction enabled him to correct the coma of each half separately. The lens thus became convertible. *i.e.*, each component could be used separately, or two similar components of different focal lengths could be combined together to make a satisfactory double objective. Thus, a pair of components having focal length of 8 and 10 in., could be used either separately or together to form a lens of about 5-in. focus. These convertible sets of lenses were quite popular early in the 20th century, but their use died out nhen large view cameras became replaced by small roll-film hand cameras without focusing screen.

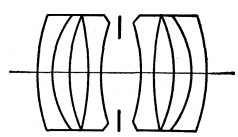

FIG. 17.—THE ZEISS CONVERTIBLE PROTAR

Double Objectives with Air Gaps.—The chief reason why lenses of the Dagor type are so limited in aperture is the need for having an increasing refractive index in the successive elements counting outward from the stop. The index difference available at each cemented face is, therefore, rather small, necessitating quite strong surfaces.

It became apparent early that by introducing an air gap (usually at the dispersive surface), the refractive index of the separated element could be varied independently. leaving a wider range of indices for the cemented elements. This type of construction was first suggested by Von Hoegh in 1899, and was used later in such lenses as the Euryplan, the Plasmat, the Orthometar and the Wide-Angle Xpres. The two latter lenses are unsymmetrical and highly corrected for distortion to render them suitable for aerial surveying over a semifield of 35°, at a speed of f/4.5.

The Airspaced Four-Element Lens.—In 1898 Von Hoegh designed the Celor, an entirely new type of lens shonn diagrammatically in fig. 1S, which as first constructed covered a 28° half field at f/8. The design may be regarded as a direct descendent from the Dagor. In each half of the Dagor lens, there are two outer surfaces. both concave to the stop, an internal divergent cemented surface and an internal convergent cemented face convex to the stop. Von Hoegh argued that the airspaced construction shown in fig. 18 is essentially equivalent to the Dagor, since each half contains two outer surfaces concave to the stop, an internal divergent surface and an internal convergent surface convex to the stop. The airspaced construction has the advantage over the cemented construction that each surface separates glass from air, with a large index difference, and, thus, the internal surfaces in this lens become much weaker than the corresponding surfaces in the Dagor. Little difficulty was found in extending the new design to f/3.5 covering 21°, an achievement quite impossible with the cemented type. The field is, however, not so wide as in the Dagor type.

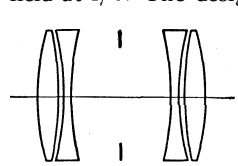

FIG. 18.—THE GOERZ CELOR

This airspaced four-element design was used by the Goerz company in the Dogmar series, and was later adopted by A. Warmisham in the Aviar lens (1915). R Steinheil used a similar design in his Unofocal of 1901, and a great many similar designs have appeared. All the Kodak anastigmats prior to about 1928 were of this type, and a number were still manufactured in 1947.

The **Tessar.**—In the preceding paragraph the evolution was

traced of the Von Hoegh quadruplet from the Dagor. At about the same time, Rudolph was following a parallel path. Whereas Von Hoegh replaced the divergent and convergent cemented surfaces in his Dagor design by glass-air surfaces, Rudolph returned to his original Protar of 1890 and replaced the cemented surface in the front component by an air lens, remembering that a convex-shaped air lens has a diverging action. In this way he designed the famous Tessar lens in 1902, shown in fig. 19. It was a successful lens, mainly as an f/4.5 universal objective covering a semifield of about 26°. By 1910, some f/3.5 designs had appeared, and in recent years, the type has been practically universal for both f/4.5 and f/3.5 lenses of the better grade. Even f/2.7 Tessars have been produced, but this high aperture requires a more complicated type of construction. In long focal lengths, f/6.3 and f/8 has been a popular speed, the angular field being then increased somewhat. A line of Apo-Tessars has been designed for process work, and a wide-angle f/8 Tessar has been used on the Zeiss Contax cameras.

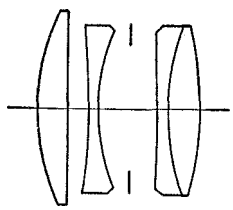

FIG. 19.—THE ZEISS TESSAR

The Gauss-Lens and Its **Application to** Photographic **Objectives.**—In 1817 the mathematician C. F. Gauss discovered that a meniscus-shaped airspaced telescope objective could be designed in such a way that the spherical aberration curve is practically the same for all wave lengths. Such a lens is said to be free from sphero-chromatism. However, because of its high manufacturing cost, it never became popular as an astronomical objective.

In 1889 the American telescope-maker Alvan Clark took out a patent (C.S. 399,499) on the use of two Gauss objectives mounted together in a single tube, concave sides adjacent, as a photographic lens. He stated that the field curvature could be varied by adjusting the airspaces in the lens. The same idea occurred independently to Rudolph, who attempted to design a properly corrected symmetrical photographic lens using meniscus-shaped elements according to this plan. He was, however. unable to achromatize the lens and decided to use buried surfaces[1] in the negative lenses to increase the dispersive effect of those elements. In this way, he produced the Planar lens, first announced as a symmetrical f/4.5 lens for process work in 1895 (fig. 20).

In 1902 K. Martin of the Busch company succeeded in achromatizing a lens of this type without the use of either barium crown glasses or buried surfaces; and announced it as the Omnar. At about the same time appeared the similar Meyer Aristostigmat and Ross Homocentric lenses, also of this so-called Gauss type. In recent years, the type has been revived in lenses of about f/6.3 aperture covering very wide angular fields, culminating in the Zeiss Topogon (see below).

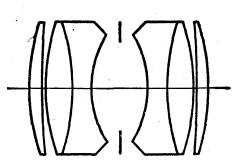

FIG. 20.—THE PLANAR

All interest in this type of construction apparently disappeared from 1902 until 1920, when H. W. Lee of the Taylor, Taylor and Hobson company in England revived it. He went back to the original Planar design and decided to see how far he could increase the aperture. He realized that Rudolph had wasted many possible degrees of freedom by insisting on a symmetrical construction and burying the cemented surfaces of the negative elements so that they were optically nonexistent so far as the monochromatic aberrations were concerned. Lee departed from these two artificial limitations and succeeded in designing an f/2 lens covering a semifield of almost 25°. This was marketed as the Cooke Opic lens, in several sizes up to five-and-one-half inches focal length. Such a huge aperture was entirely revolutionary for photographic lenses covering a 24° semifield. Higher apertures can be reached by the Petzval type of construction, for a 5° or 7° field, but this was the first lens to combine high aperture and field successfully. The Opic lens ushered in a period of 20 years of strenuous effort on the part of many manufacturers to outdo everyone else in the matter of high-aperture lenses. Notable achievements were the Zeiss Biotar of 1927, covering a 14° half field at f/1.4 for 16-mm. motion-picture cameras, the Leitz Summar f/., having a 20" half angle, the Kodak f/-. Ektar covering 26° for the Bantam Special camera and the Cooke Speed Panchro f/2 lens for 3j-mm. motion-picture cameras. Other manufacturers have used the same general type of construction for lenses of about f/2 aperture, but it does not appear to be very satisfactory for apertures higher than f/2 because of the enormous oblique spherical overcorrection which appears in the outer parts of the field, leading to marked haze and low contrast.

The **Topogon** Lens.—In 1933 R. Richter of Zeiss sought to extend the field of the Gauss type of objective as widely as possible, and finally adopted the construction shown in fig. 21, representing an f/6.3 lens capable of covering a half field of 45°. This lens may be regarded as being derived from the Harrison and Schnitzer Globe lens by separating the cemented elements, and bending the flint to a more extreme form. In World War II it was made in the U.S. by Bausch and Lomb as the Metrogon lens.

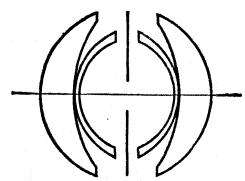

FIG. PI.—THE RICHTER TOPOGON WIDE-ANGLE LENS

The angular field covered by this lens is astonishing. For example, a 6-in. Topogon will cover satisfactorily to the corners of a 9x9-in. plate. Of course, the illumination at the corners is perhaps only 10% of that at the centre of the field, but in spite of this, the lens is much used in aerial photography.

The Cooke Triplet Lens.—In 1893 H. Dennis Taylor decided to cut aside all historical precedent and proceed to design the simplest possible photographic lens. To do this. he argued that a separated pair of approximately equal positive and negative elements will automatically satisfy the Petzval condition for a flat field and will also have some positive power by virtue of the finite separation. However, such a system will be badly unsymmetrical and will exhibit considerable distortion and lateral colour. He therefore divided the positive element into two parts and set the negative element between them. Thus, he had five degrees of freedom (three powers and two airspaces) wherewith to secure the desired over-all power, the desired Petzval sum, to achromatize and to correct the distortion and lateral colour. In addition, he could bend or alter the shape of each of the three elements to eliminate spherical aberration, coma and astigmatism. In this way, Dennis Taylor produced the first modern triplet known as the Cooke lens (fig. 22). It was made in several series, including a narrow-angle f/4.5 design for portraiture, a wide-angle f/6.3 for landscapes, etc. Originally, no barium crown was employed, but its use greatly facilitates the design and shortens the over-all length of the lens, thus improving the corner illumination.

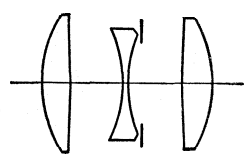

FIG. 22.—THE COOKE LENS

Since 1893 this type of lens has been made by millions, in apertures up to as high as f/2.7 in short focal lengths, but mostly as a low-priced f/4.5 or f/6.3 anastigmat for ordinary folding cameras. Within its limitations, it is an excellent lens, although of course it can be improved by making it more elaborate.

Modifications of the Triplet Lens.—From some standpoints, the Tessar (fig. 19) may be regarded as a modified triplet in which the rear element has been replaced by a cemented doublet. In 1902 H. Harting, of Voigtlander, felt that if a convergent cemented face in the rear component is an improvement. then the insertion of a similar surface in the front component should be a still greater improvement! and in this way he developed the Heliar lens. This form has not been commonly adopted, in spite of its merits, typical

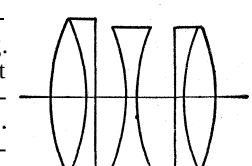

FIG. 23.—THE DALLMEYER PENTAC. DESIGNED BY L. B. BOOTH

[1] A buried surface is a cemented surface separating two glasses of the same index but difierent dispersion. Surh a surface is, of course, nonexistent so far as the monochromatic aberrations are concerned, its sole purpose being to correct the chromatic aberrations.

modern examples being the Dallmeyer f/2.9 Pentac (fig. 23) covering to 22°, and the recent Kodak f/3.5 Ektar covering to 26°.

In 1924 H. W. Lee of Taylor, Taylor and Hobson, and at the same time W. Bielicke of Astro, attempted to raise the aperture of the Cooke lens to f/2.5 by dividing the rear positive element into two closely spaced positive elements.

Although this device succeeded in reducing the zonal spherical aberration of the f/2.5 lens to an acceptable extent, the astigmatism in the field remained rather serious, and as a result this type of construction has not been much used.

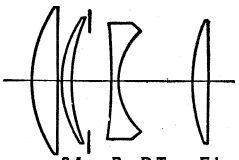

FIG. 24.—BERTELE'S TRIPLET WITH ADDITIONAL MENISCUS LENS IN THE FRONT AIRSPACE

The Sonnar Lens.—A much more profitable modification of the triplet was that originally suggested by C. C. Minor in 1916 and developed by L. Bertele of the Ernemann company during the early '20s. In fig. 24, it will be evident that in its essence. Bertele's lens may be regarded as a triplet in which a strongly bent meniscus-shaped positive lens has been inserted in the front airspace. This additional lens is shaped so that it contributes practically nothing to the spherical aberration, yet it does introduce some positive power. The power of the front and rear lenses can then be reduced by this amount, resulting in a net reduction of the spherical undercorrection contributed by them.

Lenses of this type can be designed to have an aperture as high as f/1.5, using only four single elements. The field is usually small (15°), and if attempts are made to increase it, the result is a rather large amount of astigmatism at the zones of the field intermediate between centre and edge. At f/1.9, a number of excellent lenses have been designed of this type, covering 14° half angle, mainly for cinematograph purposes.

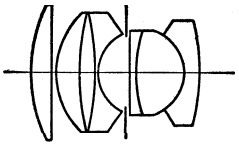

FIG. 25.—THE ZEISS SONNAR F/1.5

Many attempts have been made to improve the field coverage by adding other elements to this basic four-lens type. Notable attempts were the f/1.9 Ernostar of 1924, and the f/1.5 Sonnar of 1932 (fig. 25), both designed by Bertele. In these lenses, the second and third elements of fig. 24 were combined together with a low-index element instead of air between them. By this means, a well-corrected high aperture lens can be made, covering up to 22° from the lens axis. This general type of construction has appeared very frequently in lens patents since 1930.

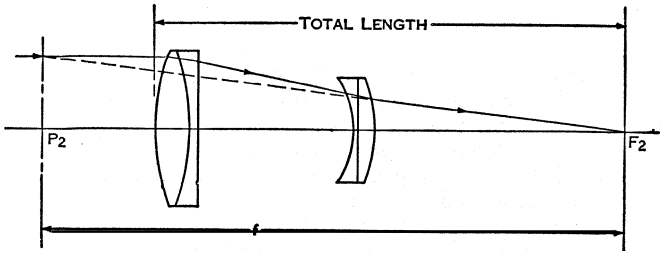

FIG. 26.— THE TELEPHOTO PRINCIPLE

The Telephoto Lens.—This type of lens was first introduced into regular use about 1891, its particular property being a shortening of the total length of the lens from the front vertex to the focal plane. Indeed, in some telephotos the total length is as little as 60% of the focal length, in contrast to the Tessar or Cooke Triplet type in which the total length may be about 115%, or the Petzval Portrait lens which may reach 140%.

The telephoto type of construction consists essentially of a positive front member separated widely from a negative rear member. the action of this combination being to move the rear principal point forward (fig. 26). Originally, a complete normal camera lens was used for the positive component, the rear membrr being a thin achromatic negative lens, the separation between the positive and negative systems being adjustable to give any desired magnification. These designs were unsatisfactory optically, had bad pincushion distortion and worked at very low apertures.

In 1905 the modern era of telephoto lenses was initiated by the Busch Bistelar, a fixed self-contained telephoto lens of f/8 aperture covering a half field of about 15°. The two components were nothing but cemented doublets, yet because the designer was released from the necessity of separately correcting the front component, the final result was superior to all previous telephoto lenses and was comparable in performance to the normal f/8 lenses of the day. However, when larger relative apertures were attempted, many difficulties were encountered, and it was not until the introduction of the Cooke and Dallmeyer f/5.6 anastigmatic telephoto lenses in 1919 and 1920 that this type could begin to compete with modern anastigmats. Nevertheless. in spite of all the efforts of lens designers, the aperture of an 80% telephoto lens had not by 1947 been raised much above f/3.5, nor the semifield much above 12° to 15°. Recent attempts to remove distortion have led to the use of either a strongly convergent cemented surface in the rear member, as in the Kodak f/3.8 Telephoto, or a definite separation of the rear component into two meniscus elements separated by an airspace shaped like a negative lens, as in the Cooke Distortionless Telephoto f/5.0 (fig. 27). During World War II, many large telephoto lenses of focal lengths ranging from 24 in. to 60 in. were manufactured for use in aerial reconnaissance cameras. The aperture was usually f/5.6 to f/8, and the angular semifield rarely more than 12°.

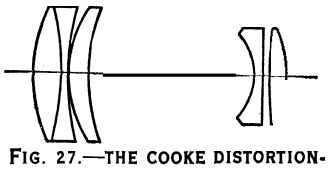

FIG. 27.—THE COOKE DISTORTIONLESS TELEPHOTO

The Reversed Telephoto Lens.—By turning a telephoto lens end-for-end, it is possible to design a wide-angle system having an exceptionally long back-focus clearance. This has been used in cases where a beam-splitting prism or other device must be inserted between the lens and the film, such as in Technicolor cameras. An extreme example of this construction is found in the Hill Sky lens (British Patent 225,398) which will compress the entire hemisphere onto a flat plate, with drastic distortion as a necessary consequence.

Apochromatic Process Lenses.—In photomechanical reproduction, it is frequently necessary to make colour-separation negatives of coloured original drawings or photographs, and the lenses used must be colour-corrected to a degree entirely beyond anything necessary in ordinary lenses. By the use of special types of glass and restricting the aperture to about f/10 or f/16, it has been found possible to design lenses, generally of a symmetrical type, in which all the colours of the spectrum are brought accurately to a common focus. It is furthermore necessary in these lenses that all the coloured images shall be of precisely the same size. Such lenses are called apochromatic process lenses to distinguish them from the ordinary achromatic lenses in common use.

Enlarging Lenses.—Enlarging lenses differ from ordinary camera lenses in that they are intended to be used at much lower magnification ratios, the field must be flat and the colour correction must be such that the best focus in visual light coincides exactly with the best focus for the extreme blue end of the spectrum for which bromide paper has its maximum sensitivity. In many cases, ordinary camera lenses make satisfactory enlarging lenses, but this is likely to be not the case if the lens is of very high aperture or if it is of a markedly unsymmetrical type of construction.

Lens Attachments.—The familiar portrait attachment for fixed-focus cameras consists of a weak meniscus-shaped positive lens having a focal length approximately equal to the distance of the subject (four feet). Stronger positive lenses are sometimes used to photograph small objects, when the focusing scale of the camera will not go down to a sufficiently close distance. Negative lens attachments are also occasionally employed to lengthen the focus of a camera objective to give a magnified picture, but their use requires a considerable bellows extension. Small Galilean telescopes have been used as lens attdchments to enlarge or

minify the picture sizes without the necessity of a change in focus or f-number, especially on motion-picture cameras.

By use of suitable prisms, or of systems of cylindrical lenses, it is possible to broaden a picture in one direction only without affecting the sharpness of focus. Such systems are called anamorphotes and find occasional application in advertising and commercial art photography.

A diffusion disk is another type of attachment which has some considerable degree of application, to soften the hard lines in a portrait or to give atmosphere to a pictorial scene. To be effective, a diffusion disk must let about 70% of the light beam enter the lens unchanged and slightly scatter or disperse the remaining 30% of the light. This is accomplished either by shallow grooves polished in the surface of the disk, or by streaks of glass of different refractive index fused into the interior of the glass disk itself. (R. KE.)

PHOTOGRAPHY, CELESTIAL. Celestial photography is the application of photography to objects in the sky and, in particular, to astronomical objects such as the sun, moon, planets, satellites, comets, stars and nebulae. Although pictures of clouds are not generally considered to be examples of celestial photography, pictures of meteors and of aurorae, which are also atmospheric phenomena, are considered within this subject. This article is divided into the following sections and subsections:

I. The Application of Photography to Astronomy
II. Photographic Telescopes

  5. Aurorae
  6. Charts of the Heavens

I. THE APPLICATION OF PHOTOGRAPHY TO ASTRONOMY

The invention of photography by Louis Daguerre in 1839 led to a great step in astronomical progress. The first application of the daguerreotype to astronomy was made by John William Draper of New York city, who photographed the moon on March 23. 1840, the exposure being 20 min. Experiments in the new method were made under the direction of W. C. and George P. Bond at the Harvard College observatory, with the assistance of John A. Whipple and his colleague Black, photographers of Boston, as operators; the first photograph of the moon was taken there on Dec. 18. 1849, with the 15-in. object glass. A daguerreotype picture of the moon shown in London by George Bond at the Great Exhibition of 1851 attracted much attention.

Having seen the Harvard pictures in England. Warren De la Rue took up the subject and presented to the Royal Astronomical society, in 1857, positive copies from a negative picture of the moon made by a collodion process that he had found practicable five years earlier. In 1864 Lewis M. Rutherfurd of New York city made a telescope with object glass of 11¼-in. aperture so corrected as to bring the photographic rays to focus. About the same time Henry Draper surpassed his father's efforts by taking photographs of the moon with a 15-in. reflector.

Probably the first photograph of a star was a daguerreotype of Vega taken at Harvard observatory on July 17. 1850, but want of sensitiveness made this process rather impracticable, and there was little success in stellar photography until the invention of the collodion plate that was used in America and England in

1852. In Nov. 1857 a photograph taken at Harvard of ζ Ursae Majoris (one of the stars of the Ursa Major cluster) with its companion Alcor was sent for exhibition at the Royal Astronomical society by W. C. Bond; an exposure of 80 sec. had been given to photograph the 6th-magnitude star with the 15-in. refractor. De la Rue at that time was making experiments on the actinic power of Jupiter and Saturn compared with that of the moon, but his photographs did not show any details of the planetary surfaces. Under De la Rue's direction, and to his design, a photoheliograph was made and set up at Kew observatory, Surrey, Eng., for the Royal society, and the work of taking daily photographs of the sun, that was later carried on successfully at Greenwich and elsewhere, began at Kew in March 1858. De la Rue did not succeed in his attempt to photograph Donati's comet of that year, but Usherwood of Walton Common, Surrey, Eng., photographed the comet in 7 sec. with a portrait lens of short focus.

Daguerreotypes of the sun taken by J. B. L. Foucault and Armand Fizeau in 1845 and photographs of the solar eclipses of 1851 and 1854 were interesting experiments, but the photographs taken by De la Rue and by Pietro Secchi of the total solar eclipse in 1860 were the first of their kind to have real scientific importance, since they established beyond doubt that the solar protuberances were really appendages of the sun and not of the moon. Ten years later, at the eclipse of Dec. 12, 1870, excellent photographs taken by A. Brothers at Syracuse, N.Y., supplied evidence that the corona was also of solar origin; from that time a photographic picture of the sun's surroundings remained an integral item in the program of eclipse observation.

In the years after 1870 many people were engaged in research and experiment in photography generally. Of particular relevance to astronomy were the studies of W. de W. Abney. It was decided, mainly at the instigation of De la Rue, that photography (in addition to visual observation) should be used by the British expeditions that were to study the transit of Venus in 1874, and the work, so far as the process was concerned, was put in Abney's charge. He realized that the circumstances of the occasion would make a wet-plate process inapplicable and, after experiments conducted at Chatham, Kent, Eng., recommended the adoption of an albumin dry process, using a highly bromized collodion and strong alkaline development.

The titles of two of Abney's papers—"On Dry Plate Processes for Solar Photography" and "On the Photographic Method of Mapping the Least Refrangible End of the Solar Spectrum"—indicate their bearing on astronomy. These papers represent a remarkable achievement in that Abney succeeded in producing a special photographic emulsion, sensitive to red light, which he used to map the solar spectrum far into the infrared.

It was pointed out by George Bond that photography might be successfully used to measure the relative positions of stars, of a group or of double stars; and in a letter to William Mitchell on July 6, 1857, he predicted, in effect, the application of photography to stellar astronomy on the magnificent scale that actually exists today. In 1864 Rutherfurd began a long series of photographs of star clusters and of the bright double stars; but apparently these measures mere never completed. In 1870–84 B. A. Gould, in an expedition to the southern hemisphere, accumulated negatives of the principal double stars and clusters. Because the wet-plate process was used in making these photographs it was not possible to give an exposure long enough for faint stars to imprint themselves. With the invention of the gelatin dry plate, which had been used by William Huggins for spectrum photography in 1876 and which came into general use about 1880, this difficulty was removed and modern astronomical photography became possible. Circumstances connected with the comet of 1882, which was especially magnificent as seen from the southern hemisphere, led to new applications of celestial photography. A photograph, taken with a camera strapped, for the purpose, to the great equatorial of the Royal observatory of the Cape of Good Hope, showed not only the comet but great numbers of faint stars around it; this at once suggested to David Gill the possibility of making star charts by photography. Effects of various kinds followed upon Gill's idea. At Paris the brothers Paul and Prosper Henry of the National observatory were engaged in the laborious task of plotting the positions of stars found by eye observation in order to make charts of the stars near the ecliptic; but they abandoned this work and devoted their efforts to making a telescopic object glass suitable for photography.

In England. Ainslie Common turned to the art and, with a three-foot silver-on-glass mirror, took a photograph of the Orion nebula on Jan. 30, 1883, with an exposure of 37 min. He earned the gold medal of the Royal Astronomical society in 1884 for this feat, which Abney called "epoch-marking" when presenting the medal to another nonprofessional astronomer for similar work 11 years later. An earlier photograph of this nebula, taken by Henry Draper of New York city on Sept. 30, 1880, is said to be the first obtained but it is agreed that this was not a satisfactory representation. The later recipient of the medal mentioned above was Isaac Roberts. In 1885 he had made a 20-in. silver-on-glass reflector of nearly 100-in. focal length for the purpose of making star charts by photography, but altered his plans and devoted the instrument to photographing star clusters and nebulae. The excellent pictures produced at his observatory at Crowborough, Sussex, are collected in two volumes published during his lifetime, supplemented by a third prepared and issued by his widow in 1928.

Common's photograph of the Orion nebula led. through Edward Holden, to the acquisition of a three-foot reflector in 1895 by the Lick observatory, Mt. Hamilton. Calif. Two mirrors made by Calver and formerly owned by Common, were presented to that institution by Edward Crossley of Halifax, Eng., and one of these, refigured by Sir Howard Grubb, forms the essential part of the instrument known by his name. In James Keeler's hands it yielded a superb series of photographs of nebulae which for the first time demonstrated the great advantages of the reflecting telescope for certain classes of astronomical photography and led to the construction of the great modern reflectors.

(H. P. H.; F. H. S.; D. E. O.)

II. PHOTOGRAPHIC TELESCOPES

The instruments used for celestial photography are telescopes of one or another kind, but without an eyepiece. Instead the light is brought to a focus at the photographic plate, as in a simple camera. Astronomical telescopes may be grouped into three classifications: (1) refractors, (2) reflectors and (3) catadioptric or composite systems (see TELESCOPE). In a refractor a lens collects and brings light to a focus; in a reflector a concave mirror, usually of glass aluminized on the curved surface; serves the same purpose; in a catadioptric system a light-transmitting plate and a mirror in combination have the same function. In addition refractors may be subdivided into two kinds: those designed for visual. observations, and those for photographic purposes. Since the development of celestial photography and its almost universal application occurred after many of the larger refractors had been constructed, a number of observatories were in the position of having to use for photography instruments originally intended for visual work. In these cases the adaptation from visual to photographic use was accomplished in a variety of ways: by adding another lens to the objective; by reversing one of the elements in the objective; by placing a small correcting lens a few feet in front of the focus; or by using a yellow colour filter and an emulsion sensitive to visual light. The last two methods, because of their simplicity, are those in commonest use respectively for photography of spectra and of star fields by the largest refractors, such as the 40-in. telescope at Yerkes observatory, Williams Bay, Wis., and the 36-in. Lick telescope. In the case of reflectors, since their mirrors bring light of all colours to the same focus, photography over a wide spectral range is possible without focal compensation.

1. Photographic Efficiency.—The aperture, focal length and focal ratio of a telescope are usually chosen to make it as efficient as possible for a particular type of problem. The larger the focal length, the larger the scale or magnification of the image. For a particular focal length, the larger the aperture, the greater the

North America nebula in Cygnus photographed in 1909 by E. E. Barnard, Yerkes observatory, using a 10-in. lens and a blue-sensitive photographic plate

North America nebula in Cygnus photographed in 1949 by the National Geographic society-Palomar observatory sky survey observers using the 48-in. Schmidt camera and a red-sensitive photographic plate

Horsehead nebula in Orion photographed with an 18-in. Schmidt camera, showing a large field, about 5° in diameter, at a relatively small scale. Horsehead is the small feature near middle of picture

Horsehead nebula in Orion photographed with the 200-in. telescope, showing a small field (Horsehead is only about 5 minutes of arc long) at a very large scale

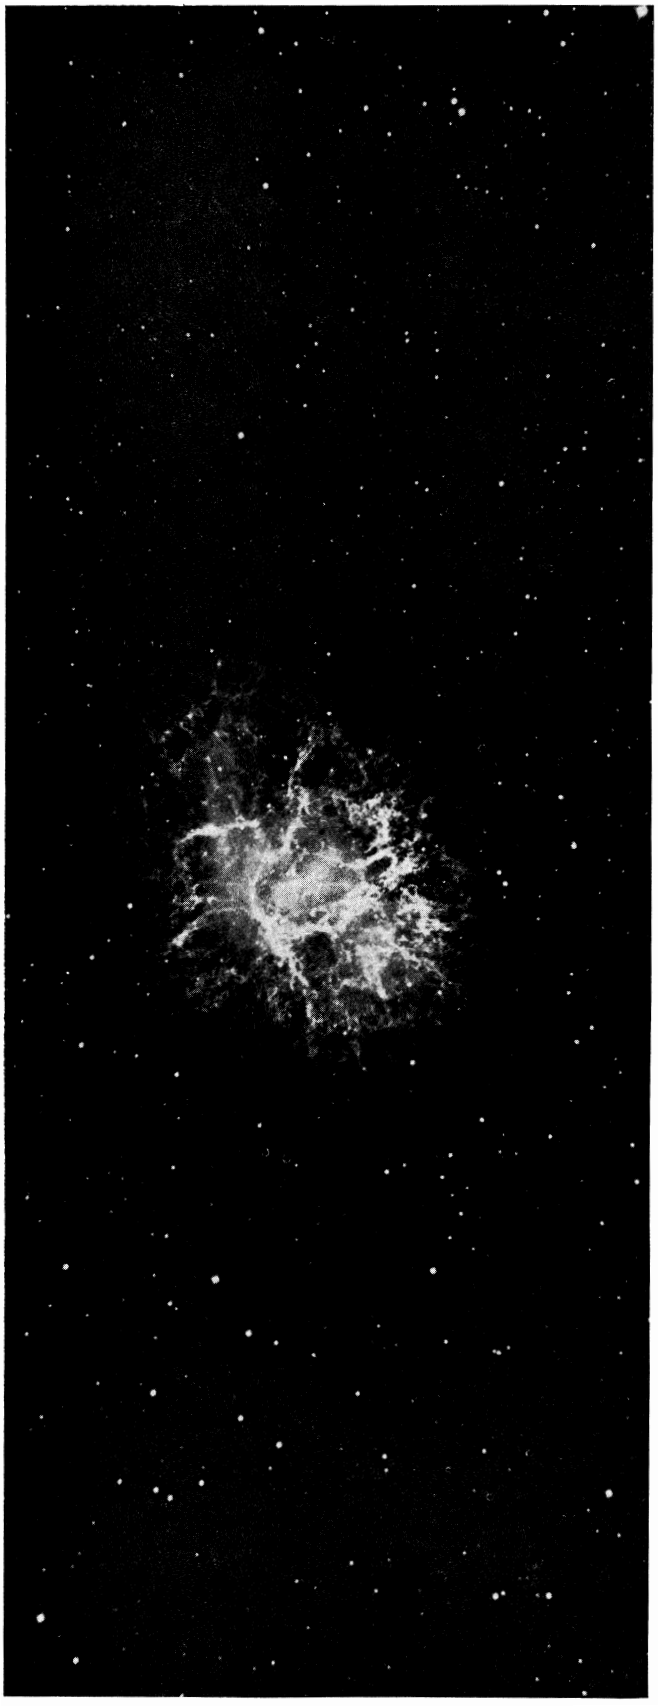
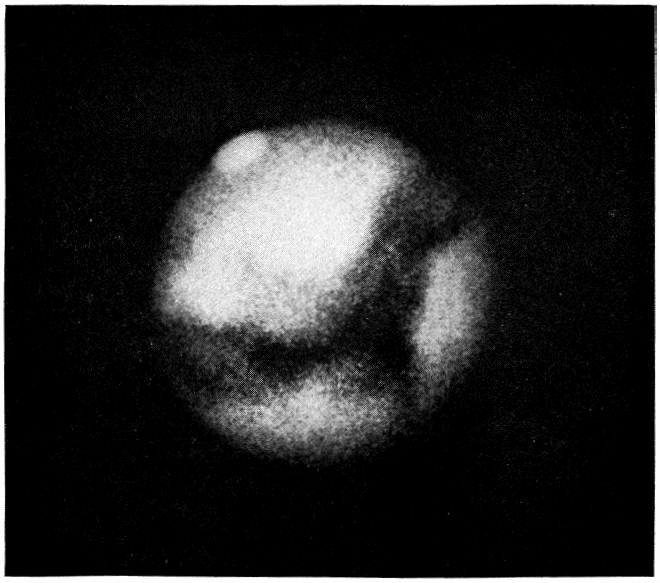
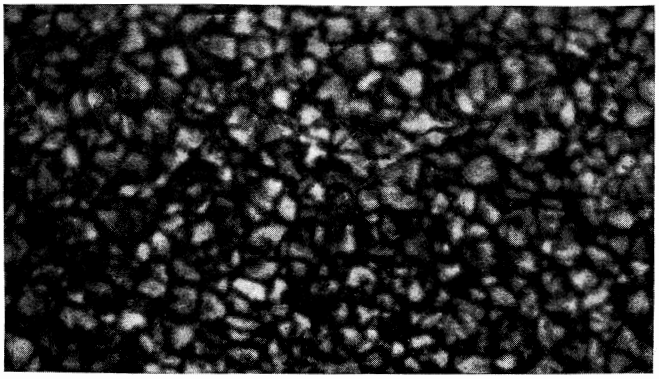
PHOTOGRAPHY, CELESTIAL



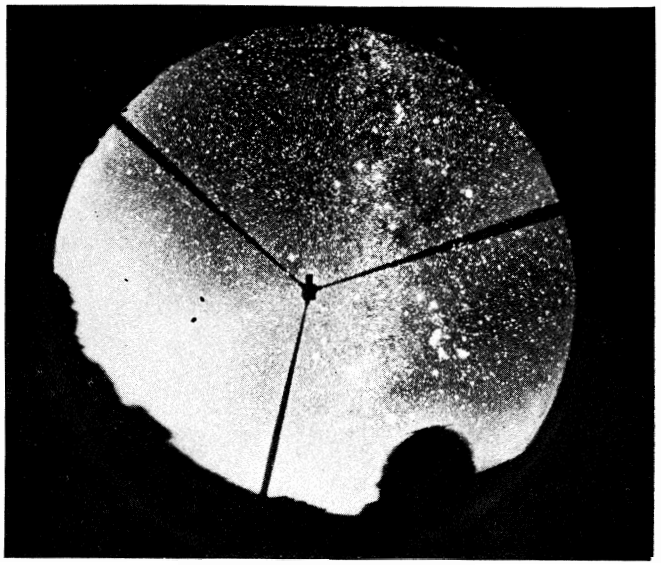
Crab nebula in Taurus photographed in red light, showing filamentary structure of expanding gaseous matter ejected by supernova of A.D. 1054



Mars photographed with the 40-in. refractor, Yerkes observatory, 1909



Solar granulation photographed with a 12-in. reflector from a balloon. Smallest detail has a size of about 0.3 seconds of arc



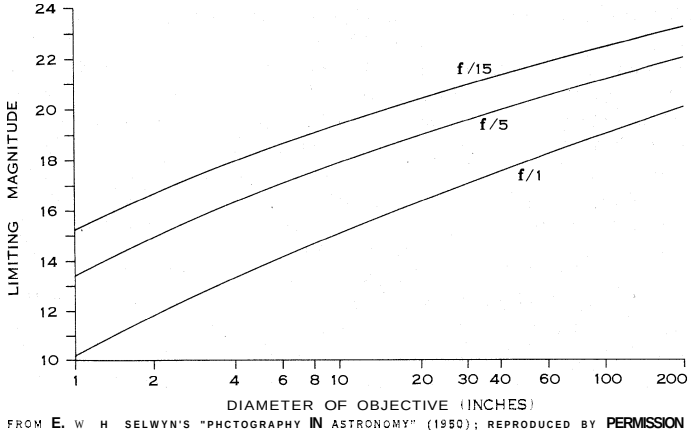
Milky Way, zodiacal light and stars photographed with the Greenstein-Henyey wide-angle camera. Diameter of picture is 1400, only a little less than whole hemisphere. Faintest stars on picture are also faintest stars that can be seen with naked eye, so picture reproduces sky as the eye sees it

ADDITIONAL EXAMPLES OF CELESTIAL PHOTOGRAPHY

BY COURTESY OF (LEFT) THE MOUNT WILSON OBSERVATORY AND W. BAADE, (TOP RIGHT, BOTTOM RIGHT) YERKES OBSERVATORY; PHOTOGRAPH, (CENTRE RIGHT: PROJECT STRATOSCOPE OF PRINCETON UNIVERSITY, SPONSORED BY THE U.S. OFFICE OF NAVAL RESEARCH AND THE U.S. NATIONAL SCIENCE FOUNDATION

amount of light collected and hence the brighter the image. For objects having extended surfaces like the sun, moon, planets and nebulae, the situation is similar to ordinary terrestrial photography. The photographic efficiency for surfaces is inversely proportional to the square of the focal ratio and is independent of the aperture; for a particular focal ratio the advantage of a large aperture is its great magnification and hence its ability to resolve small details.

For stars the situation is somewhat different. According to geometrical optics, star images are points; if diffraction is taken



FROM E. W. H. SELWYN'S "PHOTOGRAPHY IN ASTRONOMY" (1950); REPRODUCED BY PERMISSION OF EASTMAN KODAK COMPANY

PHOTOGRAPHY OF FAINT STARS

For a given focal ratio, the larger the telescope aperture the fainter the stars that can be photographed. For a given aperture, a larger focal ratio permits fainter stars to be recorded

into account. they are small disks whose linear size is proportional to the focal ratio. One might expect that the photographic efficiency would be proportional to the square of the aperture of the telescope. However. for telescopes with apertures larger than a few inches, the actual image size is determined by aberrations and imperfections in the optical elements and by the effects of disturbances in the earth's atmosphere (called "twinkling" or "seeing"). In larger telescopes, therefore, the star images are larger and the photographic efficiency does not increase as rapidly as the square of the aperture.

2. Limiting Magnitude. — For a given telescope it is impossible to photograph fainter and fainter stars merely by prolonging the exposure time. In order to record a percepttble image of a star there is required a certain minimum difference between the brightness of the stellar image and the sky background. The effect of sky illumination, the light of nhich is a faint and variable auroral glow produced in the earth's atmosphere by solar radiation, is determined by the focal ratio. For a given focal ratio. therefore. increase in linear dimensions does not affect the sky brightness in the focal plane of the telescope. From experience it is found that nhen the surface brightness of an object falls below one-sixth the sky illumination it becomes difficult to recognize the object on the emulsion. When this condition is approached the magnitude of the faintest star discernible on the photograph is termed the limiting magnitude. Because of its great practical importance. the limiting magnitude attainable nith a given telescope has been the subject of a number of studies. The results of these studies are collected in the figure. compiled by E. W. H. Selwyn, nhich shons the limiting magnitude as a function of aperture and focal ratio of the telescope.

To record a perceptible image of a nebula also there is required a minimum difference between its brightness and the general sky brightness. This contrast can be increased by taking the photograph with light of such wave length that the nebula is relatively bright and the sky is relatively faint. Because much of the nebular light is therefore rejected. this procedure requires long exposure time or particular photographic skill.

3. Field. — For most of the large refractors. nhich generally have focal ratios in the range f/15 to f/20, the field of critical definition amounts to 1° to 2° in diameter. In order to cover larger areas lenses of shorter focal length and of focal ratio f/7 to fi4.5 usually are employed. However! simple doublets of this focal ratio have only a small field of good definition and in order to photograph a larger field it is necessary to use a more complicated multielement lens. Among the most useful of these wide-field lenses are a series of four-element objectives, f/7, designed by F. E. Ross, which have a field of several degrees.

The field of good definition of a reflecting telescope also decreases with decreasing aperture and with increasing focal length, and is only a few minutes of arc for the 100-in. reflector at Mt. Wilson observatory, near Pasadena. Calif., and the 200-in. reflector at Palomar observatory, Palomar mountain, Calif. In 1929 Ross designed a lens that. when placed a short distance in front of the focus, extended the useful field to an area nearly 1° in diameter. Since lenses of this type changed the focal length very little they were called zero correctors. By the early 1960s nearly all of the large, modern reflectors were provided with auxiliary lenses of this character.

4. Schmidt Telescope. — In 1931 Bernhard Schmidt of the Hamburg observatory, Bergedorf, Ger., designed and constructed a new type of telescope that represented an ideal composite system. The Schmidt telescope consists of a figured correcting plate, which the light passes through, and a spherical reflecting mirror, which then brings the light to a focus on a spherical surface with a radius half that of the mirror. It is therefore necessary to bend the photographic film or plate to fit this curved focal surface. Since the Schmidt telescope has a much larger field of good definition than either a reflector or refractor of the same focal ratio, it is superior whenever coverage of a large area on a single exposure is required. By the 1960s many 24-in. (aperture) Schmidt cameras were in operation; the largest was the 48-in. camera of the Mt. Wilson and Palomar observatories.

5. Other Modern Telescopes. — During the early 1940s A. Bouwers in the Netherlands and D. D. Maksutov in the U.S.S.R. independently discovered a composite system somewhat similar to the Schmidt telescope. In the Bouwers-Maksutov telescope the light passes through a weak spherical lens and is focused by a spherical mirror onto a curved film. The advantage of this system is that its lens involves only spherical surfaces and for this reason it is easier to construct than a Schmidt corrector plate. Furthermore the over-all length of the telescope is shorter than that of a Schmidt telescope of the same aperture and focal length. The disadvantage of the Bouwers-Maksutov telescope is that its definition. while superior to that of an ordinary refractor or reflector over a wide field; is not as good as that of a Schmidt telescope. By the 1960s the largest two Bouwers-Maksutov telescopes in operation were the 20-in. (aperture) at Alma-Xta and the 18-in. at Simeis, both in the U.S.S.R.

With Schmidt or Bouwers-Maksutov telescopes it is possible to photograph with good definition a field of from 5° to 15° in diameter, depending on the size of the instrument. (Although this is much smaller than the field of an ordinary hand camera, it must be remembered that astronomical requirements of definition and of scale are much greater than those that can be met by hand cameras.) Various modifications of these telescopes make it possible to extend the usable field to as much as 50° but for still larger fields a different type of instrument is necessary (see *Celestial Photographs: Meteors; Artificial Satellites,* below). A very wide-field system invented by J. L. Greenstein and L. G. Henyey in the 1940s uses a spherical mirror that focuses the light on a spherical focal surface. There is, however, no film at this focal sphere; instead there is a complicated lens system some distance above it which refocuses the light onto a flat plate. In this way a different section of the mirror is used for photographing each part of the sky and the field of good definition is quite large. The largest Greenstein-Henyey camera! owned by the Yerkes observatory, has a mirror 12 in. in diameter, but the effective aperture is only 0.2 in. and the effective focal length 0.4 in. This instrument photographs a field of 140° at one time, only a little less than the whole hemisphere of 180°.

6. Photographic Plates and Films. — The photographic materials used in astronomy are ordinarily coated on glass plates

because of the relative freedom from stretching achieved in this way. Film is used only if it has some special advantage, as in some Schmidt cameras because it can be bent easily, or in solar or planetary photography because large numbers of exposures are taken in rapid succession. Ordinary photographic emulsion is sensitive only to the wave-length region 3,000 Å to 5.000 Å. (An angstrom unit, written Å, is $\frac{1}{100,000,000}$, or 10^{-8}, centimetre. The limits of human vision extend from about 4.000 Å, violet, to 7,000 A, red. while 5.000 Å is green.) After the discovery of sensitizing dyes by Hermann Vogel in 1873 the short wave-length region that can be photographed was extended to 3,000 A; more recent inventions pushed the long wave-length limit to 13,000 Å.

Astronomical plates and films are considerably more sensitive than commercially available materials but on the other hand they become fogged more easily and must be kept under refrigeration until shortly before use. There is a range of speeds of astronomical plates available: generally the more sensitive a plate is to light, the grainier its structure is when developed and the poorer its resolution is. Thus one must always compromise between speed and resolving power.

III. CELESTIAL PHOTOGRAPHS

1. Sun.—The sun is extremely bright, brighter than almost any other source, and therefore can be photographed with very long focal-length instruments and on large scale. Furthermore fine-grain (and therefore relatively slow) plates can be used for the maximum resolution of fine detail on the sun's surface. Cnder these conditions the resolution is limited chiefly by the unsteadiness of the earth's atmosphere and by the deformation of the optics of the telescope caused by solar heating. In the early 1900s George Ellery Hale discovered that a considerable part of the daytime unsteadiness occurs near the ground as a consequence of convection of heated air. Therefore he arranged for the construction of the 60-ft. and 150-ft. solar towers at Mt. Wilson, each of which has an objective lens of 12-in. aperture at the quoted distance above the focal plane. The solar towers are fixed refracting telescopes with vertical axes, equipped with coelostats, or systems of fiat mirrors driven to follow the sun's apparent daily motion, that direct the sunlight down into them. Each of the towers is actually composed of two completely independent structures, one inside the other. The outer tower serves as a screen to prevent the inner tower, which bears the optical equipment, from being set into vibration by the wind. The combination of great height above the ground and shielding from wind proved quite successful in limiting the effects of atmospheric unsteadiness and improving the image quality. Subsequently several other tower telescopes were built, including those at Potsdam, Ger., at Arcetri, Italy, and at the McMath-Hulbert observatory near Pontiac. Mich. The last observatory in particular pioneered in making motion pictures of rapidly changing solar phenomena. Solar telescopes are often used in conjunction with a spectroheliograph (*q.v.*) to record a photograph of the sun in the light of a single wave length, *i.e.,* in the light of a single element, such as hydrogen or calcium.

In an attempt to obtain solar photographs of even better resolution two groups of astronomers were led in 1956–57 to use balloons to take their telescopes to heights above nearly all the atmospheric unsteadiness. A. Dollfus of the Paris observatory and D. E. Blackwell and D. W. Dewhirst of Cambridge observatory took an 11-in. refracting telescope of 180 ft. effective focal length to a height of 20.000 ft. in a manned balloon, while M. Schwarzschild and J. R. Rogerson of Princeton University observatory and J. W. Evans of Sacramento Peak observatory, Sunspot, N.Mex., sent an automatically operated 12-in. reflector of 200-ft. effective focal length to a height of 84,000 ft. in an unmanned balloon. Both telescopes mere composite systems consisting of an objective together with an enlarging lens, so that the over-all tube length was considerably smaller than the effective iocal length, and both took many exposures on continuous rolls of film. The definition of both sets of photographs was very good, those taken from the unmanned balloon being the finest solar pictures ever taken.

The solar corona is the very faint outer envelope of the sun, only about $\frac{1}{1,000,000}$ as bright as the sun. It can be phorographed easily at eclipses—when the bright solar disk is hidden —but at other times sunlight scattered by particles in the earth's atmosphere and by imperfections in the optical parts of a telescope ordinarily completely masks the faint coronal light. In 1931, however, Bernard Lyot of the Paris observatory succeeded in photographing for the first time the solar corona outside eclipse. By using an ingenious telescope of his own design termed the coronagraph, and by working on the Pic du Midi (elevation 9,400 ft.) in the Pyrenees, Lyot was able by 1936 to photograph the inner corona out to 7′ of arc from the sun's limb. With still further instrumental refinements, and with the use of a polarizing monochromatic filter (see LIGHT: Polarization and *Electromagnetic* Theory) that transmitted a band of radiation only 1.5 Å wide, Lyot by 1941 not only obtained pictures of the corona but also made direct photographs of the chromosphere, prominences and sunspots that rivaled in quality those given by the spectroheliograph. Two more coronagraph observatories were constructed: the Zurich observatory station at Arosa, Switz. (elevation 6,600 ft.), and the Harvard station at Climax, Colo. (11,500 ft.).

2. Moon and Planets.—The moon and the planets near the earth, though fainter than the sun, are relatively bright objects, comparable with brightly illuminated outdoor scenes on the earth. Thus it is possible to use long focal ratios and short exposure times in photographing these objects. In many cases it is advantageous to use an enlarging lens to increase the effective focal length of the telescope and consequently the scale of the image on the plate. Because the main effect that limits the definition is theunsteadiness of the image caused by turbulence in the earth's atmosphere, it is customary to take large numbers of exposures in the hope that some mill be taken during short moments of "good seeing." After the films have been developed the best images are selected for further study; it is even possible to make a composite print from several different negatives of the same planet to average out the fictitious details caused on a single picture by the earth's atmosphere and by flaws in the film. Experience has shown that, except on a very few superbly steady nights. a telescope of 20- to 40-in. aperture is the best for this type of photography. A larger telescope looks through a greater volume of the earth's atmosphere and is therefore more likely to be affected by unsteadiness of the air.

Photography has made it possible to map the moon in detail and to study, particularly by comparing photographs taken in light of different colours, the surfaces and atmospheres of the planets (see VENUS; MARS; JUPITER).

3. Artificial Satellites.—In Oct. 1957 the U.S.S.R. launched the first artificial earth satellite, and a new subject for celestial photography was created. The first Russian sputniks were large and bright enough for many amateur astronomers and photographers to obtain pictures of their paths across the sky with simple terrestrial cameras. Many scientific problems can be solved by obtaining precise positions of artificial satellites. The United States put into operation a network of 12 cameras specially designed for tracking satellites. These Baker-Nunn cameras are modifications of the Schmidt camera. equipped with a complicated three-component corrector lens and a spherical mirror. The cameras have a focal length of 20 in., work at a focal ratio of f/1 and have a field of good definition 30" in diameter. They use roll film, and a single exposure photographs an area 5° wide and 30° long; inside the telescope is an illuminated precision clock, which gives the exact time of the observation. The telescopes have specially designed mountings that make it possible for them to track alternately on the orbital motion of the satellite and on the diurnal motion of the stars. In this way the image of even a faint satellite can be recorded during one phase of the exposure, and the images of faint stars near it in the sky during the other phase. By measurements of the developed film accurate positions of the satellite can be obtained. A precision of about one second of arc has been obtained with these cameras, the limiting factor being the difficulty of determining the precise time (an accuracy of bet-

ter than 0.001 sec. is required) at remote points on the earth.

4. Meteors. — Meteors or "shooting stars" are solid bodies, ranging in size from small grains to rocks as big as a house, which are heated to incandescence as they plunge through the earth's atmosphere. There is no way of predicting when or where they will appear and they burn out so quickly that once seen it is too late to turn a camera to them. Therefore it is only by accident that a telescope being used for another purpose will occasionally record a meteor trail. For serious scientific work on these objects it is necessary to patrol continuously a large area of sky nith very efficient cameras in order to record the meteors down to as faint a limit as possible. The most effective cameras employed to this end are the so-called "Super-Schmidts," designed by James G. Baker for the Harvard observatory. Each of these cameras has a four-element corrector together with a spherical mirror and may be described as a complicated combination of a Bouwers-Maksutov and an achromatized Schmidt camera. Four of these cameras were constructed, each with an aperture of 12 in. and a focal ratio f/0.67 and each nith a field of good definition 52° in diameter. The focal surface is curved too steeply for ordinary film to be bent to fit it, so the cameras use special hemispherically molded films. After development these curved films are copied photographically onto flat glass plates for measurement and storage. The Super-Schmidt cameras contain electrically driven rotating shutters, which interrupt a meteor trail at accurately known time intervals, and thus make possible a measurement of a meteor's angular speed through the sky. The cameras are operated in pairs, separated by distances of 50 to 100 mi. so that the height and space velocity of any meteor photographed from both stations can be determined by measuring its apparent shift with respect to the background stars.

5. Aurorae. — The aurora borealis, or northern lights. is one of the most impressive sights offered by the night sky Although many successful pictures of individual parts of an auroral display have been taken with hand cameras, the whole phenomenon is so vast that a camera covering nearly the whole sky is needed for a complete photograph. The Greenstein-Henyey camera. which photographs a field 140" in diameter on one exposure, has proved ideal for this work. One of these cameras fitted with a motion-picture attachment was used by A. B. Meinel and his co-norkers at the Yerkes observatory to photograph the changes in form and structure of typical aurorae. (D. E. O.)

6. Charts of the Heavens. — The advantage that photographs of clusters and nebulae have over visual observation is obvious. A glance at a photograph shons the whole of the object in all its beauty. The field of view of a telescope is small and a complete conception of the nebula has to be built up from successive elements. It has always been mentioned that Gill foresaw the possibility of recording the positions of stars from a single plate; the next step was to connect individual plates to make a complete survey of the heavens, as had been — and is — the final aim and purpose of transit observing. The first effort in this direction was made by Gill, who (1885–89), took photographs covering the sky from the south pole to declination 18° S. nhich, measured by Jacobus C. Kapteyn of Groningen. gave approximate co-ordinates and magnitudes of nearly 500.000 stars that form the *Cape Photographic Durchmusterung.* In a more ambitious scheme initiated in 1887 by Amédée Mouchez. director of the Paris observatory, 18 observatories of the world combined to make the *Astrographic Chart,* or a picture of the whole sky which should show all stars down to the 14th magnitude, to nhich was added later a catalogue of all stars to the 11th magnitude By 1958 the catalogue was substantially complete but the chart covered only approximately 50% of the sky. In this connection mention should be made of a series of plates that came later, taken by Franklin Adams in 1903–04 at the Cape of Good Hope and in 1909–10 at Godalming, Surrey, Eng.. with a photovisual objective of 10-in. diameter. Two hundred and six of these plates, each covering an area of 15° X 15°, chart the whole sky to the 16th magnitude.

The extreme delicacy of the gelatin film, especially during development and fixation, led in the beginning to a certain distrust of measurements made on photographic plates. Experience showed these fears to be groundless and photographic methods to be well suited to measurements of the most exacting kind. With properly designed instruments the economic factors are also favourable. An undertaking which effectively utilized these advantages was the reobservation by photography of the zones of the great Astronomische Gesellschaft (A.G.) catalogue, in which the positions of stars to the 9th magnitude were originally measured with meridian circles at many different observatories. In 1913 Frank Schlesinger initiated at the Allegheny observatory, Pittsburgh, Pa., a program of observations with a wide-angle lens which proved to yield accurate star places over a plate 5 square degrees (sq.deg.). Although successful results were obtained with the 25-sq.deg. field, the frequent difficulty of not having enough bright reference stars for plate reductions led Schlesinger at the Yale University observatory in 1927–28 to employ a specially designed 5-in., f/14 Ross lens that covered a field of 140 sq.deg. Other workers soon adopted the photographic method and by 1938 the northern A.G. zones had been completely reobserved by Yale and a number of European observatories.

The most ambitious project of charting the sky was the National Geographic society-Palomar observatory sky survey, made with the 48-in. Schmidt telescope during the years 1949–1956. The whole sky north of declination 27° S. was divided into fields approximately 40 sq.deg., and two photographs of each field mere taken, one in blue light and one in red, for a total of almost 1,800 photographs. These photographs show stars as faint as the 20th magnitude and permit estimates of the stars' brightness and colour to be made. The band of wave lengths used for the red exposures was so selected that the diffuse nebulae had several emission lines, and therefore appeared very bright. The sky survey provided an unusually complete record of stars and nebulae, which proved invaluable in many statistical and research programs.

The proper motions of stars can be measured by wholesale photographic methods, the most direct method being to photograph a star field at two different times, separated by several years, with the same telescope. Then if the two photographs are compared, the fastest moving stars can be identified as those whose two images are displaced by the greatest amount, while the majority of stars that move more slowly have nearly coincident images. This method of finding stars with large proper motions was pioneered by Max Wolf in Germany and by F. E. Ross in the United States. Furthermore the proper motion of every star on the pair of photographs can be measured in this way if there are some reference objects on it with known motions. Such a proper-motion survey was undertaken at the Lick observatory with a specially designed 20-in. refractor. The extragalactic nebulae, which are so far away that their apparent motions are very small, served as the reference objects. The whole northern sky was photographed for the purposes of this survey during the period 1948–56; a second series were to be taken about 25 years later.

As an early example of astronomical work made practicable by the measurement of photographs, mention may be made of the determination of stellar parallaxes by Charles Pritchard at the Oxford Cniversity observatory in the year 1887. 'lost researches that depend on the measurement of small distances are now made by means of the photographic plate, though close double-star measurement is an exception. E. Hertzsprung devised methods involving the use of a grating and colour filters to ensure freedom from error in finding the distance between the components of double stars and their position angles, but it is considered that the photographic method is unsuited for pairs whose separation is less than about a second of arc.

In addition to the advantages already mentioned, others that pertain to the sensitive plate are that its receptivity is cumulative; by continued application it can see where the eye is blind. The impressions are permanent and constitute a record that can be measured and consulted at will. Faint comets. for example, are discovered by photographing the region in which the object is believed to lie and searching the developed plate. In this manner 6 of the 11 satellites of Jupiter and 1 of the 9 satellites of Saturn were discovered; satellites X and XI of Jupiter are so small that they were found only with the 100-in. Mt Wilson reflector by S. B. Nicholson in 1938. A similar method for finding minor

planets has been very fruitful, and examination of the series of celestial photographs of the Harvard College observatory has brought to light many novae that have appeared in past years but which were not detected visually at the time of their appearance. This great collection of photographs that was accumulated systematically over many years constitutes a record of the state of the sky at approximately regular intervals. It was especially fruitful for the discovery of variable stars and for the determination of their light curves. See also Index references under "Photography, Celestial" in vol. 24.

PHOTOGRAPHY, SPARK, a technique that derives its name from the type of illumination employed for the photograph, utilizes the light produced by a small electric spark of extremely short duration and great intensity. This technique should not be confused with the electronic flash ordinarily used for photography.

The spark method finds many applications in the photography of rapidly moving objects; for example, the earliest known spark photograph was an ordinary snapshot of a newspaper clipping fastened to the surface of a rapidly spinning disk. The size of the spark is so small that it can be used to project a silhouette directly on the photographic film, and, in ordinary practice, the conventional camera with its lens is not required.

The spark itself is generated by the discharge of a high-voltage capacitor across a gap between two electrodes. The circuit consists of the condenser, the main gap, and a trigger gap formed by a third electrode placed between the two main electrodes. Electrical energy is slowly stored in the condenser over a relatively long period of time, since the spacing of the electrodes is wide enough to hold the voltage. and is discharged with sudden violence through the main gap at the instant the circuit is effectively completed by sparking the trigger gap.

The gap and condenser are designed to produce the most brilliant flash of light possible in the shortest time. By grouping the elements of the condenser in a ring around the gap so that the discharge of electricity takes place in a concentric path, the duration of the spark can be shortened to 10^{-7} seconds and good exposure obtained at spark to photographic plate distances of 4 to 10 ft. with an operating capacitance of 0.1 microfarad and voltage of 7,000 volts.

Fortunately, the light from the spark is rich in ultraviolet radiation and its photographic effectiveness is thereby increased in taking direct spark shadowgraphs. More brilliant sparks can be obtained for other applications by increasing the capacity and voltage, but the duration of the light is also increased, approaching several microseconds in extreme cases.

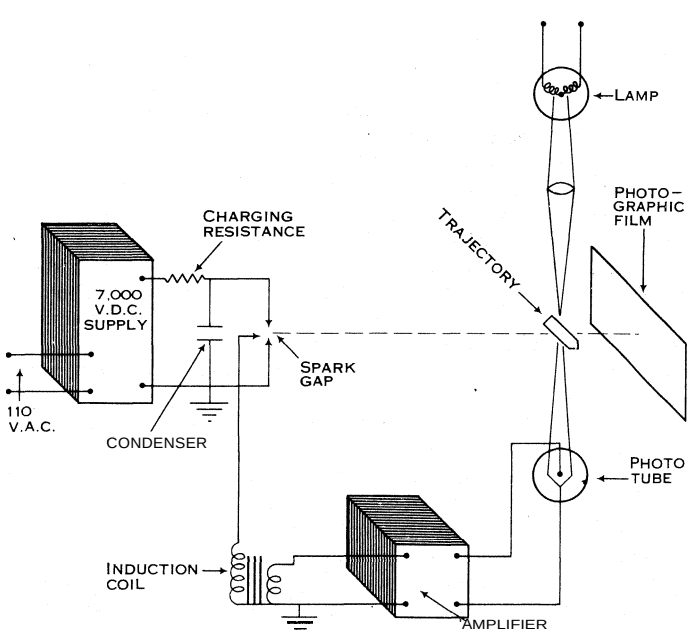

FIG. 1.—SCHEMATIC WIRING DIAGRAM OF SPARK PHOTOGRAPHY APPARATUS

Firing the spark at the desired time during the brief period the moving object is in front of the plate is usually the most difficult feature of this photographic system. and many ingenious methods of triggering have been developed. This operation must be extremely precise; a tolerance of 10^{-5} seconds is common, and fast electronic circuits are required. The particular method chosen depends on the application, but ordinarily some property of the object itself starts the trigger operation. The simplest of all methods is the make-or-break contact. If the object is made of steel, a magnetic trigger can be used; if it can be charged to a high potential, an electrostatic trigger is suitable; if the geometry of its motion can be arranged so that it cuts the path of a beam of light, a photoelectric trigger gives good results; or, if the object is traveling faster than the speed of sound, a sonic trigger will work.

The over-all operation is conveniently illustrated by tracing through the sequence of events involved in taking the spark photograph of a bullet in flight using the apparatus shown in the fig. 1. The room is darkened. the photographic plate put in position, and the gun is fired. Since a photoelectric trigger is used, the gun is aimed so that the trajectory intersects the beam of light from the lamp to the phototube. As the bullet interrupts this beam, it changes the amount of light falling on the phototube and thereby generates a voltage pulse in the electronic circuit. This pulse is amplified and used to fire a gas discharge tube in the output of the amplifier. The discharge tube in turn sends a surge of current through the primary of an induction coil, and the high voltage surge resulting in the secondary is applied to the electrode of the trigger gap producing a weak spark across this gap. The trigger spark ionizes the air in the main gap, causing it to break down, the condenser discharges through the main gap, and the spark photograph is taken. The duration of the light is sufficiently short to arrest the motion of even the highest velocity projectiles.

Applications to Ballistics.—Spark photography is of great value to the ballistics engineer, enabling him to answer many questions on the flight of bullets and the flow of the air about them. Such problems as that of determining the distance from the muzzle at which the velocity of the erupting gas becomes less than that of the bullet are readily solved. It is of particular interest in the case of shot shells where the disposition of the shot and wads may be easily observed. Work of this nature led to the commercial development of shot shells without the top card wad over the shot, for it was observed by spark photography that this wad interfered with the proper flight of the shot.

Aerodynamics Range.—As the projectile flies from gun to target, it experiences violent resistive forces because of its high-velocity motion through the air, and if the flight path is to be computed, these forces must be measured. Here spark photography gives the ballistician a tool of great precision in the so-called "aerodynamics range." The projectile is fired into a long, enclosed gallery containing from 10 to 25 spark-photography stations spaced at intervals along its length. As the projectile passes each station in turn. two spark pictures are taken in perpendicular planes (one horizontal, say, and the other vertical) and the time of the event is recorded on a high-speed chronograph.

Thus, each pair of spark photographs records the position of the projectile at a measured time, and all of the records can be combined to determine the retardation of the projectile's motion and the aerodynamic drag. The inclination of the projectile's axis to its direction of motion can also be measured from each pair of pictures, and from these measurements the projectile's stability can be computed.

Applications to **Physics.**—Many processes of physics not only take place with extreme rapidity, such as the flight of bullets, but also require special optical apparatus in order to be recorded in a useful manner. For example, the flow of air over an airplane in a supersonic wind tunnel is quite invisible to the naked eye but can be seen clearly if viewed through the particular combination of light sources, mirrors and lenses known as a Schlieren

SPARK PHOTOGRAPHY OF BULLETS IN FLIGHT

1. Smooth cone-cylinder projectile (20 mm.) at 1,850 ft. per second
2. Rough cone-cylinder projectile (20 mm.) at 1,530 ft. per second
3. A 9116-in.-diameter sphere (cannonball) at 2,050 ft. per second
4. Smooth cone-cylinder projectile (½-in. diameter) at 4,046 ft. per second
5. A 12-gauge shot charge from cylinder-bored gun, photographed three feet from muzzle
6. A 12-gauge shot charge fired from choke-bored gun, three feet from muzzle

system. Near the speed of sound the flow over the airplane becomes unsteady and changes violently from one instant to the next. Waves sweep back and forth over the wings at high speed, and the exposure must be as brief as in ballistic photography if the details of the flow processes are to be recorded clearly.

Spark photography furnishes the key to the instrumentation by providing a light source having both a short duration and the very small size required by optical systems. Its use in a Schlieren system is shown in the accompanying diagram. 411 of the light from the spark is brought to a focus at the knife edge, and the lateral dimension of the spark must be limited to a small value, ranging from 0.01 in. in small Schlieren systems to 0.1 in. in large. If a limited number of photographs are to be taken in rapid succession. several sparks placed side by side may be used in a Schlieren system with small orifices replacing the knife edges, each orifice being located at the conjugate focus of one of the sparks. Rates of up to 1,000,000 pictures per second have been obtained.

Other processes in physics require the photography of high-speed objects which are brightly luminous themselves, such as a rocket with a burning jet of exhaust gases or a very high-speed missile that glows like a meteor as it streaks through the air. The light from these objects would fog the film of a direct shadowgraph or obscure the image of a microflash photograph. Again, a spark light source can be combined with an optical system to provide a suitable means of photography. In one system, the spark casts a shadow of the object on a motion-picture screen rather than on a photographic film directly. The screen is photographed by a camera placed adjacent to the spark but to one side so that the images of the object itself and its shadow on the screen are displaced from one another on the camera's plate. In this way. the light from the object is separated from the shadow on the movie screen and does not impair the silhouette of the object seen in the spark photograph.

Shock Wave Phenomena. — One of the most spectacular examples of spark photography is the shadows produced by compression waves in the air. These waves are seen as lines. usually curved, with a dark front edge and a light rear edge. Strong compression waves, known as shock waves. have fronts that amount to surfaces of very small thickness through nhich the pressure, density. temperature, and, consequently, index of refraction change violently. They are roughly similar to the fronts of naves rolling up a shallow beach. The rays of light from the spark passing tangent to these wave surfaces are refracted to form lines of alternate dark and light representing the projection of the wave surfaces on the photograph. The technique is very sensitive and wave patterns are recorded in fine detail.

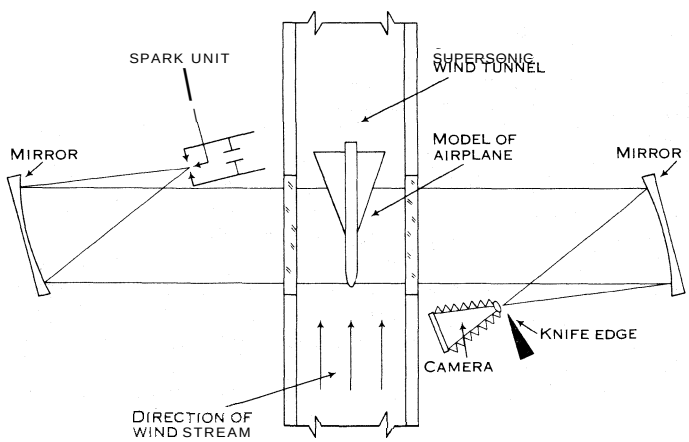

FIG. 2.—SCHEMATIC DIAGRAM OF SCHLIEREN OPTICAL SYSTEM FOR PHOTOGRAPHING FLOW OVER MODEL OF AIRPLANE IN SUPERSONIC WIND TUNNEL

Shock waves are produced in air by any disturbance that is sufficiently strong and abrupt. Electric sparks. explosives, projectiles and aircraft traveling at speeds close to or greater than the speed of sound all generate shock waves. An example of pure wave photography is found in the study of the reflection of shock waves from solid surfaces. The wave patterns surrounding bodies at transonic and supersonic velocities are of particular interest since they tell much about the nature of the air flow over the body. Even the turbulent layer of air next to the projectile's surface and the wake following it are visible. (R. E. E.; A. C. Cs.)

PHOTOGRAPHY, STROBOSCOPIC. The term stroboscopic photography should apply strictly to the use of multiflash techniques. However, it has become commonly used to describe single-flash photography and the contraction "strobe" is often heard when referring to single-flash electronic equipment and photographs taken with it.

Nearly all electronic photography systems of short flash duration rely upon the electrical capacitor to supply the high peak power needed to flash the lamp. The instantaneous power must be about 100,000 watts even for a small, portable flash lamp. The important criterion for exposure is the quantity of light produced, beam-candle-power-seconds (b.c.p.s.), which depends upon the efficiency of conversion of electrical energy to useful light and the storage capacity of the capacitor.

The capacitor is the most important component in a flash unit, other than the flash lamp itself, accounting for most of the weight, volume and cost of the equipment. The capacitor has the ability to accumulate energy at a slow rate and discharge it suddenly into the lamp at a high rate for a short time. Many oi the advances in modern electronic flash-equipment design have been concerned with improved capacitors, such as the electrolytic type.

Electronic-flash tubes are made in many sizes and forms, such as the straight, U-shaped and spiral, as required for different applications. The gas in the tube, usually xenon at a pressure of 0.1 atmosphere, and the electrode spacing are arranged so that the lamp will not flash by itself in most applications. The flash is initiated when a pulse is applied to an external starting wire, causing internal ionization; the tube flashes when the capacitor discharges. Flash duration for a specific flash tube and circuit can be portrayed as a curve showing the initial delay, the rise, the peak and the decay of the light intensity. From a practical standpoint the entire duration of the flash is a negligible amount of time if the motion of the subject is effectively stopped. The duration is defined as the time between instants when the light is at one-third of its peak.

The output oi a flash tube is rated as the integral of light as a function of time. An approximate value can be obtained by taking the product of the flash duration and the peak light, the latter being measured in candle-power-seconds. Special exposure meters are available which integrate the light during the flash and present a meter reading of the integral of the light as a function oi time, Some of these meters have phototubes in probes that are used to read the light at the film position in the camera.

The electronic flash tube has an unusual volt-ampere characteristic. At the start of the discharge the resistance is infinite since no current is flowing. Then as current starts to flow the resistance drops rapidly, reaching a value of a few ohms during the main portion of the discharge. Finally the current again becomes zero and the resistance, infinite. During most of the flash, however, the volt-ampere characteristic is similar to that of a resistor, and the circuit transients can be calculated approximately by considering the flash lamp to be a fixed resistor. For example, the resistance of the FX-1 flash tube manufactured by Edgerton, Germeshausen and Gricr, Inc., is about 2 ohms. This lamp has an effective length of 6 in. and an inside diameter of 4mm. Extrapolations to other lengths and diameters of flash tubes can be made as though the tube were a resistor of uniform conductivity, especially if the stored energy per unit of lamp volume and the voltage per unit of length (or mean free path) are the same as in the FX-1 flash lamp at rated value (2,000 volts and 200 watt-seconds). The flash duration equals $\frac{1}{2}RC$ seconds, where C is the value of the capacitance in farads and R is the flash-lamp resistance as defined by

$$R = \frac{\text{initial capacitor voltage}}{\text{peak current}}$$

where the energy density is more than about 40 watt-seconds per cubic centimetre in the lamp.

There is a large variety of electronic flash tubes available for the equipment designer to consider and newer ones appear frequently. Some of the factors to be considered in designing a flash tube for any specific purpose are shape, efficiency, flash duration, voltage and spectral output.

In considering shape, a concentrated lamp is more effective in a reflector when control of the light is required, but some light may thus be lost by self-absorption,

Each lamp has its maximum efficiency for a particular output. The designer should attempt to use the lamp at or near this maximum (about five candle power per matt) although he usually cannot for such reasons as heating or life of the rube.

If a specific duration is required, the design voltage is usually fixed

for a specific lamp.

Efficiency needs to be considered in terms of voltage since the efficiency usually drops when the tube is used at low voltage.

The xenon flash lamp has a spectral output very similar to that of daylight except for an excess in the blue and near ultra\-iolet. It is known that a flash lamp with a large voltage per mean free path and high energy per unit volume will have a greater excess in the blue compared to the output of a lamp operating at small values. The differences, however, are small and difficult to detect, even with colour film. A long flash lamp operated at low voltage has a large relative proportion of infrared output.

There are many instances in which the most eificient flash tube cannot be used because of heat storage and conductivity problems. This is the usual case with stroboscopic sources, and particularly with those lamps that operate at high frequency and high power for extended periods of time.

Multiple-Flash Photography. — The first multiexposure photographs were made with a slotted disk as a shutter, or with a series of cameras. Electronically produced flashes of light at accurately controlled intervals of time are an excellent method of producing stroboscopic photographs. Two practical problems arise, however, when an electronic flash tube is required to run as a stroboscopic source. First, the flash tube may become so hot that it does not function properly and may misfire due to improper starting. Second, the flash tube may fail to deionize, thus preventing the capacitor from building up a charge for the subseauent flash. The Dower unit then supplies continuous current to the lamp in a condition known as holdover.

A hot lamp may fail for several reasons, such as electrical puncture of the glass by the external sparking circuit, short circuiting of the triggering spark by the conduction of the hot glass or actual collapse of the glass mall of the tube. Failure of a tube to deionize, in addition to the holdover condition, may result in self-flashing due to the lowering of the holdoff voltage by residual ionization, high temperature or overheated electrodes. Tubes of quartz are much more capable of operation at high-power rates since the quartz has a higher melting temperature than glass. Several special circuits have been used to operate flash tubes at high flash rates per second. Examples are the series mercury-arc rectifier of the pool type and the hydrogen thyratron, of the type used in radar modulators.

The stroboscopic light can be synchronized mith the motion of the film to produce framed pictures for projection. This is commonly done mith the 16-mm. high-speed rotating prism camera. Magnetic pickups can be used to trigger the flash lamp at the correct instants of time so that the flashes are synchronized with the film position. There is another general type of multiflash equipment that is capable of great speed and flexibility and which is useful when a limited number of photographs are needed. Each flash ior this method is powered by a separate capacitor, connected either to separate lamps or to a common lamp. Such circuits become bulky when a large number of flashes are desired since each flash requires a separate storage system, as contrasted to a single-storage capacitor. (H. E. ED.)

PHOTOGRAVURE: see GRAVURE.

PHOTO-LITHOGRAPHY: see LITHOGRAPHY.

PHOTOMETRY deals with the calculation and measurement of light. Here the word "light" may be restricted to electromagnetic radiations of those wave lengths that are capable of' affecting the eye. In modern photometry, however, the same physical methods of measurement can often be employed also in the nearby ultra-violet and infra-red regions. Thus in many cases, photometry has come to mean the measurement of electromagnetic radiation over a somewhat wider range of wave length than is included in the strictly visible region.

Photometry may be divided into theoretical photometry or photometrics, and experimental photometry:

1. Theoretical photometry
   a. Physical photometrics
   b. Geometrical photometrics
2. Experimental photometry.

Photometrics includes the establishment of the various concepts and units needed in the quantitative specification of light. It also deals with methods of calculating any one of these quantities in terms of the others. Theoretical photometry may be divided into two parts, analogous to the division of optics into physical optics and geometrical optics. Physical photometrics is the part of the subject that deals with the spectral distribution of radiant energy and its evaluation with respect to the receptor. Geometrical photometrics considers the space distribution of radiant energy. Experimental photometry treats of the apparatus and experimental methods that are used in the measurement of light.

The literature of photometry includes the classic treatises of François Marie (1700), Pierre Bouguer (1729), Johann Heinrich Lambert (1760) and August Beer (1854) and the more recent books by John William Tudor Walsh, Charles Fabry, A. A. Gershun and others. The subject is still in the process of rapid growth, as attested by the large numbers of original researches described in the journals of the optical societies and illuminating engineering societies. A few references are given at the end of this section.

Physical **Photometrics.**—The early photometrists (1760) based their work on the idea of light as a separate entity produced by a candle, and these crude ideas persisted even into the 20th century. But today everyone knows that visible light is physically the same as other electromagnetic radiation, the only difference being that visible radiation is of such wave lengths that it affects the eye while other radiations are of longer or shorter wave lengths to which the eye does not respond. Thus the modern approach to lighting is through the physics of radiation.

Electromagnetic radiation includes the wide range of radio (wireless) waves, the infra-red region, the visible region, the ultra-violet, X-rays, etc. All of these radiations are of the same nature and are separated into regions on the basis of wave length. The wave length of electromagnetic radiation is measured in any convenient units of length. For radio broadcasting, wave lengths may be expressed in metres (1 m. = 39.37 in.). For visible radiation, the metre is too big a unit so the millionth part of a metre is ordinarily employed. This unit is called the micron. Two other units of wave length are sometimes used:

1 micron (μ)	$=10^{-6}$ metre
1 millimicron ($m\mu$)	$=10^{-9}$ metre
1 Angstrom (Å)	$=10^{-10}$ metre.

The approximate limits of the visible region are 0.4μ and 0.7μ, or $400m\mu$ and $700m\mu$, or 4000 Å and 7000 Å. Radiation at 0.4μ gives the sensation of violet. As the wave length is increased beyond 0.4μ, the colour sensation changes through blue, green, yellow, orange and red. Radiation at 0.7μ appears as a deep red, while radiation much beyond 0.7μ is invisible. This is the infra-red region. If radiation is much shorter than 0.4μ, it is likewise incapable of affecting the eye, and the radiation is said to be in the ultra-violet region.

When radiation occurs in a very narrow band of wave lengths, it is said to be homogeneous radiation. The yellow light produced by heating common salt in a Bunsen flame is practically homogeneous, as is the radiation from the sodium-vapour lamp used in highway lighting.

Some electric discharge lamps, such as mercury-vapour lamps and neon lamps, produce line spectra. That is, homogeneous radiation is emitted simultaneously at several distinct wave lengths. The set of wave lengths at which energy is emitted is a characteristic of the gas or vapour in which the discharge takes place. A lorn-pressure mercury-vapour lamp, for example, produces four strong radiations in the visible region. It radiates at 0.406μ (violet), 0.435μ (blue), 0.546μ (green) and 0.578μ (yellow). There are additional lines in the ultra-violet and infra-red. An incandescent lamp, on the other hand, radiates at every wave length in a wide band, producing a continuous spectrum. Sunlight is also essentially continuous. In fact, continuous spectra are produced by all sources that radiate because of their temperature.

The physicist and the engineer must know not only the wave length but also the amount of radiation. The sole way in which this amount can be measured is to transform some of the radiant energy into another form, such as thermal energy, and measure the result. A blackened surface can be placed where the radiation is to be measured. Most of the radiant energy incident on the surface is converted into heat and causes a temperature rise of the blackened surface. This temperature rise is measured and constitutes a means of determining the radiant power (watts) per unit area, incident on the surface.

Thus the specification of homogeneous radiation incident on a given receiving surface requires a knowledge of two quantities: (a) the wave length, and (b) the radiant power being received

by the surface per unit area (expressed in watts per square metre). The specification of a line spectrum consists in a designation of the wave lengths of the radiations and the radiant power per unit area associated with each wave length. A continuous spectrum is specified by giving the radiant power incident on a given receiving surface, per unit area of surface and per unit wave length band.

An example is shown in fig. 1, which represents measurements made on direct sunlight. The ordinates of the curve are expressed in watts of radiant power incident on a square metre of surface at the earth, per micron band width.

Similar spectroradiometric curves are available for blue sky and cloudy sky, as well as for incandescent lamps and fluorescent lamps.

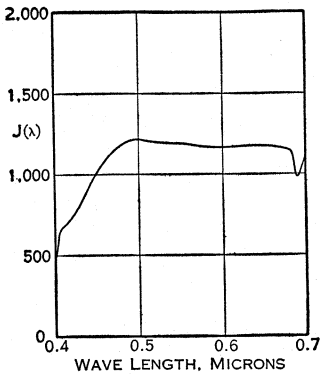

FIG. 1. — SPECTRORADIOMETRIC CURVE FOR DIRECT SUNLIGHT. THE VERTICAL SCALE REPRESENTS WATTS PER SQUARE METRE PER MICRON WAVE LENGTH BAND. THE OBSERVER IS AT SEA LEVEL, THE SUN IS AT 60° FROM THE ZENITH AND THE RECEIVING SURFACE IS TILTED SO THAT IT IS PERPENDICULAR TO THE SUN'S RAYS

From such a curve, the total radiant power per square metre of surface, between any two wave lengths, λ_1 and λ_2, can be obtained by measuring the area under the curve. Expressed mathematically,

$$D_r = \int_{\lambda_1}^{\lambda_2} J(\lambda)\, d\lambda \qquad (1)$$

where D_r = radiant power per unit area (watt m.$^{-2}$), $J(\lambda)$ = ordinate of spectroradiometric curve (watt m.$^{-2}$ micron^{-1}), λ = wave length (micron). D_r and $J(\lambda)$ refer to a particular receiving surface, such as the surface of the earth or a surface set up at a known distance from a lamp. D_r and $J(\lambda)$ may be employed also in specifying the radiation emitted by a given surface.

The evaluation of equation (1) with $\lambda_1 = 0.40\mu$ and $\lambda_2 = 0.70\mu$ gives the total radiant power per unit area for the visible spectrum. The mere specification of radiant power in the visible region, however, is not the best criterion of the visual effectiveness of this radiation. A blue lamp, for instance, may radiate the same number of watts in the visible region as a green lamp, but the latter will appear to be much brighter because the eye is more sensitive to green light than to blue light. Experiments show that under daylight conditions the human eye is most sensitive to yellow-green light ($\lambda = 0.554\mu$) and is progressively less sensitive as the ends of the visible spectrum are approached. Also, there are, strictly speaking, no "ends" of the visible spectrum; radiation somewhat shorter than 0.4μ or longer than 0.7μ can be detected if the radiation is strong enough.

This experimentally determined property of the eye is shown graphically in fig. 2. The ordinate $\bar{y}(\lambda)$ indicates the relative visual effectiveness of homogeneous radiation of wave length λ. Such a curve can be obtained by comparing a yellow-green of wave length 0.554μ with homogeneous radiation of any wave length λ. The observer arranges two contiguous white surfaces in such a way that one is illuminated by each of these sources. If the variable radiation is also at $\lambda = 0.554\mu$, the observer finds that the two surfaces appear equally bright only when he adjusts the lamps so that the same number of watts per square metre are incident on each half of the comparison screen. Thus $\bar{y}(0.554) = 1.00$. But if λ is any other wave length, less radiant power is needed in the 0.554μ comparison radiation than in the radiation of wave length λ to obtain a brightness match. For instance, if an average observer compares a red light of $\lambda = 0.650\mu$ with the standard radiation, he finds that to balance 1 watt/m.^{2} at 0.650μ he requires only about 1/10 watt/m.^{2} of the yellow-green radiation. Thus at 0.650μ, $\bar{y} = 0.10$.

The curve of fig. 2 may be called the lamprosity curve (Gr. $\lambda\alpha\mu\pi\rho\acute{o}s$, luminosity). Other names for it are luminosity curve and visibility curve. These older names are more familiar but they have been used with such a variety of meanings that it seems advantageous to employ a new word to designate this specialized curve. "Visibility" and "luminosity," besides their popular meaning, have other specialized scientific meanings and their use for $\bar{y}$ tends to cause confusion.

The experimental data for fig. 2 were obtained by several methods, all of which are basically equivalent to that described in the preceding paragraph. There is considerable variation in the data resulting from different experimental methods and obtained by different observers. As the result of experiments made with a large number of observers, however, K. S. Gibson and E. P. T. Tyndall of the national bureau of standards recommended the numerical values that are plotted in fig. 2, and these values were adopted by international agreement in 1924.

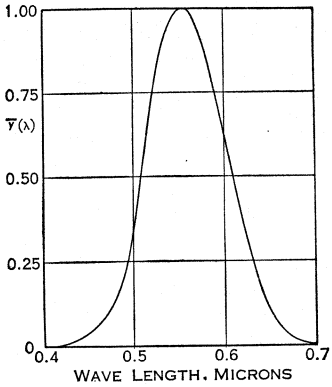

FIG. 2.—STANDARD LAMPROSITY FUNCTION $\bar{y}$ (λ) ("LUMINOSITY," "VISIBILITY") FOR THE EYE. INTERNATIONAL STANDARD CURVE FOR DAYLIGHT VISION, SHOWING HOW THE EYE RESPONDS TO RADIATION OF DIFFERENT WAVE LENGTHS

The existence of these standard values of $\bar{y}(\lambda)$ allows us to weight each small wave length band of a given radiation in accordance with its ability to excite the eye. Instead of taking the entire radiant power in the visible region as in equation (1), we weight each wave length with respect to its lamprosity and write

$$D_l = 647.8 \int_0^{\infty} \bar{y}(\lambda)\, J(\lambda)\, d\lambda. \qquad (2)$$

D_l is a new quantity which is defined by equation (2). It is called luminous flux density or luminous pharosage. It cannot be expressed in watts per square metre but requires a new unit, the lumen per square metre. The conversion factor 647.8 happens to appear because of the way in which the lumen was originally defined in terms of the standard candle instead of by the modern method of equation (2).

Fig. 3 shows how any spectroradiometric curve can be evaluated with respect to the eye. Curve (A) represents sunlight (fig. 1), curve (B) is the lamprosity function for the eye (fig. 2), while curve (C) is obtained by multiplying the ordinates of (A) and (B) at each wave length. In other words the ordinates of the radiation curve (A) have been weighted with respect to $\bar{y}(\lambda)$. The area under curve (A) represents the integral of equation (1) and is expressed in watts per square metre. Measurement with a planimeter shows that in this particular example 328 watts per square metre are being received from sunlight. Similarly, the area under curve (C) represents the integral, equation (2), and is expressed in lumens per square metre. Measurement of this area shows that the visually weighted sunlight is specified as 82,700 lumens per square metre.

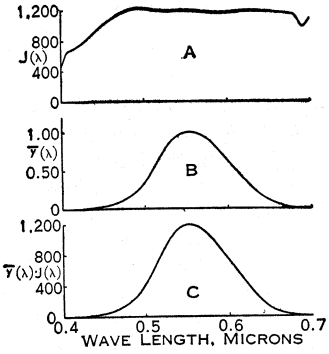

FIG. 3.—METHOD OF CALCULATING PHAROSAGE (LUMEN M.$^{-2}$) BY MEANS OF THE STANDARD LAMPROSITY CURVE

Geometrical Photometrics.—The foregoing section on physical photometrics has shown how photometric magnitudes are based on physical measurements of radiant power per unit area, weighted by means of standard data on vision. Besides the quantity D_l, it is convenient to have a number of related photometric magnitudes. These additional quantities are associated with D_l in a simple geometric manner, and the relationships

among the quantities are covered in the subject of geometrical photometrics.

Luminous flux or pharos F_l is obtained by integrating:

$$F_l = \int D_l dS \tag{2a}$$

where dS is the element of area. In many cases D_l is essentially constant over the area, and luminous flux is obtained by multiplying D_l by area. For instance, if the sunlight of fig. 3 falls on an opening having an area of $\frac{1}{2}$ m.^{2} perpendicular to the sun's rays, the number of lumens through the opening is

$$F_l = D_l S = 82{,}700 \times \tfrac{1}{2} = 41{,}350 \text{ lumens.}$$

In fig. 3, the data are given for a surface that is normal to the sun's rays. Evidently if the surface is tilted from this optimum position, a gix-en amount of radiant power will be spread over a greater area and the amount per unit area will be reduced. This fact is expressed by the cosine relation:

$$D = D_m \cos \psi \tag{3}$$

where D=pharosage (flux density) on tilted surface, D_m=pharosage (flux density) on surface that is normal to the incident rays, +=angle between the direction of the rays and the inward-drawn normal to the surface. This equation applies to radiant pharosage D_r (watt m.$^{-2}$) and also to luminous pharosage D_l (lumen m.$^{-2}$).

Another important equation is the inverse-square relation, which applies if the dimensions of the light source are small compared to the distance from the source to the receiving surface. The inverse-square relation states that if the receiving surface is moved along a line that passes through the centre of the light source, then D varies inversely as the square of the distance between surface and source. In combination with equation (3),

$$D_2 = D_m \left(\frac{l_1}{l_2}\right)^2 \cos \psi \tag{4}$$

where D_2=pharosage (flux density) on tilted surface at distance l_2 from source, D_m=pharosage (flux density) on a surface that is normal to light rays and at a distance l_1 from source, ψ=angle of incidence.

This relation applies either to radiometric quantities (watt m.$^{-2}$) or to photometric quantities (lumen m.$^{-2}$). A knowledge of pharosage D_m at a known distance l_1 allows the calculation of pharosage D_2 at any distance l_2 and at any angle. In the older literature, equation (4) is written

$$\mathrm{D} = \frac{I}{l^2} \cos \psi \tag{4a}$$

where I=intensity of the source (candles) $= D_m l_1^2$.

The concept of intensity or candlepower is rapidly becoming obsolete. In the older days, when candles and oil lamps were still employed, the dimensions of the source were so small that the inverse-square relation was applicable in almost all cases. With modern lamps, such as fluorescent lamps, the dimensions are often so large that equation (4a) does not apply and thus the concept of candlepower is essentially useless.

Caution in the application of equations (4) and (4a) should be emphasized. The inverse-square relation is significant only at distances that are large compared with the dimensions of the source. Experience shows that in general the distances l_1 and l_2 must be at least five times the greatest dimension of the source if equations (4) and (4a) are to give results that are correct to within 1%.

For instance, with an incandescent lamp having a clear bulb and a filament 3 cm. in greatest dimension, the inverse-square relation should not be used at distances less than 15 cm. from the centre of the filament. For a fluorescent lamp 1.22 m. long, the inverse-square relation is invalid at distances less than approximately 6 m. Before the more general method of calculation can be treated, one more photometric concept must be introduced.

This concept is helios, which is associated with the popular idea of brightness. The helios produced by a large, uniform source is defined as π times the incident pharosage per unit solid angle, or

$$H = \pi \frac{D_m}{\omega} \tag{5}$$

where H=helios (blondel), D_m=pharosage incident on the cell (lumen m.$^{-2}$), w=solid angle (steradian) subtended at the cell by the opening in the shield.

To measure the helios of a uniform sky, for instance, one can take an ordinary photographic exposure meter of the photoelectric type and point it at the sky. The photocell produces a current that depends on the lumens per square metre incident on the cell from the sky, and the microammeter in the instrument can be calibrated to read directly in any units desired. The cell is shielded so that it receives light only from the sky.

But ordinarily the helios of the sky is not uniform. To obtain the value in a particular direction, one must change the shield on the photocell so that it cuts out all the light except that from a small part of the sky. This condition is expressed mathematically by specifying that the solid angle w shall be small, or

$$\mathrm{H} = \pi \lim_{\omega \to 0} \frac{D_m}{\omega} \tag{5a}$$

Naturally, helios is not limited to the sky of the foregoing example. The light through the solid angle may come from the sky or from a lamp or may be reflected from a surface. Equation (5a) gives the helios at any point in space and in any direction. Helios is a generalized and extended concept which includes as a special case the older idea of brightness of a surface. In fact, if the source is a surface and the medium between it and the observer is nonabsorbing and nonscattering, then brightness and helios are identical. Ordinarily a surface will be found to have a different helios when viewed from different directions. Matte surfaces, however, are found to have essentially the same helios, no matter how they are viewed. A piece of white blotting paper, for example, seems equally bright in all directions. This characteristic is idealized in the perfectly diffusing surface, which is defined as a surface whose helios is independent of viewing angle. It can be proved that a perfectly diffusing surface having a helios of one blondel emits one lumen per square metre, or

$$H = D_0 \tag{6}$$

where D_0 is the pharosage (lumen m.$^{-2}$) from the surface. Equation (6) applies to perfectly diffusing surfaces only.

The definition of helios allows us to present a general method of calculating pharosage. Unlike the inverse-square relation, this method applies to sources of any size and shape. From equation (5a),

$$D = D_m \cos \psi = \frac{1}{\pi} \int H \cos \psi \, d\omega$$

where the integral is taken over the entire lightcone determined by the source. If H is a constant, equation (7) assumes the simple form,

$$D = \frac{H}{\pi} \sigma''. \tag{8}$$

D is the pharosage (lumen m.$^{-2}$) on any surface. The area a'' is obtained by projecting onto the illuminated plane the portion of a unit sphere which is cut out by the convergent lightcone.

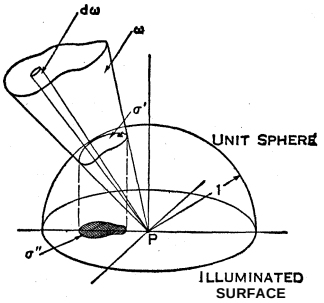

FIG. 4.—THE UNIT-SPHERE METHOD OF CALCULATING PHAROSAGE FROM LARGE SOURCES. THE LUMENS /M.^{2} INCIDENT ON THE HORIZONTAL SURFACE AT P ARE TO BE CALCULATED. THE LIGHT SOURCE WHICH FILLS THE LIGHTCONE OF SOLID ANGLE ω IS NOT SHOWN.

Fig. 4 shows the lightcone and the unit sphere. The light source itself is not shown. It may be any surface or volume source whose boundary determines the lightcone w. The pharosage (flux density) is to be calculated at the point P. The convergent lightcone determined by the source cuts the unit sphere in some kind of an irregular contour. This area a' on the unit sphere is

projected onto the illuminated surface to give the area σ''. The unit-sphere method is a very powerful one and allows the calculation of pharosage (lumen m.$^{-2}$) from sources of any shape.

Besides the photometric concepts considered in the foregoing paragraphs, the concepts of reflectance and transmittance are often useful. The luminous reflectance of a surface is equal to the lumens reflected from the surface, divided by the lumens incident on the surface, or

$$\rho_l = F_{lo}/F_{li} = D_{lo}/D_{li}. \qquad (9)$$

Similarly, the luminous transmittance is defined as the ratio of transmitted lumens to incident lumens.

$$\tau_l = F_{lo}/F_{li} = D_{lo}/D_{li}. \qquad (10)$$

For example, what is the helios of a perfectly diffusing surface having a reflectance of 0.60 when this surface is illuminated normally by direct sunlight (fig. 1)? According to fig. 3, the incident luminous pharosage is D_{li}=82,700 lumens per square metre. From equation (9), the reflected pharosage is $D_{lo}=\rho_l D_{li}$=49,600 lumens per square metre, and by equation (6) the helios (brightness) of the surface is H=49,600 blondels.

The principal concepts of radiometry and photometry are summarized in Table I. The two columns on the right give the names of photometric concepts and units. The columns on the left refer to the corresponding radiometric concepts. The same symbols are employed in both systems, a subscript r or l being used when necessary to distinguish the radiometric from the photometric. The two systems differ only in that the radiometric quantities are true physical magnitudes, while the photometric quantities are these physical magnitudes evaluated with respect to the eye. This evaluation is done by means of the $\bar{y}(\lambda)$ curve shown in fig. 2. Thus $\bar{y}(\lambda)$ is not in either system but effects a liaison between them. Another quantity of similar character is the total lamprosity $\bar{y}_t$ which expresses the total lumens per watt for an entire spectrum. It is evaluated by means of the expression,

$$\bar{y}_t = \frac{\int_0^\infty \bar{y}(\lambda)\, J(\lambda)\, d\lambda}{\int_0^\infty J(\lambda)\, d\lambda} \qquad (11)$$

and is useful in expressing the photometric effectiveness of a given radiation.

TABLE I.—Concepts and Units

Symbol	Radiometric System Name	Radiometric System Unit	Photometric System Name	Photometric System Unit
F	radiant pharos (radiant poner, radiant flux)	watt	luminous pharos (luminous flux)	lumen
D	radiant pharosage (radiant flux density)	watt m.$^{-2}$	luminous pharosage (luminous flux density, illumination, luminosity)	lumen m.$^{-2}$
$J(\lambda)$	phengosage	watt m.$^{-2}$ micron^{-1}	.....	
H			helios (brightness)	blondel
ρ			luminous reflectance (reflection factor)	numeric
τ			luminous transmittance (transmission factor)	numeric
$\bar{y}(\lambda)$	spectral lamprosity (luminosity, visibility), lumen/watt			
$\bar{y}_t$	total lamprosity (luminous efficacy, luminous "efficiency"), lumen/watt			

Note: The word pharos is pronounced far'os (far'os in phonetic symbols). Pharosage is accented on the final syllable, far o sazh' (far o saz'). Helios is pronounced hail' ee os (hel' i os). See J. Opt. *Soc. Am.* 32:348 (1942).

The concepts, names and units of phorometry have never been thoroughly standardized, so the reader will find considerable variation of nomenclature as he reads the literature. Table I is an attempt to present the simplest possible system of photometric concepts. Besides these quantities, there is the concept of intensity or candlepower, which was mentioned previously. There is also phos (quantity of light) in lumen-seconds and phosage in lumen-seconds per unit area. In place of the single concept of pharosage or flux density, some writers prefer to use the two ideas of illumination (lumens per unit area incident on a surface) and luminosity (lumens per unit area emitted by a surface).

Moreover, numerous units are employed in practice. In most countries the unit of illumination is the lumen per square metre, called by various names:

1 lumen per sq.m. ≡ 1 lux ≡ 1 metre-candle.

In Great Britain and the United States however, commercial practice still favours the lumen per square foot:

1 lumen per sq.ft. ≡ 1 foot-candle.

Brightness units are even more numerous and confusing. The simplest way is to ignore these units, to do all one's thinking in a single system and to convert quantities to that system when necessary by use of the conversion factors of Table II.

TABLE 11.—Conversion Factors

Multiply	By	To obtain
Illumination		Pharosage
Foot-candles	10.764	Lumens per sq.m.
Metre-candles (lux)	1	Lumens per sq.m.
Lumens per sq.cm.	10,000	Lumens per sq.m.
Pharosage		Illumination
Lumens per sq.m.	0.0929	Foot-candles
Lumens per sq.m.	1	Metre-candles (lux)
Lumens per sq.m.	10^{-4}	Lumens per sq.cm.
Brightness		Helios
Lamberts	10,000	Blondels
Millilamberts	10	Blondels
Foot-lamberts.	10.764	Blondels
Stilbs	3.14×10^4	Blondels
Apostilbs	1	Blondels
Candles per sq.in.	4,869	Blondels
Candles per sq.ft.	33.82	Blondels
Candles per sq.cm.	3.14×10^4	Blondels
Candles per sq.m.	3.14	Blondels
Equivalent ft.-candles	10.764	Blondels
Helios		Brightness
Blondels	0.10	Millilamberts
Blondels	0.0929	Foot-lamberts
Blondels	2.054×10^{-4}	Candles per sq.in.
Blondels	2.957×10^{-2}	Candles per sq.ft.
Blondels	0.3183	Candles per sq.m.

Experimental Photometry. — As suggested in the foregoing paragraphs, the fundamental measurement in photometry may be considered as the determination of spectroradiometric curves such as fig. 1. The spectrum is obtained by means of a prism or a diffraction grating, and the radiant power is measured at various wave lengths. Such a spectral distribution gives complete information, for from it can be calculated (fig. 3) the radiant pharosage (watt m.$^{-2}$), the luminous pharosage (lumen m.$^{-2}$), and the colour.

Unfortunately, however, a good spectroradiometer is a large and expensive piece of equipment, and the most painstaking care is required in its use. Thus there is need for simpler methods of measuring the various photometric quantities (Table I). In direct photometric methods, it is convenient to have a physical standard against which the photometers can be calibrated. Theoretically, a photometric standard is a redundancy, since everything can be referred to the watt and the standard lamprosity function. But in practice a photometric standard is useful. The early standards were actual candles, but they were replaced by carefully specified lamps such as the Harcourt pentane lamp and the Hefner amyl-acetate lamp. Such lamps could be set up in any laboratory throughout the world and would give fairly reproducible results. In 1909, these lamps were abandoned in Great Britain, France and the United States and the standard was based on calibrated carbon-filament electric lamps. In 1931 the national bureau of standards (U.S.) developed the platinum black body standard. A small tube of fused thoria acts as a black body radiator (see HEAT, Radiation) and is held at constant temperature by being

immersed in pure platinum at the melting point of that material. The helios of this radiator is defined as 1.885×10^6 blondels (brightness = 60.0 candles per sq.cm.).

Naturally, such standards are used only by the basic standardizing laboratories such as the national physical laboratory (Great Britain) or the national bureau of standards (U.S.). Other photometric laboratories employ tungsten-filament incandescent lamps which have been standardized.

Next consider the receptors which are sensitive to radiation in the visible region and which therefore can serve in various types of photometers. Receptors may be listed as follows: (a) thermocouples and bolometers, (b) vacuum and gas-filled photocells, (c) barrier-layer photocells, and (d) the eye.

Thermocouples and bolometers depend on the heating effect of the radiation. When radiant energy falls on a blackened body, most of the energy is transformed to the thermal form and raises the temperature. This temperature rise can be measured in various ways and provides a means of determining the amount of radiant energy. Such devices are essentially nonselective; that is, they are equally sensitive to radiation of all wave lengths. By using suitable optical filters, however, it is possible to cut out all wave lengths except those in the visible region and to make the instrument respond to these wave lengths in accordance with the standard curve for the eye. Such instruments have been built for experimental purposes but have not been used commercially because the response is small and thus difficult to measure.

The thermocouple uses the Seebeck effect to measure the temperature rise caused by the absorption of radiant energy. At the junction between two metals (copper and constantan, for instance), a small blackened target is attached. When radiation falls on this target, its temperature rises and an e.m.f. is generated. The resulting electric current is measured by means of a galvanometer, the galvanometer deflection being directly proportional to the incident radiant pharosage. In the bolometer, a wire or thin metal strip is blackened and absorbs radiant energy. The temperature rise of the metal increases its resistance, and the change is determined by use of a Wheatstone-bridge circuit. The bolometer has been employed extensively by the Smithsonian institution for the spectral measurement of sunlight, and it has also been used in stellar photometry.

Much more sensitive than the nonselective receptors are the photoelectric devices. Vacuum photocells using caesium have been employed successfully in many photometers. Unfortunately the response curves for all such cells are very different from the curve for the eye. Photocells are sensitive in the near ultraviolet and some of them also have high response in the infra-red. To evaluate the different wave lengths in the proper manner, therefore, the cell should be fitted with coloured glass or gelatin filters. Photocells are often used with D.C. amplifiers so that a larger current can be obtained. Another method is to flicker the light by means of a motor-driven shutter, which allows the use of a multi-stage A.C. amplifier. A modification of this method is employed in the Hardy photoelectric spectrophotometer.

Another photoelectric device is the barrier-layer cell. This receptor is of the utmost simplicity. It consists of a metal disk coated with selenium, and it requires no battery. Copper-oxide cells are also used. When light falls on the surface, electrons are released and a current flows through a microammeter which can be calibrated to read directly in photometric units. The entire photometer, consisting of barrier-layer cell and microammeter, can be made so compact that it can be carried in the pocket. The response curves for barrier-layer cells are more nearly like the curve for the eye than in the previous cases, and the curve can be corrected rather easily by use of a green filter.

Many photometers of this type are made without correction and are calibrated with light from incandescent lamps. They can then be used in measuring lighting installations that employ tungsten lamps, but large errors may be introduced if they are used with other kinds of light. Fatigue and cosine-law error are other things that must be guarded against.

The eye was for many years the only receptor used in photometry, and even in 1945 visual photometers were still widely used. It should be realized that the eye is not a measuring instrument, though it does provide a delicate means of determining equality. Thus in visual photometers, a standard must be provided and means must be arranged for varying either the standard or the unknown until equality is reached. As might be expected from this cursory description, visual photometry is a tedious and time-consuming process which will probably be entirely superseded by photoelectric methods.

We now consider the application of the foregoing receptors to the measurement of (1) pharosage (luminous flux density), (2) pharos (luminous flux), (3) helios (brightness), and (4) intensity (candlepower).

First consider the measurement of the pharosage (lumen $m.^{-2}$) at a given point on a given surface. One way is to place a barrier-layer cell at the given point and to measure the photoelectric current. The microammeter may be separate, connected to the cell by flexible leads, or cell and current-indicating instrument may be built together to form a self-contained unit. In either case, the scale can be calibrated to read directly in lumens per square meter or in lumens per square foot. The instruments are calibrated by placing a standardized incandescent lamp at known distances and using the inverse-square relation, equation (4).

Meters of this type are available from a number of manufacturers and in various styles and sizes. They are very convenient instruments and are accurate enough for most engineering purposes. For precise work, however, the user should be careful about cell fatigue, spectral-response error, and cosine-law error.

Another type of instrument that is available commercially for measuring pharosage employs a caesium photocell, connected with flexible leads to a box containing amplifier, batteries, and ammeter. Obviously, this is a more complicated arrangement than the barrier-layer cell instrument, though it can be built to measure smaller amounts of light. Thermocouples and bolometers are also possible.

Visual methods of measuring pharosage (flux density) were employed universally until the advent of the photoelectric cell. Perhaps the best-known instrument of this type is the Macbeth illuminometer. A matte white "test plate" is placed on the illuminated surface. The observer looks through the illuminometer at this test plate and compares it with the outer part of a photometric field which is lighted by means of a small incandescent lamp contained in the instrument. The brightness of the outer part of the field may be varied by moving the incandescent lamp, and the position of the lamp is read on a scale which may be calibrated directly in lumens per square metre. The current through the lamp is kept constant by use of a rheostat and an ammeter. To use the Macbeth illuminometer, the observer places the test plate, adjusts the lamp current to the correct value, sights at the test plate, and adjusts the position of the internal lamp until the two parts of the photometer field appear to be of equal brightness. The value of pharosage is then read on the scale attached to the illuminometer lamp.

Another important measurement is the determination of pharos or total luminous flux. The total number of lumens emitted by a lamp can be measured by finding the pharosage (lumen $m.^{-2}$) in all directions at constant distance from the lamp and summing these values after multiplying by proper weighting factors. A much simpler method is to take a single reading with an integrating sphere photometer or Ulbricht sphere. The lamp to be tested is placed in a sphere whose interior is coated with a matte white paint. Theory shows that the pharosage produced by reflected light at any point on the sphere wall is independent of how the light is distributed from the lamp and depends only on the total pharos. Thus if an opening is made in the sphere wall at any place and a barrier-layer cell is inserted, its reading will be directly proportional to the total lumens from the lamp and the instrument can be calibrated to read total lumens.

Integrating spheres are employed extensively by lamp manufacturers in testing their product. Obviously, the barrier-layer cell is not the only possible receptor for the Ulbricht sphere. Caesium photoelectric cells are often employed in integrating

spheres, and many such photometers still use visual methods.

Helios may be obtained by a modification of the barrier-layer pharosage (illumination) meter. Instead of accepting light from all directions, the helios meter (fig. 5) shields its cell and allows light to enter only through a solid angle ω, equation (5). The scale can be calibrated to read blondels or any brightness unit (Table II). The Macbeth illuminometer is used also in measuring helios. The Luckiesh-Taylor brightness meter is another visual instrument. It operates like the Macbeth illuminometer but is more compact.

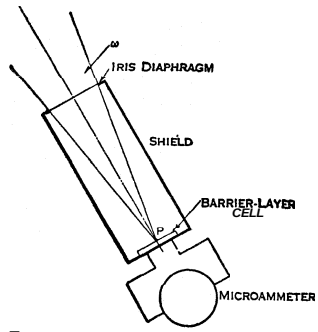

FIG. 5.—A PHOTOELECTRIC HELIOS (BRIGHTNESS) METER

In the older treatises on photometry, attention was given principally to visual methods of comparing intensity (candlepower) of lamps. The standard lamp and the unknown lamp are set on a bar photometer. Between them is a screen, by means of which it is possible to visually compare the separate pharosages produced by the two lamps. The best comparison screen is the Lummer-Brodhun type shown in figure 6.

Distances are varied until the two half-fields appear equally bright, and the intensity of the unknown is then calculated by use of the inverse-square relation, equation (4a).

As mentioned previously, the concept of luminous intensity is an antiquated one, for which there is very little need in modern lighting. When light sources were always of small dimensions (candles. oil lamps, bare incandescent lamps), a knowledge of intensity was convenient in the calculation of illumination by means of equation (4a). But the modern tendency is to use large sources to which equation (4a) does not apply.

Thus the bar photometer and all the paraphernalia of the conventional photometric treatise are rapidly becoming a thing of the past. The only reason that visual methods have persisted in the face of modern photoelectric methods is that the latter are subject to many errors which can be eliminated only by painstaking attention to detail.

In fact, the only reason that visual photometry has survived so long is that the early light sources all produced light of about the same quality. In other words, the problem was one of homochromatic photometry, in which visual matches were comparatively easy to make. With the advent of electric-discharge lamps and fluorescent lamps, heterochromatic photometry became important and visual methods less applicable.

Photometry in 1945 mas in much the same condition that electrical measurements were in about 1880. After that date, however, highly accurate and convenient electrical instruments were developed so that electrical engineering was able to advance safely and rapidly on the basis of precise measurement. A similar development is needed in illuminating engineering, where research is continually frustrated by the lack of accurate measuring instruments. Further research and development in photometry will ultimately yield dividends in the shape of better visual conditions in schools, factories and homes.

PHOTOMETRY, CELESTIAL. Celestial photometry deals with the measurement and evaluation of light from the stars. This article covers the techniques of visual, photographic and physical photometry, considering in detail photoelectric photometry, a physical technique which had reached great importance by mid-20th century.

Historical Survey.— It requires only an elementary casual observation to realize that the stars are of different brightnesses, and, by a mere inspection of the sky, anyone could for himself arrange the stars in order of brightness. This is exactly what the ancient astronomers did: in Ptolemy's *Almagest* (*c.* A.D. 150) the stars visible to the naked eye are divided into six classes of magnitudes, the brightest stars being designated "first magnitude stars" and those just visible to the naked eye forming the sixth magnitude. Each magnitude class is further divided into three subgroups. When the telescope was invented it was at first used merely as a means of extending to the fainter stars this process of assigning magnitudes by simple eye estimation, a process which culminated in the 19th-century publication of the great visual "Durchmusterungs" or surveys of which the Bonn *Durchmusterung* (B.D.) was the first. It gives magnitude estimates for 324,188 stars, the estimates being made by Friedrich W. A. Argelander and his colleagues. The work was extended to the southern hemisphere by E. Schonfeld who produced the *Südliche Durchmusterung* and by J. M. Thome and C. D. Perrine who were responsible in the 20th century for the *Córdoba Durchmusterung.*

But before the completion of the publication of the Cordoba estimates the *Durchmusterungen* had become out of date, and eye estimation had been replaced by photometric measurement. The magnitude nomenclature was retained but attention had been devoted to giving it a precise quantitative meaning. In 1854 N. Pogson argued in favour of adopting a light ratio of 100 to 1 for a difference of five magnitudes, the difference of magnitude between two stars being then defined as 2.5 times the logarithm (to base 10) of the measured ratio of the amounts of light received from them. This definition (which requires further examination—see below) gives values in rough agreement with the older visual estimates and has been universally adopted; but it still remains to fix some definite magnitude of the scale. It is natural to aim at doing this in such a way as to make measured magnitudes correspond roughly to the *Durchmusterung* values and this has been done in different ways for the different visual catalogues referred to through the bibliography attached to this article. The Harvard system of visual magnitudes (due to Edward Charles Pickering and his collaborators) came to be generally recognized as standard. and the zero point of the Harvard system was, in effect. fixed by making the mean measured magnitude of certain selected stars agree with the mean of the B.D. values for the same stars.

Once the magnitude divisions of the *Durchmusterung* catalogues had a rational basis of measured intensity ratios, the census of

the stars contained in them could be used for statistical studies which sought to determine the distribution of stars in depth and thus to learn the structure and extent of the universe as then known. As astronomy developed in the early years of the 20th century, there were many other lines of investigation in which the magnitudes of the stars. which originally had only a descriptive significance, became increasingly important in gauging their distance and their physical characteristics. These applications of stellar photometry are considered later in the present article; one example would be the powerful method of distance determination based on the periods of Cepheid variables. (See STAR.)

At the turn of the century the photographic plate was rapidly taking over the role of receiving and recording the star images in the focal plane of the telescope. As the human eye was displaced, systems of magnitudes other than visual were developed; the magnitudes based on the blue-sensitive photographic plate were called photographic magnitudes. The labour of extending the census of the stars begun in the *Durchmusterungen* to the faint limits reached with large telescopes was a natural task for photographic methods, because of the great number of star images that could be recorded on a single exposure. This information was needed for the analytical studies of the galactic system being undertaken by statistical astronomers.

By 1920 photoelectric photometry was being used on the brighter stars, particularly for astrophysical problems where high accuracy was required. As the sensitivity gradually improved, photoelectric methods assumed increasing importance. and by mid-century were becoming the standard of reference by which other systems were calibrated.

In all of these nonvisual systems, it was necessary to fis the zero point of the scale by assigning a definite magnitude to a particular star, or to the mean of a selected group of stars. In the case of photographic magnitudes the zero was defined to make the average agree with visual magnitudes between magnitude j.j and 6.5, for stars of spectral type Ao (white stars). This having been done, it is found that for other stars the photographic and visual magnitudes do not agree. Thus for the average of what are known as "main sequence" stars of spectral type Ko (reddish stars) the photographic magnitudes are about 0.8 greater than the visual. The difference is due to the colour of the stars; since the maximum responses of the eye and the photographic plate are to light of different wave lengths, the difference of photographic magnitude between two stars will only be equal to the difference of visual magnitude between the same two stars if the stars involved are of the same spectral energy distribution, that is, of the same colour. The difference between the photographic and visual magnitude of a star is, in fact, a recognized measure of the star's colour. This difference is taken in the sense photographic minus visual. and is known as the star's colour index. The colour index is directly related to the star's surface temperature, being negative for the hottest (bluish white) stars. and positive for the cool (reddish) stars. This relation is an example of the physical information about a star derivable from photometric measurements.

Definition of Magnitude. — The circumstance that the colours of the stars are not all the same requires a more careful examination of the definition of magnitude. Pogson's definition states that two stars differ by one magnitude if the logarithm of the ratio of the quantities of light received is 0.3. that is, if the light ratio is 2.j12 (the antilogarithm of 0.4). But the question arises: what light ratio? If the stars are of the same spectral energy distribution it does not matter; if the light ratio is 2.512 for one wave length. it is 2.512 for every other wave length. But if the two stars are of different spectral energy distribution. then the light ratio can only be 2.512 for one wave length, and the difference of magnitude between them will vary with wave length. How then are we to define magnitude?

The definition has clearly to be related to the physical operation of measurement. The general principle of measurement of the difference of magnitude between two stars is that the light from each is received in some definite apparatus, and the beam from the brighter star is reduced until the response of the apparatus to the two beams is the same. The reduction of the light from the brighter star must be achieved by some definite physical operation. subject to the condition that the reduction factor is the same for all wave lengths, and this reduction factor must be measured by a physical method for each operation. This having been done, the measured reduction factor is the ratio of the brightnesses of the two stars, and the difference of magnitude is then 2.5 times the logarithm of the brightness ratio, that is. 2.5 times the logarithm of the reduction factor. This defines the concepts of "brightness" and "magnitude" with respect to the particular apparatus used. and it is easy to see that, with one exception, this is all that can be done, and that the terms "brightness" and "magnitude" cannot have an absolute meaning but can only be defined with respect to some specified apparatus.

The exception referred to is the case in which the apparatus is sensitive only to a very small range of colour, that is, of wave length, and provided this condition is satisfied the magnitudes obtained will not depend on the particular kind of apparatus used. Such magnitudes are called monochromatic magnitudes, and each system of monochromatic magnitudes refers to a specified wave length. It is now being realized that monochromatic magnitudes are of importance in various astrophysical problems, and more attention is being paid to them (see section on spectrophotometry below). But they suffer from the defect that a severe restriction is imposed on the quantity of light available; and accordingly for the fainter stars it is on the older heterochromatic magnitudes that we have to rely. that is. on magnitude measurements in which the receiving apparatus is operated by light of a considerable range of colour. We have seen above that under these conditions the concept of magnitude can be defined with respect to the particular apparatus used.

It is easy to see that this restriction cannot be removed. Consider the simplest case of heterochromatic photometry, this being the case in which the brightness is the integral or' the quantity of light received at each wave length multiplied by the sensitivity factor of the apparatus at that wave length. the sensitivity factors being regarded as constant for the apparatus used (*i.e.*, not dependent on the light intensity). and the integration being taken over the whole range of colour to which the apparatus is sensitive. Taking. for example, the case of visual photometry, the receiving apparatus is the combination of the human eye and the optical train used, and the sensitivity factors will involve the transmissive properties of the optical train to light of different wave lengths. Consequently: for stars of different colour, the ratios of the integrated brightnesses, and so the differences of magnitude, will depend on the particular photometer and telescope used. The same is true for photographic photometry, in which the receiving apparatus is the combination of plate and optical train, it being understood that some specified process of measurement is applied to the photographed images. In particular. we must expect photographic magnitudes to be different for different types of photographic emulsion. and for different kinds of telescopes. Thus photographic magnitudes determined with refractors, for which most of the ultra-violet light is absorbed by the lenses, will be different from those determined with reflectors, for which a large part of the ultra-violet is reflected by a silvered surface. and still more by an aluminized surface. Further, the earth's atmosphere has to be regarded as part of the optical train. Its effect on the difference of magnitude between tn-o stars can be eliminated if both are observed at equal angular distances above the horizon. But observers who do not use the same equal altitude above the horizon must still expect small differences between their results. And observers at mountain stations have less atmosphere over them than those near sea level. The preferred method is to determine the atmospheric absorption in each photoinetric system by measures of standard stars at varying altitudes above the horizon, and then to compute the magnitude differences that would be observed for all stars outside the atmosphere.

While the effects of the earth's atmosphere can be eliminated by reasonably straightforward procedures. there are more serious complications. In the case of visual photometry the Purkinje effect compels us to regard the sensitivity factors as being dependent on the intensity of the light received, and so, if two stars

of different colour are equal in magnitude when a small telescope is used. the redder of the two will appear the brighter if we employ a larger telescope the transmissive properties of which, with respect to wave length, are similar to those of the smaller one. For this reason alone a system of visual magnitudes must be defined with respect to a definite instrument. There is an analogous effect for emulsions which introduces a further restriction in photographic work. If, using a definite instrument, under definite standard conditions. two stars are found to be of the same magnitude for one duration of exposure (by which is meant that some definite process of measurement applied to the two images gives the same result), they will not necessarily be of the same magnitude for a different duration of exposure. Accordingly, strictly speaking, a system of photographic magnitudes must be defined, not only with respect to a definite instrument: working with a definite type of emulsion, under definite atmospheric conditions and applying a definite process of measurement to the images, but also with respect to a definite duration of exposure.

'These difficulties all disappear in monochromatic photometry, which will be discussed later, but in heterochromatic photometry the magnitude of a star can be defined precisely if, and only if. a definite instrument is specified! working under definite conditions. Systems of magnitude obtained with different instruments working under different conditions will be different, the differences depending on colours. It 'is possible, by careful intercomparison between the different systems of visual or photographic magnitudes. to deduce, in an empirical way, corrections whereby each system can be reduced to some standard system. The corrections will depend on the colours of the stars, which are measured by their colour indices; they can be considerable and may amount to a third of a magnitude in extreme cases. If, however, the wave length range used in a given magnitude system is restricted by carefully specified filters, the transformation equations between observers using different telescopes will have quite small correction terms and simple linear relations will be adequate. It is particularly important to control the ultra-violet radiation which enters into the heterochromatic summation which forms, say, a photographic magnitude, or indeed any magnitude system which is centred on the blue-violet part of the spectrum. By excluding wave lengths shorter than 3.800 Ångström (Å) units several troublesome factors which introduce differences between observers of the same stars with different telescopes are eliminated. These factors include the most variable part of the atmospheric absorption, the unequal ultra-violet absorption of the flint glass in different refracting telescopes, the decreasing ultra-violet reflectivity of silver mirrors as they tarnish, and the varying weight given to the wave lengths shorter than 3,650 Å, where the Balmer discontinuity due to hydrogen absorption causes a precipitous drop in the radiation from stars of early type (see SPECTROSCOPY! ASTRONOMICAL: Continuo *Spectra*).

Nevertheless it is still true that magnitude systems, and the colour indices which are the differences between them, are rarely capable of exact repetition on any telescope other than the one on which they were derived. The numerical results obtained on a specified list of standard stars remain the best definition of a particular system.

The following is a formal definition of magnitude difference: For a definite instrument, working under definite conditions, the difference of magnitude between two stars is 2.5 times the logarithm, to base ten, of the ratio by which the beam from the brighter star has to be reduced so as to make the instrumental respbnse to it the same as the response to the beam from the fainter star, it being stipulated that the two beams are transmitted through the optical train in an identical manner. and that the method of light reduction employed is such that the light for each wave length involved is reduced in the same ratio.

It is important to notice that an implication of this definition is that if two precisely similar stars: both emitting the same total amount of light at any wave length, differ in magnitude by Δm, as measured by any instrument, then, provided there is no obscuring matter in interstellar space. the distance of the fainter star will be $10^{0.2\Delta m}$ times the distance of the brighter. To see this we apply in imagination a method of light reduction which is actually used for photometric work in the laboratory We imagine the distance of the nearer star to be increased until the instrumental response to its beam is the same as that for the more distant star; since the stars are supposed to be precisely similar this means that a e have now placed them at the same distance. If there is no obscuring matter in space the light reduction produced by the change of distance mill be the same for all wave lengths, and so will conform to the condition of the definition above; further, the reduction ratio will be determined by the inverse square law. Hence the difference of magnitude Δm between the stars is 2.j times the logarithm of the ratio of the squares of their distances. and by taking antilogarithms the result follows. Since this result is the basis of modern gaiactic research, it is of high importance that our definition of magnitude should be correctly translated into photometric practice.

It is convenient to remark at this point that the imaginary process, used above, of varying the distance of a star, is employed to define an important conception. The absolute magnitude of a star is defined as being the magnitude that the star would have if moved to a standard distance of ro parsecs (see PARSEC) from the earth. The absolute magnitude of a star is an expression of its intrinsic brightness, not its apparent brightness as seen from the earth; the apparent brightness depends on the distance of the star as well as on its intrinsic brightness. It should be noticed that absolute magnitude has been defined with reference to some specific instrument. since the definition involves the conception of magnitude. For each magnitude system there is thus a different absolute magnitude for the same star. In particular, visual and photographic absolute magnitudes of a star may differ considerably.

In visual photometry the fundamental operation is the measurement of the difference of magnitude between two stars. Visual magnitudes are essentially determined by a series of photometric operations involving pairs of stars. these operations leading to a knonledge of the mutual differences between the magnitudes of the stars over the whole sky. In photographic photometry the mutual differences between the magnitudes of all stars in a field small enough to be photographed on one plate are obtained from a single set of photometric operations, and other photometric operations give magnitude differences between different fields. For both visual and photographic work. and for other measurements in nhich a "physical" receiver takes the place of the eye or photographic plate. the result is the same; photometric methods only measure differences of magnitude, and, indeed. the definition given above is restricted to a definition of magnitude difference. For any particular magnitude system it remains to assign a definite magnitude to some star or to the mean of some group of stars. It has been indicated in the previous section how this has been done for visual and photographic systems.

Modern Astronomical Photometry.— We now turn to a brief survey of the work of the three decades after 191j. It was for the most part photographic, this being due to the circumstances that the problems before astronomers required photometric results for faint stars, and the power of the photographic plate of accumulating the effect of continued exposure to light renders it appiicable to extremely faint sources. The photographic plate also has the great advantage of registering a large number of images at a single exposure, and some modern problems demand results for all stars in various sample areas of the sky, each sample area being small enough to be covered by one plate Naturally enough the work that was carried out was indicated by problems of current interest, and it will be as well to review in brief what some of the main problems are, and to indicate as we go what photometric programs have been carried through to meet their needs.

Our knowledge of the dimensions of the galactic universe.. and of the distances and dimensions of the extragalactic nebulae. is based on photometric observations of Cepheid variables. The median absolute magnitude (*i.e.*, the mean of the absolute magnitudes at maximum and minimum light) of a Cepheid is related to its period by what is known as the period-luminosity relation,

and consequently photometric observations of a Cepheid will lead to a knowledge of its distance. For the photometric observations give both the apparent median magnitude and the period; the latter gives the median absolute magnitude. using the period-luminosity relation, and then the distance can be calculated from the apparent and absolute median magnitudes. It is in this way that the distances of the globular clusters, and of the extragalactic nebulae are ultimately determined, the distances of the former leading us to a knowledge of the dimensions of the galactic system, and those of the latter opening up the way to an extended knowledge of the universe. It is thus important to be able to make photometric measures of Cepheids in any part of the sky, and this can be most conveniently done by establishing a number of what are known as magnitude sequences in various parts of the sky. Each such sequence consists of a series of stars in the same field of view, selected so that their magnitudes form a series with, so far as is possible, roughly equal magnitude intervals between consecutive members, the magnitudes themselves having been measured carefully. Any Cepheid can then be investigated photometrically by a series of comparisons between it and the members of a conveniently near sequence. The sequences are also used for the photometry of other variable stars.

In connection with the study of galactic structure we require to know the numbers of stars, in various parts of the sky, down to various magnitude limits. It mould be quite impracticable to survey the whole sky to faint magnitude limits! but valuable information can be got by confining the measures to sample areas, as has been done in the *Harvard-Gröningen Durchmusterung*, which is a photographic catalogue extending down to the 16th magnitude. Another valuable catalogue of the same kind is the *Mount Wilson Catalogue of Selected Areas,* which gives photographic magnitudes for stars in sample areas extending from the north celestial pole to declination $-1j^{\circ}$, and reaches stars of the 18th magnitude.

Another important development lies in the measurements of the integrated magnitudes of extragalactic nebulae. that is, magnitudes. not of individual stars in the nebulae, but of nebulae as a whole. For the remote nebulae it is impracticable to detect individual stars and measure their magnitudes. and so the Cepheid method of determining distances is not directly available; but measures of the integrated magnitudes lead to a statistical knowledge of the distances; since it may be assumed that on the average the measure of the brightness of a nebula is a measure of its distance. the fainter nebulae being the more distant. From the measures of integrated magnitude a statistical relationship has been discovered between magnitude and displacement of spectral lines to the red. and this has been interpreted as a relation between the distance of a nebula and its velocity of recession. This velocity-distance relation is the observational foundation on which the relativity theory of the expanding universe is based, and the importance of nebular photometry in connection with this theory needs no stressing. An essential hypothesis in the theory is the interpretation of the shifts of the spectral lines as Doppler shifts due to velocity of recession. and it has been pointed out that a possible test would consist of the determination of the total numbers of nebulae down to assigned limits of integrated magnitude, and the comparison of the results with numbers calculated on the assumption that the Doppler interpretation is correct. There is, however, another assumption involved in this calculation, namely, that on the whole the nebulae are evenly distributed in space. *(See* LIGHT: *Waves and Interference.)*

From what has been said it will be apparent that a good deal of modern photometric work aims at the obtaining of data for the whole sky, and so the whole of a program cannot be carried out at a single observatory. This means that the various systems of magnitude involved must be reduced to a common standard. Such a reduction is vital to modern work, and to facilitate it considerable attention has been devoted to the derivation of standard magnitudes for a sequence of stars. known as the north polar sequence. which consists of a set of stars down to the 20th magnitude in the neighbourhood of the north celestial pole. These standard magnitudes were adopted as the result of a careful intercomparison of photographic magnitudes measured at Gottingen, Greenwich, Harvard, Mt. Wilson, Potsdam and Yerkes; and they represent a magnitude system known as the international system. The main object of laying down this standard system was to make it available as a reference system with which any particular system of measured magnitudes can be compared, and since. as we have pointed out, the corrections required to reduce one photometric system to another depend on the colours of the stars. the colours of the standard sequence must be known. The older colour indices were derived by differencing photographic and visual magnitudes. but the measurement of visual magnitudes for the fainter members of the sequence is impracticable, and accordingly visual magnitudes have been replaced for this purpose by what are known as photovisual magnitudes. These are obtained by the methods of photographic photometry, but using plates sensitized to green and yellow light in conjuction with a filter removing the violet end of the spectrum. Photovisual magnitudes have been determined at Mt. Wilson for the stars of the north polar sequence down to the 19th magnitude (photographic). They form a system which is naturally not identical with any of the visual magnitude systems. but they approximate to visual magnitudes, and serve for the purpose of giving, by differencing from the standard photographic magnitudes, the colours of the north polar sequence stars.

If in any program of measures obtained at a northern observatory the precaution is taken of including the stars of the north polar sequence, the material is available for reducing the program measures to the standard international system, provided the program includes measures of the colours of the program stars. For equatorial or southern observatories the north polar sequence is not directly available for observation, and an intermediary sequence has to be employed.

In the following sections some details will be given of the technique of astronomical photometry. These sections will be followed by a section dealing with the new and expanding subject of spectrophotometry, to which only a passing reference has so far been made.

Methods of Light Reduction. — From what has been said above it is obvious that a vital operation in any kind of practical celestial photometry is that of reducing a beam of light from a star and measuring the ratio in which it has been reduced, an essential condition being that the reduction ratio should be independent of wave length. The following are the methods most favoured.

Variable Aperture Methods.—The original beam of light from a star is perfectly uniform in cross section, hence, if the area of the beam utilized is varied. the light will be varied in the same ratio. For this purpose diaphragms. circular- or sector-shaped. or gratings of wires or tapes equally spaced may be used. If the uniform cross section of the original beam is subsequently disturbed, an appropriate correction must be applied—thus care must be exercised in employing these methods when a refractor is used since the lens may absorb differently over different parts of its area. The weak point about variable aperture methods is that the reduced image has a different diffraction pattern from the original.

Polarizing prism arrangements are used in some well-known photometers, including the Zoellner photometer and Pickering's Meridian photometer; but the prisms must be carefully selected by independent tests.

Filter and Wedge Methods.—A neutral-tinted glass may be cut in the form of a plate, or made into a wedge with a wedge of clear glass cemented to it so that the combination is achromatic. The fraction of the light absorbed by the plate or any part of the wedge may be found by laboratory methods, the most accurate being photoelectric methods using a rotating sector. The direct use at the telescope of the rotating sector does not appear to have found favour in celestial photometry. In applying it to photographic photometry there would be the difficulty that Talbot's law is not obeyed unless the sector is run at very high speeds; for speeds of the order of 50,000 r.p.m. for a sector disk with one slot it appears to be obeyed to an approximation of the order

of 1%. *(See* VISION or SIGHT: *Response to Variable and Intermittent Illumination.)* Wire gauze screens are a special case of variable aperture methods, but the absorption of the screen is not readily calculated and must be measured and tested for uniformity in the laboratory. Wire gratings, in addition to their use in variable aperture methods, give diffracted images, and the ratio of the light falling into the diffracted image to that falling into the main image may be computed from a knowledge of the dimensions of the wire and spacing, or may be measured by a separate method. The grating method has been used in photographic photometry and possesses the advantage that images of a known magnitude difference are obtained from the same exposure.

Visual **Photometers.**—We have seen that the essential principle of every photometric measurement is that the light from the brighter oi two stars should be reduced till the response of the receiving apparatus to it is the same as the response to the beam from the fainter star, and that the two beams should be transmitted through the apparatus in an identical manner. This last condition is essential, since, if it were not satisfied, the absorptions of the two beams by the apparatus would not necessarily be the same. But in visual photometry, in which the human eye is involved, the operation becomes one of reducing the intensity of the brighter of two images until the eye judges that it is of the same brightness as the fainter; and this means that the two images must be viewed simultaneously. It is clearly impossible to do this for two stars in different parts of the sky, and at the same time to adhere to the condition that the two beams must be transmitted in an identical manner through the same apparatus. Accordingly each of the two star images is matched successively with an intermediate image; the beams from the two stars are transmitted identically through the same optical train, and the light from the intermediate source can be transmitted through a different optical train. The intermediate source of light may be an artificial star, or it may be a real star in the sky, and visual stellar photometers may be divided into two classes according to which of these alternatives is employed. Examples of the first type are the Zoellner photometer and Pickering's wedge photometer, the latter representing a type of instrument used at the Lick, Yerkes and Leander McCormick observatories for measuring the magnitudes of comparison stars against which the magnitudes of variables are estimated. The Pickering meridian photometer with which the Harvard photometry was performed is an example of instruments using a real star as intermediary, as is also Danjon's "cat's eye" photometer. For details of these and other visual stellar photometers the paper by W. Hassenstein (see *Bibliography)* should be consulted. (W. M. H. **G.** ; E. A. BR.; A. E. W.)

Photographic Photometry.——In photographic photometry the distinctive part of the receiving apparatus is the photographic plate used in conjunction with some definite operation of measurement applied to the developed images. Both the size and density of the image vary with magnitude, the developed image of a star being denser and larger the brighter the star. The operation which gauges the total effect may consist of measuring the size of the image, or of measuring the absorbing power of the image when it intercepts a light beam, or of a combination of the two in the so-called iris photometer. In the latter, the size of the aperture centred on the image, which will permit a given constant amount of light to come through and around the image, is used as a measure of the total effect. These measurements. whatever the method, arrange the stars in a sequence of increasing brightness, but with the true brightness ratio between any unequal pair still unknown. Just as in visual photometry. an intensity reducer of known reduction ratio must be introduced to equalize such pairs of stars, and thus to build up a scale of true relative brightness.

Double exposures are the usual method of introducing the known intensity ratio. The first exposure is taken in the normal yay. Then after a slight shift to avoid superposition, the same field is photographed a second time with the known reduction factor imposed. The reduction may be by means of a gauze screen, or by a calibrated neutral glass filter, or by diaphragming the telescope to make a smaller aperture. As a practical matter only one selected reduction ratio can be applied to all the stars on one plate. The intensity ratio of a nearly equalized pair can be found by interpolation on the numerical scale which gauges the blackness or diameter of all the images. Then by an overlapping process involving many such pairs a graphical relation between photographic effect and true relative brightness or magnitude difference may be built up.

Once a scale of magnitudes has been established for the stars in a standard field. stars in any other area of the sky may be compared with them by exposing the same plate successively to each field, both exposures being of equal length. In less accurate survey work. where an accuracy of o.1 magnitude is adequate, magnitudes are read off by visual estimation of steps between images of calibrated standard stars.

In addition to the standard photographic and photovisual magnitudes which are the basis of the international system, other magnitude systems based on photography are sometimes used. The magnitudes obtained with a panchromatic plate and a red filter are called photored magnitudes. Infra-red-sensitive photographic emulsions and a deep red filter have been used for an effective wave length still farther removed from the normal photographic range. The latter combination strongly favours the coolest stars with large positive colour index. Red and infra-red photographs are better able to show distant stars in directions where there is heavy obscuration because they use light of a wave length which suffers much less attenuation in interstellar dust clouds.

Two defects of photographic photometry must be mentioned. The total range of magnitudes that may be successfully measured on one plate is limited, and the reduction ratio used in the standardization of the intensity must be small enough so that there will be a good number of overlapping steps in that range. In the successive application of this relatively small reduction factor to cover the enormous range between stars which appear bright to the naked eye and the faintest star images registered on plates from the great reflecting telescopes, there is danger of accumulation of error. This accumulation can arise from multiplication of only a small error in the original evaluation, or from the random errors in its repeated use in equalizing ever fainter star images. For this reason the photoelectric method, treated in a later paragraph, has been adopted increasingly as the one to be relied upon in establishing standard magnitudes.

A second defect of photographic photometry is the difficulty, especially with large telescopes, of transferring a magnitude scale from a standard area to a new field by the method of superposition of equal exposures. The procedure assumes identical image quality in the two cases, which, because of unavoidable small differences in guiding, seeing (atmospheric turbulence) and focus is rarely achieved. The difficulty may be circumvented by spreading out the image into a small uniformly blackened area. On some telescopes, extrafocal images may be used for this purpose. The *Schraffierkasette* spreads in-focus images over a small square by giving an oscillatory motion to the plateholder. The latter method has been valuable for comparing the integrated light of diffuse sources such as extragalactic nebulae with stars of known magnitude. The faintest images, however, are lost in the spreading out process, and the practical limit of photometry is at least two magnitudes brighter than the in-focus limit of the telescope.

The modern technique to avoid difficulty in transfer of standards involves establishing a few photoelectric standards in the field in question. Then interpolation by the photographic method can give magnitudes of hundreds of stars on a single plate with an accuracy only slightly below what would be obtained by laborious photoelectric measurement of each in succession. Prior to improvements in photoelectric methods made between 194j and 19j5, however, this was not possible. Photographic magnitudes were the almost universal standard of photometric comparison for the 30 years between 191j and 1945 because only by photography could the measurements be extended to the extremely faint objects at the limit of large reflecting telescopes. And it was just in the range near the limit that some of the important advances were made. The knowledge of the distances and dimensions of extragalactic nebulae that followed E. P. Hubble's identification of

Cepheid variables in the nearer external systems is an example of the advances that were made entirely within the domain of photographic photometry.

Physical Photometers. — The auxiliary instrument, often called a microphotometer, which evaluates the absorbing power of a star image on a photograph gives an impersonal numerical result in the form of a scale reading. Photographic photometry of stars is thus "objective" in that the human eye is not called upon to make a judgment of equality, as it is in visual photometry. The distinguishing characteristic of physical photometers is the use of a detector of radiation which converts the starlight directly into an impersonal "pointer reading." In one form the absorbed radiation is converted into heat. A classic illustration of this type of instrument is afforded by Sir William Herschel's exploration of the solar spectrum with a blackened thermometer bulb — the motion of the mercury thread constituting the pointer reading. In a second type the radiation releases electric charges — internally as in a selenium or lead sulphide film to produce increased electrical conductivity, or externally as from the cathode of a photoelectric cell. The latter phenomenon is the basis of astronomical photoelectric photometry, a technique which had assumed so important a place by the 1950s that extended treatment is reserved for a later section. In both types of physical photometer it is usually true that the pointer reading is directly proportional to the quantity of incident radiation. The calibration or equalization procedures that form so large a part of photographic photometry are thus eliminated. This simplification is a contributing factor to the higher precision that is regularly obtained with physical photometers.

The photometers which depend on heating effect are in general nonselective; they measure the incident radiant energy irrespective of its wave length or spectral distribution. C. G. Abbot's water-flow pyrheliometer for measuring total solar radiation is an example of such an instrument. It was based on the simple and fundamental principle of registering the temperature rise in a stream of water flowing around the absorption vessel. S. P. Langley's bolometer, developed in 1880 for measuring the energy in the various parts of the solar spectrum, was much more sensitive. It depended on the increase in electrical resistance of a thin blackened platinum strip warmed by the absorbed radiation.

Photometry of stars with a heat-sensitive detector has been done principally with the radiation thermocouple. This instrument consists of a tiny disk of blackened metal foil attached to the junction of two dissimilar metals; bismuth and antimony are a favourable combination. The warming of the junction by the heat of the star absorbed on the metal foil generates a thermoelectric voltage which is read on a sensitive galvanometer. Sir William Huggins obtained a barely measurable indication from several bright stars with such an arrangement in 1868. Improvements in the construction of the instrument led to considerably increased sensitivity, and in 1914 W. W. Coblentz was able to measure more than 100 stars with a 36-in. reflector. The work was extended by E. Petit and S. B. Nicholson with the 100-in. reflector of the Mt. Wilson observatory (Pasadena, Calif.). The magnitude thus obtained mas called a radiometric magnitude. The scale was made to agree with the visual scale for Ao stars, as had previously been done for the photographic magnitude scale. One value of this magnitude scale is its close approach to the hypothetical concept of bolometric magnitude, defined as a measure of the total radiation from a star, over the entire range of its spectrum, as received at the top of the earth's atmosphere. This concept, introduced by A. S. Eddington, is useful in studies of the internal constitution of stars.

Radiometric magnitudes of stars are heavily influenced by the radiation coming in the unseen infra-red portion of the spectrum. and the cool red stars show the greatest difference (called the heat index) from visual magnitudes. Long-period variables, such as Mira (Omicron Ceti), have a heat index as high as 8 magnitudes at minimum and are among the radiometrically bright stars at all phases of their cycle. But for most stellar types. measurements with the 100-in. telescope were limited to objects visible to the naked eye.

The thermocouple technique thus fails by several orders of magnitude of serving as the basis of a generally useful magnitude scale. It is, however, the only technique that can detect the infrared thermal radiation from relatively cool bodies such as the moon and the planets. Direct indication of the surface temperature of these bodies was first obtained from thermocouple measurements made by Coblentz at Lowell observatory (Flagstaff, Ariz.) in 1922.

PHOTOELECTRIC PHOTOMETRY

In principle photoelectric photometry consists of measuring the electrical current flowing in the external circuit of a photoelectric cell when the various quantities of luminous flux to be compared are allowed to fall successively on the cathode. (See PHOTOMETRY; PHOTOELECTRICITY.) The extension of this principle to astronomical sources requires electrical instruments capable of measuring very small currents, since the amount of light available, even with a large telescope, is so much smaller than that commonly encountered in illuminating engineering. The low intensity makes cathode fatigue unimportant, and strict proportionality between quantity of light and current holds over an extremely wide range of intensities. Modern developments in photoelectric technique have improved the sensitivity to the point where the whole range of astronomical intensities may be covered. Any object that can be photographed can, with sufficient pains. be measured photoelectrically. The photoelectric cathode is, however. a selective detector of radiation; like the photographic plate or the human eye, it responds unequally to different wave lengths. By the choice of cathode material and the addition of suitable filters. the range of wave lengths used in photometry can be varied over wide limits.

Historical Development. — The first practical photoelectric cells were made by J. Elster and H. Geitel in 1890, only two years after W. Hallwachs established the existence of the photoelectric effect. The first astronomical use of the photoelectric cell was the measurement of ultra-violet light from the sun by Elster and Geitel in 1892. The step from this observation to the measurement of starlight was a considerable one, and did not come until 1913. P. Guthnick in Berlin, H. Rosenberg in Tubingen and J. Kunz and J Stebbins at the University of Illinois (Crbana) made successful observations in that year, all independently and all with similar apparatus. The photoelectric cells were of the Elster and Geitel type, aith hydrogen-sensitized potassium cathodes. An electrometer was used to measure the current, since even the bright stars produced an effect too small for a galvanometer. The practical working limit for the Illinois apparatus was a current of 10^{-14} amp., corresponding to seventh magnitude with a 12-in. telescope. Great care was necessary to avoid spurious effects from leakage currents over the surface of the photoelectric cell, or over other insulators in the system.

The improvements in sensitivity that came in the succeeding decades consisted partly of refinements in the method of measuring the current from the cathode, and partly in improvements in the yield from the cathode itself. Sinclair Smith showed in 1932 that a stable electrometer at the fixed Coudé focus of a reflecting telescope (*q.v.*) could give considerably higher sensitivity than the type customarily used at the end of a moving telescope. The development of electronic tubes with extremely high input resistance (the so-called electrometer tubes) enabled A. E. Whitford to develop an amplifier that could be moved about at the end of a telescope; this type of current measuring apparatus was carried to its ultimate limit by G. E Kron. In order to avoid fluctuations caused by cosmic ray ionization, it is advantageous to put the amplifier tube and photocell in an evacuated container. In this type of amplification, it is necessary to use a high resistance in series with the photocell in order to obtain a voltage to apply to the input grid of the amplifier tube. The "resistance noise" generated by this high resistance adds to the unavoidable "shot noise" fluctuations in the cathode current caused by the random spacing of the photoelectrons released by the incident light. When the over-all accuracy is determined by cathode shot noise alone, then the equipment is doing as well as it can with the particular cathode being used.

With the introduction of secondary emission multiplication as an amplifying principle in the years 1936–39, the offending load resistor could be removed and a close approach to the ultimate shot-noise limit became possible. In the practical form of the multiplier phototube there are 9 to 12 multiplying surfaces in cascade. Each photoelectron impinging on the first multiplying surface releases three to four secondary electrons, which are multiplied in turn at the second multiplying surface and so on. A total amplification of the cathode current by a factor of a million or more is common. a value more than adequate to insure that any further amplification by traditional vacuum tubes will not add to the over-all noise level. In the decade after 1946, the multiplier phototube became the almost universal tool in astronomical photoelectric photometry.

The potassium-hydride cathode used in the first successful photoelectric measurements of stars in 1913 remained the principal type in use until about 1940. It is sensitive to a relatively narrow band of wave lengths in the blue-violet. The much greater spectral range of the cesium oxide cathode. with its peak response in the near infra-red, was first used for astronomical photometry by John S. Hall at the Yale observatory. The thermionic emission from this cathode at room temperature is larger than the photoemission produced by most stars, and had to be reduced by refrigeration with solid carbon dioxide. A major improvement in cathode efficiency was realized from the cesium-antimony surface developed by P. Görlich in 1938. It is sensitive from the ultraviolet through the yellow with a maximum response in the blue-violet. One electron is emitted for something like eight incident quanta. a ratio so markedly superior to that for other cathode surfaces that its use has become standard.

Modern Techniques of Observation. — The photoelectric photometer at the end of a telescope may be considered to begin with a small diaphragm in the focal plane. Csually a series of diaphragms of graduated diameters is provided, so that nebulae as well as stars may be measured. and so that the smallest practical diaphragm may be chosen in cases where it is necessary to exclude the light of the sky. or stars adjacent to the one being measured. There is provision for sliding filter glasses into the beam, often in front of the diaphragm. A total reflecting prism slides in just back of the diaphragm to provide visual inspection of what is in the diaphragm area. If faint stars are to be measured, the multiplier phototube is mounted in a thermally insulated box with provision for surrounding it with solid carbon dioxide for refrigeration. This is necessary because all sensitive cathodes have a thermionic emission level higher than the response caused by a faint star. After the millionfold amplification on the secondary emission surfaces. the output current will generally be in the range 10^{-6} to 10^{-11} amp. Further amplification will be needed. Usually this is arranged so that the final output is recorded on a moving paper chart. Assuming that 1 milliampere will be required to operate the recording meter. the over-all amplification may be as high as 10^{14}. The wide range of currents that must be measured is covered by gain controls in the amplifier. These ratios can be made to be simply the ratio of certain fixed resistances.

With bright stars, the light of the night sky is unimportant, and a moderately large diaphragm can be used. The recording meter operates similar to a laboratory voltmeter and little time need be spent on each star. On telescopes smaller than 24 in.. scintillation of the star may be the main source of noise. This effect averages out on telescopes of larger aperture. As fainter stars are attempted, however, more care must be exercised. The smallest diaphragm that will safely contain the atmospheric tremor disk of the star is chosen, in order to reduce the contribution from the light of the night sky. An auxiliary guiding eyepiece working on a second star around the edge of the field is advisable in order to insure that the star being measured stays on centre. The faintest objects cannot be seen with the eye, and must be centred in the diaphragm by an offset procedure. using a co-ordinate system based on a photograph of the region made nith the same telescope. The offset proceeds from a star near the object in question which is sufficiently bright to be centred in the diaphragm by visual means.

On the faintest objects the light of the night sky becomes the major fraction of the light coming through the diaphragm, and the measurement consists of determining as accurately as possible the relatively small difference between the diaphragm area containing the object in question and an equivalent blank sky area adjacent to it. The cathode shot noise, generated mainly by the unavoidable light of the night sky, may have an amplitude larger than the star signal. Considerable averaging is necessary to obtain a reliable measurement, and a program of alternate exposures to sky and star lasting an hour or more may be needed to build up sufficient accuracy. In this range, integration of the charge coming from the multiplier offers some advantage; the longer the exposure time the greater the accumulated difference between sky and sky plus star. Electronic schemes involving the storing of the charge on a condenser have been developed by H. L. Johnson and others. An alternative approach uses counting methods to perform the integration. Each photoelectron released at the cathode becomes a burst of a million electrons at the output of the multiplier phototube, a signal easily registered on electronic counting devices. This technique was used by W. A. Baum to push the photoelectric technique to the very limits of the faintest photographic images detectable with the zoo-in. telescope of the Palomar observatory (Calif.). The limit reached was photographic magnitude 23.8.

Special Applications of Photoelectric Methods. — The higher photometric accuracy obtainable by photoelectric methods was applied very early to observations of the light curves of eclipsing binaries. A single observation gave an accuracy of the order of 0.01 magnitude, as opposed to .05 to .08 magnitude by visual photometry, and an intermediate accuracy by photographic methods. By combining observations extending over many cycles, Kron was able to achieve a final curve with a probable error of only 0.001 magnitude, corresponding to a relative error of 0.1%. With this increased precision the full power of the methods that had been norked out for deriving the physical properties of stars from analysis of the light curve and the radial velocity curve could be realized. Shallow eclipses that had previously been missed were found at their predicted times. Not only was the list of stars with well-determined diameters and densities considerably lengthened, but secondary features such as the reduced brightness of a star at the outer edge (darkening at the limb) could be derived with real confidence. The latter effect. directly observable only on the sun, gives information on the atmospheric structure of a star.

The simplicity of colour measurements by the photoelectric method led to its early use in that field. The ratio of response through two chosen filter glasses gives a colour index directly, without establishment of two separate magnitude scales. The method is thus suited to colour surreys of widely scattered objects. From such a survey of B-stars. Stebbins and his collaborators found that almost all of the more distant ones in the plane of the Milky Way had been reddened by interstellar dust clouds. The normal or intrinsic colours, as tested on the nearer stars, had the expected correlation with spectral type. The difference between observed colour and normal colour, called the colour excess, is a measure of the reddening and also of total absorption of light suffered as a result of scattering by interstellar dust clouds.

Distances calculated from the spectroscopically determined luminosity of giant or supergiant stars, or from the period-luminosity relation of Cepheids, had previously assumed that space was transparent; for reddened stars the inferred distances were therefore too great. Correction for absorption losses by means of the measured colour excess has become one of the essential steps in establishing distances by the photometric method. and photoelectric colour measurements are usually used in determining the excess.

Photoelectric methods are well adapted to measurement of small differences because the linear response lends itself so directly to simple subtraction of a large background. The detection of very faint stars against the light of the night sky has already been mentioned. The photometry of extragalactic nebulae, where the

tenuous outer portions have a surface brightness only a few per cent of that of the sky. is a similar case. Another example is the demonstration by Hall and by W. **A.** Hiltner that starlight which has passed through interstellar clouds is slightly polarized. This observation has been interpreted as evidence for a weak magnetic field in the Milky Way which aligns interstellar dust particles. In a differential measurement between two planes of polarization on the same star, Hiltner was able to maintain an internal probable error of only 0.016%, or one part in 6,000.

Photoelectric observations have not produced any general catalogues of stellar magnitudes comparable with the *Durchmusterungen* of the visual era, or the *Mt. Wilson Catalogue of Photographic Magnitudes in Selected Areas.* The more limited programs for establishing standard photoelectric magnitudes have in general used yellow and blue filters which give a close approximation to the International system of photographic and photovisual magnitudes. At the Cape of Good Hope observatory a systematic program to cover 4,000 southern stars brighter than magnitude 6.5 was partially complete by 1957. Other published lists, such as O. J. Eggen's and Johnson and W. W. Morgan's, were selected to include representative stars of the various stellar types, nearly all brighter than 11th magnitude.

Special studies of a number of open clusters (such as the Pleiades) provide standard magnitudes down to the 15th magnitude. The purpose of the latter studies was to establish data for an accurate colour-magnitude diagram of each cluster. Superposition of such diagrams for different clusters shows population differences which give important clues to the age of the cluster and the evolution of the stars within it..

Beyond the 1 jth magnitude, photoelectric magnitude work has concentrated on recalibration of stars in certain selected areas, particularly those most used in establishing the magnitudes of Cepheid variables in external galaxies. The initial study by Stebbins, Whitford and Johnson showed the first serious systematic difference in scale between the photographic and the photoelectric method. The photographic results had made the stars too bright by a third of a magnitude at 18th magnitude, an error in the sense that leads to an underestimate of the true distance of the galaxies. Completion of the photoelectric calibration of magnitude standards to the limit of the 200-in. telescope. as undertaken by Baum, is an essential step in establishing a correct cosmic distance scale. In order to be satisfactory measuring rods for the known universe, stellar magnitudes must cover an enormous range of intensities. The ratio between the brightest and faintest stars is 10^{10}; if the sun is included the ratio approaches 10^{20}. A single photoelectric photometer can cover a factor of 10^4 to 10^5 with good precision. so that not many overlaps using different optical systems are necessary. The photoelectric method has therefore been considered the one to be relied upon in establishing magnitude standards.

SPECTROPHOTOMETRY

Spectrophotometry of stars seeks to derive information about their physical properties by studying the distribution of energy through the range of the observable spectrum. A colour index is the simplest possible measurement of this type; the finest detail would be represented by high-dispersion analysis of the star's spectrum, including determination of the intensity profile of each spectrum line. Between these extremes, relative intensity measurements on short segments of the continuous spectrum of stars may be made with a resolving power ranging from 1 Å to a few hundred A. When the band is not more than a few Å wide, the measured intensity ratios can be said to represent a system of monochromatic magnitudes. Such a system has not been used to any extent in comparing the brightness of stars. even though it would have an advantage in elimination of the previously mentioned instrumental differences between observers which make a unique definition of heterochromatic magnitudes so difficult. Too small a fraction of the total light is contained in the narrow portion of the spectrum specified for the monochromatic magnitude, and the measurement is restricted to the brighter stars; heterochromatic magnitudes have to be used to reach the faint stars so important in cosmological problems. But for the comparison of the spectral distribution of radiation in different stars, the brighter stars furnish examples of most recognized types, and the specification of narrow bands gives the same advantage of uniqueness in defining the differences of magnitude that describe the distribution. The magnitude differences are in effect a series of colour indices, without the ambiguities that inevitably accompany heterochromatic photometry.

Photographic methods have been used for most of the spectrophotometric studies of stars. The spectrum is formed by placing a prism in front of a small telescope. A grating over the objective is a common method for introducing the intensity steps needed for calibration of the photographic intensities. W. M. H. Greaves, C. R. Davidson and E. G. Martin began the first series of measurements by this method at the Greenwich observatory in 1926. H. Kienle at Gottingen, R. C. Williams at the University of Michigan (Ann Arbor), and D. Barbier and D. Chalonge of Paris made important contributions. The French workers used the clear air of a high altitude station on the Jungfraujoch in the Alps to extend their measures farther into the ultra-violet.

Spectrophotometry by photoelectric methods labours under the handicap that only one portion of the spectrum can be measured at a time. On account of the long observing periods that would be necessary, high resolving power is not ordinarily attempted. When wide bands must be used in order to reach faint objects, a series of filters is a simple expedient. A single photoelectric cathode can cover the spectrum from 3,400 Å to 10,000 Å. Stebbins and Whitford used six filter bands distributed over this range. Because of the lines and bands of the star's spectrum necessarily included, results with filters are not strictly comparable with monochromatic magnitudes read at selected points in the continuous spectrum. Hall introduced the technique of scanning the spectrum with a photoelectric cell behind the exit slit. In this early work the exit slit was 400 Å wide. A. D. Code was able to reduce it to 10 Å, narrow enough to show the principal spectrum features and to give true monochromatic magnitudes.

The temperatures of the stars can be found much more precisely from monochromatic magnitudes than from colour indices. It is necessary, however, to establish an absolute standard for the relative monochromatic comparisons between stars. This can be done by comparing the stars with a terrestrial source of known spectral energy distribution, such as a carefully calibrated tungsten filament lamp. Such a source serves as an artificial star at a suitable distance from the telescope. and is measured in the same way as are the actual stars. The stellar temperatures derived in this way are called colour temperatures. For the range of the spectrum between 3,700 Å and 4,500 Å, Barbier and Chalonge found that an Ao star had a colour temperature of 16,500° K.

Spectrophotometric comparisons of reddened and unreddened stars of the same type have shown how the interstellar absorption varies with wave length. Since most of the highly reddened objects thus far identified are O- and B-stars. whose spectra are not complicated by strong spectrai lines and bands. photoelectric photometry with filters is well adapted to the study. The wide range of the cesium oxide cathode is an advantage. The law of variation of absorption with wave length appears to be the same for all parts of the interstellar medium. Once the law is known. a measured colour excess. which is merely the amount that the absorption in the shorter wave length band of a colour system exceeds that at the longer, can be multiplied by an appropriate factor to give the total absorption at any desired wave length for any specified magnitude system. Then the observed magnitude may be corrected to restore the star to its unobscured brightness, as is required in proper calculation of its photometric distance.

Spectrophotometric analysis of the light of galaxies has also been a task for photoelectric filter photometry. The diffuse nature of galaxies makes it impractical to form a spectrum of a whole system with spectroscopic equipment. As would be expected from a composite source made up of stars with a variety of spectral types. the spectral distribution is not like that of any single star. But since most of the light of external galaxies comes from stars that can never be resolved and studied individually, the spectral

distribution curve contains one of the slender clues to the nature of the stellar population in these systems.

PHOTON: see COMPTON EFFECT; NUCLEUS; PHYSICS; SPECTROSCOPY.

PHOTOPERIODISM, the responses of organisms to certain durations of light or darkness. Under natural conditions the periods are day and night. which vary with season and latitude. Temperature. nutrition and other environmental factors interact with photoperiod and modify the response. Closely related varieties of a species may respond differently to identical photoperiodic conditions because of inherited differences. Photoperiodism was discovered first in plants and soon afterward in animals, and they are here considered in that order.

Plants.—W. A:. Garner and H. A. Allard. of the U.S. department of agriculture. first reported in 1920 that flowering of some kinds of plants was controlled by the daily duration of light. They suggested the term "photoperiodism" to designate "the response of organisms to the relative length of day and night." Garner and Allard recognized three types of plants on the basis of day lengths Favourable to flonering: short-day plants, which fail to flower when days exceed a certain duration called the critical day length; long-day ones, u-hich fail to flower unless the days exceed a critical day length; and indeterminate ones. which flower about equally well regardless of day length. Critical day lengths for both long- and short-day plants differ widely from species to species and even among varieties of a single species.

Responses of plants other than flowering are influenced by pliotoperiod. Among these are the formation of bulbs, tubers, thickened roots and runners, colouration of stems and leaves, abscission of leaves and development of certain anatomical features.

The photoperiod response of plants depends on duration of darkness. not light. a fact not understood at the time the phenomenon was named. Thus, a short-day plant flowers when nights are long and a long-day one when nights are short or absent. A brief period of artificial light in the middle of a long dark period divides it into two short ones and thus promotes the flowering of long-day plants and inhibits that of short-day ones.

Growers of chrysanthemums now produce these highly seasonal flowers throughout the year by proper control of night length and other cultural conditions for adapted varieties. Artificial light keeps the plants from blooming until they attain sufficient size or until the desired date is reached. The light is then discontinued or in some times of the year the plants are covered with black cloth during part of the day. thereby increasing the night length adequately to bring them into bloom. This practice is in extensive use in greenhouse production of chrysanthemums in the United States and over several hundred acres of plants grown out-of-doors in Florida and California.

Artificial control of day length is similarly used to regulate the time of dowering of orchids. China asters, feverfew, and tuberous-rooted begonias. Experiments show that the growth of some kinds of woody nursery plants can be maintained in the greenhouse during the winter by the use of artificial light. The uses of artificial light to improve production of various kinds of plants are constantly increasing.

The photoperiodic reaction occurs in the leaf, but the response generally occurs elsewhere. A product generated in the leaves evidently moves to the growing points, where it controls flower-bud formation. This product is a flower-promoting one produced by dark periods favourable to flowering. not a flower-inhibiting one produced by unfavourable dark periods. Some workers believed this flower-inducing material to be a special flower-forming hormone, "florigen," but such a substance had not been isolated from a plant and identified by the late 1950s. Knowledge of the initial photochemical step in photoperiodism was obtained by studies of the way in which light acts. Red light having a spectral range of about 5,500 to 7,000 Å (Angstrom units) and an absorption maximum near 6,500 Å is more effective than any other kind for preventing flowering of short-day plants and promoting flowering of long-day ones. A second but far less effective region of absorption occurs in the blue. Flowering is controlled in both kinds of plants by light of the same wave length ranges; indicating that the basic photochemical reactions are identical. although in one type they suppress and in the other promote flowering.

Response of plants to light of certain wave lengths. but not of others. means that plant cells contain a pigment or pigments that absorb these particular wave lengths. The red-absorbing pigment involved in photoperiodism and related plant responses had not been isolated and identified by the late 19jos; since it absorbs red radiation its colour cannot be red; probably it is blue.

The inhibition of flowering of some short-day plants by red light can be prevented by red light of greater wave length: *i.e.,* far red of about 7,350 Å. A similar reversal of the action of red by far-red radiation occurs in the germination of light-sensitive seeds and in the control of growth of the various parts of dark-grown seedlings. Reversal of the red action by far red indicates the presence of another pigment having a far-red absorption. These photochemical actions of red and far red are repeatedly reversible. the kind of response depending on the kind of radiation given last. Reversibility is believed to result from photochemical interconversion of the two pigments, one having an absorption near 6.500 Å and the other near 7,350 Å. The chemical identities of the pigments and the kinds of reactions in which they participate were not known in the early 1960s, but the reversibility of responses such as flowering, seed germination, seedling growth and probably others by radiation of 6,500 and 7,350 Å showed that these seemingly unrelated phenomena were controlled by the same initial photochemical reactions. Photoperiodism is thus but one manifestation of a photochemical control mechanism of wide, perhaps universal occurrence among higher plants.

Animals. — The most conspicuous activities of animals which are closely correlated with certain seasons of the year, and hence with changes in day length, are bird migration, reproduction and changes in pelage and plumage. Each of these occurs with marked regularity at a particular time each year. By retaining animals in captivity and subjecting them to artificial increases and decreases in day length. bird migration. reproduction and other activities have been induced out of season. It has been concluded, therefore, that in nature the changing daily periods of light and darkness determine to a great extent when many seasonal activities occur. Before the northward migration to the breeding grounds in spring. birds undergo a marked change in physiological state. This is shown by increased activity of the reproductive organs and deposition of large amounts of fat. When these same changes were induced experimentally in winter by exposing captive birds to artificial increases in day length, the birds migrated northward in winter when released. By employing different schedules of day

length at various seasons of the year. it has been demonstrated that the rate of change in physiological state depends on the daily amount of illumination. As little as nine hours of light per day is stimulating. The response is rapid under long days and slow under short days. Gradual increase in amount of light per day is not necessary. Constant day lengths are effective. as are decreasing day lengths, provided that the daily amount of light is stimulating. Therefore, migratory birds which winter on or near the equator. where the day lengths are constant, or in the southern hemisphere, where the day lengths decrease after Dec. 21, could have the onset of their spring migration regulated by day length. Prerequisite to the response to light which occurs in winter and spring is exposure to short days or long nights in autumn. Day lengths in autumn wind the "clock" within the bird. so to speak, while the day lengths of winter and spring make it run and determine how fast it runs.

In most birds. mammals and other vertebrates breeding is seasonal. By experimental manipulation of day length, reproductive activity has been induced out of season. Where the species breed normally beginning in autumn (*e.g.*, brook trout. deer, sheep and goats), decreasing or short days following long days are effective. For species which breed in spring (*e.g.*, starling. junco. ferret and mink). increasing or long days following short days are effective. Change in breeding season occurs in some birds and mammals when they are transported from the southern to the northern hemisphere, or from the region of the equator to temperate latitudes. Although day lengths are constant on the equator and change little in the tropics, there is some evidence that day length regulates the breeding and plumage cycles of tropical birds. Experimental modification of the breeding cycle of invertebrate animals (*e.g.*, snails. crustaceans and insects) by means of day length has also been demonstrated.

Attempts to discover how day length affects the breeding cycle have shown that the light stimulates the eye or part of the brain near the eye. The stimulus produced by the light eventually reaches the pituitary gland (the master endocrine gland located at the base of the brain). which secretes the hormones that. among other functions, control the growth of the reproductive organs. There is good evidence that the length of the dark period and the ratio of light to darkness are important factors in determining the reproductive response. The effects of day length on the migratory response (mentioned above) also apply to the reproductive response in some birds. Response to light can he modified by temperature, nutrition and inherent internal iactors. A few species of birds and mammals studied did not show any influence of light on the reproductive cycle.

The most conspicuous seasonal change in pelage and plumage occurs in those mammals and birds which are white in autumn and winter and brown in spring and summer (*e.g.*, varying hare, ermine and ptarmigan). By experimental manipulation of light, either of these colours was produced out of season. Molt into white plumage or pelage was induced by short days. Temperature was not a factor. Day length also influences the time of annual molt in birds, growth of wool in sheep and production of winter pelage in mink and ferret.

A number of less obvious seasonal activities also occur in response to day lengths. In the potato aphid, the production of winged individuals (as opposed to wingless individuals) normally occurs in autumn and is dependent on a period of darkness of 12 to 14 hours. In the strawberry root louse, occurrence of sexually reproducing individuals, which occurs normally in autumn, was produced out of season by shortening the days.

Practical application of knowledge of photoperiodism is feasible and common in poultry management, ior day length affects laying, sperm production and body weight of the fowl.

PHOTOSPHERE of the sun, the layer from which most of the sun's light is emitted which reaches us directly; *i.e.,* without absorption and re-emission. The sun is a globe of gas with no sharply defined surface, and we look down into it through absorbing layers of very low density; the photosphere may be regarded as the layer which is the limit to which we can see into the interior. (See SUN.)

PHOTOSYNTHESIS. Photosynthesis is the process by which green plants harness the energy of sunlight absorbed by chlorophyll to build carbohydrates from carbon dioxide and water. This reaction is often referred to as assirnilation or fixation of carbon.

Fundamental Role of Photosynthesis. — For their subsistence. growth and multiplication all living beings, plants and animals alike, need organic food. The organic foodstuffs are 'utilized by living cells as building stones and as sources of energy. The energy stored in the foodstuffs is released mainly by respiration, the reaction in which organic matter combines with the oxygen of the air yielding carbon dioxide and water as final products. The rate at which living beings die and consume each other is so high that they would all disappear from the earth within the lifetime of a human generation if there were not a process providing for the reformation of organic matter. While there are many ways by which organic substances are decomposed in respiration and similar reactions, there is only one reaction. photosynthesis. which for millions of years has counterbalanced death and decomposition. In the course of photosynthesis the hydrogen of water is used to transform carbon dioxide into carbohydrate; simultaneously the oxygen of the water is liberated as free oxygen gas. Among the many pigments appearing in plants only chlorophyll and. to a lesser extent. carotenoids and phycobilins are known to convert sunlight into chemical energy (*see* below). Chlorophyll is the green dye whose colour is so characteristic of meadows and forests. The green plants may transform the carbohydrates produced by photosynthesis into fats. proteins and many other substances. Thus. directly or indirectly, all the organic food of plants or animals depends upon the photosynthetic process. In the cycle of synthesis and death the basic materials. carbon dioxide and water, can be used over and over again. while the energy released upon the destruction of organic matter is lost forever; it is dissipated as heat in space and must constantly be replaced by the sun's radiation.

Rate of Carbon Dioxide Reduction. — In bright sunlight the rate of the photosynthetic reaction is about 15 to 30 times the respiratory rate. A sunflower leai may gain 9% of its dry weight per hour. Considering that respiration proceeds continuously while photosynthesis occurs only during the hours of light, the net rate of the latter is about five times greater. This means an excess of carbohydrate, which is partly stored and partly used ior the growth oi the plant. Nongreen plants and animals, which constitute the hcterotrophic organisms, depend upon this excess ior their organic food.

Land plants utilize the carbon dioxide present in the air. This averages only 0.03% of the gas volume at the earth's surface. Aquatic plants thrive on the carbon dioxide dissolved as gas or as carbonates in the water. The best estimate ior the rate of the total carbon dioxide reduction on earth is a turnover oi 10^{11} tons of carbon per year, more than four-fiiths oi which is contributed by the flora of the oceans. An amount of carbon dioxide equal to the total readily available reservoir passes through the liie cycle in about 350 years. The cycle of carbon requires also one oi oxygen and of hydrogen. Since both these elements are available in larger quantities, it takes about 2,000 years to renew all the osygen in the air and 2,000,000 years to decompose all water on earth. The land plants grow faster if supplied with more carbon dioxide than they can now find in nature. It may be assumed that at the time in the history of our planet when its crust cooled down below the boiling point of water—the upper temperature limit for the existence of liie--there was little or no free oxygen but plenty oi carbon dioxide present. It is quite probable that our entire supply oi iree oxygen, one-fifth of the atmosphere, has been furnished by photosynthesis.

Origin of Life.—The chlorophyll system is a highly complex structure which ceases to iunction whenever its protein components are damaged. Obviously, thrreiore, life cannot have started with that particular synthetic reaction which at present is its sole support. Liie probably began with the aid of organic substances produced by ultraviolet radiation or by electrical discharges when the earth's atmbsphere

consisted mainly of hydrogen, methane, ammonia and water vapour. Experiments have shown that such a gas mixture, if subjected to electrical discharges, yields amino acids, the building stones of proteins.

Factors Governing Photosynthesis. — Photosynthesis is influenced by temperature, light intensity, carbon dioxide concentration and water supply as external factors. The internal factors influencing its course are twofold: first, the concentration of the pigments and the activity of the enzymatic catalysts involved in photosynthesis; second, other metabolic reactions, such as respiration and fermentation, which have no direct connection with the photosynthetic process. Among the internal factors must be included also the inherited traits characteristic for different species. It is well known that certain plants can grow in arctic regions and others only in the tropics. It has been found, however, that the chemistry of photosynthesis is identical in lower and in higher plants. For experimental purposes, therefore, the plant material suitable for the particular measuring device may be chosen.

Each of the factors influencing photosynthesis may become the one which is mainly responsible for the limitation of the over-all rate. At low light intensities and otherwise favourable conditions, photosynthesis proceeds at a rate directly proportional to the incident radiation. Under these circumstances the light energy is utilized with the greatest efficiency. At high light intensities and high temperatures, the rate remains a function of the carbon dioxide concentration so long as the mechanism of photosynthesis is not saturated with this substrate. If carbon dioxide also is present in sufficient amounts, the rate is determined by internal factors, most likely by the slowest of several enzymatic processes connected with the reduction of carbon dioxide. Since a truly photochemical reaction is not influenced by changes in temperature which determine the rate of ordinary processes, the rate of photosynthesis remains practically constant in spite of temperature changes as long as the light intensity is the rate-determining factor. This is the case at low or moderate light intensities and high temperatures. Conversely, in bright sunshine and at moderate temperatures photosynthesis is influenced by changes in temperature exactly as are other metabolic processes. These observations on limiting factors were among the first which led to the concept of photosynthesis as consisting of a sequence of photochemical and thermal enzymatic or "dark" reactions. An ingenious way of separating photochemical from dark reactions in the analysis of photosynthesis was first described in 1929. It consists of illuminating a plant with light flashes of very short duration (less than 1/1000 sec.) separated by dark periods of considerably greater length (1/100 sec. to 1 sec.). In this way the temperature dependencies just mentioned were clearly demonstrated. It was further shown that most metabolic poisons inhibit not the photochemical but the dark reactions in photosynthesis. Studies of the influence of poisons on the course of photosynthesis, performed in analogy to similar investigations in the field of respiration, allowed for a separation, in theory, of reactions preceding the photochemical reduction of carbon dioxide and reactions following it. These theoretical deductions were borne out by later experimental analyses of the mechanism of photosynthesis (see below).

Active Pigments. — (See also CHLOROPHYLL, CHEMISTRY OF; PLANTS AND PLANT SCIENCE.) The site of photosynthesis is in very small structural units called grana. In most plants the grana are arranged within larger structures, the chloroplasts. The green or brown colour of most chloroplasts is attributable to the chlorophylls and carotenoids. The two green chlorophylls a ($C_{55}H_{72}O_5N_4Mg$) and b ($C_{55}H_{70}O_6N_4Mg$) were isolated in 1905 and their structure finally established about 1936. The bacterio-chlorophylls a and b, occurring in purple bacteria, are related pigments whose absorption spectrum is shifted toward the infra-red. The chlorophylls are identical in all plants. They belong, like haemin — the dye responsible for the colour of blood — to the class of porphyrin metal complexes. An important difference between chlorophylls and haemins exists in their photochemical properties. The presence of a complex bound atom of magnesium does not destroy the typical porphyrin fluorescence of the chlorophylls, but the presence of the heavy metal iron in the haemins quenches the porphyrin fluorescence completely and makes the latter dyes photochemically inert. The slight difference between chlorophyll a and chlorophyll b — a formyl group (—C.H:O) in b where a has a methyl group (—CH_3) — is reflected in the absorption spectrum. Chlorophyll b absorbs at slightly shorter wave lengths.

One of the side chains of the porphyrin ring in chlorophyll is esterified with phytol, $C_{20}H_{40}O$, a colourless alcohol, which also is found as a side chain in vitamin K. The role of phytol in both substances is obscure. Chlorophyll looks green because it is somewhat more transparent for green light than for blue and red, yet green light is equally effective if absorbed. For the wave lengths longer than 7,300 A chlorophyll is quite transparent. This is the reason a landscape seen through a dark-red filter shows the leaves of trees and the lawn brighter than the surroundings (including the blue sky), an effect familiar from infra-red photography. Chlorophyll is insoluble in water. Extracts can be obtained simply by immersing green leaves in alcohol or acetone. In the cell, chlorophyll is bound to protein. It can be extracted in its combination with protein, in the form of a colloidal aqueous solution, if the plant cells are mechanically crushed.

The carotenoids present in the chloroplasts vary in composition and number with different species of plants. Their chemical structure has nothing in common with that of chlorophyll. The formula for carotene is $C_{40}H_{56}$, for xanthophyll $C_{40}H_{56}O_2$ and for fucoxanthin $C_{40}H_{56}O_6$. Some of these pigments were known to act as photoreceptors in such phenomena as phototaxis and phototropism, but until 1930 it was believed that only the light absorbed by chlorophyll was available for photosynthesis. Botanists, however, wondered how brown algae, in which most of the incident radiation is absorbed by the yellow pigments, could use light so effectively for growth. In 1941 it was finally established that some of the yellow pigments participate in photosynthesis. The degree to which this takes place varies considerably in different plants. In the diatoms, which are responsible for the bulk of photosynthesis in the ocean, the light absorbed by carotenoids is just as effective as that absorbed by chlorophyll. The mode of action of the carotenoids is, however, merely that of an "accessory pigment." The excitation energy is not utilized within the molecule itself but is transferred to chlorophyll a as shown by the colour of the resulting fluorescence. This is also the way in which phycocyanin and phycoerythrin, the characteristic pigments in blue-green and red algae, contribute to photosynthesis in these plants. No cell capable of photosynthesis has been found which did not contain chlorophyll a in addition to the other pigments mentioned. Even chlorophyll b seems to act as an accessory pigment by letting the excitation energy go over to chlorophyll a. The latter, therefore, appears to be the one pigment engaged in the actual conversion of light (electromagnetic energy; photons) into chemical energy.

Photochemically inactive pigments of the cytochrome type have been extracted in small amounts from chloroplasts of green plants and from purple bacteria. They are believed to act catalytically in the disposal of the hydroxyl groups derived from the photolysis of water.

Activity of Chloroplasts. — Photosynthesis survives for a short time in chloroplasts which have been removed from the cell. Certain cofactors restore some activity even to washed chloroplasts. Whenever the fine structure of the protoplasm or of the chloroplasts has been damaged, the process stops and only partial reactions can be seen to continue. In 1939 it was first shown by R. Hill that it is possible to obtain suspensions of chloroplasts from higher plants which still produce oxygen upon illumination yet have lost the ability to reduce carbon dioxide. The chloroplasts have to be suspended in a solution of ferric oxalate and ferricyanide. The ferric salts are photochemically reduced to ferrous salts. No carbon dioxide takes part in this reaction. In the same way quinones and dyestuffs are reduced in the light while oxygen is evolved. These experiments show that the chlorophyll complex and the enzyme system concerned with the photolysis of water can be kept functioning after the faculty to fix carbon dioxide has been lost. If enzymes and substrates extracted separately from either plant or animal tissues are recombined with illuminated chloroplasts, carbon dioxide may be taken up and incorporated into the carboxyl group of phosphoglyceric or malic acid.

Illuminated chloroplasts, as well as intact green cells, phosphoresce after illumination ceases. With sensitive instruments it can be shown that after the light has been turned off a red light of the same colour as the fluorescence of chlorophyll is emitted. Its intensity first declines steeply within a few seconds, but some residua: light emission lingers on for many minutes. This phenomenon, a chemiluminescence, is caused by the reversal of the very first photochemical steps in photosynthesis.

Efficiency of Photosynthesis. — The average data available to the mid-1950s concerning land plants indicated that between 1% and 3% of the light falling upon a green plant is transformed into chemical energy. Important as this answer may be for problems of agriculture, it is of no value in respect to the theoretical understanding of the process of photosynthesis. Most of the incident radiation is lost by reflection, transmission and ineffective absorption by pigments other than those in the chloroplasts. Only a fraction is absorbed by the active pigments. The efficiency with which this latter fraction is utilized in the course of the photochemical process is of great theoretical interest. It is measured by the minimum number of light quanta necessary to bring one molecule of carbon dioxide to the energetic level of a carbohydrate. From the mid-1920s to the mid-1950s, a prodigious amount of work was devoted to the determination of this number. It is certain that eight quanta of red light totalling 320 kg.cal. suffice to store the equivalent of 112 kg.cal. in terms of organic matter. The net efficiency of photosynthesis, therefore, is about 35%. Much higher efficiencies are alleged to have been found in certain experiments where plants were kept under unusual conditions, but these reports remained unconfirmed in the 1950s. In the unicellular green alga Chlorella the quantum yield remains essentially constant over the entire range of the chlorophyll absorption spectrum. This means that expressed in terms of calories the efficiency increases in the direction from blue to red in the spectrum, because the energy content of the light quanta decreases according to the laws of physics. Chlorophyll in the living cell obeys these laws exactly as do the chlorophyll-sensitizing photochemical oxidations in vitro.

Products and Intermediates of Photosynthesis. — The photosynthetic reaction is summarized in the most general chemical terms by the equation:

$n CO_2$ (carbon dioxide) $+ n H_2O$ (water) $+$ light $= n O_2$ (oxygen) $+ (CH_2O)_n$ (carbohydrate).

The factor n is introduced because a number of different carbohydrates are made in the course of the reaction. It is a matter of definition which ones should be called the "product(s) of photosynthesis." A derivative of a three-carbon sugar, triose phosphate, is the first carbohydrate to appear after the photochemical reduction of carbon dioxide has run its course, but only cane sugar (sucrose) or starch or, in some cases, fats are accumulated as storage products in the plants. The validity of this equation was established beyond doubt by the following experimental results: First, all measurements of photosynthesis extending over periods longer than 30 minutes showed that the volume of oxygen evolved is exactly equal to the volume of carbon dioxide absorbed; the assimilatory quotient is unity ($AQ = \triangle O_2 / \triangle CO_2 = 1$). Second, the amount of carbohydrate accumulated during 15 minutes of illumination was found to be equivalent to the amount of carbon dioxide taken up during the same time. In the above equation for the over-all process, the carbohydrate formed is symbolized by $(CH_2O)n$ and not by CH_2O, the formula of formaldehyde. For 60 years after it was first proposed in 1870, the hypothesis that formaldehyde is produced in photosynthesis was a favourite assumption in various theories. This hypothesis can safely be discarded because, mainly through the efforts of M. Calvin and A. Benson, it is known definitely that the first recognizable organic compound which contains the carbon dioxide taken up by the plant is phosphoglyceric acid:

$H_2O_3P.OCH_2.CHOH.COOH.$

The newly assimilated carbon forms the carboxyl group —COOH of this acid. An important step forward in research on photosynthesis was made possible by the discovery since 1939 of the isotopes of the element carbon (see ISOTOPE: *Naturally Occurring Radioactive Isotopes)*. The bulk of the ordinary carbon has the atomic weight of 12. The other isotopes have the weights of 10, 11, 13, 14 and 15. All are radioactive except C^{13} which is stable like C^{12}. C^{11}, C^{13} and C^{14} have been used in research in photosynthesis to trace the path of freshly fixed carbon on its way into various organic compounds of increasing number and complexity. The first attempts to use such "tracer" carbon in 1940 could not get very far because only C^{11}, whose half life is about 20 minutes, was then available. The atomic bomb project after World War II provided comparatively large amounts of C^{14}, which, having a half life of about 5,000 years, made possible many kinds of analyses requiring considerable time. The very first experiments with isotopes settled the long-disputed question of whether carbon dioxide reacts directly with chlorophyll, particularly with the magnesium atom in the molecule. No such reaction occurs.

The same experiments revealed that in a growing photosynthesizing plant the reduced carbon is quickly distributed among all organic compounds taking an active part in the metabolism of the cell. After a few minutes of illumination, a tiny fraction of the radioactive carbon was found even in the basic skeleton of the chlorophyll. Thus it became clear that the use of radioactive carbon would not automatically divulge the path of carbon in photosynthesis proper, since the assimilation of carbon is so interwoven with its utilization in other processes, such as fermentation, respiration and prntein synthesis.

Mechanism of Photosynthesis. — A few species of autotrophic bacteria are known to grow with carbon dioxide as the sole source of carbon in the absence of light. They utilize the energy derived from the oxidation of inorganic compounds, such as ferrous iron salts, sulphur, thiosulphate, hydrogen sulphide and molecular hydrogen. This fact was generally ignored in earlier attempts to understand the mechanism of photosynthesis. The amount of oreanic matter formed hy this means was considered insignificantly small as compared with photosynthesis, and the reduction of carbon dioxide in the dark appeared to be fundamentally different from photochemical reduction. In the decade between 1930 and 1940, however, it became evident that many organisms and tissues, from propionic acid bacteria to pigeon liver, include carhon dioxide among their metabolic substrates. In these cases a specific enzymatic system provides for the proper coupling between an energy-yielding reaction, respiration or fermentation, and a reaction in which hydrogen is transferred to carbon dioxide or its equivalent derivative. The great difference between these oxidoreductions and photosynthesis lies not in the way by which the carbon dioxide molecule is attacked but in the energy balance. No ordinary metabolic synthesis can end with an over-all gain and storage of chemical energy, because an excess of combustible material, previously synthesized, has to be sacrificed to make the reaction go. In photosynthesis it is the energy of light which in the course of the very rcaction furnishes the necessary combustible material or hydrogen donor by the "oxidation" of water. The utilization of light energy, however, is not sufficient to guarantee a successiul accumulation of chemical energy. This was shown by studies on the metabolism of purple bacteria, strongly coloured yellowish, red or purple unicellular microorganisms. Because their growth depends on light. they were first believed to photosynthesize as do the green plants. Investigations after 1930 proved that purple bacteria are unable to produce molecular oxygen and are unable to reduce carhon dioxide simply with water. In addition to radiant energy they need energetically valuable hydrogen donors. According to the specificity of each species, the purple bacteria require for the assimilation of a certain amount of carbon dioxide an equivalent amount of either sulphur, hydrogen sulphide, thiosulphate, molecular hydrogen, aliphatic acids or alcohols. In purple bacteria, therefore, the energy of light is not successfully stored as in the green plants, but is partially or completely wasted. The light serves here only as a promoter, as it were, of reactions which might as well be carried on thermally in the dark. In 1940, however, it was found that the photochemical reaction proper is the same in purple bacteria and in green plants. Certain species of unicellular green algae change to a type of metabolism similar to that of some purple bacteria if they are incubated during a few hours in pure hydrogen gas. Upon subsequent moderate illumination, they reduce carhon dioxide as usual, but they do not evolve oxygen. Instead they absorb the equivalent amount (twice the volume) of hydrogen. Once adapted to the use of hydrogen the same algae can reduce carbon dioxide, as do the "Knallgas" bacteria, in the dark, if some oxygen is supplied instead of light. Under the influence of intense irradiation the algae revert to normal photosynthesis with the production of oxygen. This reversible separation of carbon dioxide reduction from oxygen evolution or from the absorption of light demonstrated — what had been postulated long before — that photosynthesis consists of a series of complicated reactions which must be studied separately before the process as a whole is clearly understood. After 1940 all students of the problem agreed that at least three sets of partial reactions may be distinguished: (1) decomposition of water with the aid of light absorbed by chlorophyll, leading, on the one hand, to compounds (as yet unknown) having a surplus of hydrogen and serving as intermediary hydrogen donors, and, on the other hand, to compounds having a surplus of oxygen; (2) transfer of hydrogen from the intermediary donors to carbon dioxide; (3) disposal of the compounds having a surplus of oxygen. The permanent conversion of radiant energy into chemical energy is possible only because green plants accomplish the task of removing the surplus of oxygen by liberating molecular oxygen and not by consuming hydrogen donors, as do, for instance, the purple bacteria. This picture of photosynthesis requires, among other things, that all the oxygen evolved be derived from water and not from the reduced carhon dioxide molecule.

The discovery of phosphoglyceric acid as the first intermediate fixation product by means of the radioactive tracer method showed that an organic two-carbon compound (or two-carbon fragment derived from a larger molecule — probably pentose) must be the substance which accepts carbon dioxide and thus is transformed into the three-carbon acid. The acceptor molecule is constantly regenerated from the sugars produced by photosynthesis. A special metabolic cycle, therefore, exists which furnishes the two-carbon acceptor. Since this cycle has phosphoglyceric acid as one of its intermediates and since the latter is known to be aiso an intermediate in the respiratory metabolism of most living organisms, including the plants, it can be understood why, occasionally, respiration and photosynthesis in the same cell seem to influence each other quite strongly. By increasing or decreasing the amount of a photosynthetic intermediate, respiration can interiere with the kinetic pattern of the reaction proceeding in the light. This is particularly true in dim light when the reactions leading to the synthesis of sugars are not much faster than those causing their breakdown.

Food Production and Artificial Photosynthesis. — Because the earth's human population is increasing so rapidly with no corresponding increase in iood production, scientists have wondered how much more food would be available if full use could be made of the great efficiency of photosynthesis, which in laboratory experiments has been found to approach 35% of the intensity of the radiation absorbed by the active pigments. The average acre of land under cultivation yields hardly more than one ton of total dry organic matter per year because most of the light falling on the suriace is not trapped by chlorophyll and thus is lost for photosynthesis. If agriculture were superseded by the continuous cultivation of tiny aquatic algae in thin layers of fertilized water, the same area could produce between 30 and 50 times more edible material. Before such a project can become practical two other problems must be solved: how to maintain easily and cheaply over large areas conditions for optimal growth of algae, and how to induce people to eat them.

Of even greater importance is the relation of photosynthesis to the problem of a continuous supply of energy. The supply of oil, coal and nuclear energy on earth is definitely limited. Sooner or later every one of these sources will be exhausted. The only source of energy which cannot be depleted by the activities of the human race is solar radiation. Continued research in photosynthesis may teach us how to transform, in an entirely artificial way, visible light into a form of potential energy suited for general energy needs. *(See* also PHOTOCHEMISTRY.)

PHRAATES (PHRAHATES), the name of five Parthian kings.

1. PHRAATES I. son of Priapatius, reigned c. 176–171 B.C. He subdued the Mardi, a mountainous tribe in the Elburz. He died young, and appointed as his successor not one of his sons but his brother Mithradates I.

2. PHRAATES II, son of Mithradates I, the conqueror of Babylonia, reigned 138–128 B.C. He was attacked in 130 by Antiochus VII. Sidetes. who, however, in 129 was defeated and killed in a battle in Media, which ended the Seleucid rule east of the Euphrates. (See SELEUCID DYNASTY.) Meanwhile the kingdom was invaded by the Scythians (the Tochari of Bactria), who had helped Antiochus. Phraates was defeated and killed.

3. PHRAATES III, "the God," succeeded his father, Sanatruces, in 70 B.C., at the time when Lucullus was preparing to attack Tigranes of Armenia, who was supreme in western Asia and had wrested Mesopotamia and several vassal states from the Parthian kingdom. Naturally, Phraates declined to assist Mithradates of Pontus and Tigranes against the Romans. (See TIGRANES.) He supported his son-in-law. the younger Tigranes, when he rebelled against his father, and invaded Armenia (65 B.C.) in alliance with Pompey, who abandoned Mesopotamia to the Parthians. But Pompey soon overrode the treaty; he acknowledged the elder Tigranes, took his son prisoner, occupied the vassal states Gordyene and Osroene for the Romans, and denied the title of "king of kings," which Phraates had adopted again, to the Parthian king. About 57 Phraates was murdered by his two sons, Orodes I and Mithradates III.

4. PHRAATES IV, son of Orodes I, by whom he was appointed successor in 37 B.C., after the death of Pacorus. He soon murdered his father and all his 30 brothers. He was attacked in 36 by Antonius (Mark Antony), who marched through Armenia into Media Atropatene. and was defeated and lost the greater part of his army. Believing himself betrayed by Artavasdes, king of Armenia, he invaded his kingdom in 34, took him prisoner, and concluded a treaty with another Artavasdes, king of Atropatene. But when the war with Octavianus Xugustus broke out, he could not maintain his conquests; Phraates recovered Atropatene and drove Artaxes, the son of Artavasdes, back into Armenia. But by his many cruelties Phraates had roused the indignation of his subjects, who raised Tiridates II to the throne in 32. Phraates was restored by the Scythians, and Tiridates fled into Syria.

The Romans hoped that Augustu's would avenge the defeat of Crassus on the Parthians, but he contented himself with a treaty, by which Phraates gave back the prisoners and the conquered eagles (20 B.C.); Armenia also was recognized as a Roman dependency. Soon afterward Phraates. whose greatest enemies were his own family, sent five of his sons as hostages to Augustus, thus acknowledging his dependence on Rome. This plan he adopted on the advice of an Italian concubine whom he made his wife under the name of "the goddess Musa"; her son Phraates, commonly called Phraataces (a diminutive form), he appointed successor. In 2 B.C. he was murdered by Musa and her son.

5. PHRAATES V, or PHRAATACES. the younger son of Phraates IV and "the goddess Musa," with whom he is associated on his coins. Under him a war threatened to break out with Rome about the supremacy in Armenia and Media. But when Augustus sent his adopted son Gaius Caesar into the east in order to invade Parthia. the Parthians preferred to conclude a treaty (A.D. 1) by which once again Armenia was recognized as in the Roman sphere. Soon after Phraataces and his mother were slain by the Parthians. about A.D. 5. (ED. M.)

PHRAORTES, the Greek form of *Fravartish*, king of Media. According to Herodotus (i. 102) he was the son of Deioces, and began the Median conquests. He first subjugated the Persians, and then a great many other peoples of Asia, till at last he attacked the Assyrians. He was defeated and killed in a battle. after a reign of 22 years. about 646–625 B C

When after the assassination of Smerdis all the Iranian tribes. the Babylonians and the Armenians rebelled against Darius and the Persian rule. "a man of the name of Fravartish (*i* e., Phraortes), a Mede. rebelled in Media and spoke to the people thus: I am Khshathrita, of the family of Uvakhshatra (Cyaxares)." He reigned for a short time, but was defeated by Hydarnes, and aftenvard by Darius himself, taken prisoner in Rhagae (Rai), and executed in Ecbatana (520 B.C.). (ED. M.)
