The rarity of freshwater luminous organisms is a puzzle. No luminous fauna is known from the two deepest lakes in the world, Tanganyika in Africa and Baikal in Siberia. While Tanganyika contains no oxygen below about 200 metres (650 feet), Baikal is oxygenated at all depths yet still has no luminous forms in the dark depths, where it would seem an advantage for at least some organisms to be luminescent.

THE BIOCHEMICAL EVENTS OF LIGHT EMISSION

Enzymatic systems. The essential light-emitting components are the oxidizable organic molecule luciferin and the enzyme luciferase, which are specific for different organisms. The present custom is to use generic names according to origin; *e.g.*, firefly luciferin and luciferase, *Cypridina* luciferin and luciferase. The luciferin–luciferase reaction is actually an enzyme–substrate reaction in which luciferin, the substrate, is oxidized by molecular oxygen, the reaction being catalyzed by the enzyme luciferase, with the consequent emission of light. The light emission continues until all the luciferin is oxidized. This type of reaction is found in *Cypridina*, *Latia*, and many fish (see below).

Luciferin–luciferase reaction

The chemistry of many bioluminescent reactions has been elucidated. Most of the early chemical studies dealt with the *Cypridina* system, largely because the organism could be collected in large quantities, and the light-emitting components were fairly stable. Systematic studies led to the isolation of luciferin and luciferase in a highly pure state and finally to the determination of the chemical structure of firefly luciferin, *Cypridina* luciferin, and *Latia* luciferin. The three types of luciferin have been synthesized in the laboratory. *Cypridina* luciferin is an orange-coloured indole compound ($C_{22}H_{27}N_7O$, molecular weight 405); firefly luciferin is a thiazole compound ($C_{11}H_8N_2O_3S_2$, molecular weight 280), and *Latia* luciferin ($C_{15}H_{24}O_2$) has a molecular weight of 236. The chemical and conformational structures of the respective luciferases are unknown. Bacterial luciferin appears to be the reduced form of flavin mononucleotide, which is a highly important compound in cellular respiration.

In firefly luminescence, the substance adenosine triphosphate (ATP) initially reacts with firefly luciferase, magnesium ion, and firefly luciferin to form a complex (luciferase-luciferyl-adenylate) and pyrophosphate. This complex then reacts with molecular oxygen to emit light. Enough energy is liberated in the last step to convert the electronic configuration of the luciferase-luciferyl-adenylate complex from a low-energy ground state to a high-energy excited state. The high-energy complex then loses energy by radiating a photon of visible light and returns to the ground state. The colour of light emitted by different species of fireflies ranges from intense green to bright yellow, probably influenced by the enzyme luciferase. The common eastern firefly of the United States, *Photinus pyralis*, emits light in wavelengths ranging from 500 to 660 nanometres, for example, with an emission maximum at 562 nanometres, which expresses itself as a cool yellow green. The energy required for emission of light in this range is at least 60,000 calories.

Among fireflies of the genera *Photinus* and *Photuris*, which emit short, sharp flashes, the light organ has a regularly arranged air-supply system, consisting of tubules called tracheae, whose branches run into tracheal end organs (tracheal end cells and tracheolar cells). *Diphotus* and *Pyrophorus* lack the end cells, and they produce long, lingering glows. In *Photuris*, control of flashing appears to involve a three-element neuroeffector system, consisting of a peripheral nerve, a tracheal end organ, and a light-emitting cell, or photocyte. The nerve terminates in the tracheal end organ. It appears that in the transfer of excitation from the peripheral nerve to photocyte, via the tracheal end organ, a chemical mediator secreted by the nerve ending acts on the photocyte.

The *Renilla* system, like that of the firefly, requires an activation reaction. Luciferyl sulfate reacts with diphosphoadenosine to form luciferin. The luciferin then reacts with molecular oxygen in the presence of *Renilla* luciferase to give light.

Luminescent bacteria employ the enzymatic oxidation of reduced flavin mononucleotide ($FMNH_2$). In the complete reaction, bacterial luciferase reacts with $FMNH_2$ and oxygen to form a long-lived intermediate complex, which then reacts with a long-chain aliphatic aldehyde molecule (*e.g.*, decanal) to emit light. Aldehydes of eight to 15 carbon atoms in chain length are very effective in increasing luminescence intensity by a factor of 100 or more.

The marine worm *Balanoglossus biminiensis* possesses a still different type of light-emitting system. When disturbed, the worm secretes a greenish-blue luminous slime from its surface epithelium. Balanoglossid luciferase, luciferin, and hydrogen peroxide are all that is required for luminescence, no oxygen being needed.

When the luciferin and luciferase of certain different species are mixed, a light-emitting cross-reaction occurs. Reciprocal light-emitting cross-reactions exist among apogonid fishes, the pempherid fish, *Parapriacanthus ransonneti*, the batrachoid fishes *Porichthys notatus* and *P. porosissimus*, and the crustacean *Cypridina hilgendorfii*. In fact, the *Cypridina* system represents the only luminescent cross-reaction known among such disparate organisms as fish and crustaceans. The question as to whether the apogonids, *Parapriacanthus*, and *Porichthys* thus obtain their luciferin and luciferase by ingesting crustaceans is under study.

Other fishes that emit light via a luciferin–luciferase mechanism are the mesopelagic (200–1,000 metres) lantern and hatchet fishes. In *Porichthys notatus* the luminescent system is characterized by rows of more than 700 small, white photophores scattered over the body surface. The photophores light up when a small amount of epinephrine is injected beneath the skin or when electrical stimulation is given. The former result suggests that light emission may be partially under hormonal control. Light production in these fishes may be associated with mating. The reactions in lantern and hatchet fishes are very similar to the *Cypridina* reaction.

Photoprotein

Nonenzymatic systems. A bioluminescent reaction that does not employ an enzyme and is not analogous to the luciferin–luciferase system involves a luminescent protein, or photoprotein, with varying molecular weights in different organisms. This system is found in two genera of jellyfishes (*Aequorea* and *Halistaura*), in the marine worm *Chaetopterus*, and in the euphausiid shrimp *Meganyctiphanes norvegica*. Light is emitted when the photoprotein of either *Aequorea* or *Halistaura* is mixed with calcium ion. Oxygen is not required in the reaction. In the *Chaetopterus* system light emission occurs when the photoprotein is mixed with molecular oxygen; a hydroperoxide; iron (ferrous ion); and two cofactors, one resembling a nucleoprotein, the other a lipid. In the *Meganyctiphanes* system light is produced when the photoprotein is mixed with an unidentified heat-stable fluorescent compound (molecular weight less than 1,000) and molecular oxygen. In the boring clam (*Pholas dactylus*) luminescence results from the reaction of a photoprotein, another protein, and molecular oxygen.

An additional system is found in the marine dinoflagellate *Gonyaulax polyedra*. A crystalline-like particle called scintillon, which has been isolated from that unicellular organism, emits a flash of light when the surrounding fluid is acidified by lowering the pH from about 8 to 5.7. Soluble luciferin and luciferase, which emit light when mixed in the presence of oxygen and salt, can also be dissociated from the scintillons.

Summary. The biochemical reactions discussed above may be classified into the following five reaction types: (1) substrate oxidation (*Cypridina*, *Apogon*, *Parapriacanthus*, *Porichthys*, lantern and hatchet fishes, and *Latia*); (2) substrate activation followed by oxidation (firefly and *Renilla*); (3) reduction followed by oxidation (bacteria); (4) peroxidation (*Balanoglossus*); and (5) "precharged" systems, the photoprotein and scintillon reactions, which possess the unique feature of being readily triggered to emit light.

Bionics

The word bionics was coined in 1958 by Maj. Jack E. Steele, of the Aerospace Division of the United States Air Force, to describe a new science of constructing artificial systems that resemble or have the characteristics of living systems. Bionics is not a specialized science but an interscience discipline.

Relationship of bionics and cybernetics

Bionics may be compared with cybernetics, another interscience discipline. Bionics and cybernetics have been called the two sides of the same coin. Both use models of living systems, bionics in order to find new ideas for useful artificial machines and systems, cybernetics to seek the explanation of living beings' behaviour.

Bionics is thus entirely distinct from bioengineering (or biotechnology), which is the science of using living beings to perform certain industrial work, such as the culture of yeasts on petroleum to furnish food proteins, the use of micro-organisms capable of concentrating metals from low-grade ores, and the digesting of wastes by bacteria in biochemical batteries to supply electrical energy.

Mimicry as the basis for bionics. Mimicry of nature is an old idea. Many inventors have modelled machines after animals or flying birds. An 18th-century French mechanical engineer, Jacques Vaucanson, for example, constructed, among other automata, a duck that swam, flapped its wings, and quacked. Direct imitation of nature is a dead end, however. Much more promising is indirect imitation. An example is the medieval whirligig. When maple-tree fruit falls from the tree, the winged membrane of the fruit causes it to spin around its axis; it can fly long distances in favourable wind. From observation of this fruit arose the idea of making an artificial screw or helix of this kind and of making it fly by giving it a rapid movement around itself. Leonardo da Vinci sketched this type of helicopter, which in his day was a popular children's toy. In the same notebook, Leonardo drew a flying machine based on the bat's wing. Four hundred years later the first man-made machine reputed to have flown was constructed by a French engineer, Clement Ader, in the shape of bat's wings. Ader did not try to move the wings as in the natural model, however: he used propellers made of quill feathers.

Nevertheless, direct inspiration from nature and close imitation of it are still useful today, as the following examples will show. The dolphin moves at great speed with a minimal muscular effort. One reason for this lies in a peculiar characteristic of the dolphin's skin, which damps out turbulence of the water. Artificial skins similar to that of the dolphin have been devised for torpedoes to reduce turbulence and achieve greater speed with the same engine power. In 1964 a new type of ship propeller modelled on a fish tail was invented by a French engineer; this design has distinct advantages over conventional propellers, in particular a high thrust at low speed. It can also function in very shallow water and is not fouled by vegetation. Vehicles have been designed by the

United States Army that, in place of wheels, have legs directly copied from the articulated legs of certain insects (arthropods) to permit movement in swamps or over very rough terrain (see illustration).

Copying from nature has distinct advantages. Most living creatures now on the earth are the end product of 2,000,000,000 years of evolution, and the construction of machines to work in an environment resembling that of living creatures can profit from this enormous experience. Although the easiest way may be thought to be direct imitation of nature, this is often difficult if not impossible, among other reasons because of the difference in scale. Though Ader's flying machine was inspired by the bat's wing, Ader realized that there was no point in trying to make the wings move, as others had already done without success: the increase in dimensions from those of a bat's wing to a 14-metre (46-foot) wingspan required a different method of propulsion. Bionics researchers since have followed the same path in solving engineering problems. The essential is not to copy in detail but to understand the principles of why things work in nature.

The use of natural models. The next step is the generalized search for inspiration from nature. Living beings can be studied from several points of view. Animal muscle is an efficient mechanical motor; storage of solar energy in a chemical form is performed by plants with almost 100 percent efficiency; transmission of information within the nervous system is more complex than the largest telephone exchanges; problem solving by a human brain exceeds by far the capacity of the most powerful computers. The field of action opening to bionics appears nearly unlimited in scope.

Efficiency of natural processes

Because a living organism is a system that either transforms energy or deals with information or both, two main fields—information processing and energy transformation and storage—for bionics activities exist.

Sense organs of living beings. The general pattern of the information network of living organisms is the following: environmental sensations are received by the organs of sense and then coded onto nervous-impulse signals that are transmitted by nerves to the centres of processing and memorization of the brain. Pit vipers of the subfamily Crotalinae (which includes the rattlesnakes), for example, have a highly sensitive infrared heat-sensing mechanism located in a pit between nostrils and eyes. This organ is so sensitive that it can detect a mouse at a few metres' distance. Though much more sensitive man-made infrared detectors exist, bionics can still profit from study of these sensing mechanisms. First, it would be interesting and of potential value to understand the principle of energy transformation (thermal to chemical) involved in the rattlesnake's infrared pit. Second, unlike man-made detectors, the rattlesnake's has no amplifying mechanism between the heat detector and the neural network; therefore, its sensitivity must be quite high. Another striking example is the odour-sensing organ of the *Bombyx mori*, silk moth. The male can detect the chemical secreted by the female in a quantity as small as a few molecules.

Research prototype of a four-legged walking vehicle developed for the U.S. Army. The 11-foot, 3,000-pound machine, whose movements correspond to those of its operator, was designed to increase the capabilities of the foot soldier in modern combat.

Neural information network. Bionics must be prepared to consider any natural model as potentially useful for providing new ideas. It can also learn from the natural transmission of signals by the nerves. In a conductor such as a long-distance telephone wire, the signal is attenuated as it travels along the wire, and amplifiers must be placed at intervals to reinforce it. This is not the case for the animal nerve axon: the neural impulse issued from sense organs does not weaken in travelling along the axon. This impulse can travel in only one direction. These properties make the nerve axon a very special kind of cable capable of logic operations. In 1960 a new device called a neuristor was devised, capable of propagating a signal in one direction without attenuation. It is possible to build such neuristors with very small pieces of semiconductor material similar to that used in transistors and to arrange these devices in such a manner that they can perform numerical and logical operations. The neuristor computer is an example of bionics in two senses: the components are inspired by a natural model, and the behaviour of the components when arranged as computing circuits imitates the dynamic behaviour of natural neural information networks in contrast to conventional computers. The properties of neuristor computers are thus entirely new: each circuit can serve sequentially for different operations in a manner similar to that of the nervous system.

Pattern-recognition and learning machines. Bionics collaboration between the data-processing specialist and the specialist in nerve physiology produced the neuristor computer. This idea is far from being alone in this important field.

Another question of interest to bionics is how a living system makes use of information. Faced with a given environment, man begins by considering what would be the results of alternative courses of action. No situation is entirely new; there is always some resemblance to a situation experienced before. "Pattern recognition" is obviously an important element in human action, and as such it has implications for bionics.

One way to design an artificial machine capable of pattern-recognition properties is to use learning processes. In 1957 such a machine, called Perceptron, was built. Perceptron learns by establishing and modifying connections among a large number of possible alternative routes in a net of pathways. This learning, however, is still rudimentary and far from human.

Perceptron learning machine

The neural nets in the human brain are extremely complex, the interconnections growing during the first months of life. Science and technology do not yet know how to realize such complexity with man-made components. Before constructing a truly intelligent machine it is necessary to understand better the faculty in man.

Man's associative memory. Man is an astonishing information-processing system, using an extremely small amount of energy with an indefinitely small failure rate and a virtually unlimited memory. To produce a machine capable of translating one natural language into another natural language, a machine that will have the volume of one litre (about one quart) and the weight of one kilogram (about 2.2 pounds) might well be considered impossible; yet such a machine already exists: the human brain. The problem of automatic language translation, quite apart from the size specification, remains

intractable, although this does not mean that the problem eventually cannot be solved but rather that it is necessary to find new approaches to its solution.

Computer and human memories

The first essential difference between existing electronic computers and the human brain lies in the way their memories are organized. In either the memory of a living being or that of a machine the main problem lies in retrieving information once it has been stored. The method computers use is called "addressing." A computer memory can be compared to a large rack of pigeonholes, each having a particular number or address (location). It is possible to find a certain piece of information if the address—that is, the number of the pigeonhole—is known. The human memory works in a very different way, using association of data. The retrieval is done according to the content of the information, not according to an external address artificially added to the useful content. That difference is qualitative as well as quantitative. Man-made memory devices are now constructed using associative principles, and there is a great potential in this field with such new technologies as holography and optical storage of data.

The second main difference between the existing electronic computers and the human brain resides in the manner of dealing with the information. A computer processes rigorously precise data. Man accepts fuzzy data and carries out operations that are not strictly rigorous. Also, computers perform only very simple elementary operations, producing complex results by performing a vast number of such simple operations at very high speed. In contrast, the human brain performs at low speed but in parallel rather than in sequence, producing several simultaneous results that can be compared.

In a computer, memory and treatment are distinct; in man, they are mixed. With the technology of the 1970s it is possible to imagine devices that could both store and process large amounts of data at the same time. The combination of new man-made components with new ideas coming from bionics could result in entirely new computers in the near future.

Thus, it is not in the field of arithmetical calculation that bionics can bring in new ideas, because in that area the human brain has limited capacity. But in the realm of decision making and problem solving it can serve as an invaluable model for creating artificial intelligence.

The association of the two words artificial and intelligence is shocking. Computers and computer programming are man-made, and therefore the machine cannot do more than the man. The machine can do more in another sense, however, because of its higher speed and its low failure rate, properties that can be exploited.

Energy transformation and storage. As noted before, every living system can be studied from two main points of view: energetic and informational. Bionics can supply fresh ideas in the information field. It can perhaps be even more productive in the field of energy.

The world energy consumption doubles regularly every 20 years, with increasing environmental degradation among the consequences. Though the most convenient energy form for most purposes is electrical, such energy cannot be stored and must be constantly supplied. In the living world, energy is stored in the form of chemical composites; its use always brings about chemical reactions. The use of solar energy by plants involves complex chemical processes. The muscular motor is a chemical motor. The light produced by such living organisms as mushrooms, glowworms, and certain fishes is of chemical origin. In every case the energy transformation is remarkably efficient compared with thermal engines.

A beginning is just being made in understanding how these transformations take place in living material and the nature of the complex role played by living membranes. Living molecules are extremely complex and relatively fragile. If a biochemical reaction is too strong or violent, the heat exchanged might destroy life instead of maintaining it. Perhaps some of these limitations could be overcome in man-made artificial-energy machines and better results achieved than in natural membranes. Studies are now in progress in this field.

BIBLIOGRAPHY. LUCIEN A. GERARDIN, *La Bionique* (1968; Eng. trans., *Bionics*, 1968), presents a general view; while VINCENT J. MARTEKA, *Bionics* (1965), deals mainly with bionics as mimicry of nature. The proceedings of various bionics symposia are reprinted in the following publications: *Bionics Symposium: Living Prototypes, the Key to New Technology*, 32 reports, WADD Technical Report 60–600 (1961); E.E. BERNARD and M.R. KARE (eds.), *Biological Prototypes and Synthetic Systems: Proceedings of the Second Annual Bionic Symposium*, 48 reports (1962); bionics issue of the *IEEE Transactions on Military Electronics* (April–July 1963), an account of the third symposium of bionics, including 29 reports; *Bionics Symposium, Dayton, Ohio 1966* (1968), 61 reports published by the Aerospace Medical Division, Wright–Patterson Air Force Base; and the report of the colloquium on *Les Modèles bioniques des systèmes sonars animaux* held in Frascati in September 1966 (1967).

(L.A.G.)

Biophysics

In its broadest sense, biophysics is concerned with the solution of biological problems in terms of the concepts of physics and other physical sciences. The relatively recent emergence of biophysics as a scientific discipline may be attributed, in particular, to the spectacular success of biophysical tools in unravelling the molecular structure of deoxyribonucleic acid (DNA), the fundamental hereditary material, and in establishing the precisely detailed structure of proteins such as hemoglobin in order that the position of each atom may be known. Biophysics and the intimately related subject molecular biology now are firmly established as cornerstones of modern biology.

HISTORICAL ASPECTS

Origins. The origin of biophysics antedates the division of natural sciences into separate disciplines. Bioluminescence must be considered among the most ancient objects of biophysical exploration, because the emission of light by living organisms has long stimulated the curiosity of natural philosophers. Perhaps the first scientific investigation of animal luminescence was that of Athanasius Kircher, a 17th-century German Jesuit priest, who devoted two chapters of his book *Ars Magna Lucis et Umbrae* to bioluminescence. In the midst of his more scientific observations, Kircher found time to expose as a fallacy the notion that an extract made from fireflies could be used to light houses.

The relation between electricity and biology became a subject of speculation in the 17th century and one of intense exploration in the 18th and 19th. Sir Isaac Newton in the *Principia* (1687) wrote of "a certain most subtle spirit which pervades and lies hid in all gross bodies," and that "all sensation is excited, and the members of animal bodies move at the command of the will, namely, by the vibrations of this spirit, mutually propagated along the solid filaments of the nerves, from the outward organs of sense to the brain, and from the brain into the muscles." Man's fascination with animal electricity is illustrated in a letter written by John Walsh in 1773 to the American inventor and statesman Benjamin Franklin; Walsh wrote the details of his discovery of the electrical nature of the discharge from the torpedo or electric ray:

> I am concerned that other engagements have prevented me from giving to the Royal Society, before their recess, a complete account of my experiments on the electricity of the torpedo; a subject not only serious in itself, but opening a large field of interesting inquiry, both to the electrician in his walk of physics, and to all who consider, particularly or generally, the animal oeconomy.

The role of physical and chemical studies. Typical of the unity of science that then prevailed were the advances sometimes made either by professors of physics who were interested in biological phenomena or professors of anatomy, a subject that at that time included physiology. Thus Abbé Giovanni Beccaria, professor of physics in Turin and Italy's leading student of electricity in the mid-18th century, carried out experiments on the electrical stimulation of muscles. Albrecht von Haller, professor of anatomy and surgery at Göttingen, discussed "the nervous fluid" and conjectured as to whether "electrical matter"

Electrical stimulation of muscles

and "animal spirits" were the same. In 1786 Luigi Galvani, a physician in Bologna, made the crucial experiment that helped end this controversy. Galvani supposedly was performing experiments with a machine in the company of friends, when, by chance, one member of the party idly probed with a knife the nerves of the thigh of a skinned frog to be used for soup. As the muscles of the frog leg suddenly and unexpectedly contracted, Galvani's wife noted that a spark had been produced by the electrical machine and "fancied that there was an agreement in point of time." Although Galvani's own account of the occurrence differed somewhat in detail from the preceding, it is certain that the experiment was repeated and verified, setting the stage for a long controversy between the advocates of Galvani's view that current generated by an animal can cause contraction and those of Alessandro Volta, who claimed that the frog leg served only as a detector of minute differences in electrical potential external to it. The Galvani partisans performed an experiment in which no external sources of electricity were present, thus proving that current generated by an animal could cause the muscle contraction. But it was also possible to cause contraction by contact with metals; Volta performed such investigations, and they culminated in his invention of the electrical battery, which was so important that it overshadowed Galvani's research. As a result, the study of electrical potential in animals disappeared from scientific consideration until 1827.

Because for many years the frog leg was the most sensitive detector of differences in electrical potential, final acceptance of the view that currents can be generated by living tissues had to await the construction of galvanometers sensitive enough to measure the minute currents generated in muscles and the small potential differences across nerve membranes. Galvanometers were built by the great German 19th-century electrophysiologist Du Bois-Reymond, professor of physiology in Berlin. His investigations of muscular current and electrical potential of nerves depended upon a galvanometer of his own devising that required 3.17 miles (5.10 kilometres) of wire wound in 24,000 turns. Research in this subject, called neurophysiology, grew in stature with increased understanding of both electrical phenomena and cellular physiology; it served as one point of origin for biophysics.

Biophysics also grew out of investigations on diffusion gradients and osmotic pressure—two forces responsible for the passive flow of matter in living organisms. Osmotic pressure, the pressure that develops in a solution separated from a solvent by a membrane permeable only to solvent, was first described by Abbé J.A. Nollet, who became professor of experimental physics at the College of Navarre. The semipermeable membranes required to produce the fluid flow that characterizes osmotic phenomena initially came from biological sources; French scientist René Dutrochet wrote in 1828, "it appears from these new studies that the endosmotic and exosmotic phenomena, which I discovered, belong to a new class of physical phenomena, whose powerful intervention in the vital phenomenon is no longer doubtful." Following the first quantitative measurements by the botanist W.F.P. Pfeffer, the fundamental laws governing diffusion were enunciated by Adolph Fick, who in 1856 published what is probably the first biophysics text, *Die medizinische Physik* ("Medical Physics"). Fick developed the laws of diffusion not from experiment but by analogy with the laws governing the flow of heat; subsequent laboratory experiments proved the analogy to be quantitatively exact.

The development of physical chemistry

Physical and chemical investigation coalesced in physical chemistry, a subject that began to develop with the emergence of the *Zeitschrift für Physikalische Chemie* in 1887, a journal founded by Dutch chemist Jacobus van't Hoff and German chemist Wilhelm Ostwald. The first volume contains contributions from the most noted physical chemists of the time, including van't Hoff, Ostwald, François Raoult, and Svante Arrhenius. They were concerned with reactions in solution, a central topic in biology because the interior milieu of all living cells is aqueous, and the chemical reactions that sustain life take place in water. The scientific interests of van't Hoff in particular transcended the boundaries between disciplines. He stressed the importance of the laws of osmosis, which he had clearly delineated, to the economy of all living processes.

SCOPE OF BIOPHYSICS

Interdisciplinary nature. The biophysical approach is unified by a consideration of biological problems in the light of physical concepts, so that biophysics is, perforce, interdisciplinary. Biophysics may be thought of as the central circle in a two-dimensional array of overlapping circles, which include physics, chemistry, physiology, and general biology. Relations with chemistry are mediated through biochemistry and chemistry; those with physiology, through neurophysiology and sensory physiology. Biology, which may be viewed as a general subject pervading biophysical study, is evolving from a purely descriptive science into a discipline increasingly devoted to understanding the nature of the prime movers of biological events. The evolution of biology in these directions has received great impetus from the biophysical and biochemical discoveries of the 20th century. An understanding of the physical principles governing biological effects is the proper end of biophysics.

The content of biophysics. The content and methods of biophysics are illustrated by examining several notable contributions to science.

Protein structure. Within two days after the initial publication of the discovery of X-rays in 1895 by Wilhelm Röntgen, a surgeon in Scotland used X-rays to observe a needle as he extracted it from the palm of an unfortunate seamstress. Although this medical application resulted in the development of radiological diagnosis and treatment of disease by radiation, physical aspects of Röntgen's discovery also provided the means for elucidating the structure of proteins and other large molecules. The laws governing the diffraction of X-rays were discovered by the two Braggs, Sir William and Sir Lawrence, who were father and son. At the Cavendish Laboratory at the University of Cambridge, where Sir Lawrence was professor, the scientist J.D. Bernal was studying the use of X-ray diffraction for the determination of the structure of large biological molecules. He had already used X-rays to define the size and shape of the tobacco mosaic virus and showed it to have a regular internal structure. At the Cavendish Laboratory the group that formed around Bernal, a man of wide public and scientific interests, included the Nobel Prize winners Max Perutz and John Kendrew, who in 1937 began to use X-rays to analyze two proteins fundamental to life, myoglobin and hemoglobin, both of which function in the transport of gases in the blood. Twenty-two years passed before the structures of these proteins were established; the significance of the work is that it provided the basis for an understanding of the mechanism of the action of enzymes and other proteins, now an active and fruitful subject of investigation.

The significance of X-rays

Deoxyribonucleic acid. Interest in biophysics at the Cavendish Laboratory resulted in another important discovery, the structure of deoxyribonucleic acid (DNA), the genetic material. This achievement by a British biophysicist, Francis H.C. Crick, and by a U.S. biochemist, James Watson, was based on X-ray data obtained by Maurice Wilkins at King's College, London. When Crick first went to the Cavendish Laboratory for education in biophysics, he worked under Perutz's direction; when Watson came to the Cavendish, he and Crick began the collaboration that led to the establishment of the structure of DNA, for which Watson, Crick, and Wilkins later were awarded a Nobel Prize.

Much impetus for biophysical investigation following World War II came from the desire of physicists to move away from physics and into biology; this drive was strengthened by the publication in 1944 of Erwin Schrödinger's book *What is Life?* Schrödinger, the Austrian physicist who contributed substantially to the development of wave mechanics, was anxious to determine whether biological events could be accounted for in

terms of known laws of physics and chemistry, or whether a full explanation would require the formulation of physical laws not yet known to exist. Because biological reproduction seemed to pose intractable problems, he devoted a chapter of his book to a consideration of the gene. The discussion was based on the model put forward by Max Delbrück, a physicist who had for some years been studying the genetics of viruses that infect bacteria (bacteriophages). Delbrück's summer course on bacteriophages in 1945 at Cold Spring Harbour in New York set in motion the chain of events that led to understanding the genetic code by which the sequence of the nucleotides in DNA is translated into the sequence of amino acids in a protein. The use of bacteriophage also provided an opportunity for experiments with a primitive living organism that could be studied without anatomic complexities. This aspect of biophysics has become more biochemically oriented as it has developed and is now known as molecular biology; sometimes it is considered a distinct discipline, and other times it is subsumed under the biophysical sciences.

The nerve impulse. Important aspects of biophysics have been derived from physiology, especially in studies involving the conduction of nerve impulses. One important scientific product of World War II—the development of vastly improved electronics—largely resulted from radar devices that had been used primarily for locating aircraft. Another product, the atomic bomb, was constructed by way of nuclear reactors that could, in peace time, provide an abundant supply of radioactive isotopes, which are now of great value not only in biophysical research but also in biochemistry and medicine. These two disparate advances were important to the work of two Nobel Prize winners, Alan Hodgkin and Andrew Huxley, who showed how the flow of sodium and potassium across the membranes of nerves can be coupled to produce the action potential, a brief electrical event that initiates the action potential, which propagates the nervous signal.

A model of the nerve axon proposed by Hodgkin and Huxley grew from a 19th-century confluence of ideas. Julius Bernstein, an experimental neurophysiologist, used physical chemical theories to develop a membrane theory of nervous conduction; Hodgkin's initial experiments were designed to test specific predictions of the Bernstein hypothesis. Early in 1938 Hodgkin learned of the important results of a newly developed technique that allowed examination of the time course of nervous conduction. After World War II, Hodgkin, joined by Huxley, again took up the research. They presented their explanation of the mechanism of nervous conduction in five scientific papers between October 1951 and March 1952.

Biological membranes. The availability of radioactive isotopes provided the technology necessary for understanding how molecules are transported across biological membranes, which are the very thin boundaries of living cells; the environment maintained by membranes in cells differs from the external environment and permits cellular function. The Danish physiologist August Krogh laid the groundwork in this subject; his pupil, Hans Ussing, developed the conceptual means by which the transport of ions (charged atoms) across membranes can be identified. Ussing's definition of active transport made possible an understanding, at the cellular level, of the way in which ions and water are pumped into and out of living cells in order to regulate the ionic composition and water balance in cells, organs, and organisms. The molecular mechanism by which these processes occur, however, remains to be discovered.

Conceptual explanation of active transport

In addition to the function of transport, membranes also are utilized as templates on which such molecules as enzymes, which must function in a sequential fashion, can be kept in the requisite order. Although great progress has been made in understanding the mechanisms by which specific atoms are assembled into large biological molecules, the principles involved in the assembly of molecules into membranes, which are organized structures of a higher degree of complexity than large molecules, are not yet very well understood. There is reason to believe that the incorporation of a molecule into a membrane endows it with properties that differ from those of a molecule in solution. A primary task of biophysics is to understand the physical character of these cooperative interactions that are essential to life.

Muscle contraction. One influential early proponent of biophysics—the British biophysicist A.V. Hill—developed exquisitely sensitive temperature sensors for measuring heat generated during muscular contraction; he initiated studies relating this heat to the thermodynamic parameters responsible for it. The electron microscope in the years following World War II made possible the description of muscular contraction at a structural level, although the mechanisms involved in the flow of heat during the process are not yet known. Simultaneously, in the 1960s, but independently, various physicists postulated the sliding-filament theory of muscular contraction, according to which muscles contract by the sliding of one filament along another and not by a springlike coiling. Remarkable advances, based on the use of techniques such as X-ray diffraction and electron microscopy, have made it possible to visualize many of the molecules involved in the process. The entire process of muscular contraction, in terms of an identification of the molecules and a description of the chemical reactions in the muscle fibre, has now been almost completely explained.

Sensory communication. The above comprise a few specific examples of the scope of biophysics. One area, difficult to discuss in specific terms, is that of sensory communication. Because stimuli, particularly those of a visible or auditory nature, can easily be specified in exact physical terms, they have excited the interest of physical scientists since before 1850. Modern electronic techniques make it relatively easy to distinguish true signals from noise; in addition, computers make possible the performance of significant experiments concerning the complex relationship between stimulus and action. Quantitative analysis of sensory response is very difficult, however, because it involves a synthesis of the action of many cells. It has been pointed out that

> An adequate theory of sensory function implies an adequate theory of brain function. And an adequate theory of brain function in its turn requires that the nervous system's behavioral repertory be predictably related to the behaviour of the elements that compose it.

THE STUDY OF BIOPHYSICS

The nature of the biophysicist and his work. A.V. Hill has written that

> Biological phenomena, like many others, show aspects and relations susceptible of physical analysis and interpretation. It is by the choice of problems and by the intellectual processes with which they are formulated and attacked, more than by the particular techniques employed, that a subject can be most clearly defined. There are people to whom physical intuitions come naturally, who can state a problem in physical terms, who can recognize physical relations when they turn up, who can express results in physical terms. These intellectual qualities, more than any special facility with physical instruments and methods, are essential to the make-up of a biophysicist. Equally essential, however, are the corresponding qualities, intuitions, and experience of the biologist. A physicist who cannot develop the biological approach, who has no curiosity about vital processes and functions, who is not willing to spend time in learning the habits of living things, who regards biology simply as a branch of physics has no important future in biophysics. (From *Science*, Dec. 21, 1956.)

Most biophysical research has been carried out by physicists with an interest in biology; therefore, there must be a way by which scientists educated in physics and physical chemistry can find their way into biology and become familiar with problems that may be open to a physical interpretation. Although classically oriented biology departments now often offer positions to biophysicists, they are not substitutes for centres in which biophysical research is of central importance.

Tools of the biophysicist

The biophysicist possesses the ability to separate biological problems into segments that are amenable to exact physical interpretation and to formulate hypotheses that can be tested by experiment. The primary tool of the

biophysicist is an attitude of mind. To this might be added the ability to use complex physical theory to study natural objects—for example, that involved in the X-ray diffraction techniques used to determine the structure of large molecules such as proteins. The biophysicist usually recognizes the utility of new physical tools—*e.g.*, nuclear magnetic resonance and electron spin resonance—in the study of specific problems in biology. But he may also, through previous experience in building specialized equipment to solve physical problems, not have to rely on commercially built instruments.

Applied biophysics. The development of instruments for biological purposes is an important aspect of applied biophysics. Biomedical instrumentation is probably most widely used in hospitals. Applied biophysics is important in the field of therapeutic radiology, in which the measurement of dose is critical to treatment, and in diagnostic radiology, particularly with techniques involving isotope localization and whole body scanning to aid in tumour diagnosis. As aids in diagnosis and patient care computers are of increasing importance. Automation of the chemical analyses routinely carried out in hospitals will soon be a reality. The opportunities for the applications of biophysics seem limitless because the lengthy delay between the development of a research instrument and its application means that many scientific instruments based on physical principles already known will be shown to have important potential for medicine.

Biophysical societies and journals. Many of the ways in which scientists come together to deal with matters of common concern are found in biophysics. The first biophysics department in the United States was probably the Johnson Foundation for Medical Physics, which opened in 1929 at the University of Pennsylvania in Philadelphia. Although biophysics had been developed in England before 1952, stimulated in large measure by A.V. Hill, not until that year was a university department in biophysics begun—at University College, London.

The first society of biophysics was the Dutch Stichting voor Biofysica, in 1932. After the Biophysical Society in the United States was formed in 1957, there shortly appeared similar groups in Japan (1960), in Great Britain (1961), and in the Soviet Union and many other countries. The International Organization for Pure and Applied Biophysics was formed in 1961; after that organization became a member of the International Council of Scientific Unions in 1966, its name was changed to the International Union for Pure and Applied Biophysics. Thus, biophysics has taken its place with the older established disciplines of mathematics, physics, and chemistry, and has become an equal partner with biology, physiology, and biochemistry.

Biosphere

Before the coming of life, the Earth was a bleak place, a rocky globe with shallow seas and a thin band of gases—largely methane, ammonia, hydrogen sulfide, and water vapour. It was a hostile and barren planet. This strictly inorganic state of the Earth is called the geosphere; it consists of the lithosphere (the rock and soil), the hydrosphere (the water), and the atmosphere (the air). Energy from the Sun relentlessly bombarded the surface of the primitive Earth and in time—millions of years—chemical and physical actions produced the first evidence of life, formless, jellylike blobs that could collect energy from the environment and produce more of their own kind.

This generation of life in the thin outer layer of the geosphere established what is called the biosphere, the "zone of life," an energy-diverting skin that uses the matter of the Earth to make living substance. When man appeared, the biosphere became more and more influenced by his presence and was transformed into the anthroposphere by his activities. Within a relatively short span, geologically speaking, man attained a threatening mastery over the Earth and began exploiting it. The age of ecological enlightenment has brought with it a new term, the ecosphere, which implies a responsible stewardship of Earth. Beyond and superimposed on these spheres lies another dimensional sphere, the noosphere, a figurative envelope of conceptual thought, or reflective impulses produced by the human intellect, that can be imagined to weigh upon the entire globe in a mystical way. It is not scientifically measurable, of course, but its presence is strangely felt and its influence all-pervading.

GENERAL FEATURES

Preconditions of the biosphere. The Earth is an ideal medium for life. It is at precisely the proper distance from the Sun to receive neither too much nor too little sunlight. It spins on its axis at a rate fast enough to allow the daytime side to warm in sunshine and the nighttime side to cool. Its mass—and therefore its gravity—is such that it holds a wide variety of molecules, including the lighter ones that otherwise would drift off into space. Its magnetic field deflects back to space the Sun's highly energetic radiation, which otherwise would destroy life if free to bombard the Earth's surface directly. The bio-

sphere, then, is the result of many improbable events that occurred during the time the Earth cooled from hot molten rock to its present crusted state. Life arose gradually as each succeeding event occurred (see the article LIFE for a detailed account of this process).

The life-supporting sphere

The biosphere is a system characterized by the continuous cycling of matter and an accompanying flow of solar energy in which certain large molecules and cells are self-reproducing. Water is a major predisposing factor, for all life depends on it. The elements carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur, when combined as proteins, lipids, carbohydrates, and nucleic acids, provide the building blocks, the fuel, and the direction for the creation of life. Energy flow is required to maintain the structure of organisms by the formation and splitting of phosphate bonds. Organisms are cellular in nature, always contain some sort of enclosing membrane structure, and all have nucleic acids that store and transmit genetic information.

Levels of organization. All life on Earth depends ultimately upon green plants, as well as upon water. Plants utilize sunlight in a process called photosynthesis to produce the food upon which animals feed, to provide, as a by-product, oxygen, which most animals require for respiration. At first, the oceans and the lands were teeming with large numbers of a few kinds of simple single-celled organisms, but slowly plants and animals of increasing complexity evolved. Interrelationships developed so that certain plants grew in association with certain other plants, and animals associated with the plants and with one another to form communities of organisms, including those of forests, grasslands, deserts, dunes, bogs, rivers, and lakes. Living (biotic) communities and their nonliving (abiotic) environment are inseparably interrelated and constantly interact upon each other. For convenience, any segment of the landscape that includes the biotic and abiotic components is called an ecosystem. A lake is an ecosystem when considered in totality as water, nutrients, climate, and all of the life contained within it. A given forest, meadow, or river is likewise an ecosystem. One ecosystem grades into another along zones termed ecotones, where a mixture of plant and animal species from the two ecosystems occurs. A forest considered as an ecosystem is not simply a stand of trees but is a complex of soil, air, and water, of climate and minerals, of bacteria, viruses, fungi, grasses, herbs, and trees, of insects, reptiles, amphibians, birds, and mammals.

Anatomy of the biosphere

Stated another way, the abiotic, or nonliving, portion of each ecosystem in the biosphere includes the flow of energy, nutrients, water, and gases and the concentrations of organic and inorganic substances in the environment. The biotic, or living, portion includes three general categories of organisms based on their methods of acquiring energy: the primary producers, largely green plants; the consumers, which include all the animals; and the decomposers, which include the micro-organisms that break down the remains of plants and animals into simpler components for recycling in the biosphere (see ECOSYSTEM). Aquatic ecosystems are those involving marine environments and freshwater environments on the land. Terrestrial ecosystems are those based on major vegetational types, such as forest, grassland, desert, and tundra. Particular kinds of animals are associated with each such plant province (see AQUATIC ECOSYSTEM; TERRESTRIAL ECOSYSTEM).

Ecosystems may be further subdivided into smaller biotic units called communities. Examples of communities are the organisms in a stand of pine trees, on a coral reef, in a cave, a valley, a lake, or a stream. The important consideration in the community is the living component, the organisms; the abiotic factors of the environment are excluded.

A community, in turn, is a collection of species populations. In a stand of pines may be many species of insects, of birds, of mammals, each a separate breeding unit, but each dependent on the others for its continued existence. A species, furthermore, is composed of individuals, single functioning units identifiable as organisms. Beyond this level, the units of the biosphere are the units of the organism: organ systems composed of organs, organs composed of tissues, tissues of cells, cells of molecules, and molecules of atomic elements and energy. The progression in the biosphere, therefore, proceeding upward from atoms and energy, is toward fewer units, larger and more complex in pattern, at each successive level.

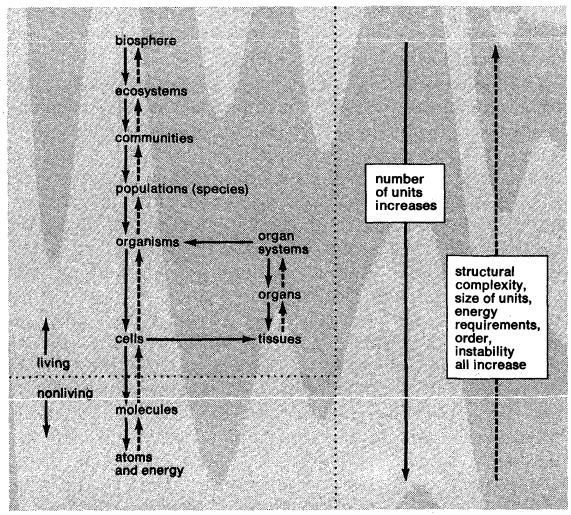

Figure 2: Hierarchy of levels in the biosphere.

ENERGY FLOW IN THE BIOSPHERE

Energy and organization. A unique characteristic of life is that it is an organized system capable of creating more order from less order. This seems contrary to the general trend of the universe, in which there is a tendency to move toward maximum disorder (entropy) as expressed in the second law of thermodynamics. Life results from the steady-state, or balanced, situation in which there is a flow of energy from the Sun to the Earth and then to the cosmic cold of outer space. The first law of thermodynamics, the conservation of energy, states that energy is neither created nor destroyed but remains constant for the universe. It does not indicate how energy is transformed but only that all the energy within the system must be accounted for.

The constancy of energy in the universe

In order for sunlight to organize life on Earth, it must irradiate the surface with electromagnetic frequencies harmonious with the peculiar chemical bonds of organic molecules. Whereas the very short-wave ultraviolet, gamma rays, and X-rays are destructive of organic molecules, and the long-wave infrared radiation is absorbed and dissipated as heat, the near-ultraviolet and visible wavelengths interact well with matter to stimulate the formation of bonds and the arrangement of organic molecules.

The single most important photochemical reaction in the world is photosynthesis, the union of carbon dioxide and water in plants through the interaction of sunlight and chlorophyll molecules. In the photosynthetic process, light energy is absorbed by chlorophyll to convert carbon dioxide and water into carbohydrate and oxygen. This photochemical event is a stepwise process by which electrons are energized within the chlorophyll molecule and raised to higher energy levels with the formation of carbohydrate. In the process, which is complex, high-energy phosphate bonds are formed, and adenosine triphosphate (ATP) results. The end products within green plants are carbohydrates and energy-rich compounds that become food for plant-eating (herbivorous) organisms and a succession of animal-eating organisms. The food web of ecosystems is provisioned in this way.

The importance of phosphorus

The universal fuel within all organisms is ATP, in which high-energy phosphate bonds store energy and release it when the bonds are broken. The complex reactions within a cell that lead to the formation of ATP combine at least one phosphorus atom per adenosine molecule. Without phosphorus no life could exist, since the entire linkage between photosynthesis and cellular activity

would be missing. One process by which the energy stored in ATP is utilized is in the transformation of glucose sugar to sucrose, or ordinary sugar.

Efficiency of utilization of solar energy. The intensity, as well as the composition, of the sunlight irradiating the Earth's surface is important to life. The tremendous amount of solar energy incident upon the Earth's outer atmosphere each day is distributed unevenly over the world, with the greatest amount of solar radiation reaching the desert regions and the least amount reaching the polar regions, where the slanted rays of the sunlight through the atmosphere are long. Temperate regions of the world, where food crops are grown, receive an intermediate amount of solar radiation, but a substantial fraction of this sunlight is received during the winter, when temperatures are too low for maximum plant growth. When intense winter cold grips the Arctic landscape, there is little light and no plant growth; only higher members of the food chain, birds and mammals, move about the land. In the tropics, temperatures are warm and constant throughout the year; the land is irradiated by sunlight more evenly throughout the seasons and plant growth is abundant. Although desert regions receive by far the greatest amount of sunlight, the lack of water limits plant productivity.

The conversion of energy into matter

Only about 25 percent of the sunlight reaching the ground is in wavelengths useful for photosynthesis, and only a fraction of useful light is available to green plants. An understanding of the performance of the biosphere requires an appreciation of the efficiency of the primary production process. The efficiency of energy conversion from incident sunlight into organic matter (net primary productivity) seldom is as large as 3 percent and usually is 1 percent or less. Estimates for a cornfield, for example, show that only slightly more than 1 percent of the total sunlight striking it ends up as part of the corn plants; about 44 percent is used in the evaporation of water from soil and plants, 54 percent is reflected or dissipated as heat, and a fraction of a percent is consumed by the respiration of plants and animals in the field. Not that all these other processes are not important, for indeed they are necessary to the proper functioning of the biosphere, but only a little more than 1 percent of the total incident energy ends up in new plant material. Other estimates of the net productivity of various vegetation types are:

Vegetation type	percent productivity
Tropical rain forest	1.4
Perennial grass–herb field	1.05
Coniferous forest	0.9
Deciduous temperate forest	0.4
Temperate lake	0.3
Desert	0.03

Animals grazing on the primary production convert only about 10 to 15 percent of the energy stored in plant material into animal tissue, and man eating the animals converts only about 1 percent of this energy stored in animal tissue into human tissue. The total conversion process from sunlight to plants to animals to man operates at an overall efficiency of about 0.001 percent.

Energy balance of organisms. Organisms utilize heat energy as well as light. All plants and animals must remain in reasonable energy balance. A plant leaf has a temperature that depends upon the amount of radiation absorbed, the flow of air over its surface, and its rate of transpiration, or gas exchange. The temperature a plant leaf assumes for any set of environmental conditions is of great importance to the plant, since all chemical reactions, including photosynthesis, are influenced by temperatures. A plant is coupled to its environment through the exchange of energy, gases, and nutrients.

A warm-blooded (homeothermic) animal remains in energy balance with approximately a constant body temperature. It moves about in its environment in such a manner that the amount of radiation it absorbs, the amount of energy it exchanges by convectional heating or cooling, and the quantity of energy it consumes by respirational water loss and evaporative cooling are such that its body temperature remains within a narrow range. A cold-blooded (poikilothermic) animal, on the other hand, has much less control over its body temperature. It nevertheless seeks the combination of radiation, air temperature, wind speed, and humidity that will result in an energy flow compatible with its body-temperature limits. Each and every animal in the world, depending upon its coloration, body size, shape, quantity of thermal insulation (fat, fur, or feathers), metabolic and water loss rates, and preferred body-temperature range and limits, has a well-defined climate space within which it must live in order to survive. Each species is restricted to its particular climate space as defined by its physiology and general body characteristics. Many animals will live in a somewhat restricted climate space, but none can live beyond its maximum climate space limits. The animals of the world are distributed accordingly (see DISTRIBUTION OF ORGANISMS).

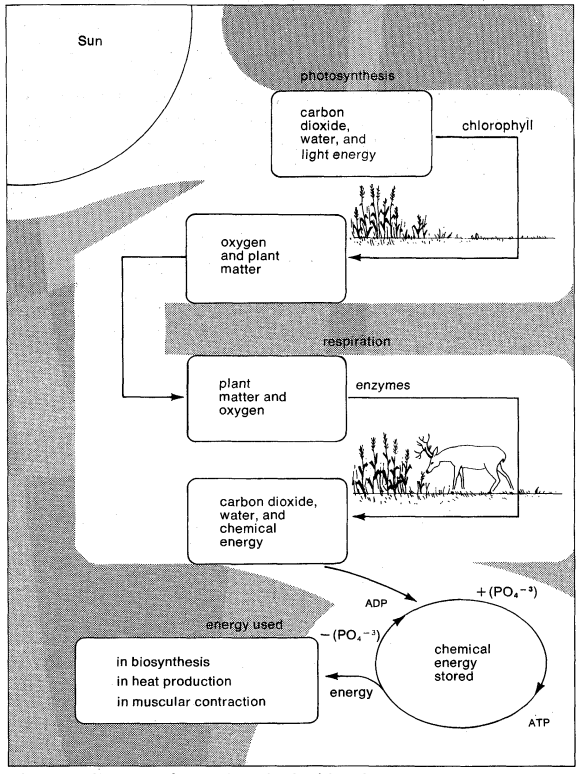

Figure 3: Energy relationships in the biosphere.

CYCLING OF MATTER IN THE BIOSPHERE

The general pattern of chemical cycles in nature. All life depends upon the cycling of matter (nutrients and water), as well as upon the flow of energy. Clearly, no organism can grow, propagate, and continue its kind for millions of generations without replenishing the elements that support it. Like birth and growth, death and decay are rules of the living landscape. Even the purely physical world has its cyclic processes of evaporation and condensation of water and the rise and erosion of rocks. In contrast to the unidirectional flow of energy through the ecosystem, whereby sunlight is absorbed by plants and heat is emitted to space at every conversion of energy from the eaten to the eater, any living and most nonliving entities emerge from the surface of the Earth only to return to their original point of origin in one form or another. Such a movement is called a biogeochemical cycle, in reference to the biological and geological phases of chemical substances, impelled by the Sun's energy.

All organisms contain water and utilize carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur in order to form carbohydrates, proteins, fats, lipids, and other structural materials. Most elements are obtained by plants through compounds such as water, H_2O; carbon dioxide, CO_2; nitrate, NO_3; ammonia, NH_3; sulfate, SO_4; and hydrogen sulfide, H_2S. Oxygen is taken in by animals

through respiration, bound up in organic products, and converted to water, in which form it is eventually returned to the environment. Plants utilize soil and water and, through photosynthesis, return oxygen to the air. Phosphorus, which is so desperately needed by organisms that its abundance or lack often limits populations, does not cycle easily in the ecosystem. Eutrophication is a condition of lakes that results from phosphorus enrichment of the water. Much phosphorus is lost from soils by erosion, and the sediment deposits in the bottom of the ocean keep phosphorus out of circulation for extended periods. Nitrogen, the most abundant of atmospheric constituents, is a relatively inert gas that most organisms cannot use directly but that is essential to life. Fortunately, certain species of bacteria and some blue-green algae are able to utilize gaseous nitrogen that diffuses into the soil from the atmosphere. These soil organisms convert nitrogen (N_2) into ammonia (NH_3). Some plants utilize the ammonia directly, but most depend upon the oxidation of ammonia to nitrite (NO_2^-) and then to nitrate (NO_3^-) by other soil bacteria before it is absorbed by plant roots. This process is known as nitrification.

The mixed blessing of rain

Mineral elements such as calcium, sulfur, magnesium, potassium, and boron are taken up in solution from soils by the roots of plants and are returned to the soil by decomposers, organisms that promote breakdown and decay of the dead litter of forests or fields. Although rainwater slowly washes out, or leaches, some minerals from an ecosystem, it also brings in with it some nutrients during the precipitation process. As rainwater runs down mountains and hills it gradually picks up nutrients and makes them available to green valleys below. When man cuts the forest and exposes the soils to sun and rain, he accelerates the leaching process, often with disastrous consequences. In order to maintain high agricultural productivity he must then apply increasing quantities of synthetic fertilizers to replace those nutrients washed away.

The carbon and oxygen cycles. The total biosphere contains approximately 20,000,000,000,000,000 (2×10^{16}) tons of carbon, mostly in the form of inorganic carbonates in the rocks and oceans, and in organic fossil fuel deposits such as coal, oil, and natural gas. The atmosphere contains 7×10^{11} tons of carbon in the form of carbon dioxide, and the green plants of the world contain 4.5×10^{11} tons as carbohydrates and other organic compounds. The exchange of carbon dioxide with the atmosphere by means of photosynthesis and respiration in plants results in a net annual productivity of the land of about 2.5×10^{10} tons per year and of the oceans of about 2×10^{10} tons per year. During the daytime, photosynthesis often produces a 12 percent drop in atmospheric carbon dioxide in the vicinity of plants, but at night, respiration by soil bacteria, plants, and animals often produces a 25 percent increase in carbon dioxide concentration near the ground.

New plants from old

Man, by burning fossil fuels, releases carbon dioxide into the atmosphere at a rate of 5 to 6×10^9 tons per year, which should increase the atmospheric concentration by 2.3 parts per million (ppm) per year; in fact, the increase is only 0.7 ppm per year. Much of the carbon dioxide released from fossil fuels may have gone into the oceans, and it is possible that a considerable fraction has been bound up in new plant growth. (This is not unlikely, since photosynthesis increases correspondingly, for most plants, with an increase of carbon dioxide concentration in the range of 300 to 400 ppm; only when the concentration approaches 1,000 ppm does the photosynthetic reaction rate approach saturation.) It would seem that man is inadvertently fertilizing the land and ocean by releasing to the atmosphere the carbon dioxide bound up in fossil fuels.

Carbon dioxide is extremely soluble in water. It is not surprising, therefore, that the oceans play a significant role in the global distribution of carbon dioxide and that rainfall sometimes contains about 0.3 cubic centimetre of CO_2 per litre of water. Carbon dioxide combines with water to form carbonic acid (H_2CO_3), which dissociates into hydrogen ions (H^+) and bicarbonate ions (HCO_3^-); the bicarbonate ions, in turn, dissociate into hydrogen and carbonate ions (CO_3^{--}). These reactions can be expressed:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2H^+ + CO_3^{--}.$$

These reactions are readily reversible, the direction depending upon the concentration of the components. The amount of carbon present as bicarbonate or carbonate depends upon the alkalinity or acidity (pH) of the water. If the water is alkaline, more carbon is present as carbonate than if the water is acid. High amounts of dissolved carbon dioxide in water produce high plant productivity (*e.g.*, algal blooms), but often this results in higher respiration, depleted oxygen, and subsequent fish kills. Acidic waters usually have low productivity.

Another gas of enormous significance to life is oxygen, which is cycled between the lithosphere, the atmosphere, and the biosphere. Plants are primarily responsible for the presence of atmospheric oxygen through the photosynthetic process. Oxygen in metabolism and in the production of energy-rich phosphorus bonds provides the power for all higher forms of life. Although oxygen is utilized within cell constituents such as mitochondria for the release of energy and the synthesis of ATP, other cellular bodies called peroxisomes appear to protect the cell from too much oxygen, which would result in destruction of the cell. Hence it seems that life has had to evolve within an environment in which some organisms utilize oxygen, some must be protected against oxygen, and some generate oxygen, all at the same time.

The nitrogen cycle. The atmosphere contains nearly 80 percent nitrogen. Ironically, most green plants are unable to use free nitrogen and must have it converted to soluble compounds of nitrogen, such as ammonia (NH_3), nitrite (NO_2), or nitrate (NO_3), which can then be taken up by their roots and the nitrogen converted into amino acids and plant proteins. The Earth's primitive atmosphere apparently contained ammonia, so the necessity for conversion of nitrogen into soluble products (nitrogen fixation) did not arise until more recently. Nitrogen fixation, or nitrification, is performed by a few species of micro-organisms. The reverse process—by which soluble compounds of nitrogen are reduced to molecular nitrogen (N_2)—is called denitrification and is accomplished by other micro-organisms. Micro-organisms that decompose the remains of dead plants and animals reduce amino acids containing nitrogen to ammonium ions and other products. This process is known as ammonification. The rate at which nitrogen fixation removes nitrogen from the atmosphere is almost balanced by the rate at which denitrification returns nitrogen to the atmosphere. (The large-scale and widespread use of fertilizers by man may be upsetting this balance, however.)

The indispensability of micro-organisms in the movement of nitrogen

Nitrogen is a versatile element in living processes because of its ability to form many different kinds of compounds and to release energy when moving from one compound to another. Nitrogen is cycled in nature from reduced inorganic compounds to oxidized compounds by atmospheric oxygen, with the release of energy; when oxygen is unavailable, oxidized nitrogen compounds can in turn oxidize organic compounds. Two main types of bacteria and algae participate in nitrogen fixation. One lives in a mutualistic partnership (symbiosis) with higher plants; the other is a free-living form that derives energy directly from sunlight and indirectly from plant materials. *Rhizobium* species, the most abundant of the root-nodule symbiotic bacteria, are found on the roots of legumes, alders, and buckthorns. Legumes, which include peas, soybeans, and alfalfa are often used in agriculture to increase the productivity of the land. Symbiotic nitrogen fixers seem to have a critical need for certain trace elements such as molybdenum or cobalt. When these are absent, the bacteria do not function effectively, and the rate of nitrogen fixation is reduced.

Symbiotic micro-organisms occur only in terrestrial ecosystems as far as is known. Among the nonsymbiotic nitrogen fixers are aerobic soil bacteria such as *Azotobacter*, which supply fixed nitrogen in grasslands and in marine and other ecosystems where symbiotic micro-organisms are absent. Blue-green algae are an important source of fixed nitrogen in rice paddies and in aquatic

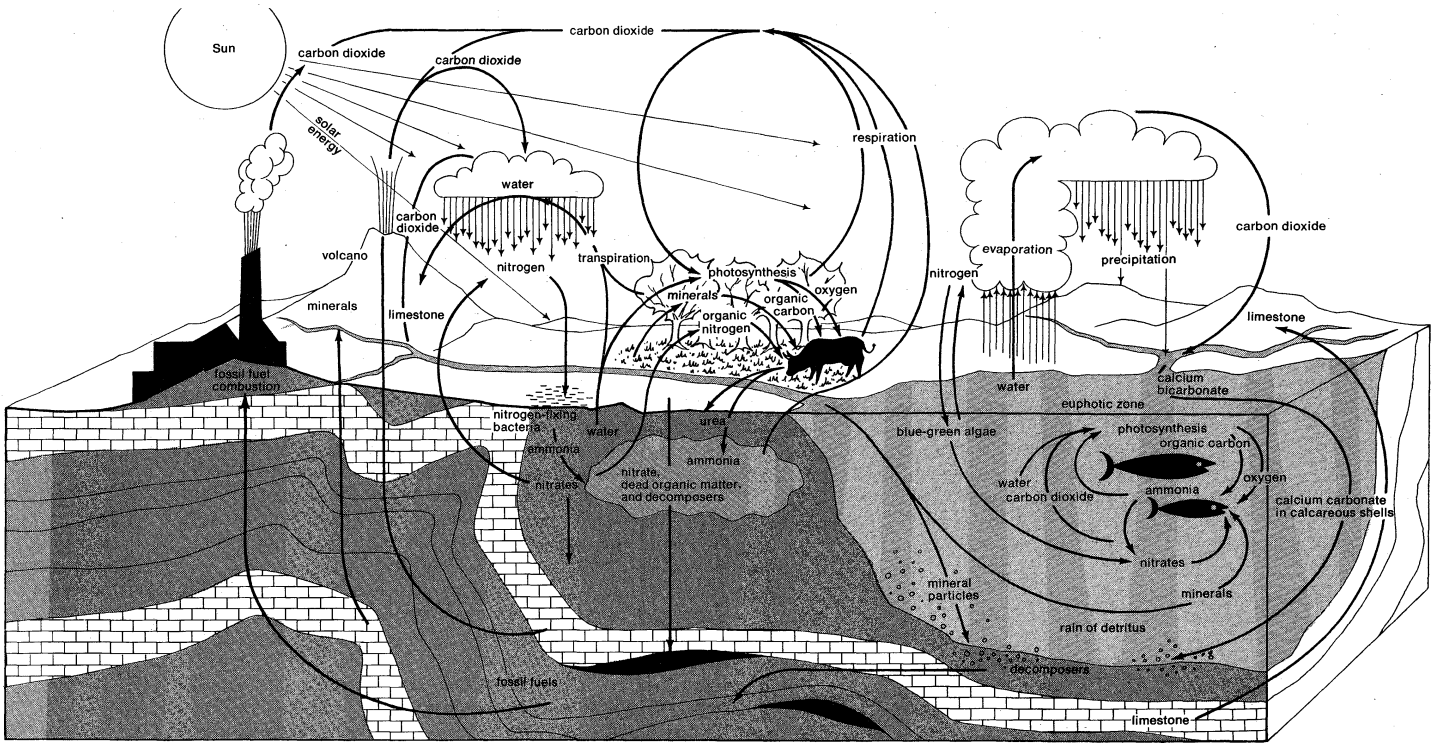

Figure 4: Major cycles of the biosphere.

systems. One free-living nitrogen-fixing bacterial genus lives only without oxygen is *Clostridium*.

A group of micro-organisms known as autotrophs function without an organic source of energy by oxidizing various forms of soluble nitrogen compounds. *Nitrosomonas* species oxidize ammonium to nitrite with the release of water and energy. *Nitrobacter* species, in turn, oxidize nitrites to nitrates with the release of energy. Nitrates are highly soluble in water and are easily taken up by roots and assimilated by plants.

Pseudomonas species and some fungi use nitrate as an oxygen source; they draw on the energy available in glucose and phosphate to convert the nitrate to molecular nitrogen and then to nitrous oxide and nitric oxide. Some denitrifiers reverse the process only partway by reducing nitrate to nitrite or ammonia. Denitrification proceeds best under anaerobic conditions, since whenever oxygen is present it is more efficient for organisms to use it than to use the oxygen bound up in nitrate ions. This suggests that denitrification would occur best in the soil and in deeper portions of the waters of the world. From the enormous amount of nitrogen fixed annually, however, about 92,000,000 tons, it is obvious there must be enormous anaerobic reserves in the world in order to return this amount of nitrogen to the atmosphere each year. It is entirely likely that man's use of fertilizers is causing more nitrogen fixation to occur than the biosphere can return through denitrification, in which case there would be a gradual buildup of nitrates, nitrites, and ammonia.

The nitrogen cycle is obviously extremely complex and very important in the balance of the biosphere. Many things about it are not yet clearly understood.

Mobile sulfur in the biosphere

The sulfur cycle. For materials to cycle easily throughout the biosphere they must be not only water-soluble but volatile as well. In addition to carbon and nitrogen, sulfur is a highly mobile constituent of the biosphere. Furthermore, all proteins incorporate sulfur in their molecular structure to form bonds that give them well-defined three-dimensional shapes. Just as carbon and nitrogen are reduced during the formation of proteins, so also is sulfur. In distinction to carbon, however, which requires green plants and sunlight for reduction, nitrogen and sulfur reductions are most often accomplished anaerobically by micro-organisms. Most of this anaerobic activity occurs in oxygen-deficient soils, bogs, and swamps. The sulfur cycle is not nearly so well understood as are the carbon and nitrogen cycles.

When an organism dies and decays, much of its incorporated sulfur is returned to a mineralized state by bacteria and fungi, but some is reduced under anaerobic conditions directly to sulfides, such as the evil-smelling hydrogen sulfide (H_2S), some of which escapes to the atmosphere. Man's burning of fossil fuels sends massive quantities of sulfur dioxide into the atmosphere as a pollutant. When the sulfur dioxide combines with water in rainfall it forms dilute sulfuric acid (H_2SO_4). Inorganic sulfate (SO_4), formed by the decomposition of organic matter, is readily soluble in water and serves as a further source of sulfur to plants and animals. Sulfate is reduced under anaerobic conditions to elemental sulfur or to sulfides by bacteria. Large quantities of hydrogen sulfide occur in the anaerobic (deeper) portions of aquatic ecosystems. The anaerobic bacteria utilize the sulfate in metabolic oxidation much as bacteria denitrify nitrate and nitrite.

There are sulfur-utilizing bacteria that play the same role with sulfur compounds as nitrifying bacteria do with nitrogen compounds. These include the green and purple photosynthetic bacteria; the green bacteria oxidize sulfide to sulfur and the purple bacteria generate sulfate.

Sulfur precipitates in lake waters as iron sulfide in the presence of iron under anaerobic conditions. Some sulfide is insolubly bound with iron in the bottom muds of lakes, bogs, swamps, etc., where other elemental metals, such as copper, cobalt, cadmium, and zinc, also become bound as precipitates.

The vital role of water

The water cycle. Water is a ubiquitous and unique substance necessary for life on Earth. Water in liquid and vapour states in the atmosphere regulates and ameliorates the climates of the Earth. Strictly speaking, water conforms to a gaseous cycle, but because of its great importance in the biosphere it is here discussed separately. Life began in the oceans, evolved in the waters of the world, and spread upon the land; yet life has always remained dependent upon the availability of water. The relative distribution and availability of water on the land determines the vegetative character of the landscape. Water erodes and sculpts the rocky surface of the Earth, transports nutrients and sediments, and forms the lakes, swamps, rivers, and seas. Sunlight evaporates water from land and sea into the atmosphere, where it is transported

with the global circulation of air and precipitated onto the surface as rain or snow.

The topography of continents and islands affects very strongly the precipitation pattern of the Earth. Windward mountain slopes are wet, as warm moist air rising into cooler air expands and condenses its moisture as rain or snow. The leeward sides of mountains are dry, since the moisture has already been wrung from the air on the other side of the divide, and the air moving down the leeward face compresses and warms, thereby retaining whatever moisture it still has. Semi-arid regions with sparse vegetation often occur to the leeside of mountain ranges. Cold polar ice caps have relatively low precipitation since very cold air can contain little moisture. Deserts generally occur where the air is stable. The trade winds move toward the Equator from cooler latitudes, picking up moisture and heat as they go; hence the coast lines of southern California, Mexico, and Chile are relatively dry, and the equatorial regions are wet.

Water has amazing properties, particularly when compared with most other forms of matter known in nature, that make it chemically and physically suitable for life. It is a liquid at ordinary temperatures, contracts on cooling down to 4° C (39° F), then expands on further cooling to the freezing point at 0° C (32° F). Solid water, or ice, is thus less dense than liquid water and floats on water. The fact that water expands on freezing makes it a powerful agent for the breakdown and fragmentation of rock into soil particles. Water warms up less rapidly and in turn cools more slowly than other substances. Lakes and oceans, therefore, have a different temperature from the adjoining landmasses, with a seasonal lag. Water tends to hold dissolved material in solution and also has the greatest surface tension of any known liquid. Moist air is less dense than dry air and rises above it, contributing to the weather dynamics of the atmosphere.

The global distribution of water

Taken over the world as a whole, the horizontal distribution of moisture must always add up to zero—the amount of water falling as precipitation is equal to the amount of water vapour taken up by evaporation. For any single region of the world, however, there may be a water surplus or a water deficit, differences that are theoretically balanced by ocean currents or river runoff. The Northern Hemisphere, for example, has an excess precipitation over the Southern Hemisphere, and the difference is redistributed by means of ocean currents. The drier the continent, the smaller the fraction of the annual precipitation that runs off. Australia and Africa, as a whole, are relatively dry continents in which large areas are covered by deserts and more than 75 percent of the annual precipitation is lost through evaporation.

In order for evaporation to occur, two conditions must exist. There must be energy available, which is derived largely from sunlight, and there must be a water vapour gradient from a moist surface to air that is less moist. In other words, heat and dryness aid evaporation.

Interrupting this cycle of simple precipitation and evaporation are the organisms of the world, which divert water for their own use. Water relationships are most dramatic in land situations. Soils hold considerable amounts of water. On the average, worldwide, this may be a reserve of about ten centimetres (four inches) in depth. In some parts of the world, such as North Carolina, where soils are thin, the total amount of water held in the soil may not exceed five centimetres (two inches), but in the deep volcanic soils of east Africa as much as 50 centimetres (20 inches) is held in the soil.

Plants take up water largely through their roots and evaporate water through the leaves in a process known as transpiration. A green plant may transpire three to five millimetres (about ⅛ to ⅕ inch) of water a day, depending upon the amount of energy available. Maximum rates in sunny, hot, irrigated regions may reach eight millimetres (⅓ inch) a day.

An important ratio for plants, known as the transpiration ratio, is the amount of water used to the weight of accumulation of dry matter in the plants. For corn (maize) it is 317 grams of water per gram of dry weight, for cotton 568, brome grass 880, deciduous trees 825, and evergreen trees 140. Taken over a whole growing season, although highly variable among crops, one can estimate that a production of 20 fresh-weight tons of crop will require 2,000 tons of water from the soil. Of the 20 tons of crop only about three tons comprise water molecules utilized in photosynthesis, the remainder being evaporated as transpiration.

In addition to their physiological need for water, large numbers of terrestrial animals use bodies of water as sanctuaries. The eggs of many insects are laid in water, larvae live in water, and the adults emerge from ponds or rivers to spend their adult lives on the land. Amphibians occupy a narrow zone between land and water, in which they can move from the harsher, more variable climate of land into the milder, more comfortable conditions of water. All land animals give off moisture when they exhale, and some animals pant or sweat to evaporate moisture and thus cool themselves.

The sedimentary cycles of essential minerals. While many elements give rise to gaseous compounds that are significant parts of biogeochemical cycles, some elements in the biosphere cycle primarily through water transport and sedimentation in bodies of water. For any soluble but nonvolatile compound a natural cycle is only possible when life is involved, since otherwise the compounds wash from the land to the rivers and oceans, where they remain in the sediments. Green plants pick up the compounds in the nutrient-rich soil water and convert them into plant cells where they may be passed to animals in the food chain; they eventually return to the soil through death and decay of plants and animals. Some compounds soluble in water are carried into the atmosphere by water evaporation and returned to the surface in rain.

The transport of essential minerals

The elements calcium, potassium, silicon, and magnesium each have important biological roles in the biosphere. Magnesium, for instance, is an essential element in the chlorophyll molecule, and calcium and silicon help form the hard parts of shells, bones, and teeth of animals. Iron, manganese, and sodium are present in organisms in minute, or trace, amounts, but nevertheless are vitally important. As mentioned earlier, phosphorus is probably the most important element among those that form nonvolatile compounds. A deficiency of phosphorus is most often responsible for poor crop production. Free phosphorus as such is not found in the atmosphere. If it were not for green plants absorbing its salts from the soil and transporting it to the leaves, phosphorus would not rise above the surface of the ground. So it is also for trace elements such as iron and manganese. Some trace elements such as vanadium, cobalt, nickel, and molybdenum are found primarily in aquatic plants, since they accumulate in bottom sediments.

Phosphorus is soluble in acidic waters; under special environmental conditions it is bound up as calcium phosphate or iron (ferric) phosphate. Phosphorus is extremely scarce in the geosphere, concentration normally being a few parts per thousand million. But great supplies of phosphorus are found in bird guano, the excrement of fish-eating gulls, cormorants, pelicans, and penguins, on the islands and in the ocean sediments off the coast of Peru. Artificial, or chemical, fertilizers are made from phosphate rocks and marine phosphates. Great quantities of these phosphates are used in detergents and wash into lakes and streams. Such phosphate enrichment creates rapid and excessive growth of algae, especially the blue-green algae. Increased decay and respiration result in oxygen depletion of the water and the suffocation of more sensitive species of fish, usually the game fish. This enrichment process, called eutrophication, usually results in a simpler animal and plant community, a shortening of the food web, and a less stable ecosystem.

The problem of phosphate enrichment

MAN'S PLACE IN THE BIOSPHERE

Man as an exploiter of nature. For perhaps 3,000,000 years or more, man lived in reasonable balance with the organisms about him. Parasites, disease, and the difficult search for food kept man's numbers low and he was on equal footing with other animals within the natural system. Although he utilized the plants and animals that

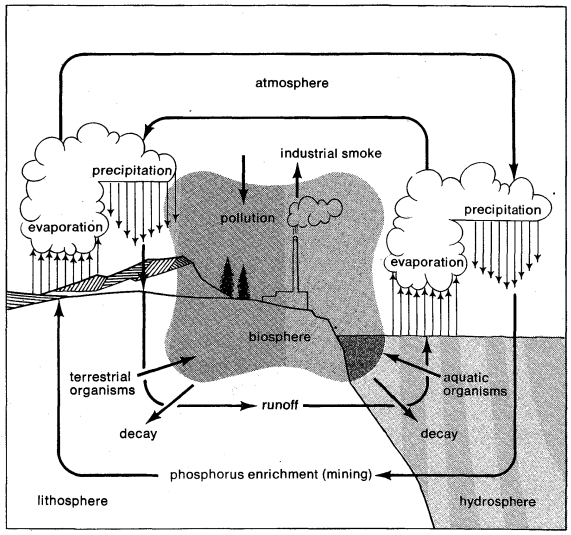

Figure 5: The intensive cycling (eutrophication) of phosphorus, nitrogen, and sulfur in the biosphere.

surrounded him, the extent of his depredations was limited and reversible since his numbers were few. More than 10,000 years ago, however, man learned to select and cultivate plants, a progressive step that helped free him from the labour of bare subsistence and allowed him to engage in creative endeavours and to congregate in ever larger groups for mutual benefits. His heightened capacity for reasoning, his memory, and his ingenuity led him to improve still further his well-being. It was then that the consequences of man's activities began to extend beyond the borders of his limited fields and towns. He may have extinguished such Pleistocene animals as the woolly mammoth. His use of fire on the prairies appears to have maintained grasslands where otherwise trees might have grown. The smoke from these fires and from extensive slash-and-burn agriculture filled the skies with haze long before photochemical smog ever stung his eyes. By his ingenuity and inventiveness he learned to release energy by burning coal and oil, to manufacture machines that would greatly amplify the labours of his hands, to work metals and to forge new alloys, while at the same time selecting and cultivating better crops and improving his domesticated stock of animals. These various skills and practices eventually encouraged the world-wide proliferation of man.

The exploitation of resources

Man discovered the benefits of mining the great ore deposits, pumping the reservoirs of oil, digging the rich coal beds from carboniferous strata, plowing and planting the prairies, cutting the forests, and generally helping himself to the abundant and apparently limitless resources of the world. In the process he became sedentary rather than nomadic, he improved his health, extended his life-span, reduced his working time, added leisure hours, lived more comfortably, increased the abundance of his food supply, and increased in numbers exponentially (10 to 100 to 1,000 . . .). He could hunt, fish, harvest, and exploit without concern for the consequences to the environment. Then suddenly, very suddenly, within the most recent decades of man's time on Earth, he began to realize that resources were limited and hastily instigated some attempts to conserve the environment. Still, his behaviour generally belied any conviction that he should live in a prudent society. Man's population still doubles in number every 35 years; his demand for domestic products doubles every 14 years; and his consumption of energy doubles, in the United States, every 8.5 years and worldwide at a slower, yet rapidly increasing, rate. Man manufactures exotic products that are generally nondegradable (*i.e.*, they do not decay) but are carried by the sedimentation cycle to accumulate in the bottoms of lakes, rivers, and oceans or are piled in refuse heaps or are strewn about the landscape. Considering that these products consume resources that are nonrenewable, man's failure to recycle these materials may be seen as an act of irresponsibility toward the needs of future generations. The careless and greedy consumption of resources by any group of people cannot be justified in the context of the ultimate well-being of mankind.

When the first men landed on the Moon in July 1969 and reported during the voyage their views of the planet Earth, seen as a lonely, isolated, utterly self-dependent satellite of the Sun suspended in space, the ordinary citizen began to realize how limited and finite his space and resources really were. The biosphere was seen indeed as a very thin shell, protected from Sun and space by a veil of air and supported by a fragile and disturbed rocky crust. Coupled with this new appreciation was the realization that the world's population was expanding at an alarming rate, a rate that, if continued for another century, almost certainly would mean mass starvation, pandemic outbreaks of disease, and general degradation of society. It no longer was self-evident that man could manage such a complex society, keep it in good health, and maintain a high standard of living indefinitely.

Man as a manager of nature. If man expects to have a future on earth, it is clear that he must use his resources in the most prudent manner possible. Conservation does not mean hoarding; it means the wise management of resources to provide a continuing supply for a long time into the future. It suggests continual renewal of a resource and recycling, reusing, and recovering the products produced. Conservation of a natural area may mean its maintenance in a natural state for purposes of enjoyment or study in order to understand and appreciate the complexities of ecological laws. Man, of course, must continue to reserve forests for timber and other lands for agricultural production. But he must also set aside some regions for recreational purposes. The best use of each resource must be carefully determined. Once land is abused, it is very costly to reclaim it and put it to more suitable use. It is nearly impossible, for example, to return urban or industrial land to agricultural land use.

Man is not only a part of his ecosystem but is the most powerful force within it. He is simultaneously the most precious resource within the biosphere and the most dangerous. In many parts of the world the human population already exceeds the capacity of the land to feed it. By modern standards two-thirds of the world's population is ill housed, ill fed, and ill clothed. Through clever management of resources, including the management of his own numbers, man must improve the standard of living for all peoples or risk the slow degradation of mankind.

The growing need for new sources of energy

Man must further devise new energy sources to replace the coal, gas, and oil reserves that will have been exhausted, perhaps within 200 years. Nuclear energy is one of man's great hopes for the future; failure to achieve its potential in the form of a breeder reactor as a positive energy source would be one of the great tragedies in human history (see CONSERVATION OF NATURAL RESOURCES).

Man's ability to grow and survive in a complex world depends upon his ability to develop more productive, more adaptable, and more resistant strains of domesticated plants and animals through scientific principles of breeding (see ANIMAL BREEDING; PLANT BREEDING).

Diets in various parts of the world are very different from one another. Eastern peoples eat primarily plant foods, whereas Western peoples consume a considerable amount of meat. Grain consumption in India is about 350 pounds per person per year, of which 320 pounds per person per year are eaten directly. In the U.S., 1,700 pounds per person per year of grain is consumed, but only 200 pounds per person per year is eaten directly. Most of the grain is fed to cattle and indirectly is consumed by man as meat. Animals are such an important part of the Western diet that a great deal of selection and breeding has resulted in highly productive stock. Food is not the only reason man has selected and bred animals, for cattle, horses, and dogs are used for draft purposes, sheep for wool, goats for fleece, and cats and dogs for companionship.

Man's phenomenal success with breeding crop plants for

production around the world has become known as the "green revolution." Along with developing new hybrids it was necessary to produce a revolution in techniques of fertilizing, harvesting, storing, distributing, and marketing. Although man can come close to feeding the present world population, the chances of continuing to do so in the future are diminishing. If the world population ever approaches 12,000,000,000 (in 1971 it was about 3,706,000,000), it is likely that mass starvation will occur in many underdeveloped countries. Man will need to make the fullest use of potential food resources, both marine and terrestrial, if he is to support a larger global population than now exists.

Man has successfully selected specific strains of domesticated plants and animals and, in principle at least, can do the same with respect to the human race. Racial groups of man differ in various ways, and yet within each racial group there is a vast amount of diversity in, among other things, facial features, body build, height, shape, physical coordination, and mental traits. Racial groups, of course, overlap a great deal with respect to genetically determined traits that affect such things as blood substances, serum proteins, hemoglobin, and enzymes.

Average body sizes of man vary enormously, from the Pygmy to the tall Watusi. Facial features of Caucasians differ from Orientals. Some of these differences are simply the result of isolation of peoples, while other features have resulted from selective pressures of an environmental nature. Dark-pigmented skin is common in the tropics and serves to filter out excess ultraviolet radiation, some of which is required for the production of vitamin D by the skin. (Too much ultraviolet radiation, however, can result in excessive vitamin D production and calcium deposits that can cause crippling.) In temperate climates, on the other hand, the slanted rays of the Sun irradiate the surface with much less intensity, and inhabitants of such regions benefit from transparent skin, which allows sufficient amounts of vitamin D to be generated. It is possible that peoples whose members have long limbs and slender bodies have an advantage in the tropics over short stocky peoples because they can dispel heat quicker. By contrast the Eskimo has a thick, heavy-set body that seems better adapted to conserve body heat in the Arctic climate.

The mass production of men

Man could select and breed for particular characteristics by working with each consecutive generation of persons, but the process would be slow. Much more efficient and more revolutionary ways of selecting for specific human types now loom as possibilities. One method, nuclear implantation, has been successful in remaking amphibians. Unfertilized eggs are removed from the oviduct of a female, the nuclei of these removed and replaced by the nuclei of body cells of chosen animals. The eggs are then replaced in the oviduct of the females from which they came, the embryos develop, and normal birth occurs. The result is the replication many times over of identical animals, each having the traits selected for; the entire procedure is accomplished within one generation. Whether man can do the same with his own species is a moot point. To most people the idea is repulsive, yet the fact remains that man is today on the threshold of guiding his own evolutionary destiny and may perhaps someday be forced to take such measures.

Epilogue: the prospect. The point has been made abundantly regarding the untoward effects of man's activities on the biosphere. Past centuries of public and private greed may now cost man centuries of deprivation. Hope diminishes with each decade. There is a persistent personal unconsciousness regarding the numerous individual actions that affect nature; these seemingly insignificant events, when multiplied by man's numbers, constitute a tremendous assault on the biosphere. As a civilization develops, its technology improves and the needs of its citizens become displaced by wants, simple unalloyed desires for the trappings of technology.

The need for recognition of personal responsibility

The burden must be shared by both private and public sectors of society. Industries and institutions, which historically are heavy despoilers of the environment, must be held accountable for their actions; they must realize their responsibility to the continuance of the biosphere. But man as an individual must learn to live with fewer unnecessary items, so as to drain less heavily on the Earth's limited resources.

(ed.), *Man's Role in Changing the Face of the Earth* (1956), a record of a symposium, consisting of several definitive essays of remarkable insight into problems of the biosphere.

(D.M.G.)

Biotic Interactions

In a biological community no species lives in isolation from other species. Plants grow together in spatial patterns determined in part by competition and are fed upon by characteristic herbivorous animals, which in turn serve as food for carnivorous animals. Both plants and animals are attacked by parasites. Animals interact with each other competitively and sometimes beneficially. Some of these interactions are temporary, casual, and of minor importance, whereas others are permanent, vital, and of major significance.

Biotic interactions may occur between members of the same species (intraspecific interactions) or between two or more species (interspecific interactions). They may involve nutritional benefits, space in which to live, shelter or protection, transport, or reproductive capability. Many interactions are highly specialized and complicated, involving adaptive changes in structure, function, behaviour, and ecology. Some create negative effects upon the interactants, reducing survival or reproductive success; other interactions produce positive effects, increasing survival or reproductive success. In some cases, members of an interaction are apparently unaffected.

Biotic interactions are significant not only because they influence individual species but also because they constitute the principal stabilizing, connective linkages among the various species contained in a biological community. In a general sense, species in a biological community persist in relative harmony because of biotic interactions, despite individual gains and losses. As a consequence of this web of interactions, the community as a whole persists, with all species ultimately contributing to its continuation.

INTERACTIONS WITHIN A SPECIES

The individuals in a population often interact with other members of the same population. Such intraspecific interactions can be either negative, as in competition for limited resources, or positive, as in group protection, parental care, and social integration. Because these matters are of such great concern in biology, they are generally treated under behavioral studies; for details see the article SOCIAL BEHAVIOUR, ANIMAL.

Negative interactions. Intraspecific competition provides the ultimate force limiting the abundance of a species in a community. Natural enemies may be present or absent, but others of the same species are always present, providing the competition that insures against overexploitation of available resources and the irreversible destruction of a community due to overpopulation.

Cannibalism, fighting, and territorial defense are some of the overt methods by which competition manifests itself. Many animals, both herbivores and carnivores, exhibit cannibalism when overcrowded, and some are cannibalistic whenever they contact another of their own

species. The codling moth caterpillar in the apple is of the latter sort; hence, there is never more than one worm per apple. Mice and rats, when crowded, undergo psychological disturbances leading to excessive fighting and litter destruction. Territoriality, the dividing up of resources, mostly space, is a common means of defense against overcrowding. It differs from simple aggression in that, instead of involving individuals against individuals, it involves groups of individuals, breeding pairs, families, or herds. Migration away from overcrowded conditions is another common intraspecific response. It may be individualistic, with each member of a population going its own way, or it may involve mass flight, such as occurs with locusts, butterflies, and birds (see MIGRATION, ANIMAL).

Migration

Positive interactions. On the positive side, numerous interactions among individuals of the same species lead to clustering, aggregation, swarming, herding, and, ultimately, development of social groups. Tent caterpillars live together in large colonies, foraging together in masses and resting at night in communally spun silk tents. Isolated caterpillars are unable to survive; only the aggregation thrives. Parental care provides the basis for many aggregations of like individuals. Parental protection of the egg, as occurs in birds, some insects, and some fish, is the simplest form of care. Feeding and protection of the young is a more advanced level of care. Living together in social groups, in which one reproductive adult, the queen, is served by her own progeny, is the ultimate in parental care. In such cases the offspring remain with the parents, providing protection for the colony, care of younger members, nest building and cleaning services, and food gathering and storage. Division of labour to attend to these services is common, particularly in insect societies.

Some species live in habitats where—because of small size and weak flight ability, limited and scattered resources, and relatively low population densities—the chances of the mature sexes meeting for reproductive purposes are low. One method for overcoming this hazard is the phenomenon of autoparasitization, in which one sex lives as a virtual parasite on the other, an unusual form of intraspecific interaction. Certain insects exhibit this mode of life: the males of scale-insect parasites develop as hyperparasites on their own females. Some deep-sea angler fish also employ this habit, with the very small adult male living in permanent attachment to the body of the larger female. In such situations the association of the sexes is facilitated, and reproduction in hazardous environments is insured.

THE RANGE OF INTERSPECIES ASSOCIATIONS

Positive, negative, and neutral effects

One system of analyzing two-species interactions assigns positive (+), negative (−), or neutral (0) value to the interactants on the basis of how they affect each other. If the survival or reproduction of a species is enhanced, it is a gain and given a plus value. If survival or reproduction is reduced, it is a loss and given a minus value. If survival or reproduction is unaltered and the species unaffected, it rates a zero value. From such a rating scheme, a two-species (A, B), three-effect (+,0,−) table can be constructed in which the bases for association (symbiosis) of all biotic interactions can be defined (see table).

species A (large, strong) \ species B (small, weak)	+	0	−
+	+, + interdependence (obligative mutualism) protocooperation (facultative mutualism)	+, 0 commensalism	+, − herbivory predation
0	0, + commensalism	0, 0 neutralism	0, − amensalism (competition)
−	−, + parasitism parasitoidism	−, 0 amensalism (antibiosis)	−, − mutual antagonism

Mutualism (+,+) is an association of two different species that results in mutual benefit or gain. Obligative mutualism requires that both members interact together, or neither survives. Facultative mutualism, or protocooperation (+,+), refers to a less-rigid association in which one or both members can survive in the absence of the other. In commensalism (0,+) one member benefits while the other remains unaffected. Cases in which the small or weak species is unaffected while the larger or stronger benefits, especially in nutritional relations, is sometimes called allotrophy (+,0).

In parasitism (−,+) the smaller organism benefits at the expense of the larger. Many parasites are microorganisms that cause disease, but not usually the death, of the host. A special case of parasitism, which involves insects that do kill their hosts, is called parasitoidism. Predation (+,−) refers to an association in which a large or strong animal consumes a small or weak animal. Herbivory (+,−), the consumption of plants by animals, is generally comparable to predation. Amensalism (0,−) occurs when one organism loses while the other organism is unaffected. Unilateral competition, to which the term competitive exclusion refers, and antibiosis, in which one species remains unaffected while a competitor is deprived, are examples of amensalism. In antagonism (−,−) both species lose or are harmed. Neutralism (0,0) is an association in which neither species is affected by the presence of the other, the two species sharing a localized resource or habitat.

The following sections will provide selected examples of the various forms of biotic interactions, based on the definitions above. The emphasis rests on the pattern of the interactions rather than the symbiotic associations themselves.

CONSUMPTION: ORGANISMS EATING ORGANISMS

Herbivory: animals eating plants. Herbivory, the consumption of plants by animals, constitutes one of the most important classes of biotic interactions. It serves as the main connection between all plant and animal life, the basic food association (trophic link) through which the composition, dynamics, and variation of community structure takes place. All higher organisms, primary and secondary carnivores and scavengers—essentially all the remaining links in the community food chains and food webs—are more or less dependent on this basic link.

The basis of community food webs

Herbivory is encountered at all levels of animal life, from the smallest to the largest animal, and in all habitats. No plant species is exempt, whether in the Arctic tundra, the tropical forest, or the desert and whether on the highest mountain, along the seashore, or in midocean. It is a reciprocal interaction, or coaction, wherein the number or quantity of plants is altered by the number and consumption rates of the herbivores and in which, conversely, the number of herbivores is limited by the quantity of plants. This coaction, therefore, may approach a state of balance in which the amount of plant material is just sufficient to sustain the number of herbivores associated with it, and the herbivores collectively remove only the surplus plant material produced. The manner in which specific herbivores respond to the results of this interaction is dependent on their food habits. Species that require one kind of plant material are very sensitive to changes in abundance of their preferred food, whereas less-specialized species simply shift their attentions to other plants when the quantity of a given one fluctuates.

The degree of herbivory is rather wide. A plant may be totally consumed, as it is when a protozoan or a fish consumes unicellular planktonic algae. Vital parts of a plant may be eaten, leading to the eventual death of the individual, as occurs when bark beetles girdle a pine tree or when birds eat the tender tips of germinating plants. When only nonvital parts of a plant are eaten—including leaves, twigs, and roots—the plant may be stunted or not affected at all. In the latter case, which is quite common, the herbivore is truly living on "surplus" plant life.

Herbivory is one factor responsible for limiting the

amount of plant life in a community and, therefore, influencing the composition of communities. It serves as an important means of recycling plant tissues back into the nutrient minerals, carbon dioxide, and water from which they were derived and enters into the determination of the numbers and kinds of animals associated with the community.

Many biologists contend that herbivorous organisms rarely influence the abundance of plant life notably, since plants manage to survive, or persist, without noticeable injury in communities, and starvation does not seem to play an important role in the survival of herbivores. Agricultural experience, however, suggests that substantial interactions between plants and herbivores do occur, since plant pests can drastically reduce the growth or productivity of crop plants. Successful attempts to use specific herbivorous insects to control certain weed species (*e.g.*, cactus in Australia or the poisonous Klamath weed in California) and the remarkable recovery of plant populations when an adverse factor is removed (*e.g.*, a pest) or a stimulating factor is added (*e.g.*, nutrients) suggest that herbivore–plant interactions are of critical importance to community composition. Plant–animal interactions are also illustrated in the overgrazing that occurs when deer, protected against predators, increase to such numbers that a plant community is threatened by excessive browsing. Grazing by stock animals, sheep, and cattle is an important factor in the composition of range and pasture lands; if excessive, grazing can actually destroy such communities. A rapid increase in plant growth brought about by excessive nutrient deposition (eutrophication) in bodies of water through runoff of soil fertilizers and discharge of municipal and industrial wastes results in "blooms" of aquatic algae and the disruption of the normal trophic balance between algae and algal feeders.

Herbivores to control weeds

The concentration of a few plant species into large areas, as is the general practice in agriculture, provides a potential for excessive herbivory. Such large tracts of single crops (monocultures) concentrate and augment the numbers of herbivores (when insects, they are usually called phytophages) to the point that massive population outbreaks commonly occur. By contrast, natural communities, which are diverse in species, are much less prone to support pest outbreaks: an expression of the ecological principle of stability in diversity in community life.

Predation: animals eating animals. Just as most plant species are fed on by herbivores, so are most animal species subject to predation by other animals. By feeding upon and reducing the numbers of both herbivores and other carnivores, predators constitute the higher links in the nutritional pathways characteristic of communities. Predators substantially affect the numbers of herbivores and thus influence their impact on plants. When the numbers of predators fluctuate, their effects upon prey and plants vary accordingly.

Quantitative effects of predators on prey

The quantitative effects of a predator population upon a prey population are determined by the number of prey consumed per predator and the total number of predators. In areas where prey are abundant, they become easier to find, more are consumed, and predator numbers increase through augmented reproduction and concentration. As predators increase, they eventually cause a reduction in prey numbers. Eventually, because of the biotic interaction between the two species, the number of predators also declines. This constitutes the predator–prey oscillation characteristic of many animal populations. An example is the cyclical pattern of abundance shown by the lynx and the snowshoe hare in the northern coniferous forests. These species fluctuate with a periodicity of about ten years. Biologists agree that predator density follows and is very likely determined by prey density. The opposite conclusion, that predator numbers determine prey numbers, has been less generally accepted. More commonly accepted are the predator-induced oscillations of insect prey. The biological reason for this is that insect predators commonly attack and destroy immature prey individuals, so that the effects of predation are more important in determining the population status of the prey. Vertebrate predators, on the contrary, seem to concentrate on the weak, sick, or old, the effects of which are less important in the population dynamics of the prey.

Because of the obvious importance of and interest in the mechanics of predation, predator–prey interactions have been the subject of much scientific research. Laboratory and theoretical studies have been made of isolated predator–prey "systems" and of predator–prey "models." The degree to which such systems and models simulate natural predator–prey population fluctuations has been used as a basis for judging the "soundness and realism" of the scientific methods and for "explaining" the process of predation. Simple mathematical expressions have been devised that represent predator and prey numbers and indicate that predators vary in numbers in a smooth, oscillatory manner purely as a result of prey abundance changes, and vice versa. This latter result, that prey oscillate due to predation, is the important new "evidence" that prey–predator interactions are, indeed, reciprocally coupled.

The importance of predation in determining prey abundance and community stability can be illustrated by several examples. When man (a predator) overexploits his animal resources (in effect, prey), they decline in numbers sufficiently to affect subsequent utilization (consumption). Such is the result when fish, whales, sea otters, buffalo, and other animals are excessively hunted. Whales and sea otters have declined drastically; buffalo became exterminated as a wild animal, and grizzly bears, mountain lions, and elks similarly are threatened with extinction.

Predators to control pests

An illustration approaching the point from the opposite side is the employment by man of predators to control pests, a technique called biological pest control. The effective suppression of the cottony-cushion scale pest of citrus in California in the late 1800s by use of an imported lady beetle, *Rodolia cardinalis*, is a classic example. Since that time more than 100 successful cases of biological control, leading to permanent suppression of pests, have been accomplished.

The unintentional unleashing of new pests through the use of pesticides, which cause the destruction of natural-enemy predators, illustrates the delicate balance between predator and prey that exists in most communities.

Occasionally, outbreaks of predators occur, with resultant drastic impact on prey populations. An example of such a case is in the Great Barrier Reef, Australia, and near Guam, in the western Pacific, where the crown-of-thorns starfish (*Acanthaster planci*), a predatory species, has increased in numbers that have seriously reduced the abundance of many corals. Sometimes the predator attacks a valuable resource of man. The whelk, a marine snail, attacks oysters. An American whelk, *Urosalpinx cinerea*, has invaded oyster beds off southern England, causing severe reductions in harvest since the late 1950s. And man has always been uneasy about both bird and mammal predators—such as hawks, eagles, coyotes, wolves, and foxes—that attack his domesticated animals.

PARASITIC INTERACTIONS

Parasitism. In practically every community, plant and animal populations are burdened with parasites, which include viruses, fungi, protozoans, nematodes, many marine and freshwater coelenterates, flukes and tapeworms, leeches, some insects, certain birds, and higher plants such as dodder, mistletoe, and broomrape. A parasite usually does not kill its host (if it does, the parasite itself may die before reaching a new host), but it generally reduces the growth rate, survival ability, and reproductive capacity of the host. From an ecological standpoint, therefore, parasitism does constitute a considerable burden on a host population.

Ectoparasites and endoparasites

Parasites that live on the body surface of the host are called ectoparasites. They do not commonly cause disease in their hosts but rather suck blood or create superficial damage to the skin; examples include leeches, fleas,

lice, and ticks. Other parasites live inside the host's body —either in cells or in spaces lined by cells (*e.g.*, intestine, blood vessels, mouth, etc.). Parasites that live within host cells—such as many bacteria and viruses—are called intracellular endoparasites; those that inhabit spaces within the host's body are called intercellular endoparasites.

Many disease-causing organisms, or pathogens, are endoparasites carried from host to host by some other organism; malaria, for example, is caused by a protozoan endoparasite transmitted by mosquitoes. In such situations, the biotic interaction involves three necessarily coexisting species: the pathogen, the carrier (or vector), and the host. A number of plant diseases transmitted by insects are dependent on carrier density, pathogen abundance and virulence (disease-producing power), and host density. Host susceptibility is also a significant factor in influencing the outcome of host–parasite interactions. In Europe the Dutch elm disease fungus (*Ceratocystis ulmi*) is a minor pest of elm trees. When this pathogen established itself in North America, however, it severely infected native American elms, which were more highly susceptible than their European counterparts. A similar event occurred when the chestnut blight, a fungus native to chestnuts in China and Japan, invaded North America and devastated stands of native chestnuts.

Not all invading parasites are micro-organisms, however. The sea lamprey, an ectoparasite on fish, attaches itself to its host by means of a sucker-like mouth with which it sucks blood and soft tissues. The sea lamprey is native to the North Atlantic, living in the ocean but breeding in coastal rivers and streams. It was able to move into Lake Ontario but no farther, being blocked by Niagara Falls. After construction of the Welland Canal, however, which bypassed the falls, the lamprey invaded the remaining Great Lakes and began decimating the populations of commercially valuable fishes.

Intermediate hosts

An intermediate host—interposed between the target host and parasite—adds ecological complications to host–parasite interactions: the parasite, host, and intermediate host must all be present in the same community in suitable numbers at the same time. The liver fluke that attacks sheep and cattle, for example, requires an aquatic snail as an intermediate host; there is no direct transmission of the fluke from sheep to sheep. Sheep, snail, fluke, pasture, and aquatic habitat must all coexist in the same community. Many other common parasites similarly require an intermediate host; *e.g.*, malaria, sleeping sickness, wheat stem rust. One reason that such complicated three-component interactions are so common is that with at least one of the organisms the reproductive capacity is very high; this increases the likelihood of continuation of the pathogen. Furthermore, in the case of parasites carried by insects, the motility and numerical abundance of the insect carrier facilitates parasite dissemination.

Parasitoidism. Parasitoids—insects that parasitize other insects—differ from true parasites in that, like predators, they always kill their hosts. Most are free-living in the adult stage. In a typical life history, the female parasitoid lays an egg in or on a host; the ensuing larva feeds upon host fluids and tissues, eventually killing the host; and the fully developed larva pupates and later emerges as an adult. Most species of parasitoids have a distinct preference as to the stage of host attacked, whether egg, larva, pupa, or adult.

Parasitoids are among the most important agents in limiting the numbers of other insects. For this reason they, along with true insect predators, are frequently sought and used by man as control agents for insect pests. Almost all insect species are attacked by one parasitoid or another. Some parasitoids are gregarious, with several living in one host simultaneously; others are solitary, with only one developing in a host. Certain wasp parasitoids exhibit polyembryony, wherein one egg deposited in a host may give rise to dozens or thousands of parasitoid embryos, and the host is literally overwhelmed by the developing parasitic larvae. In some parasitoid flies the female lays her eggs on leaves, and the host becomes infected by eating the egg-bearing leaves. Other parasitoid flies lay their eggs on the backs of hosts, and the larvae hatch out and bore into the host body.

The parasitoid's life cycle is always well attuned to that of its host. If the host is a leaf feeder and found only in the foliage of trees, that is where the female parasitoid searches for them. If the host has but one generation a year, so usually does the parasitoid. If the host passes the winter hibernating in the soil, the parasitoid generally does likewise, emerging from the soil in the spring soon after the host does.

Hyperparasitism

A parasitoid may itself sometimes be parasitized. In such cases its parasites are called hyperparasites. The hyperparasitic habit, commonly found in insects, may extend to several levels; for example, an aphid can be attacked by a solitary, endoparasitic aphidiid wasp, which, in turn, may be parasitized while still within the host's body by an endoparasitic cynipid wasp. Moreover, the cynipid can itself be attacked by an ectoparasitic pteromalid wasp. In theory even additional levels of parasitism are possible.

The free-living habit of the adult parasitoid enables it to spread rapidly from host to host throughout a community. Because the host almost always dies as a result of a parasitoid attack, few host-immunity responses have evolved. Only when parasitoids attack unusual hosts—those not in their normal host range—can a host survive and sometimes elicit an immune response to further attacks. The true parasite and the parasitoid can sometimes interact in their association with a host insect. Some parasitoid wasps coincidentally distribute pathogens from host to host when they deposit their eggs.

Brood parasitism. Brood parasitism, the laying of eggs in another animal's nest to be reared therein by the host, occurs in certain birds, including the cuckoo and the cowbird, and in certain insects, including cuckoo wasps. The female cuckoo bird lays an egg in the host's nest, where the hatched cuckoo chick either kills or pushes out the host's brood, so that it is reared alone until it can fly. The cuckoo wasp accomplishes much the same result, except that its host is one of the social wasps or bees. It enters a colony and lays an egg in one of the compartments, or cells. After hatching, the parasitic larva destroys the normal cell occupant and is taken care of by the colony workers.

The cuckoo habit is a balanced one, not being so efficient as to suppress unduly the host population but effective enough to assure perpetuation of the habit. In most cases, the reproductive habits of the host species enable progeny to be produced at times when the brood parasite is not active.

AMENSALISM AND ANTAGONISM

Competition. Competition occurs when two species utilize a common, limited resource (such as food, space, or moisture), and, in so doing, one species interferes with, injures, or deprives the other. When the competitors are of the same species, intraspecific competition occurs (dealt with earlier). Populations of two species cannot persist together for very long in the same community when both compete for and are limited by a common resource. This principle, known as Gause's hypothesis, further suggests that the species having the greater competitive advantage—manifested in greater searching ability, more rapid exploitation of the resource, greater numerical growth rate per unit of resource attained, greater aggressive or fighting ability—in time gains more and more of the limited resource. Competitive interactions between species are resolved in either of two ways: (1) the exclusion or displacement of one species by the other; or (2) the coexistence of the two competing species as a result of minor differences in habit or because their numbers are limited by factors other than the resource under consideration. When a species invades the habitat or community of another species and both occupy the same niche (the totality of its resource needs, its habits, and its mode of life), either the incumbent will persist and the invader will disappear, illustrating competitive exclusion, or the invader will become established and the

Gause's hypothesis

incumbent will disappear, resulting in competitive displacement.

Actual competition is difficult to see in nature, since a community usually contains "superior" competitors only, the lesser adapted species having already been ejected from the area. When a species invades a new habitat, however, either through its own dispersive powers (rare) or through man's activities (common), competition can be observed in operation. Hence, when settlers established themselves in western North America and brought with them grains and forage grasses for their livestock, they also brought, unwittingly, many weed seeds from Europe. Many of those weeds and foreign forage plants became established, forcing out or eliminating many native plants. The Klamath weed (*Hypericum perforatum*) is a remarkable example of the way in which weedy competitors can succeed in a new habitat. Gaining a foothold in California a few years before 1900, Klamath weed established itself as the dominant perennial on low-elevation rangelands. Several decades later, millions of acres of land were infested. Only when the weed itself was suppressed by biological control agents in the late 1940s were the displaced native species able to return to their old habitats. In England the shrub *Rhododendron ponticum*, an invader from the Continent, has become a pest in wooded areas, displacing holly and preventing regeneration of oaks and other desirable trees.

Insect invaders

Many insect invaders have displaced incumbent species through competition. The Argentine ant (*Iridomyrmex humilis*) and the imported fire ant (*Solenopsis saevissima richteri*), both invaders of North America from South America, have displaced many native ant species. When the fruit fly *Dacus dorsalis*, the maggots of which feed on tropical fruits, invaded Hawaii in the mid-1940s, it apparently displaced an earlier invader, the Mediterranean fruit fly *Ceratitis capitata*, from all the low-elevation habitats that the latter had occupied for so many years. The Mediterranean fruit fly was forced up into higher elevations on volcanic slopes, where coffee remained its major host, leaving the lower slopes and shores to the newer invader.

In aquatic habitats, aggressive fish such as carp and perch commonly displace trout and other game fish. When the long-legged crayfish (*Potamobius leptodactylus*), a native of eastern Europe, was introduced into some central European lakes, it totally displaced the native broad-legged crayfish (*P. astacus*).

Laboratory experiments also show the nature of competition. When two species of the single-celled protozoan *Paramecium* compete for food and space in small glass tubes, one displaces the other, even though both thrive when grown alone. Similar results are obtained when two flour beetles, *Tribolium confusum* and *T. castaneum*, are cultured together in jars of medium. Either species, living alone, limits its own population numbers (intraspecific competition) through such self-regulatory actions as cannibalism (adults and larvae feed on eggs and pupae), interference with female egg laying, and defilement of the common food supply. When populations of the two species are grown together, one species is eventually eliminated; the other persists. The interesting difference in these experiments is that, possibly because of slight variations in genetic composition of the organisms used, the same species does not always survive in every experiment. Rather, there is an element of probability as to the outcome. The probability of winning the competition can be varied, sometimes substantially, by altering the physical conditions for growth, such as temperature, moisture content, or humidity.

When two species of closely related water fleas, *Daphnia pulicaria* and *D. magna*, are cultured together with algae as food, both species increase in numbers for about three weeks; then the *D. magna* population ceases to grow and instead gradually declines to extinction at the end of the sixth week. The competition for the common food supply, not important while the populations were small, soon becomes severe enough to affect strongly the less adapted of the two competitors. On a different food supply, yeast cells, *D. magna* actually increases at a greater rate at first, but after about 24 days it reaches a peak and declines to extinction, as in the previous case.

Coexistence of potentially competitive species

It often happens that two species with similar niches occur in adjacent geographic areas and partially overlap. Coexistence in the area of overlap is then possible as a consequence of the continuous migration of the "excluded" species from its area of exclusivity. Displacement takes place, but the dispossessed are constantly being replaced by new immigrants into the "overlap" area. Eventually, if the area of overlap is broad enough, niche separation may occur through the process of evolution. Niche separation, or displacement, is the shifting of one or the other competitor species from the common, limited resource to another resource not competitively limited. This can be a different food, different spatial habitat, or different nesting site. An example of niche displacement is that of the finches on the Galápagos Islands. Some of the 12 or so finch species that have evolved from a mainland insect-eating finch have become vegetarian, whereas others have remained insectivores; some occupy ground-level habitats, others inhabit trees, and one lives on cactus; some eat seeds, others fruit. These are all ways by which the original stock extended into unutilized niches.

Occasionally, niche displacement is reflected in a structural or behavioral change in the species involved, a phenomenon called character displacement. The change in character, or feature, occurs in the region of overlap but not in the regions of exclusive occupancy. A good example is provided by the same Galápagos finches. Two species living on separate islands have approximately the same bill length; when they occur together on other islands, they exhibit altered bill dimensions, which reflect changes in food resources brought about by competitive interactions. A similar displacement of characters is seen in two related ant species—*Lasius flavus* and *L. nearcticus*—that coexist in the eastern United States and differ in at least eight features. These differences are not apparent in *L. flavus* in areas where it occurs alone in the western United States.

Antibiosis. Antibiosis occurs when one species interferes with or injures another through the secretion of a chemical substance. This commonly occurs among the bacteria and fungi and to a lesser extent among higher plants and some animals. The observance of such an effect in certain *Penicillium* molds is well-known. A bactericidal substance secreted into the growth medium prevented the growth of competing micro-organisms and led to the discovery of the antibiotic penicillin. A more complicated example concerns the grass *Aristida oligantha*, which invades old-field communities. It secretes phenolic acids, which inhibit the development of nitrogen-fixing bacteria and the blue-green algae of the soil. This, in turn, suppresses the production of available nitrogen in the soil, thus slowing the invasion of other competing, nitrate-requiring plants into the grass community.

Plant resistance

Antibiosis is the basis of the resistance exhibited by certain varieties of crop plants to insect attack. Corn varieties resistant to the European corn borer, for example, contain benzoxazolinones, chemicals that adversely affect larval growth and survival.

The discovery that many plants and some animals contain or secrete chemicals injurious to competitors or natural enemies has led to development of the study of allelopathy; the chemicals are called allelochemics. This phenomenon—the suppression of some higher plants by chemicals released by another higher plant—has been extended to include chemical defenses of plants against herbivores, phytophagous insects against predators, and the resistance of hosts to parasitoids.

Some of the more interesting examples of plant-to-plant antibiosis based on allelochemics include the chaparral plants, whose toxic phenolic secretions are washed by rains into the soil, where they inhibit the germination and growth of herb seeds close enough to provide competition. The milkweed-feeding caterpillar of the monarch butterfly acquires toxic chemicals from its host plant, thereby rendering the adult butterfly distasteful to bird predators.

Antibiosis can take forms other than chemical defense. They include immune responses, whereby hosts defend themselves against invading parasites. Immune responses of a host to an invading organism can involve engulfment (phagocytosis), chemical inactivation (precipitation), dissolution (lysis), or encystment.

Mutual antagonism. Mutual antagonisms occur when a biotic interaction between two species results in harm or death to both. Most mutual antagonisms occur as a result of competition for a limited resource. In some cases two pathogenic species together invade a host and thereby bring about its death, but in the process they destroy themselves; either pathogen alone would normally not destroy the host. An insect parasitoid and a predator occasionally engage in competitive interactions that result in death to both competitors, a phenomenon called synnecrosis.

When more than one insect parasitoid parasitizes a given host, competition for the host results. For example, when the female wasp parasitoids *Praon exsoletum* and *Trioxys complanatus* both attack the same aphid host, usually only one parasitoid survives, but occasionally the competition is so disruptive that the host dies as well, and with it all competitors. A variation of this habit is superparasitism, or the depositing by one species of more eggs into a host than can survive. The usual, adaptive outcome of such a situation is the death of all but one, an example of intraspecific competition. When hosts are in relatively short supply, however, superparasitism to an excessive degree commonly takes place. The result often is the death of both the parasitic larvae and the host itself.

Superparasitism

It has been said that the true parasite rarely exploits its host to the point of death, for the death of the host means the death of the parasite. The "prudent" parasite has evolved to avoid such drastic interaction, and the host likewise has evolved a resistance (immunity) to a parasitic species of long-standing association. When the pathogen, however, invades a new host species or subspecies or a previously unparasitized, susceptible host population, the resulting association may be one of extreme virulence, with rapid onset of death of the host.

Another example of mutual antagonism that is clearly harmful to both interacting species is the case in which cattle consume *Halogeton* plants, whose leaves contain a poison that frequently kills the cattle.

COMMENSALISM

In many communities there are species that benefit through interaction with other species, while the latter remain indifferent or unaffected. Such unilateral benefits include attainment of nutrients, space or support, shelter or protection, and transport. The commensal population is, by virtue of the association, increased in numbers through improved survival. If the commensal is obligatorily associated with a host, it cannot live in a community that does not contain the host in question.

Nutritional commensalism. Nutritional commensals, or allotrophs, are well illustrated by the many organisms found in the alimentary tracts of higher animals. Such endosymbiotes use host waste products for food and acquire suitable water supplies and a suitable microclimate in which to live. No harm is done to the hosts. Endosymbiotic bacteria and yeasts are found in most large mammals, particularly cattle, horses, sheep, deer, and buffalo.

Endosymbiotes

Numerous bacterial and yeast colonies grow on the bark, twigs, and leaves of trees and large shrubs, particularly in tropical habitats. These nonparasitic organisms live on the nutritious exudates and the decomposing bits and flakes of dead bark that coat the surfaces of such plants. In the soil many fungi and bacteria live on nutrients derived from the root exudates of higher plants.

Aquatic organisms with poor dispersal powers or poor food-gathering capabilities often attach themselves to species on whom they can depend to provide those qualities. The small crab *Lissocarcinus* lives commensally on the surface of sea cucumbers, being protected by colour camouflage from natural enemies and gaining its food simply by diverting bits of the plankton that is pulled into the sea cucumber's mouth by feeding currents. Clown fish (*Amphiprion*), which habitually swim among the tentacles of sea anemones, are unaffected by the stinging cells (nematocysts) of the host, but they receive protection from small predators and also partake of surplus bits of any food captured by the anemone. The well-known remora and the pilot fish also obtain their food from the activities of such hosts as a shark, marlin, or swordfish. The remora attaches itself to its host by a sucker organ, whereas the pilot fish swims in close association with the host. Both commensals feed on the leftovers of their host's meals.

Numerous birds are food commensals of other animals. Cattle egrets in Africa follow herds of elephant, buffalo, or antelope, feeding on insects and grubs turned up by the grazing activities of such animals. The cowbird (*Molothrus*) behaves similarly with cattle in the Americas. In northern Europe, ptarmigan travel with caribou in order to get the insects uncovered from the semifrozen sod. Gulls, lapwing plovers, and herons follow the farmer's plow to attain soil organisms turned up to the surface. Gulls and albatrosses follow ships at sea, feeding on garbage tossed overboard or on small fish stirred up by the passing vessel. Vultures follow carnivores such as lions, leopards, jackals, and hyenas and scavenge upon what is left of a killed carcass.

Scavenging as a form of commensalism

Insects such as biting lice, fleas, and louse flies, commonly categorized as ectoparasites, are more correctly designated ectosymbiotic commensals; they feed on feathers, sloughed-off flakes of skin, or waxy epidermal exudates. Only in the few cases of blood sucking are they regarded as true parasites.

Some insects and spiders closely resemble ants and associate with army ants in their foraging columns. These mimics feed on the booty flushed up by the foraging ant column. Certain ant mimics live within the nests of the host and as such are termed symphiles. Such symphiles include some of the rove beetles, claviger beetles, and certain mirid bugs.

Physical commensalism. The need for living space is a common basis for commensalism. In overcrowded communities, offshore marine habitats, or tropical rain forests, many nonmotile (sessile) micro-organisms are unable to find adequate sites on which to become established; hence, many of them attach themselves to the surfaces of other plants or animals. Most sessile or slow-moving marine animals—sponges, corals, bivalves, snails, turtles, and whales—carry ectocommensals such as algae, hydroids, and barnacles about with them. Woody plants physically support numerous orchids, ferns, bromeliads, grasses, and mosses of the tropics in tropical habitats. Trees in the temperate zone provide support for mosses and lichens.

Insects and mites live in bird's nests or rodent burrows, feeding on dead organic litter. Nest inquilines—insects living in the nests of bees, wasps, termites, or ants—subsist on excess food stores, nest materials, or dead hosts. Some inquilines apparently find the internal physical habitat of these social insect nests favourable for their own well-being.

Batesian mimicry, the morphological and colour-pattern resemblance of certain animals to other animals, is a form of protective commensalism. Edible butterflies, through natural selection by predatory birds or toads, come to resemble, or mimic, distasteful butterflies, which are avoided by these same predators. Drone flies gain protection from predatory toads by mimicking bees that sting and hence are avoided. In such situations the mimicking species benefits by avoidance of predation, whereas the model is little affected, neither being harmed nor benefitted by the mimicry (see also MIMICRY).

Protective commensalism

Examples of protective commensalism include the bird species that build their nests near those of aggressive species, such as predatory birds or certain venomous or predacious insects. In Europe, house sparrows and starlings often locate their nests at the sides of an eagle's nest. In North America, house sparrows and grackles often nest in close contact to nests of ospreys. In both

cases the "protector" species are interested in other prey: the eagles usually attack large rodents or larger birds; the osprey preys on fishes. The cordon bleu weaver, of Africa, nests directly above colonies of the predatory, fiercely stinging papernest wasps, and the Asiatic woodpecker *Micropternus* often builds nests inside the larger nest complexes of pugnacious ants of the genus *Crematogaster*. These weavers and woodpeckers rarely feed on their insect protectors, and the latter appear never to attack the birds in their nests.

MUTUALISM

Facultative mutualism: protocooperation. Many plant and animal species interact facultatively in ways that are general and indirect but beneficial to both species. These relations, called protocooperation, can be considered the first evolutionary step toward mutualism.

The interactions that occur between soil bacteria and fungi and between them and higher plants growing in the soil are protocooperative. No species is dependent on such an association, but collectively all microflora and higher plants, with associated soil fauna, participate in determining soil composition, structure, and fertility. In the zone of plant roots, soil bacteria and fungi interact with each other, some producing nutrients (metabolites) required by others and all obtaining nutrients ultimately from root exudates and decaying organic matter. Plants benefit from the actions of this microflora by acquiring needed mineral nutrients and carbon dioxide.

Plants also interact protocooperatively with grazing herbivores. Although this relationship constitutes herbivory, grazing herbivores such as deer or cattle maintain a characteristic plant association in their habitual grazing habitats. Removal of the grazing herds soon exposes the range or pasture to invasion by aggressive pioneer plants, including woody shrubs, brambles, and trees. If the grazers are returned, the carrying capacity of the range, much reduced at first, is gradually restored as the grasses and browse plants return. The reason for this interaction is that grasses and browse plants grow from their bases rather than from their tips, so grazers rarely injure the growing crowns of such plants. Shrubs and seedling trees, on the other hand, grow from the tips of their stems and hence are usually destroyed by grazing.

Maintenance of pasturage by grazing animals

The natural control of herbivore populations by natural enemies provides an indirect, protocooperative benefit to plants. These natural enemies (predators, parasites, and pathogens), whose direct influence on herbivorous and other animals has already been described, are some of the major factors that keep herbivore numbers in check. At a community level, this interrelatedness of trophic levels, plant–herbivore–carnivore, constitutes a large-scale protocooperative interaction.

Some of the relationships exhibited between ants and aphids are examples of protocooperation. Benefits are provided to both ant and aphid, but the relationship is often quite loose and facultative (a few such ant–aphid associations are obligatory and are treated in the next section). Generally, the ant member forages for food on trees and shrubs infested with such honeydew-secreting species as aphids, mealybugs, and some scales, collecting the sugary material and transporting it to its nest as food for developing young. In some cases the ant actually stimulates the aphid to secrete honeydew directly into its mouth. Some ant species even protect the honeydew producers from natural enemies, the consequences of which are noticeable: ant-attended trees usually bear much heavier infestations of aphids.

Plants whose flowers are pollinated by insects and birds benefit protocooperatively, particularly when the pollinator is a general one, and the plant is attended by many different pollinator species. Many plants, particularly those with colourful, showy flowers bearing nectar glands, are the beneficiaries of cross-pollination accomplished for them by insects. The insect, of course, benefits from the supply of food in the form of pollen and nectar. Honeybee colonies are used commercially to ensure pollination of many agricultural crops.

An interesting and apparently widespread form of protocooperation, called cleaning symbiosis, appears most noticeably in birds and fish. The Egyptian plover picks insect pests from the backs of buffalo, antelope, giraffes, and rhinoceroses and even leeches from the open mouths of crocodiles. The cattle egret in America performs the same function. In the offshore marine habitat, certain fishes function habitually as cleaners of other fishes, nibbling away at ectoparasites, wounded tissues, and dead flesh. Even predatory fish search out such cleaning symbiotes and remain passive while they are worked over. Such fish cleaners are often concentrated in fixed sites, called cleaning stations, where other fish come to be cleaned.

Cleaning symbiosis

Müllerian mimicry, the close similarity in appearance of two or more unrelated species in which each species is more or less distasteful to predators, is a form of protocooperation. Such mimicry presumably benefits all participating species (see MIMICRY).

Obligative mutualism: interdependency. In many communities the most stable, persistent, and interdependent associations between species are those based on obligative mutualism. Since the association is mandatory for the survival of each participant, the coexistence of both in a given habitat is always required. Because of this, ways have evolved to assure the perpetuation of the association from one generation to the next. Some of these means are intricate, involving adaptations in structure, behaviour, or life history so as to guarantee the coexistence of the partners. On the other hand, some mutualistic relationships are maintained simply through the high probability of mutual encounters as a result of the population density or great reproductive powers of one or both mutualists, or symbiotes.

How nature assures continuation of interdependencies

A number of bacteria–protozoan associations occur in aquatic environments. In certain cases, endosymbiotic bacteria, which exist in the cytoplasm of protozoan flagellates, are able to digest cellulose in quantities to provide for themselves and their hosts. Associations of fungi and single-celled algae include the well-known lichens, in which the fungal member penetrates algal cells with feeding tubes or haustoria, thus effecting an intimate physical interconnection. The mutual benefits derived from this association are nutrient exchange, maintenance of water and mineral balance, and resistance to drying or to extreme temperatures. Whether the association is truly mutualistic is difficult to resolve on formal grounds; some authorities contend that the fungi parasitize the algae. Ecologically, however, there is no question that the lichen is far better able to cope with its environment and to invade many more habitats than can either partner living alone.

Single-celled algae also enter into symbioses other than lichen formation, particularly in marine habitats where photosynthesis is restricted. Algae are symbiotic with, among other groups, protozoans, sponges, coelenterates, rotifers, flatworms, mollusks, echinoderms, and tunicates. The algal cell provides oxygen and manufactured food to its partner and, in turn, receives physical support, water, minerals, and a proper environment. Some algae are acquired by ingestion (the more primitive mechanism), whereas others are inherited; *i.e.*, transmitted during cell division of the host (the more advanced mechanism).

The association of algae with a motile coral polyp is accompanied by remarkable behavioral alterations in the host, which reinforce the benefits derived. Free-living larvae (planulae) of certain corals that contain yellow-green algae move toward light, whereas planulae lacking such algae are unresponsive to light. Corals endowed with algae grow more rapidly, take on different shapes, and are much denser than corals without algal members. In Caribbean mangrove swamps, certain algae-containing anemones distribute themselves in zones of intermediate light intensity; bleached anemones become indifferent to light or shade.

The important association of nitrifying bacteria with the roots of certain mostly leguminous plants is well-known. Nitrogen fixation—the extraction of nitrogen from the environment—occurs only after the bacteria

The unusual case of nodule bacteria

have invaded the plant roots and stimulated the host to form nodules that encapsulate the bacteria (a response of the host to infection). This association is closely related to parasitism. Nevertheless, the mutual benefits to the interactants are substantial: an environment and nutrients for the bacteria and improved fertility of the soil (by addition of nitrogen compounds) for the plant host.

Many insect species (perhaps most) contain microbial endosymbiotes, including bacteria, rickettsiae, fungi, yeasts, and protozoans. These organisms provide required nutrients for the host—often vitamins, occasionally digestive enzymes, and sometimes simple foodstuffs such as glucose sugar. The host provides the symbiote with a protected microhabitat containing food, water, minerals, and the proper chemical environment. The endosymbiotes are rarely found in the free-living state, and their hosts are unable to survive in their absence. They may be either extracellular—residing in the mouth, gut, rectum, blood spaces, or excretory tubules—or intracellular—living in the cytoplasm of various cells of the host. Because of the intimacy of such symbioses and the dependent nature of the associations, intricate mechanisms have evolved for the transmission of the endosymbiote from one generation of the host to the next. In some triatomid and lygaeid bugs, intestinal symbiotes are deposited as fecal material with the egg, and newly hatched larvae regain the symbiotes by consuming this material. In some pentatomid bugs the symbiotes are smeared on the oviposited egg shell, reinfecting the new hatchling as it emerges from the shell. In the olive fly (*Dacus oleae*) the egg is smeared with bacteria as it passes down the ovipositor, the bacteria penetrating the egg and becoming enclosed in the developing embryo. Finally, there are cases where the symbiotes penetrate the female ovary to invade the egg before it is even deposited; this occurs in some roaches, weevils, and ants.

One of the most notable mutualistic associations is that between certain wood-eating insects and cellulose-digesting protozoans. The wood roach (*Cryptocercus punctulatus*) acquires the intestinal cellulose-digesting symbiotes at an early age, retaining them for life. The wood-eating termite loses its symbiotes at each molt (shedding of skin) during its immature stages. The termites, however, reinfect themselves: newly molted nymphs ingest anal secretions from nonmolting nymphs and thereby obtain the intestinal organisms.

Insects that cultivate fungi

Numerous insects have become adapted to the use of fungi as specific food resources. These include the wood-boring insects that introduce and maintain fungal growths in their nest galleries and termites and ants that cultivate fungal "gardens" in their subterranean colonies. Four groups of wood-boring insects possess this habit: ambrosia beetles, bark beetles, timber borers, and sawflies (wood wasps). The adult ambrosia and bark beetles introduce the fungus into the brood galleries they make when they invade a tree. The adult timber borers and sawflies lay their eggs on or beneath the surface of the bark of a tree, introducing the fungus along with the eggs. The fungi then grow in the galleries formed in the wood and provide food for the developing insect larvae.

Myrmicine ants and certain tropical termites also are fungal "gardeners." The fungus-raising termites apparently utilize the fungi to control the localized climate of the nest rather than to obtain food. In termite nests where fungal gardens thrive, both the relative humidity and temperature are maintained at relatively constant, high, favourable levels as a result of the metabolic activities of the fungi. Fungus-culturing ants, however, clearly acquire nutrients from their gardens. Leaf-cutting ants, including the parasol ant, clip off and carry to their nests pieces of fresh leaves on which the fungi grow. The gardens are established usually in enlarged underground cavities, well ventilated, and tended by a class of workers who remove undesirable fungi and bacteria. All members of the colony feed on strands of the cultured fungi.

Certain insects are obligatory mutualists of the plants they pollinate. The California desert yucca can be pollinated only by the pronuba moth; the moth, in turn, is wholly dependent on the yucca flower ovary as a place to deposit its egg and develop its young. The common Smyrna fig can fruit only after pollination by the wasp *Blastophaga psenes*. This is a much more complicated process, since three different kinds of figs are involved in proper sequence: one for maintaining an overwintering population of wasps, one for producing adult wasps during the growing season, and one (the edible fig) that requires pollination but is otherwise unavailable for wasp reproduction.

Insects also enter into protective relationships with plants. The ant *Pseudomyrmex ferruginea*, which lives on and derives its food from the bull-horn acacia, protects the acacia from intruding vines, competing plants, and herbivorous insects. The ant depends upon the acacia, and the acacia cannot survive without the ant. A concomitant development of this mutualism is that this particular acacia has lost the chemical defenses against insect defoliators that other acacias possess.

NEUTRALISTIC INTERACTIONS

The final category of interspecies association commonly encountered in communities is neutralism, the persistent appearance of two or more species together with neither benefit nor harm accruing to any. It is a commonplace that seems self-evident and without significance; thus, it is often ignored in discussions of symbiosis. Indeed, in some cases—perhaps most—this interaction is trivial or accidental, yet in many communities such interspecific associations are characteristic. Most often, neutralistic associations occur when a common resource for several species is highly localized within the community, as when numerous species aggregate about water holes or streams. Insectivorous birds and predatory insects and rodents are persistent followers along foraging columns of army or driver ants, not to prey on the ants but rather upon the organisms stirred up by the mass advance. Neutralistic associations are characteristic in the distribution of trees in forests. The common situation is mixed stands of different species rather than pure stands of single species.

Simple aggregations

POPULATION EFFECTS OF INTERACTION

At the population level the interaction between different species can have two different effects, particularly when the interaction influences the survival or reproductive success of either species. One effect is on the numbers of individuals in the interacting populations. The other is on the qualities, or properties, of the individuals in these populations. The first effect—the quantitative one—is the basis for the balance of nature, the state of rareness or commonness of different species. The second effect—the qualitative one—is an aspect of evolution. Biotic interactions, when influencing the survival of a species, tend to produce changes in such aspects as structure, function, behaviour, and colour of the affected species. Since inherited changes in one species can serve as the basis for change in the other, biotic interactions between two species often lead to mutually induced changes in both, or coevolution.

Ecological aspects. The effect of one population on the numbers of another can be either positive or negative. A positive effect occurs when the survival or reproductive success of individuals of one species, or both, is enhanced and leads to an increase in the numbers of one or the other interacting population. Hence, an insect that consumes pollen in seeking a meal will generally bring about the pollination of the flowers of the host plant concerned; the result is an increase in the reproductive success of the host plant. Algae in such hosts as coral polyps stimulate the growth rate of coral colonies, and the enhanced growth of the coral benefits the algae.

Negative effects on a population

A negative effect occurs when the survival or reproductive success of one or both interacting populations is reduced, usually leading to a reduction in numbers of the affected populations. Negative interactions are those resulting from herbivory, predation, or parasitism, in which the food, prey, or host species suffers and may therefore diminish in abundance, or from competition or

mutual antagonism, in which both interacting species may suffer, be reduced in numbers, or even be eliminated from the habitat altogether.

In cases in which the biotic interaction is obligatory for one or both participating species, both species must appear together in the same community for the interaction to persist and for one or both participants to survive. A host species that is dependent upon an endosymbiote to provide necessary dietary components will usually not survive in the absence of the symbiote, and vice versa. A predator in consuming prey thereby reduces the numbers of the prey population to a point at which the prey becomes scarce and more difficult for the predator to find. The predator population then comes into balance with the diminished prey population. Any later increase in the prey results in an increase in the predator, and so on.

Evolutionary aspects. Since all species gradually change in response to selective factors, biotic interactions can serve as the means by which one of the interacting species brings about evolutionary change in the other. Just as predators can alter the numbers of a prey, and vice versa, evolutionary change in one interacting population can result in the evolutionary response of the other. For example, if a prey, through natural selection, becomes swifter or more agile in escape, a predator may develop, also through natural selection, capabilities for better pursuit. Plants, under the selective pressure of herbivory, often evolve a capability to produce toxic poisons that discourage herbivores. Subsequently, however, the herbivore, especially if it is dependent solely on the particular plant group involved, tends to develop tolerance for or resistance to the poisons. These examples of coevolution illustrate the dynamics of the process, the constant influence of each participant upon the other.

Convergent evolution

Since two interacting species tend to influence each other's evolution, it is not surprising that evolutionary convergence occurs in dissimilar organisms involved in similar biotic interactions. Convergence is the acquisition, through natural selection, of similar structure, function, or behaviour by unlike and totally unrelated species. One interesting example of convergence is a consequence of insect herbivory. A variety of unrelated insect species attack members of the Cruciferae (Brassicaceae), the plant family that includes mustard, cabbage, brussels sprout, radish. All crucifers contain chemical irritants or poisons that affect many animals and many microorganisms. Such toxins very likely were evolved as chemical defenses in response to herbivore pressure. The insect species that now attack crucifers, however, have not only become capable of detoxifying the poisons but in some cases are even able to utilize them, either as attractants or as feeding stimulants.

Through coevolution, interspecific interactions among mutualists have led to mutual adaptations of unusual complexity. The mutualistic associations between the yucca plant and the pronuba moth, the Smyrna fig and the fig wasp, and the bull-horn acacia and the acacia ant have already been described. An even more striking example concerns the mimicry developed in the orchid, *Ophrys insectifera*, commonly called the fly orchid or bee orchid. The flowers of this unusual orchid—pollinated chiefly by a species of bumblebee—simulate very closely the shape and colour of a female bumblebee, so much so that male bumblebees frequently try to mate with it and in that attempt pollinate the flower.

Polymorphism is the occurrence in the same species of two or more different forms, distinguishable by colour, pattern, function, body dimensions, shape of the appendages, or behaviour. Often, polymorphism in one species occurs as a consequence of biotic interactions with another species. Character displacement in overlapping competitor species may present a situation in which the taxonomist often wonders whether he is not dealing with three or four different species rather than just two. Similarly, the discovery of noninterbreeding species, identical in every morphological detail but coming from different regions, also poses problems for the taxonomist. Such so-called sibling species often can be recognized only through differences in the nature of their biotic interactions. An example is the two parasitoid species *Trioxys complanatus* and *T. pallidus*. They are virtually identical in structure, yet each attacks and is specific to altogether different aphid hosts.

The taxonomic utility of biotic interactions

Biogeographic aspects. The geographic distribution of interdependent species also presents some interesting problems, particularly when the interrelationship is obligatory. When a herbivore is limited to a particular food plant (a not infrequent occurrence), the herbivore obviously cannot extend geographically farther than the range of the host plant. Parasites and predators are similarly limited by the distributions of their hosts or prey. On the other hand, neither the host plant, in the first case, nor the host or prey species, in the second, is so limited. On the contrary, some very interesting cases of population explosions or pest outbreaks have occurred when a species has, by invasion into a new region, escaped the natural restraints imposed by its normal predators or parasites.

Where the association of two species together is mandatory for the survival of each, as occurs in obligate mutualism, for example, the biogeographic problems are of a different sort. As has been shown, many obligate mutualists have, through coevolution, developed mechanisms for the transmission of the association from one generation to the next. Such transmission has reached the peak of development in the case of those insects that pass on their internal symbiotes via the ovarian egg. The symbiote never reaches the outside; it is passed on as faithfully as are the genes of the parents to the offspring.

A most interesting example of the value of knowledge of biotic interaction and geographic distribution is the case of the introduction of the common fig into California in the mid-19th century. Seedling figs were imported, planted, and nourished to maturity but failed to set fruit, even though they flowered profusely. Only when it was realized that the small fig wasp (*Blastophaga*) was required to insure fruiting in the Mediterranean countries from which the imported fig stock came was the problem solved. Importation and colonization of the fig wasp restored the obligatory mutualism between the fig and the fig wasp, and the plants were able to set fruit.

(P.S.M.)

Bird

Birds are numerous, conspicuous, and widespread. Their world, like man's, is primarily one of sight and sound, and they resemble man in possessing colour vision, a rather poor sense of smell, and a limited auditory range. Like man, birds care for their young and most are diurnal. Thus their ways are easily appreciated and studied by man. Their ability to fly stimulated the minds of poets and inventors for centuries before man's first successful flights.

Man has long used birds and their eggs for food, falcons for hunting, pigeons for carrying messages, the guano of seabirds for fertilizing crops, and the feathers of many species for ornaments. Some birds are destructive to man's crops and small livestock, and others act as carriers for various diseases that affect man. Bird-watching is a hobby of increasingly large numbers of people, and amateur naturalists have made many important contributions to the science of ornithology.

GENERAL FEATURES

The smallest living bird is generally acknowledged to be the bee hummingbird of Cuba, which is 6.3 centimetres (2½ inches) long and weighs less than three grams (about one-tenth of an ounce). The largest living bird is the ostrich, which may stand 2.5 metres (eight feet) tall and weigh 135 kilograms (300 pounds). Some extinct birds were even larger: the largest of the moas of New Zealand and the elephant birds of Madagascar may have reached ten feet in height. Among flying birds, the wandering albatross has the greatest wingspan, up to 3.5 metres (11½ feet), and the trumpeter swan perhaps the greatest weight, 17 kilograms (38 pounds). A Pleistocene condor-like bird, *Teratornis incredibilis*, had an estimated wingspan of about five metres (16½ feet) and was by far the largest known flying bird.

The ability to fly has permitted an almost unlimited radiation of birds, so that they are now found virtually everywhere on earth, from occasional stragglers over the polar ice caps to complex communities in tropical forests. In general the number of species found breeding in a given area is directly proportional to the size of the area and the diversity of habitats available. The total number of species is also related to such factors as the position of the area with respect to migration routes and wintering grounds of species that nest outside the area. In the United States, Texas and California have both the largest number of species recorded (545 and 461, respectively, including both resident and migrant species) and breeding (300 and 286). Seven hundred and seventy-five species, 650 of them breeding, have been recorded from North America north of Mexico. The figures for Europe exclusive of the U.S.S.R. are 577 and 420, and the figures for the U.S.S.R. are 704 and 622. Costa Rica, with an area of only about 20,000 square miles and a known avifauna of at least 758 species, probably has the most diversified for its size of any country.

IMPORTANCE TO MAN

Wild birds and their eggs have been at least incidental sources of food for man since his origin and still are in most societies. The eggs of some colonial seabirds, such as gulls, terns, and murres, or guillemots, and the large young of some shearwaters (muttonbirds) are even now harvested in large quantities. As man changed from hunting to agrarian cultures, several species of birds became domesticated. Of these, chickens, ducks, geese, and pigeons, descended from the red jungle fowl (*Gallus gallus*), the mallard duck (*Anas platyrhynchos*), the greylag goose (*Anser anser*), and the rock dove (*Columba livia*), respectively, were taken in early and have been selectively bred into many varieties. After the discovery of the New World, the turkey (*Meleagris gallopavo*), which had already been domesticated by natives, and the Muscovy duck (*Cairina moschata*) were brought to Europe and have since produced several varieties. Guinea fowl (*Numida meleagris*) were procured from Africa and kept not only for food but because they are noisy when alarmed, thus warning other fowl, as well as their owners, of the approach of intruders. In addition to being a food source, pigeons have long been bred and trained for carrying messages, and the ability of frigate birds to "home" to their nesting colonies has enabled natives of the South Seas to send messages by these birds.

Domestication

With the development of modern culture, hunting evolved from a foraging activity to a sport, in which the food value of the game became secondary. Large sums are now spent annually on hunting waterfowl, quail, grouse, pheasants, doves, and other game birds. Sets of rules and conventions have been set up for hunting, and in one elaborate form of hunting, falconry, there is not only a large body of specialized information on keeping and training falcons but also a complex terminology, much of it centuries old.

Feathers have been used for decoration since early times. Their use in the headdresses of American Indians and New Guinea natives, as well as of more civilized peoples, are well known. Feather robes were made by Polynesians and Eskimos, and down quilts, mattresses, and pillows are part of the European culture. Large feathers have often been used in fans, thereby providing an example of an object put to opposite uses—for cooling as well as for conserving heat. Whereas most feathers used in decorating are now saved as by-products of poultry raising or hunting, until early in this century, egrets, grebes, and other birds were widely shot for their plumes alone. Ostrich farms have been established to produce plumes. The early use of large quills for writing led to the development of pens, and feathers have long been used on arrows and fishing lures.

Many birds are kept as pets. Small finches and parrots are especially popular and easy to keep. Of these, the canary (*Serinus canaria*) and the budgerigar of Australia (*Melopsittacus undulatus*, sometimes called parakeet) are widely kept and have been bred for a variety of colour types. On large parks and estates, ornamental species like peafowl (*Pavo*) and various exotic waterfowl and pheasants are often kept. Zoological parks in many cities import birds from many lands and are a source of recreation for millions of people each year.

Birds as pests

With the rise of agriculture, man's relationship with birds became more complex. In regions where grain and fruit are grown, depredations by birds may be a serious problem. In North America various species of blackbirds (*Icteridae*) are serious pests in grainfields; while in Africa a grain-eating finch, the red-billed quelea (*Quelea quelea*), occurs, like locusts, in plague proportions so numerous that alighting flocks may break the branches of trees. The use of city buildings for roosts by large flocks of starlings and blackbirds is also a problem, as is the nesting of albatrosses on airplane runways on Pacific islands. As a result of these problems, conferences on the control of avian pests are held with increasing frequency.

Although birds are subject to a great range of diseases and parasites, few of these are known to be capable of infecting man. Notable exceptions are ornithosis (or psittacosis), caused by one or more viruses that are transmitted directly to man from pigeons, parrots, and a variety of other birds, a serious and sometimes fatal disease resembling virus pneumonia. Encephalitis, an inflammation of the brain, is also serious and is transmitted from birds to man and to his domestic animals by biting arthropods, including mosquitos. Wild birds may also act as reservoirs for diseases that adversely affect domesticated birds. Much work has been done recently on the ecology of viruses, with more and more of them being found in birds.

The study of birds has contributed much to both the theoretical and practical aspects of biology. Darwin's studies of the Galápagos finches and other birds during the voyage of the "Beagle" were important in his formulation of the idea of the origin of species through natural selection. Study collections of birds in research museums still provide the bases for important studies of geographic variation, speciation, and zoogeography, because birds

are one of the best known of animal groups. Early work on the domestic fowl added to the development of both genetics and embryology. The study of animal behaviour (ethology) has been based to a large extent on studies of birds by Konrad Lorenz, Nikolaas Tinbergen, and their successors. Birds also have been the primary group in the study of migration and orientation and the effect of hormones on behaviour and physiology.

Birds feature prominently in mythology and the literature of many countries. Some of their attributes, real or imagined, have led to their symbolic use in art as in language. The esthetic and recreational pleasures of bird-watching are increasingly being recognized.

Man's impact on bird populations has become increasingly strong. Since 1680, approximately 80 species of birds have become extinct and an even larger number are seriously endangered. While pollution and pesticides are important factors in the decline of certain large species, such as the peregrine falcon, osprey, and brown pelican, the destruction of natural areas and introduction of exotic animals and diseases have probably been the most devastating. Concerted efforts are required to insure the survival of rare species and to learn as much as possible about them.

NATURAL HISTORY

Behaviour. Birds depend to a great extent on innate behaviour, responding automatically to specific visual or auditory stimuli. Even much of their feeding and reproductive behaviour is stereotyped. Feather care is vital to keep the wings and tail in condition for flying and the rest of the feathers in place where they can act as insulation. Consequently preening, oiling, shaking, and stretching movements are well developed and regularly used. Some movements, like the simultaneous stretching of one wing, one leg, and half the tail (all on the same side) are widespread if not universal among birds. Stretching both wings upward, either folded or spread, is another common movement, as is a shaking of the whole body beginning at the posterior end. Other movements have evolved in connection with bathing, either in water or in dust. Such comfort movements have frequently become ritualized as components of displays.

Many birds maintain a minimum distance between themselves and their neighbours, as can be seen in the spacing of a flock of swallows perched on a wire. In the breeding season most species maintain territories, defended areas ranging from the immediate vicinity of the nest to extensive areas in which a pair not only nests but also forages. The frequency of actual fighting is in birds greatly reduced by ritualized threat and appeasement displays. Birds range from solitary (*e.g.*, many birds of prey) to highly gregarious, like the guanay cormorants of the Peru Current off the west coast of South America, which nest in enormous colonies of hundreds of thousands and feed in large flocks with boobies and pelicans.

Vocalizations

Auditory signals, like visual ones, are almost universal among birds. The most familiar vocalization of birds is that usually referred to as "song." It is a conspicuous sound (not necessarily musical) that is used, especially early in the breeding season, to attract a mate, to warn off another bird of the same sex, or both. As such it is usually associated with establishing and maintaining territories. Individual variation in songs of many species is well known, and it is believed that some birds can recognize their mates and neighbours by this variation. Many other types of vocalizations are also known. Pairs or flocks may be kept together by series of soft location notes. Alarm notes alert other individuals to the presence of danger; in fact, the American robin (and probably many other species) uses one note when it sees a hawk overhead and another when it sees a predator on the ground. Begging calls are important in stimulating parents to feed their young. Other calls are associated with aggressive situations, courtship, and mating. Nonvocal sounds are not uncommon. Some snipe and hummingbirds have narrow tail feathers that produce loud sounds when the birds are in flight, as do the narrowed outer primaries of the American woodcock. The elaborate courtship displays of grouse include vocalizations as well as stamping of the feet and noises made with the wings. Bill clapping is a common part of courtship in storks, and bill snapping is a common threat of owls.

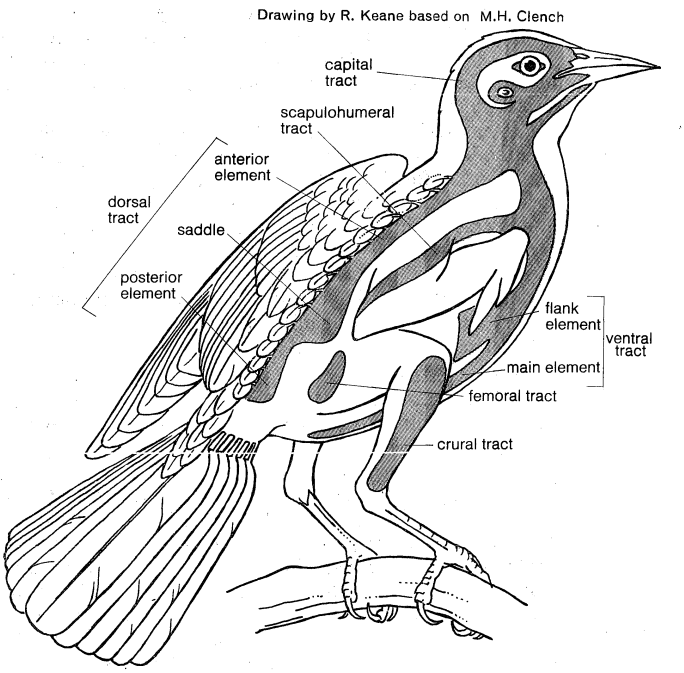

Figure 1: Basic body feather tracts on a generalized songbird. Shaded areas show the right half of each tract.

The nest

Most birds build nests in which the eggs are laid. Nests vary widely: they may be a scrape in the sand, a deep burrow, a hole in a tree or rock, an open cup, a globular or retort-shaped mass with a side entrance tube, or an elaborately woven hanging structure. The materials with which nests are made also vary widely. Some nests are lined with small stones, others are built of dirt or mud with or without plant material. Sticks, leaves, algae, rootlets, and other plant fibres are used alone or in combination. Some birds seek out animal materials such as feathers, horsehair, or snakeskin. The nest materials may be held together by weaving, sewing, or felting the materials themselves or with mud or spider webs. Swifts use saliva to glue nest materials together and to attach the nest to the supporting structure. In at least one species of swift, the entire nest is made of saliva and is the prized ingredient of birds' nest soup in the Orient. All birds incubate their eggs, except megapodes (mound builders), which depend on the heat generated by decaying vegetation or other external sources, and brood parasites, which lay their eggs in the nests of other species. Murres and the king and emperor penguins build no nest but incubate with the egg resting on top of the feet. In most birds a brood patch is developed. This bare area on the abdomen is edematous (fluid filled) and highly vascularized and is in direct contact with the eggs during incubation. Its development during the breeding season is under hormonal control. When the parent is off the nest, adjacent feathers are directed over the brood patch, and it is usually not apparent. A few birds (*e.g.*, boobies) keep their webbed feet over the eggs during incubation.

Incubation takes from 11 to 80 days, depending at least in part on the size of the bird and the degree of development at hatching. Most songbirds and members of some other groups are hatched nearly naked and helpless (altricial) and are brooded until well able to regulate their body temperature. They are fed by the parents until after they are capable of flight. The young of numerous other birds, such as chickens, ducks, and shorebirds, are hatched with a heavy coat of down and are capable of foraging for themselves almost immediately (precocial). Still others, such as the petrels and the auks, are downy

when hatched but remain in the nest and are fed by their parents.

The length of time parents care for young birds varies widely. Young megapodes can fly shortly after hatching and are entirely independent of their parents; young royal albatrosses may spend up to 243 days at the nest and in the area immediately around it before they can fly. The length of time needed to attain independence is related to size and condition at hatching. Ground-nesting birds tend to take less and hole-nesting birds more time than the average.

The number of eggs in a set varies from 1 to about 20. Some species invariably lay the same number per clutch (determinate laying), whereas in the majority the number is variable (indeterminate laying). In species of the latter category, clutch size tends to be smaller in tropical regions than in cold ones. There is also a tendency for birds in warm regions to make more nesting attempts in a given season. In the Arctic, where the season is very short, the cycle of breeding and the molt that follows it are telescoped into a minimum of time.

Feeding habits. The earliest birds were probably insectivorous, as are many modern ones, but the latter have evolved many specializations for catching insects: swifts, swallows, and nightjars have wide gapes for catching insects on the wing; some woodpeckers can reach wood-boring grubs while others can catch ants by probing anthills with their long, sticky tongues; thrashers dig in the ground with their bills; tree creepers and woodhewers probe bark crevices; and warblers glean insects from many kinds of vegetation. Raptorial birds have evolved talons and hooked bills for feeding on larger animals, and vultures have bare heads and tearing bills for feeding on carrion. Herons have spearlike bills and trigger mechanisms in the neck for catching fish, while kingfishers, terns, and boobies plunge into the water after similar prey. Long-billed waders probe for worms and other invertebrates. Of the many kinds of birds that feed on plant material, most use seeds, fruit, or nectar, which are high in food value; leaves and buds are eaten by fewer species. While some kinds of birds feed entirely on a single kind of food, others may take a wide range of foods, and many have seasonal changes.

FORM AND FUNCTION

Body proportions. Birds arose as warm-blooded, arboreal, flying animals with forelimbs adapted for flight and hindlimbs for perching. This basic plan has become so modified, through the course of evolution, that in some forms it is difficult to recognize. The maximum size attainable by flying birds is limited by the fact that wing area varies as the square of linear proportions, and weight or volume as the cube. On the other hand, the minimum size is probably governed by another aspect of the surface-volume ratio: the relative increase, with decreasing size, in surface through which heat can be lost. The largest flying birds have highly pneumatic skeletons (part of the bone is replaced by air spaces) and other adaptations for reducing weight; the small size of some hummingbirds may be facilitated by the decrease in heat loss resulting from their becoming torpid at night.

When birds lose the power of flight, the limit on their maximum size is lifted, as can be seen in the ostrich and other ratite birds. Some birds (auks, diving petrels, and certain ducks) use the wings for propulsion underwater as well as in the air. When birds that "fly" underwater lose the ability to fly in air, the wings become highly modified as paddles, as in the penguins.

Wing shape

The types of flight found in birds vary considerably. At least two major types of modifications for gliding or soaring are found. The albatrosses and some other seabirds have long, narrow wings and take advantage of winds over the oceans, whereas some vultures and hawks have broad wings with slotted tips and make more use of updrafts and winds deflected by hills. Short, broad wings are characteristic of chicken-like birds, which fly up with a rush of rapid wing beats. Birds like ducks, pigeons, and falcons, which fly rapidly with continuous wing beats, tend to have moderately long, pointed wings, while swifts and hummingbirds, with their narrow, curved wings fly rapidly and manoeuvre easily. The shape of a bird's tail also appears to be related to flight. Forms with deeply forked tails, such as frigate birds, terns, and some swallows, manoeuvre easily, whereas the opposite extreme, long, graduated tails, are often found in rapid, direct fliers like some parrots and doves. Woodpeckers and some other climbing birds have strong tail feathers with stout shafts, which they use as props while on the trunks of trees.

The bipedal gait, dictated by modification of the forelimbs for flight, necessitates manipulating food by the bill and feet and poses problems in balance. The relative lengths of the segments of the legs must be such that as the bird shifts from a standing to a sitting position, its centre of gravity remains over the feet. As some birds moved out of the trees and became terrestrial or aquatic, their legs were accordingly modified. The toes became shorter and the opposable first toe was lost in rapidly running forms like rheas and ostriches, and the toes became very long in birds that walk on aquatic vegetation or soft ground. In very large, slow-moving birds like moas, the leg bones became very heavy. Wading birds developed long legs, and climbing birds developed short legs with strongly curved, sharp claws. In swimming and diving birds, webs developed between the toes or lobes on the sides of the toes.

Feathers and molt. Feathers are unique to birds and characteristic of them. Like the scales of reptiles, and those on the feet of birds, feathers are made of keratin, a fibrous protein also found in hair. Feathers vary considerably in structure and function (Figure 2). Contour feathers form most of the surface of the bird, streamlining it for flight and often waterproofing it. The basal portion may be downy and thus act as insulation. The major contour feathers of the wing (remiges) and tail (rectrices) and their coverts function in flight. Contour feathers grow in tracts (pterylae) separated by bare areas (apteria) and develop from follicles in the skin.

The typical contour feather consists of a tapered central shaft, the rachis, with paired branches (barbs) on each side. An unbranched basal section of the rachis is called the calamus, part of which lies beneath the skin. The barbs, in turn, have branches, the barbules. The barbules on the distal side of each barb have hooks (hamuli) that engage the barbules of the next barb. The barbs at the base of the vane are often plumaceous; *i.e.*, lacking in hamuli and remaining free of each other. In many birds each contour feather on the body (but rarely on the wings) is provided with a complex branch, the aftershaft, or afterfeather, that arises at the base of the vane. The aftershaft has the appearance of a second, smaller feather, growing from the base of the first. Down feathers have loose-webbed barbs, all rising from the tip of a very short shaft. Their function is insulation, and they may be found in both pterylae and apteria in adult birds. They also constitute the first feather coat of most young birds. Filoplumes are hairlike feathers with a few soft barbs near the tip. They are associated with contour feathers and may be sensory or decorative in function. Bristlelike, vaneless feathers occur around the mouth, eyes, and nostrils of birds. They are especially conspicuous around the gape (corners of the mouth) of birds that catch insects in the air. Some bristles function as eyelashes on ground-dwelling birds, and the bristles over the nostrils may serve as filters.

The contour feathers are shed and replaced (molted) at least once a year, usually just after the breeding season. In addition, many birds have at least a partial molt before the breeding season. A typical series of molts and plumages would be juvenile plumage, postjuvenile (also called first prebasic) molt, first winter (or first basic) plumage, first prenuptial (or prealternate) molt, first nuptial (or alternate) plumage, first postnuptial (first annual, or second prebasic) molt, second winter (or basic) plumage, etc. Molt of the remiges and rectrices usually occurs as part of the annual molt and can be serial, from

the innermost feather out (centrifugal), from the outermost in (centripetal), or simultaneous. Normally it is symmetrical between the right and left sides.

Coloration

Colour in birds is caused by pigments or structure. Buffs, red browns, dark browns, and blacks are caused by melanins, pigments synthesized by the bird and laid down in granules. Yellows, oranges, and reds come from carotenoid or lipochrome pigments; these originate at least in part from the food and are diffused in the skin and feathers. Porphyrin feather pigments occur in birds but less frequently than melanins and carotenoids. Blue colours in feathers are structural, based on a thin, porous layer of keratin overlying melanin pigment. Most greens result from the addition of yellow pigment to the structural blue colour. Iridescent colours result from thinly laminated structure of the barbules and are enhanced by underlying melanin deposits.

Birds' feet are covered with scales like those of reptiles. The scales are occasionally shed, but the timing of this molt is not known. The toes are tipped with claws, and vestigial claws are not infrequently found on the tips of the first two digits of the wing.

The bill is covered with a sheet of keratin, the rhàmphotheca, which in petrels and a few other birds is divided into plates. In birds that probe for food (kiwis, woodcock, etc.), many sensory pores are found near the tip of the bill. Both melanins and carotenoids are found in the rhamphotheca and in the scales of the feet.

The skin of a bird is almost without glands. The important exception is the oil (uropygial) gland, which lies on the rump at the base of the tail. The secretion of this gland contains approximately one-half lipids (fats) and is probably important in dressing and waterproofing the plumage. In a few birds, the secretion has a strong, offensive odour. Some birds, in which the oil gland is small or absent, have a specialized type of feather (powder down) that grows continuously and breaks down into a fine powder, believed to be used in dressing the plumage.

Skeleton. The avian skeleton (Figure 3) is notable for its strength and lightness, achieved by fusion of elements and by pneumatization (*i.e.*, containing air spaces). The skull represents an advance over that of reptiles in the relatively larger cranium with fusion of elements, made possible by birds having a fixed adult size. Birds differ from mammals in being able to move the upper mandible, relative to the cranium. When the mouth is opened, both lower and upper jaws move: the former by a simple, hingelike articulation with the quadrate bone at the base of the jaw, the latter through flexibility provided by a hinge between the frontal and nasal bones. As the lower jaw moves downward, the quadrate rocks forward on its articulation with the cranium, transferring this motion through the bones of the palate and the bony bar below the eye to the maxilla, the main bone of the upper jaw.

The number of vertebrae varies from 39 to 63, with remarkable variation (11 to 25) within the cervical (neck) series. The principal type of vertebral articulation is heterocoelous (saddle shaped). The three to ten (usually five to eight) thoracic (chest) vertebrae each normally bear a pair of complete ribs consisting of a dorsal vertebral rib articulating with the vertebra and with the ventral sternal rib, which in turn articulates with the sternum (breastbone). Each vertebral rib bears a flat, backward-pointing spur, the uncinate process, characteristic of birds. The sternum, ribs, and their articulations form the structural basis for a bellows action, by which air is moved through the lungs. Posterior to the thoracic vertebrae is a series of ten to 23 fused vertebrae, the synsacrum, to which the pelvic girdle is fused. Posterior to the synsacrum is a series of free caudal (tail) vertebrae and finally the pygostyle, which consists of several fused caudal vertebrae and supports the tail feathers. The sternum consists of a plate lying ventral to the thoracic cavity and a median keel extending ventrally from it. The plate and keel form the major area of attachment for the flight muscles. The bones of the pectoral girdle consist of the furcula (wishbone) and the paired coracoids and scapulas (shoulder blades). The sword-shaped scapula articulates with the coracoid and humerus (the bone of the upper "arm") and lies just dorsal to the rib basket. The cor-

acoid articulates with the anterior (forward) edge of the sternum and with the scapula, humerus, and furcula. The furcula connects the shoulder joints with the anterior edge of the keel of the sternum. It consists of paired clavicles (collarbones) and, probably, the median, unpaired interclavicle.

Wing skeleton

The bones of the forelimb are modified for flight with feathers. Major modifications include restricting the motion of the elbow and wrist joints to one plane, reduction of the number of digits, loss of functional claws, fusion of certain bones of the "hand" (the metacarpals and most of the carpals) into a carpometacarpus, and modification of the elements, especially those toward the tip of the limb (distal), for the attachment of feathers. The wing bones are hollow, and the cavity in the humerus, at least, is connected with the air-sac system. As a general rule, large flying birds have proportionally greater pneumaticity in the skeleton than small ones. The highly pneumatic bones of large flying birds are reinforced with bony struts at points of stress. The humerus, radius, and ulna are well developed. The secondary flight feathers are attached to the ulna, which thus directly transmits force from the flight muscles to these feathers and is therefore relatively heavier than the radius. Two small wrist bones are present: the radiale, or scapholunar, and the ulnare, or cuneiform. The former lies between the distal end of the radius and the proximal part (the part toward the body) of the carpometacarpus. When the elbow joint is flexed (bent), the radius slides forward on the ulna and pushes the radiale against the carpometacarpus, which in turn flexes the wrist. Thus the two joints operate simultaneously. The U-shaped ulnare articulates with the ulna and the carpometacarpus. Anatomists differ on which bones of the reptilian "hand" are represented in the bird's wing. Embryological evidence suggests that the digits are II, III, and IV, but it is possible that they are actually I, II, and III. The carpometacarpus consists of fused carpals (bones of the wrist) and metacarpals (bones of the palm), metacarpals II and III (or III and IV) contributing the greater part of the bone. The phalanges (bones of the "fingers") are reduced to one each on the outer and inner digits and two on the middle one. The primary flight feathers are attached to the carpometacarpus and digits, the number attached to each being characteristic of the various major groups of birds.

Pelvis and leg

The pelvic girdle consists of three paired elements, the ilia, ischia, and pubes, which are fused into a single piece with the synsacrum. The ilium is the most dorsal element and the only one extending forward of the acetabulum (the socket of the leg). The ilium is fused with the synsacrum and the ischium, the latter fused with the pubis. All three serve as attachments for leg muscles and contribute to the acetabulum, which forms the articulation for the femur. The leg skeleton consists of the femur (thighbone), tibiotarsus (main bone of the lower leg), fibula, tarsometatarsus (fused bones of the ankle and middle foot), and phalanges (toes). The fibula is largest at its proximal (upper) end, where it forms part of the knee joint and tapers to a point distally, never forming part of the ankle joint. The latter joint is simplified, there being but two bones involved: the tibiotarsus, consisting of the tibia (the "shinbone" in man) fused with the three proximal tarsals (upper ankle bones), and the tarsometatarsus, resulting from the fusion of metatarsals I through IV and the distal row of tarsals. Metatarsals II through IV contribute most to the tarsometatarsus. The basic number of phalanges (sections) on the toes is two, three, four, and five, respectively; *i.e.*, one more than the number of the toe. Most birds have four toes, the fifth being always absent, but there are many variations in the number of digits, or phalanges, representing reductions of the basic arrangement.

Drawing by R. Keane based on L. Darling and L. Darling, *Bird* (1962); Houghton Mifflin Company

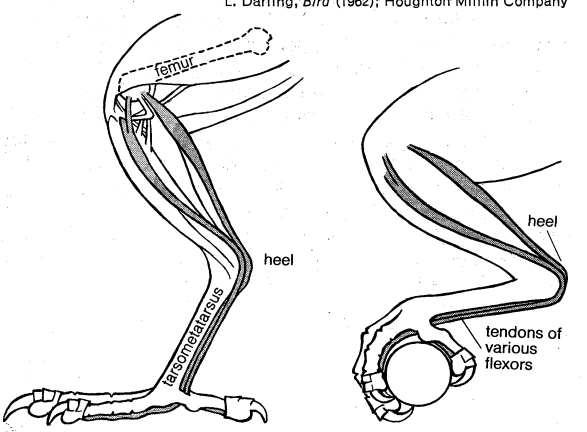

Figure 5: Perching mechanism of a pigeon with the leg extended and flexed.

The basic avian foot is adapted for perching. The first, or hind, toe (hallux) opposes the other three, and the tendons for the muscles that bend the toes pass behind the ankle joint in such a way that when the ankle is bent the toes are also. The weight of a crouched bird thus keeps the toes clasped around the perch.

Muscles

Internal organs. The cardiac (heart) muscles and smooth muscles of the viscera of birds resemble those of reptiles and mammals. The smooth muscles in the skin include a series of minute feather muscles, usually a pair running from a feather follicle to each of the four surrounding follicles. Some of these muscles act to raise the feathers, others to depress them. The striated (striped) muscles that move the limbs are concentrated on the girdles and the proximal parts of the limbs. Two pairs of large muscles move the wings in flight: the pectoralis, which lowers the wing, and the supracoracoideus, which raises it. The latter lies in the angle between the keel and the plate of the sternum and along the coracoid. It achieves a pulley-like action by means of a tendon that passes through the canal at the junction of the coracoid, furcula, and scapula and attaches to the dorsal side of the head of the humerus. The pectoralis lies over the supracoracoideus and attaches directly to the head of the humerus. In most birds the supracoracoideus is much smaller than the pectoralis, weighing as little as one-

twentieth as much; in the few groups that use a powered upstroke of the wings (penguins, auks, swifts, hummingbirds, and a few others), the supracoracoideus is relatively large. Avian striated muscles contain a respiratory pigment, myoglobin. There are relatively few myoglobin-containing cells in "white meat," whereas "dark meat" contains far more. The former type of muscle is used in short, rapid bursts of activity, whereas the latter is characteristic of muscles used continuously for long periods and especially in muscles used during diving.

The circulatory system of birds is advanced over that of reptiles in several ways: (1) there is a complete separation between the pulmonary (lung) and systemic (body) circulations, as in the mammals; (2) the left systemic arch (aortic artery) is lost, blood passing from the heart to the dorsal aorta via the right arch; (3) the postcaval vein is directly connected with the renal portal that connects the kidneys with the liver; and (4) the portal circulation through the kidneys is greatly reduced. Birds' hearts are large—0.2 to over 2.4 percent of body weight, as opposed to 0.24 to 0.79 percent in most mammals.

The avian lung differs from the type found in other land vertebrates, in containing fine tubes (capillaries) through which air passes and through the walls of which gas exchange takes place. Several pairs of nonvascular air sacs are connected with the lungs and extend into the pneumatic parts of the skeleton. The sound-producing organ in birds is the syrinx, located where the trachea (windpipe) divides into the bronchial tubes. The sounds are made by the flow of air setting up vibrations in membranes formed from part of the trachea, bronchi, or both. Muscles between the sternum and trachea or along the trachea and bronchi vary tension on the membranes.

The avian digestive system shows adaptations for a high metabolic rate and flight. Enlargements (collectively called the crop) of parts of the esophagus permit the temporary storage of food. The stomach is typically divided into a glandular proventriculus and a muscular gizzard, the latter lying near the centre of gravity of the bird and compensating for the lack of teeth and the generally weak jaw musculature. Otherwise, the digestive system does not vary markedly from the general vertebrate type.

Like reptiles, birds possess a cloaca, a chamber that receives digestive and metabolic wastes and reproductive products. A dorsal outpocketing of the cloaca, the bursa of Fabricius, controls antibody-mediated immunity in young birds. The bursa regresses with age, and thus its presence or absence may be used to determine age.

The testes of the male bird are internal, like those of reptiles. Intromittent organs are found in only a few groups (waterfowl, cracids, tinamous, ratites). The distal part of the vas deferens (the seminal sac) becomes enlarged and convoluted in the breeding season and takes on both secretory and storage functions. In passerine birds, at least, this enlargement and the adjacent part of the cloaca form a cloacal protuberance, a swelling visible on the outside of the bird. Usually only the left ovary and oviduct are functional. The albumen, membranes, and shell are laid down in the oviduct as the egg moves down it. The gonads and accessory sexual organs of both sexes enlarge and regress seasonally. In the breeding season, the testes of finches may increase over 300-fold in volume over their winter size.

Temperature control

Birds are homeothermic (warm-blooded) and maintain a body temperature of approximately 41° C (106° F). It may be 1–1.7° C less during sleep and up to 2° C higher at times of great activity. Feathers, including down, provide effective insulation. In addition, layers of subcutaneous fat add further insulation in penguins and some other water birds. Reduction of heat loss from the feet in cold weather is accomplished by reducing blood flow to the feet and by a heat-exchange network in the blood vessels of the upper leg, so that the temperature of blood flowing into the unfeathered part of the leg is very low.

Birds differ from mammals in lacking sweat glands, hence heat loss is accomplished by rapid panting, which reaches 300 respirations per minute in domestic hens. Some heat dissipation can be accomplished by regulation of blood flow to the feet. In hot climates, overheating is often prevented or reduced by behavioural means, concentrating activities in the cooler parts of the day and seeking shade during the hot periods. Temporary hypothermia (lowered body temperature) and torpor are known for several species of nightjars, swifts, and hummingbirds. Torpor at night is believed to be widespread among hummingbirds. The heart rate of birds varies widely—from 60 to 70 in the ostrich to over 1,000 per minute in some hummingbirds.

The kidneys lie in depressions on the underside of the pelvis. The malpighian bodies (the active tubules of the kidney) are very small in comparison to those of mammals, ranging from 90 to 400 per cubic millimetre. Over 60 percent of the nitrogen is excreted as uric acid or its salts. There is some resorption of water from the urine in the cloaca, with uric acid remaining. There is no urinary bladder, the urine being voided with the feces. In marine birds, salt is excreted in a solution from glands lying above the eyes through ducts leading to the nasal cavity.

EVOLUTION AND PALEONTOLOGY

Archaeopteryx

The earliest known fossil bird is *Archaeopteryx lithographica* discovered in Upper Jurassic deposits in Bavaria. This bird was about the size of a magpie. It resembled some reptiles and differed from Recent birds in many ways: (1) the jaws contained teeth set in sockets; (2) the articulations between the vertebrae were amphicoelous (concave at both ends); (3) there were only six sacral vertebrae; (4) the long tail was made up of a series

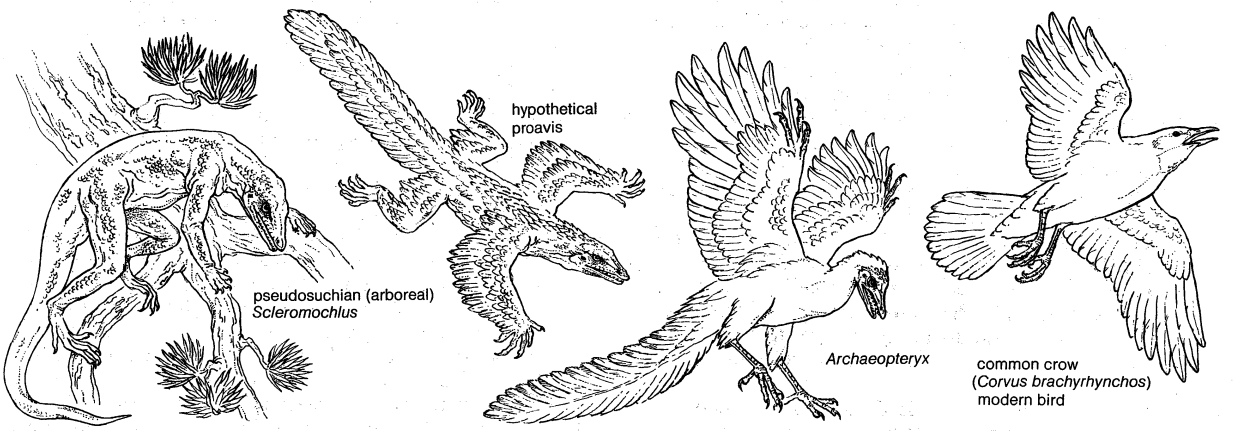

Figure 8: Four stages in the evolution of modern birds.
Drawing by R. Keane

of free vertebrae each bearing a pair of rectrices; (5) the slender ribs lacked articulations with the sternum and uncinate processes (flat upward projections); (6) ventral ribs (gastralia) were present behind (posterior to) the sternum; (7) the sternum was short and not keeled; (8) the bones were not pneumatic; (9) the third metacarpal bone in the wing was fused to the carpals, but the first two metacarpals were free, resulting in three movable digits of the "hand," all with functional claws; (10) the fibula was as long as the tibia; (11) the metatarsal bones were free; (12) the cerebral hemispheres were elongated and slender, and the cerebellum lay behind the midbrain, not overlapping it from behind or crowding it downward. Avian characters of *Archaeopteryx* included the possession of feathers, the elongated, backward-directed pubis, the furcula, and the opposable hallux. In the structure of the beak, eye, and jaw articulation, in the fusion of the third metacarpal with the carpals, and in the fusion of each of the distal tarsals with the corresponding metatarsal, *Archaeopteryx* was intermediate between reptiles and modern birds.

The absence of a keel on the short sternum indicates that *Archaeopteryx* did not fly but glided. The opposable hallux, indicative of the perching type of foot, and the clawed digits of the hand point to an arboreal existence. From the arrangement of feathers on the wing and the number and arrangement of bones in the limbs, it appears that *Archaeopteryx* was near the main line of avian evolution. From the fact that the skull was diapsid (*i.e.*, had two "windows") and from certain features of the limb bones, it appears that *Archaeopteryx* was descended from reptiles of the Triassic order Thecodontia.

The origins of flight

By the Triassic Period (225,000,000 years ago) a group of small bipedal reptiles, the pseudosuchians, were well established. Their skulls had much in common with that of *Archaeopteryx*, although they had heavier jaws and smaller eyes. It is likely that one group of pseudosuchians became arboreal. The advantages of such a life would be safety from large terrestrial predators and an abundance of insect food. Once these reptiles were in the trees, selective pressures would favour mutations leading to many avian features. The swaying of branches would favour the evolution of the grasping foot. Use of the forelimbs in climbing from branch to branch would favour enlargement of the claws and elongation of the forelimb, which was short in the bipedal ancestors. Greater visual acuity and more effective coordination are of special advantage in arboreal animals. Natural selection thus favoured larger eyes, narrower snouts (permitting better forward vision), and greater development of the cerebral lobes and cerebellum of the brain. The smaller jaws may also indicate the advantages of lightness, balance, and a specialization for feeding on insects as opposed to the apparently more general carnivorous diet of the terrestrial ancestors. Perhaps most important was the development of homeothermy (internal temperature control). A warm-blooded insect eater has an enormous advantage in being able to capture insects when they are cold and slow to react. It is also advantageous in the wind-moved environment of the treetops. In addition to increased food intake and advanced respiratory and circulatory systems, however, homeothermy requires effective insulation. It is likely that feathers evolved to fill this requirement, although many authorities believe the origin of feathers was directly connected with flight. Just how feathers evolved from reptilian scales is unknown, but it is known that the two are similar in chemical composition and that some pseudosuchians had scales bearing an imprint of a feather-like pattern on their surface. Elongated feathers on the forelimb and tail may have evolved for balancing and for gliding to produce the *Archaeopteryx* stage.

In the evolution of modern birds from an *Archaeopteryx*-like form, the development of active flight must have occurred early. This meant an increase in size of the muscles moving the wing and the development of a keel on the sternum as an added area of attachment for these muscles. As the tail took on more of a steering function and less of a supportive one, it became shorter and more readily moved as a unit. Feathers became increasingly specialized for different functions, and at the same time, the trends in the development of the eyes, brain, and respiratory and circulatory systems associated with the evolution of the homeothermic, arboreal, gliding types continued. By the time birds became strong fliers, they were ready to radiate out into many new environments; and by the Cretaceous Period (136,000,000 to 65,000,000 years ago), they had begun to do so. This radiation has produced the large array of adaptive types known today.

The lightness and pneumaticity of bird bones makes them poor candidates for fossilization. As might be expected, heavyboned diving birds and large flightless birds are disproportionally represented in the record.

Cretaceous birds

One of the best known groups of fossil birds consists of *Hesperornis* and its relatives. These birds were highly specialized foot-propelled divers of the Upper Cretaceous. The known species of *Hesperornis* were up to six feet long and had completely lost the power of flight. The sternum lacked a keel; the humerus was small and weak; and the other, more distal, elements of the wing were missing. The pelvis and hindlimb had a strong but superficial resemblance to those of modern loons and grebes—the pelvis was narrow; the femur short and stout with a hingelike articulation with the pelvis; the tibiotarsus long, with a long cnemial crest (a projection at its upper end); and the tarsometatarsus laterally compressed. Two major features (and several less obvious ones) indicate, however, that the resemblance was the result of convergent evolution: the ischia and pubes were free for most of their length, and the cnemial process was made up entirely of the patella; in the loon, this process is derived from the tibiotarsus. *Hesperornis* was remarkable for three features: it had teeth set in grooves, not sockets, in

the maxilla and mandible; the phalanges of the stout fourth toe had a unique rotary ball-and-flange type of articulation; and the free tail vertebrae had broad lateral projections and limited vertical motion, indicating that the tail was somewhat beaver-like in its action. *Baptornis*, a contemporary relative of *Hesperornis*, was smaller and less strongly modified. While flightless, it had less reduced wings than *Hesperornis*, and it lacked the peculiar modifications of the fourth toe and caudal vertebrae.

Living on the same seas as *Hesperornis* and *Baptornis* was a group of flying birds known as *Ichthyornis* and *Apatornis*. Although not related to gulls, these birds resembled them superficially and may well have been their ecological counterparts. It was long believed that *Ichthyornis* had teeth, like *Hesperornis;* but it is now thought that the toothed jaws formerly thought to belong to *Ichthyornis* were really those of a small mosasaur, a marine reptile.

Large flightless predators

After the extinction of the dinosaurs and before large carnivorous mammals evolved, two groups of large flightless birds evolved to fill a similar niche. From the upper Paleocene to the middle Eocene, *Diatryma* and its relatives were major predators in the Northern Hemisphere. The largest species stood over two metres (seven feet) tall and had stout hooked beaks. They are of uncertain relationships but may have been distantly related to cranes and rails. The second group, that of *Phororhacos* and related genera, had a long history (from the lower Oligocene to the middle Pliocene) in South America, which was without large carnivores until relatively late. Fragmentary Pleistocene material from Florida has also been assigned to this group. The *Phororhacos* line evidently evolved from cariama-like stock and radiated into numerous genera and species, the largest of them (*Onactornis*) standing 2½ metres (eight feet) tall and having a skull 80 centimetres (31 inches) long and 40 centimetres (16 inches) high.

Large grazing or browsing birds appear to have evolved several times. On continents where there are large predators, these birds have always been rapid runners (ostriches, rheas, emus), but on islands lacking such predators, they were slow-moving, heavy-bodied birds. Two such groups were the elephant birds of Madagascar and the moas of New Zealand, the largest in each group approaching ten feet in height. Fragmentary fossil material from Eocene and Oligocene deposits in Egypt indicates that similarly adapted birds occurred there before the advent of large carnivores.

Except for the *Hesperornis* line, teeth appear to have been lost very early in the history of birds, but fish-eating birds have evolved several toothlike structures for grasping their prey. Perhaps the most remarkable adaptation was that of *Osteodontornis* and its relatives, large, flying marine birds that flourished from the lower Eocene to the Miocene. In these birds, there were bony projections of the upper and lower jaws, which were covered by the ramphotheca, forming sharp, toothlike structures.

The fact that fewer bird fossils are found in earlier deposits is well illustrated by expressing the number of known species in a given geological period in terms of the duration of the period. About 35 species of birds are known from Cretaceous deposits, which were laid down over an estimated 71,000,000 years, giving a figure of 0.5 species per 1,000,000 years. The corresponding figure for the Paleocene is 1.2 (12 species in 10,000,000 years) and that for the Eocene, 5.4 (87 species in 16,000,000 years). Up-to-date figures for the later periods are not available, but estimates based on several recent sources are 7.9 per 1,000,000 years in the Oligocene, 12.3 in the Miocene, and 21.8 in the Pliocene. The Pleistocene, which lasted approximately 2,500,000 years has yielded nearly a thousand species of fossil birds. From this it is evident that very little is known about the early avifaunas. It is known, however, that, as might be expected, the birds in the earlier periods differ more from Recent species than do those of the later periods. Of the 12 families of birds recorded from Cretaceous deposits, only two are still extant, whereas the majority of species recorded from the Pleistocene were structurally little, if at all, different from living forms. Thus the absence of a group in the fossil record, especially in the earlier periods, is rarely significant.

The major diversification of birds probably took place in the Cretaceous, which lasted longer than the sum of all subsequent periods, and it must have started early in that period because fragmentary material of foot-propelled divers (*Enaliornis*) and of an early relative of the flamingos (*Gallornis*) are known from Lower Cretaceous deposits of Europe. Upper Cretaceous deposits have yielded, besides *Hesperornis* and *Ichthyornis* and their relatives, diving birds similar to *Enaliornis* (*Lonchodytes*), other early flamingo-like birds, and species in the same suborders as gannets, ibises, rails, and shorebirds.

Paleocene deposits have yielded the earliest known loons, cormorants, New World vultures, and gulls, while the large, flightless predatory birds culminating in *Diatryma* first made their appearance in this period. From the far richer Eocene deposits have come the earliest known rheas, penguins, albatrosses, tropic birds, anhingas, true flamingos, herons, storks, secretary birds, hawks, curassows, cranes, bustards, avocets, auks, sandgrouse, cuckoos, owls, swifts, trogons, rollers, hornbills, and songbirds. Almost certainly all living orders and most living families were in existence by the end of that period. One of the most interesting finds from this period was *Neocathartes*, a long-legged bird allied to the New World vultures. There are several anatomical similarities between this group of vultures and the storks, and the existence of this fossil lends support to the idea that the storks and New World vultures are more closely related to each other than each family is to the birds with which it is usually grouped.

Important Oligocene fossils include the earliest phororhacoids, one of the few groups of fossil birds that is known from enough material from over a long enough time span to show evolutionary trends, in this case, both in size and in bill form.

Fossils of Miocene birds are numerous. Several early groups of pelecaniform, cranelike, and flamingo-like birds are known last from this period, and the first of the Mancallidae, superficially penguin-like auks, appeared. Otherwise, the avifauna was essentially modern.

By Pliocene times, most modern genera were probably in existence. The Mancallidae continued on the California coast at least until the middle of the period.

The appearance and extinction of large birds as well as mammals was a feature of the Pleistocene. Perhaps most notable were the teratorns, "super condors," which were found in North America. These included *Teratornis incredibilis*, the largest known flying bird.

CLASSIFICATION

Distinguishing taxonomic features. In classifying birds, most systematists rely primarily on structural characters. Plumage characters include the number of remiges and rectrices; the presence or absence of down on the feather tracts, on apteria, and on the oil gland; and the presence or absence of an aftershaft. Characteristics of the bill and feet are useful, as is the arrangement of bones in the palate and around the nostrils. The presence or absence of certain thigh muscles and the arrangement of the carotid arteries, the syrinx, and the deep flexor tendons of the toes are employed, as is the condition of the young when hatched. Recently, advances in the study of protein structure and of chromosomes have added new evidence of taxonomic relationships.

Annotated classification. This classification is based primarily on that of the American ornithologist Alexander Wetmore but includes the ideas of a number of other authorities. It is unlikely that most avian systematists would agree on all aspects of one arrangement, but the one presented below will satisfy many. The dagger (†) indicates extinct groups, known only from fossils.

CLASS AVES

Vertebrate (backboned) animals primarily adapted for flight with feathers. Warm-blooded, 4-chambered heart, left syste-

mic arch lost. Lower jaw articulates with cranium via the quadrate; teeth absent in living forms. Reproduction by hard-shelled eggs, nearly always incubated by one or both parents. About 8,600 living species.

†Subclass Archaeornithes

†Order Archaeopterygiformes (*Archaeopteryx*). Upper Jurassic; Europe. Teeth set in sockets; long, unfused caudal vertebrae, each bearing a pair of rectrices; keelless sternum; functional claws on digits of hand. Gliding birds, about 50 cm long.

Subclass Neornithes

†Superorder Odontognathae

†Order Hesperornithiformes (*Hesperornis, Baptornis*). Upper Cretaceous; North and South America. Teeth set in groove in jaws. Flightless, foot-propelled diving birds, 1 to 2 m long.

Superorder Neognathae

Order Tinamiformes (tinamous). Upper Pliocene to present; Central and South America. Superficially quaillike or grouselike ground-dwelling birds with flat, elongated, and rather weak bills and very small tails. Size 15–50 cm. See TINAMIFORMES.

Order Rheiformes (rheas). Lower Eocene to present; South America. Ostrich-like cursorial birds with very small tails and no aftershaft on the feathers. Sexes alike. Length 90–130 cm.

Order Struthioniformes (ostrich). Lower Pliocene to present (the Eocene *Eleutherornis* may belong here); southwestern Asia and Africa (fossils from southern Europe and southeastern Asia). 2-toed (3rd and 4th) running birds. Males black and white, females brown. Aftershafts, down, and filoplumes absent. Largest living bird; length to 180 cm, height 260 cm, weight 136 kg, egg 1.6 kg.

Order Casuariiformes (emus, cassowaries). Pleistocene to present; Australia, New Guinea, adjacent islands. Very large, cursorial (running) birds. Sexes alike, brown (emus) or blackish with brightly coloured wattles and skin on head (cassowaries). Aftershaft very large. Length 130–190 cm. See CASUARIIFORMES.

†Order Aepyornithiformes (elephant birds). Pleistocene; Madagascar (upper Eocene and lower Oligocene fossils from Egypt have been placed here). Very large and graviportal (heavy bodied); height to 3 m; egg weight estimated at 10 kg.

Order Dinornithiformes (moas, kiwis). Upper Miocene or lower Pliocene to present; New Zealand. Very large (to 3 m tall) and graviportal birds (moas) or smaller (length 30–80 cm); almost wingless, nocturnal, probing birds (kiwis).

Order Podicipediformes (grebes). Lower Miocene to present; worldwide. Foot-propelled diving birds with lobed toes, minute tails, and silky plumage. Length 21–66 cm. See PODICIPEDIFORMES.

Order Procellariiformes (albatrosses, shearwaters, petrels). Middle Eocene to present; all oceans, most numerous in Southern Hemisphere. Web-footed marine birds with tubular nostrils; rhamphotheca divided into plates; musky smell. Most have narrow wings and stiff, gliding flight. Length 14–135 cm. See PROCELLARIIFORMES.

Order Sphenisciformes (penguins). Upper Eocene to present; oceans of Southern Hemisphere. Wings flipper-like, for propulsion underwater; webbed feet short and stout; stance upright. Feathers short and dense, molted in patches. Length 40–120 cm (fossil forms to 180 cm). See SPHENISCIFORMES.

Order Pelecaniformes (tropic birds, pelicans, boobies, cormorants, frigate birds). Paleocene to present; worldwide. Water birds with all 4 toes webbed; bill hooked or straight and sharply pointed. Length 50–180 cm. See PELECANIFORMES.

Order Anseriformes (screamers, waterfowl). Middle Eocene to present. Web-footed birds with broad bills containing fine plates or lamellae (waterfowl); or large-footed marsh birds with chicken-like bills (screamers). Length 29–160 cm. See ANSERIFORMES.

Order Phoenicopteriformes (flamingos). Cretaceous to present; discontinuously distributed in warm regions except Australasia. More varied and widely distributed as fossils. Web-footed birds with long legs, long necks, bent bills with lamellae, and much pink or red in the plumage. Share characters with both Anseriformes and Ciconiiformes, but evidently closer to the latter, with which they are sometimes grouped. Length 91–122 cm (some fossil forms smaller). See CICONIIFORMES.

Order Ciconiiformes (herons, storks, ibises, spoonbills). Upper Cretaceous to present; worldwide except in extreme north. Long-legged wading birds with long bills; feet not webbed. Although usually grouped together, herons and storks may prove to belong to different orders. Length 28–152 cm. See CICONIIFORMES.

Order Falconiformes (diurnal birds of prey). Upper Paleocene to present; worldwide. Diurnal raptors with hooked beaks, long talons, and short (hawks, falcons) or very long (secretary bird) legs or carrion-eating birds with weaker claws and tearing bills (vultures, condors). Length 15–150 cm (some fossil forms larger). See FALCONIFORMES.

Order Galliformes (grouse, pheasants, quail, turkeys). Middle Eocene to present; nearly worldwide, except southern South America. Terrestrial or arboreal chicken-like birds; strong, scratching feet; short, rounded wings; feathers with long aftershafts. Length 13–198 cm. See GALLIFORMES.

Order Gruiformes (cranes, rails, coots, cariamas, bustards). Upper Cretaceous to present; worldwide. Diverse group, ranging from small quail-like hemipodes to large long-legged cranes, marsh-inhabiting rails, swimming coots and fin-foots, and cursorial bustards. The Tertiary phororhacoids belong here, as may the very large *Diatryma* and its relatives. Length 11–152 cm (fossils to 200 cm tall). See GRUIFORMES.

†Order Ichthyornithiformes (*Ichthyornis, Apatornis*). Upper Cretaceous; North America. Superficially gull- or ternlike water birds of uncertain affinities. Length approximately 21 to 26 cm (estimated from reconstruction of fossils).

Order Charadriiformes (plovers, sandpipers, gulls, terns, auks). Upper Cretaceous to present; worldwide. 3 basic body plans: Suborder Charadrii—waders (shorebirds), usually feeding on small animals in mud or water, bill variable but often long and used for probing; Lari—web-footed, dense-plumaged water birds feeding by plunging into water for fish, robbing other birds, or scavenging; Alcae—dense-plumaged, web-footed, marine, wing-propelled divers, feeding on fish or invertebrates. Length 13–76 cm. See CHARADRIIFORMES.

Order Gaviiformes (loons or divers). Upper Paleocene to present; Holarctic. Foot-propelled diving birds with webbed feet and pointed bills. Cnemial crest an extension of the tibia. Length 66–95 cm.

Order Columbiformes (sandgrouse, pigeons, doves, dodos). Upper Eocene or lower Oligocene to present; worldwide except in extreme north. Fast-flying birds with pointed wings and weak bills; feed on seeds and fruit. Length 15–84 cm. See COLUMBIFORMES.

Order Psittaciformes (parrots, lories, cockatoos). Upper Oligocene to present; throughout tropics, with some temperate-zone species. Often brightly coloured. Strong-flying, seed-, fruit-, or nectar-eating birds with very stout, hooked bills and zygodactyl feet (*i.e.*, outer toe reversed). Length 9.5–99 cm. See PSITTACIFORMES.

Order Cuculiformes (touracos, cuckoos, roadrunners). Upper Eocene or lower Oligocene to present; worldwide except in extreme north. Long-tailed birds with zygodactyl or semizygodactyl feet. Feed on both fruits and small animals. Most arboreal, a few terrestrial. Some brood parasites. Length 16–70 cm. See CUCULIFORMES.

Order Strigiformes (owls). Eocene to present; worldwide. Nocturnal raptorial birds with hooked beaks, strong talons, and soft plumage. Length 13–69 cm. See STRIGIFORMES.

Order Caprimulgiformes (nightjars, frogmouths, oilbird). Pliocene to present; worldwide except in extreme north. Concealingly coloured, soft-plumaged, nocturnal birds with weak feet and very large mouths. Most feed on insects caught in flight. Length 19–53 cm. See CAPRIMULGIFORMES.

Order Apodiformes (swifts, hummingbirds). Upper Eocene or lower Oligocene to present; worldwide except in extreme north; hummingbirds limited to New World. Rapid-flying birds that feed on the wing on insects and nectar. "Hand" and primaries constitute a relatively great proportion of the wing; feet weak. Length 6.3 to 23 cm. See APODIFORMES.

Order Coliiformes (colies or mousebirds). Unknown as fossils. Africa south of the Sahara. Soft-plumaged birds with long, pointed tails and all 4 toes directed forward. Food largely vegetable, some insects. Length 29 to 36 cm.

Order Trogoniformes (trogons). Pantropical, except Australasia; upper Eocene or lower Oligocene to present. Extremely soft-plumaged arboreal birds; underparts yellow to red, head and neck often iridescent, tail long, black and white. Feet weak; 1st and 2nd toes directed backward. Food insects and small fruit. Length 23 to 34 cm.

Order Coraciiformes (kingfishers and allies). Eocene to present; worldwide except in extreme north. A heterogeneous

group of hole-nesting birds. Many with long, pointed bills and blue or green in plumage. All have 2nd and 3rd or 3rd and 4th toes joined at base. Food largely animal, except hornbills, which eat much fruit. Length 9 to 160 cm. See CORACIIFORMES.

Order Piciformes (woodpeckers, barbets, honeyguides, toucans). Upper Oligocene (possibly upper Eocene) to present. Zygodactyl (rarely 3-toed) hole-nesting birds. Food insects and fruit. Woodpeckers are modified for climbing. Honeyguides are brood parasites. Length 9 to 61 cm. See PICIFORMES.

Order Passeriformes (perching birds). Upper Eocene to present; worldwide. The large complex assemblage of perching birds, containing more than half of the known species of birds. Bill, plumage, and habits highly varied. Length 7.5 to 102 cm. See PASSERIFORMES.

Critical appraisal. It has frequently been stated that birds are one of the best known of animal groups. This is true, in the sense that most of the living species and subspecies in the world have probably been described; but because of inadequacies in the fossil record and repeated cases of convergent evolution within the group, our knowledge of the phylogenetic relationships between orders, suborders, and families of birds is inferior to that of mammals and reptiles.

The taxonomic positions of several bird groups remain open to question. The hoatzin, included above in the Galliformes, is often given its own order, Opisthocomiformes. The touracos, here included in the Cuculiformes, are considered by many authors to warrant separation as Musophagiformes. *Diatryma* and several related genera of extinct flightless predators are often placed in a distinct order, Diatrymiformes, near Gruiformes. The flamingos, which constitute the order Phoenicopteriformes above, are placed in the Ciconiiformes in many classifications. The sandgrouse, family Pteroclidae, are believed by some to be more closely related to the shorebirds (order Charadriiformes) than to the pigeons (order Columbiformes), with which they are usually grouped.

One area particularly in need of study is the relationships among the various groups of ratites (ostriches, rheas, emus, moas, etc). Formerly, some authorities argued that these birds and the penguins arose independently from cursorial reptiles, but it is now generally agreed that all of them passed through a flying stage in the course of their evolution. The ratite groups differ greatly in morphology and yet show remarkable similarities in palate and bill characters. The principal unanswered questions are how many different flightless lines evolved from flying ancestors and from how many different groups were the flying ancestors evolved. On zoogeographic grounds, it is likely that the isolated kiwi-moa, elephant bird, and emu-cassowary lines arose independently from each other and from ratites on the other continents. But the ostriches and rheas could be descended from a common flightless ancestor because of the known former land connections from Asia to North and South America.

Before organic evolution was understood and accepted, animals were grouped on the basis of general similarity. It is now known that many such groupings were unnatural from a phylogenetic standpoint but were instead the result of convergent evolution from different parental stocks. Examples are *Hesperornis*, loons, and grebes, and diving petrels and auks. It is likely that many more examples are not recognized or generally accepted. At least the following groups should be studied with this in mind: herons and storks, *Diatryma* and the phororhacoids, New World vultures and other falconiforms, sandgrouse and pigeons, touracos and cuckoos, and swifts and hummingbirds. These examples are all from the ordinal or subordinal level; examples at lower levels would be far more numerous.

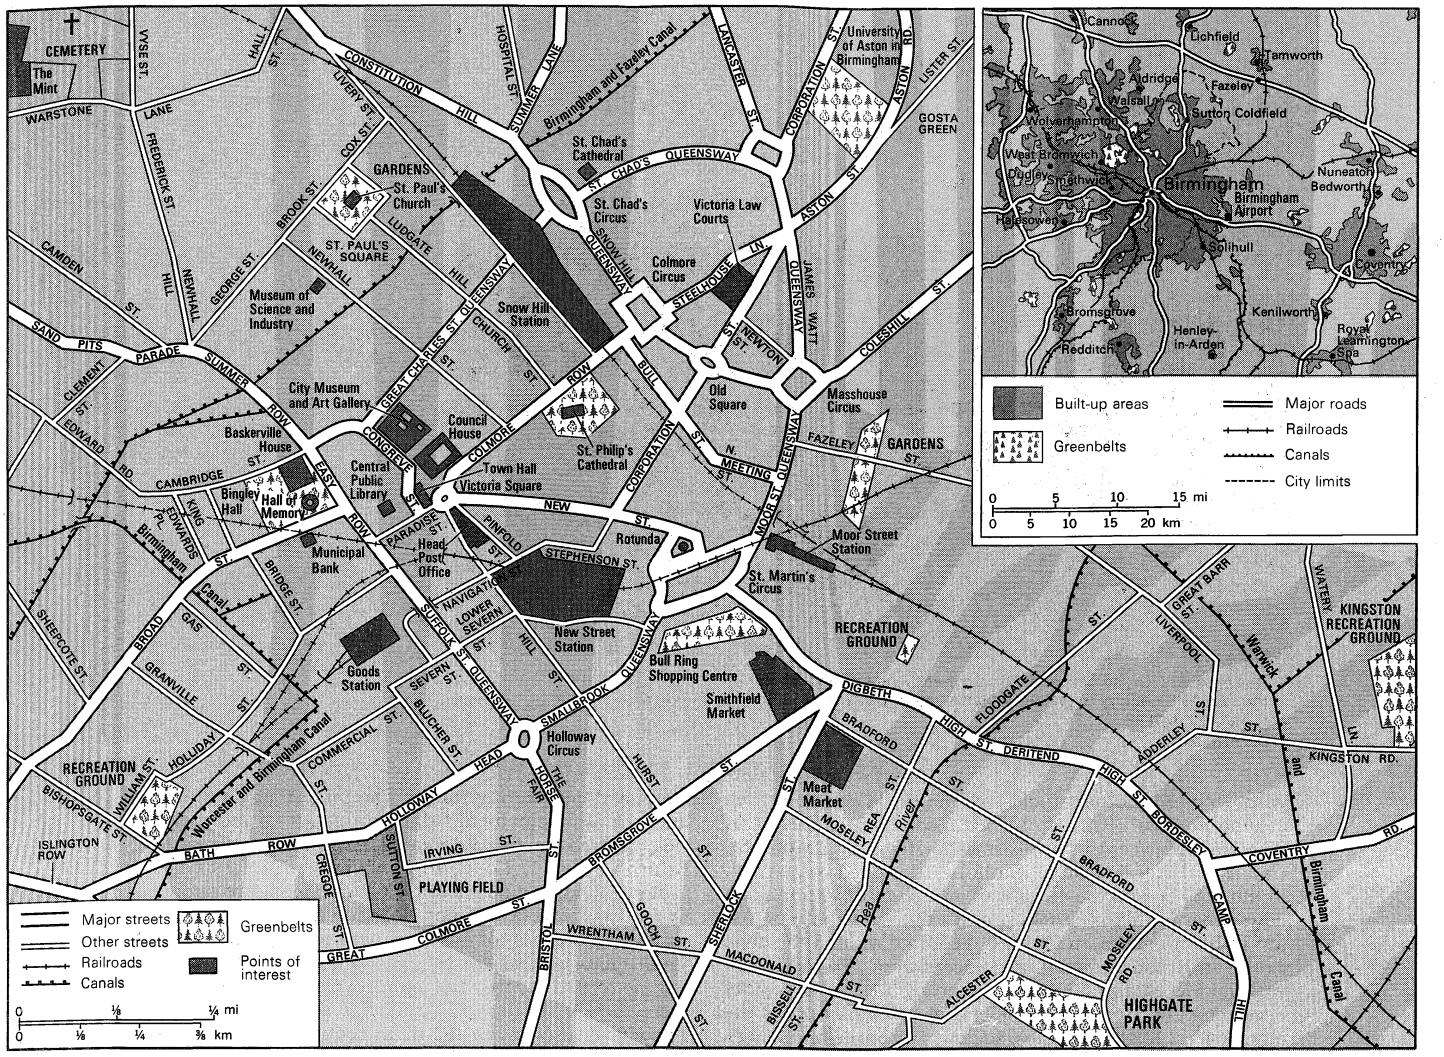
(R.W.St.)

Birmingham

A city and parliamentary borough (returning 12 members to Parliament) forming part of West Midlands metropolitan county, Birmingham is the second city in Great Britain in population (estimated in 1972 at 1,092,000) and one of the principal manufacturing and commercial regions of the United Kingdom. It lies near the geographical centre of England, at the crossing points of the national railway, motorway, and canal systems. With an area of 80.6 square miles (208.8 square kilometres) and a perimeter of 52 miles (84 kilometres), it is also the largest town in the West Midlands conurbation—itself over 20 miles (32 kilometres) across, with nearly 2,400,000 inhabitants—for which it acts as an administrative, recreational, and cultural centre.

In the late 18th century Birmingham became the leading nucleus of the Industrial Revolution in Britain, pioneering new methods of production in the metal and engineering trades. A group of men of genius lived in the city at that time, many of them members of the philosophical and scientific group known as the Lunar Society. They included the engineers James Watt (inventor of the steam engine), Matthew Boulton, and William Murdock (pioneers in steam engine development), the chemist Joseph Priestley, and the printer John Baskerville. The entire group deeply influenced the technological progress of Birmingham and the nation. Boulton's Soho Manufactory, which developed the steam engine for industrial use, became famous throughout Europe. Despite bad housing and the uncontrolled spread of industry, Birmingham became well-known in the later 19th century for its efficient and enlightened civic administration. During the 1950s and 1960s, a vast and often controversial redevelopment and road-building program transformed the Victorian city beyond recognition. Though dominated by industry, Birmingham has always been surrounded by pleasant suburbs, rich in trees and flowers, and has easy access to a beautiful countryside.

City growth. Birmingham's lack of river transport, by cutting it off from the maritime contacts important in the medieval period, impeded its development from a small manufacturing town to a large city until the late 18th century. The population of 15,000 at the end of the 17th century had become 70,000 a century later. The town



Central Birmingham and (inset) its metropolitan area.

then spread from its hilly centre, which, by 1800, contained St. Philip's Cathedral (1715) and many Georgian buildings in the St. Paul's Square area and elsewhere. The metal and gun trades expanded, fine jewelry was made alongside cheaper lines, and local buttons and trinkets, often in brass, served a world market. It was not until after the Reform Act of 1832 that Birmingham elected its own members to Parliament, and the city did not receive its charter of incorporation until 1838. In the same year, rail links to Liverpool and London were completed. In 1869 the city found the leader it needed when Joseph Chamberlain, a rich local industrialist, was elected to the council. In 1873 he was elected mayor, a position he held for three years. He initiated important reforms, among them sweeping slum and city-centre redevelopment schemes, incidental to which were the setting up of a school board and several major improvements to urban services.

Granting of a charter

Birmingham was a British pioneer in town-planning schemes (1911), one-way traffic experiments (1933), and municipal airports (1939). The Municipal Bank, still the only one in the country, opened in 1916. Wartime industrial activity and heavy bombing left the city temporarily exhausted in 1945, but it quickly recovered. Smokeless zones and the conversion of the railways to diesel oil and electricity eliminated much of the industrial haze and smog, while carefully preserved parks and open spaces kept the city and suburbs rich in greenery. A new inner ring road scheme, a rebuilt central station, and new shopping and commercial complexes began the city's transformation. The most striking visual features of this by the 1970s were the Rotunda, a circular office building 265-feet (81-metres) tall, the post office radio tower (500 feet [150 metres]), and the Bull Ring Shopping Centre, incorporating shops, a bus station, a car park, markets, restaurants, and gardens.

The small and cramped city centre has had to learn to build high, but at the same time much central industry and population have been moved out, first to five central redevelopment areas immediately adjoining the city centre, then farther out to 38 additional comprehensive redevelopment areas.

The contemporary landscape. Birmingham stands in the centre of an upland plateau shut in by the valleys of the rivers Trent, Severn, and Avon. The land rises from 267 feet (81 metres) above sea level in the east to 736 feet (224 metres) in the west. The northern suburbs adjoin Staffordshire, and the southern and southwestern suburbs border on Hereford and Worcester. On the northwest the city merges into the old industrial agglomeration of small towns known as the Black Country, a name referring to the effect of industrial pollutants on land, buildings, and the atmosphere. To the southeast it adjoins Solihull, a separate district and popular residential area, while the southern suburbs straggle out pleasantly into the Warwickshire countryside. A few medieval and Elizabethan buildings, often much altered, lie scattered through the inner and outer suburbs; a fine Jacobean house, Aston Hall (1618), is situated close to the city centre.

The Black Country

One central focus is Victoria Square with the classical Town Hall (1834) and the Renaissance-style Council House (1874–81) and City of Birmingham Museum and Art Gallery. St. Philip's Cathedral, in its green church-

Victoria Square, in the centre of Birmingham. The Council House (centre left) was built in the late 19th century in Italian Renaissance style. The statue of Queen Victoria (centre) was erected in 1899.
A. Devaney, Inc.

yard, forms another focus, while the Georgian area around St. Paul's Church (1779) also has a character of its own. Other centres are formed or forming around St. Chad's Cathedral (Roman Catholic), designed by A.W.N. Pugin (1841), and the elegant *Birmingham Post and Mail* newspaper building (1964), around the University of Aston in Birmingham, in Gosta Green, and around the civic centre in Broad Street. The adjacent area of Edgbaston, with its Georgian and early Victorian houses, is rapidly becoming an extension of the commercial districts of the city. Several former villages, such as Harborne and King's Norton, keep something of their rural aspect. More than 7,300 acres (3,000 hectares) of parks keep the district open and pleasant, though the inner circle of older former suburbs, among them Sparkbrook, Handsworth, and Saltley, are extremely dilapidated and overdue for redevelopment.

Population. The main demographic problem is the large immigrant population—white and nonwhite. The nonwhite ("New Commonwealth") population at the 1971 census in the former county borough numbered 68,000, of whom 25,000 were from the Caribbean, 38,000 from Asia (mostly India and Pakistan), and the rest from the continent of Africa and from other countries. There was an Irish population of 45,000, about 40,000 persons being Irish-born. The poorer immigrants settled in the older suburbs near the city centre. Despite some overcrowding, however, there had been no serious racial or immigrant trouble in Birmingham by the mid-1970s. The city as early as 1954 appointed an officer whose sole concern was community relations. Birmingham lost some population after the 1950s to residential districts beyond what was then the city boundary, to new towns, and to "overspill" areas. The five redevelopment areas close to the city centre, which will have their own shops, schools, doctors, and industries, and the tower, or high-rise, apartments in the city centre itself, are being constructed as part of a scheme to attract residents back to the centre. During the last years of the 1960s the former Birmingham Corporation built more than 7,250 new dwellings, and its total for the latter half of the decade was some 33,000, a record for municipal housing in Britain and possibly in the world.

The immigrants

The economy. Once known as "the workshop of the world" and still often described as "the city of 1,500 different trades," Birmingham is the centre of Britain's light and medium industry, principally concerned with the metal and engineering trades. The largest single industry in terms of employment is the production of motor vehicles, centred on the automated Austin Morris plant of British Leyland at Longbridge, with other factories of the group in and around the city. Components are supplied by firms as large as Dunlop Ltd. and the electrical accessories organization of Joseph Lucas and by hundreds of small factories and workshops, some employing only a few persons. Bicycles and motorcycles are made in the area, though the bicycle trade has somewhat declined. The city is also one of the main centres of the machine-tool industry. Local industry also includes heavy engineering, electroplating, and manufacture of aircraft components, fine and costume jewelry, silverware, plastics, sporting guns, buttons, and ornamental badges. Chemicals, furniture, and toys have their place in the city's economy, and Bournville, an early example of industrial town planning, is the site of Cadbury's chocolate factory.

The automobile industry

Administration. With the Local Government Act of 1972 coming into operation in 1974, the Birmingham City Council was replaced by a new Birmingham District Council, which took in the former borough of Sutton Coldfield. The council is also represented on the West Midlands Metropolitan County Council.

Birmingham's water supply comes from Wales, 73 miles (117 kilometres) away. Large-scale housing development took place between 1918 and 1939, and building since 1945 has included many multi-story apartment buildings, though by the 1970s there was a tendency to return to low-rise housing. The Birmingham District Council provides old people's and children's homes, residential and day nurseries, and child welfare centres. Local transport, formerly run by the corporation, is now controlled by the West Midlands Passenger Transport Executive. Snow Hill Railway Station closed its mainline services in 1967 but remained open for local services to Wolverhampton. New Street Station was completely rebuilt in the late 1960s, and a large shopping centre was erected above it. Electrification has reduced the train time between London and Birmingham to one hour and 35 minutes. The inner-ring road, completed in 1971, furthers the city's plan to segregate pedestrians and traffic and to keep unnecessary through and suburban traffic from crowding the city centre.

Cultural life. Birmingham is the cultural centre for a wide area, possessing three professional theatres and a

The Birmingham Repertory Theatre

number of amateur companies with their own theatres. The Birmingham Repertory Theatre was opened by Sir Barry Jackson in 1913 and fostered the early careers of, among others, such distinguished performers as Laurence Olivier, Ralph Richardson, Margaret Leighton, and Paul Scofield. A new theatre for the "Rep" is being built in the cultural complex in Broad Street. The Midlands Arts Centre for Young People, located in Cannon Hill Park, was an outstanding enterprise of the 1960s; when complete, the 15-acre site will house two theatres, a concert hall, a cinema, an art gallery, workshops, and studios. The City of Birmingham Symphony Orchestra plays in the Town Hall and in other Midland halls. Though subsidized by the Corporation, it faces the financial problems of all subsidized orchestras and is badly in need of a proper concert hall. It is hoped to include such a hall in the Broad Street development. The City Art Gallery is one of the largest outside London and is famous for its English watercolours and its pre-Raphaelite paintings. The Central Library contains more than 700,000 volumes, and work has started on a new library that will be among the largest public libraries in Europe. The city has two professional soccer clubs, and the Warwickshire County Cricket Club has its ground at Edgbaston.

The University of Birmingham, with over 6,750 students enrolled annually at the start of the 1970s, has an extensive campus at Edgbaston, with a medical school attached to the Queen Elizabeth Hospital; Birmingham was an early centre of medical research. The University of Aston, which opened in 1966 near the city centre, has over 3,000 full-time and more than 200 part-time students and specializes in technology. There are also educational and artistic facilities at the Birmingham and Midland Institute, now housed in the building of the Birmingham Library, a subscription library founded in 1779. The Selly Oak group of colleges provide education in religious and social subjects. King Edward's School, Edgbaston, founded in 1552, is the oldest educational institution in Birmingham; King Edward's High School for Girls stands on the same site, and other schools of the foundation are to be found elsewhere in the city.

The unusually small city centre, the lack of suitable buildings, and the short train journey to the theatres and galleries of London have hitherto adversely affected the city's native cultural life. But wide provision for a Birmingham-based culture is being made in the redevelopment. Despite controversy over details, the "new" Birmingham could ultimately rival the 19th-century city at its height, when Mendelssohn wrote *Elijah* for the city's music festival in 1846 and Joseph Chamberlain made the name Birmingham a European byword for civic progress.

Birth Control

The term birth control, coined by Margaret Sanger in 1914–15, denotes methods of preventing conception, whether involving the male or female, and now comprises all methods of fertility control, including abortion and sterilization. The term family planning came into use in the 1930s, followed by planned parenthood, denoting efforts (including the treatment of infertility) to regulate (whether by increase or decrease) the size of families. Other terms used by the early clinical movement have been contraceptive, contraception, voluntary parenthood, and family limitation and such Malthusian or neo-Malthusian terms as artificial checks, anticonception, anticonceptics, and prevenception.

HISTORY OF BIRTH CONTROL

The drive for fertility regulation by individuals has been evident in all cultures at all times, even in those societies in which social or religious rules favoured the abundant production of children. Until this century governments have more often been concerned to stimulate fertility than to encourage its limitation. The oldest recorded medical recipes to prevent conception, nevertheless, are contained in ancient Egyptian papyri, notably the Petri Papyrus, written about 1850 BC, and the Ebers Papyrus, written about 1550 BC, which describe many means of averting pregnancy. In ancient Greece and Rome there was much concern over fertility regulation. Soranus of Ephesus, a Greek gynecologist who worked in Rome, gave a lucid and detailed account of contraceptive methods in his writings during the 2nd century AD. He distinguished clearly between contraceptives and abortifacients (abortion-inducing agents) and observed that the prevention of conception is medically preferable to repeated abortions. This ancient knowledge was incorporated in the writings of Islāmic doctors and so made available throughout Europe, forming most of the scientific basis for contraception up to the late 17th century. It is evident from these works and other evidence that contraception had a place in medicine during this time—as a means either of helping to maintain the general health of women or of easing specific medical problems. Such sophisticated medical care was available to only a small percentage of the citizenry; widespread availability of medical birth control did not begin until the 20th century.

Malthusianism

Reformers and reformist groups. Since Thomas Malthus' *Essay on the Principle of Population* in 1798, birth control has increasingly been involved with concern for population size. Malthus, a clergyman, advocated the limiting of birth by sexual abstinence and late marriage. Both of these means were rejected by such reformers as Jeremy Bentham and Francis Place, who instead advised "such precautionary means as would, without being injurious to health and destructive of female delicacy, prevent conception" and "enable young men and women to remain chaste by making it possible for them to marry early." In 1831 Robert Dale Owen initiated discussion in the United States by publishing his book *Moral Physiology*. Probably the most detailed account of contraception techniques since the writings of Soranus was contained in *The Fruits of Philosophy: or, The Private Companion of Young Married People*, by Charles Knowlton, which appeared in the U.S. in 1832 (and in England in 1834); Knowlton himself was fined and briefly imprisoned as a result of his publication.

As evidence of industrial poverty and overcrowding increased in the 19th century, the secular Free Thought movement adopted neo-Malthusianism as part of its labour reform proposals. In the 1860s one of its members, George Drysdale, started the Malthusian League, in which he was joined in 1874 by Annie Besant. Under continual attack by the churches and the medical profession, however, it made little headway. In 1876 a Bristol publisher was imprisoned under the 1857 obscene publications act for selling "pornographic" books, including *The Fruits of Philosophy*, published by the freethinkers. Incensed, Charles Bradlaugh (leader of Britain's National Secular Society) and Annie Besant reissued the pamphlet themselves, notifying the police. Action was brought against them for corruption of youth, but the conviction was quashed on grounds of faulty indictment. The trial

publicity boosted neo-Malthusianism, and the Malthusian League, reformed, now aimed "to agitate for the abolition of all penalties for the public discussion of the population question" and "to spread among the people by all practicable means a knowledge of the law of population, of its consequences, and of its bearing upon human conduct and morals." A medical branch was formed to gain medical cooperation, and by agitating for discussion in the medical press, to obtain recognition of contraception's scientific basis. Its success, however, was small.

Malthusian leagues started in France, Germany, and Holland. The one in Holland started a medical service under Aletta Jacobs in 1882 and some clinics from 1890 on, and the concept of clinics spread elsewhere. Interest, despite powerful opposition, was also growing in the United States, largely involving sexual emancipation. An act of Congress penalizing contraception was passed in 1873 through the efforts of Anthony Comstock, who had founded the Society for the Suppression of Vice in New York. In 1912 Margaret Sanger began writing there in the Socialist newspaper *The Call*. After a visit to Europe to collect contraceptive information, she issued *Woman Rebel*, a monthly journal, which was barred from the U.S. mails and caused her to be indicted for "misuse of mail." In defiance she printed *Family Limitation* and left for Europe to meet her continental counterparts and see the Dutch clinic. She returned in October 1915 prepared to stand trial, but the charges were dropped. In 1916 Margaret Sanger and her sister opened a clinic in Brownsville, Brooklyn, after the police had closed it, and were arrested and convicted on charges of "maintaining a public nuisance." The appeal court's findings, however, enabled doctors to give contraceptive information "for prevention or cure of any disease." In 1915 the feminist Mary Ware Dennett formed the first U.S. birth control society. Battles against the Comstock laws ensued, but the American movement grew, becoming in 1942 the Planned Parenthood Federation of America; and in 1963, after merging with the World Population Emergency Campaign (a fund-raising organization for global birth control), it became Planned Parenthood-World Population.

Clinics and family planning associations

During and after World War I, feminist activities reinforced the neo-Malthusians, though anti-contraception legislation increased. In London in 1918 Marie Stopes published *Married Love*, followed by *Wise Parenthood*, linking birth control with marital harmony. In 1921 she started a clinic for poor women, followed by the Malthusian League demonstration clinic, modelled on a state-aided maternity centre. In 1922 she founded the Society for Constructive Birth Control and Racial Progress. Pressure on the minister of health to make advice available in maternity clinics was growing. In 1927 the medical and scientific Birth Control Investigation Committee was formed, producing after research a spermicide, "Volpar," and instituting testing of contraceptives for an "approved list." At last in 1930 the minister of health authorized local authorities to give advice to married women in medical need: and the National Birth Control Council was formed to encourage them. Progress was slow and the limitation to medical need restrictive, so voluntary clinics continued to grow, all of them, except that of Marie Stopes, uniting in 1938 to form the Family Planning Association.

By 1970, 935 British FPA clinics were advising 650,000 patients a year. In the United States, Planned Parenthood-World Population had 524 affiliated family planning centres in 38 states and sponsored research and family planning education. The Swedish association, founded in 1933, had government backing with such statutory measures as support for sex education in schools. The Dutch association received government aid and had over 50 centres. A new French association was organized in 1956, but adverse laws impeded it and similar voluntary movements in many countries. Such restrictions are being steadily reduced and are often replaced by laws and measures promoting birth control. Communist countries have introduced both abortion and contraception services for the well-being of individuals, at times adapting them to public policy. China officially approved birth control in 1956 with a countrywide campaign; in 1958 this policy changed, but birth control is now routinely facilitated. Indeed, China seems to be the developing country most successful in achieving motivation and making all methods available. In the developing countries of Asia, Africa, and Latin America, government programs are often linked with economic development and population policies.

By 1970, 103 countries throughout the world had voluntary family planning associations. There were some government provisions in 63 countries. Social surveys have indicated that about 90 percent of couples in the United States use contraceptives, about 80–90 percent in the United Kingdom, and about 53 percent in Japan.

Growth of a birth control trade. The opportunities for profitable manufacture and retailing of contraceptives have always been obvious. The proliferation of quack contraceptives and abortifacients prompted pioneer reformers to provide skilled advice for the poor. There were well-intentioned traders, too—for example, W.J. Rendell of London in 1885 marketed pessaries of quinine bisulfate in cocoa butter. As trade interest grew so did advertising, harassed by organizations like the 1851 British Union for the Discouragement of Vicious Advertisements. But with growing acceptability, advertising increased, appearing in pharmaceutical and professional journals and the press, so far as laws and trade conventions allowed. Consumer protection, however, until recently was limited. In 1962 the American Consumers' Union, and in 1963 the British Consumers' Association, began evaluations of contraceptives with criticisms of advertising, efficacy, instructions, and prices. Many countries now have official bodies that assess and regulate the quality and safety of contraceptives, particularly of drugs.

Traditional outlets for contraceptives for many years were barbers, back-street stores, tobacconists, and mail-order companies. Today in Sweden and Denmark registered pharmacists are required to stock them, and in such places as South Australia and France pharmacies are the *only* outlets. Excluding China, about 80 percent of the world distribution of contraceptives is through trade, 19 percent through governments, and 1 percent through voluntary outlets. The encouragement of trade outlets is therefore an important means of promoting birth control.

International developments. In 1900 British, Dutch, French, and German leagues formed the Fédération Universelle pour la Régénération Humaine. International work gathered momentum from the 1920s, with Margaret Sanger travelling widely to promote it. Periodic conferences took place. The International Committee on Planned Parenthood was formed in 1948 at a conference in Cheltenham (England). At a 1952 Bombay conference this committee became the International Planned Parenthood Federation. Cochairmen were Margaret Sanger and Lady Dhanvanthi Rama Rau (head of the Family Planning Association). By 1964, with regional subgroupings, it was arranging regional and world conferences; encouraging research and promotion schemes; training staff; producing handbooks, literature, and medical and research journals; devising method-testing criteria; and providing testing facilities, an information centre, library, and so forth. That year it gained consultative status with the Economic and Social Council of the United Nations, and later with the International Labour Organisation, the World Health Organization, UNICEF, UNESCO, and the Food and Agriculture Organization. By 1971 it had 70 member countries. It functions as a filter for funds to help projects and services throughout the world.

International Planned Parenthood Federation

After the mid-1960s, the United Nations Economic and Social Council and other specialized international agencies, progressively backed by the General Assembly and by the findings of the Population Commission, urged and supported measures to aid the adoption of voluntary birth control in countries around the world. In 1968 the ILO

decided to promote family planning in industrial medicine, welfare, and education; and UNESCO included a study of the interrelation of education and fertility in a ten-year mass education program. For the UN's activities 1968 had been designated the International Year for Human Rights, and the UN General Assembly and Tehrān Conference asserted that family planning was a basic human right. The secretary general started his own fund to aid UN work in the field and sponsored a declaration by 30 non-Communist world leaders that family planning enriched human life.

Contemporary views on birth control and population. In the world today there are four general views on birth control: (1) Man should intervene in natural increase and selection only to the extent possible by resorting to abstinence or "natural" contraceptive means (such as coitus interruptus or the rhythm method). (2) Man can achieve adequate numerical and eugenic control simply by individual, voluntary use of all medically acceptable contraceptives and techniques of abortion, sterilization, sex selection, and diagnosis of fetal abnormality. (3) Man should employ mass temporary sterilization with the granting of individual requests for reversal to bear children, in order to achieve more effective, though still essentially voluntary, individual control. (4) Man should resort to relatively strict governmental controls over population numbers, quality, and distribution by means of long-term sterilizing or fertility-reducing agents, compulsory sterilization of individuals, eugenic procedures, and the like—all because, with population outrunning world productivity and resources, voluntary cooperation is insufficient.

All these proposals require massive educational programs and increased administrative and technical efficiency. The entirely voluntary measures—(1) and (2)—have not yet been fully tried even with known contraceptive means. Their possible effects when universally applied can perhaps be gauged by experiences in Europe, North America, Japan, and other countries where individuals have resorted to birth control in response to general economic and social pressures, though not always in accord with government policies. In general, governments have been able to encourage trends more easily than reverse them in opposition to the social climate and individual experience. The involuntary measures—(3) and (4)—raise serious ethical, political, and administrative issues, such as deprivation of freedom. And, in any event, scientific means of mass fertility and eugenic control might take many years to develop. Some would require a degree of international consensus not yet apparent.

TYPES OF BIRTH CONTROL

Contraception. To satisfy individuals, contraceptive methods need to be sure and accurate (as well as physically and aesthetically satisfying), whereas to achieve social policies and satisfy society, only general effectiveness is needed. In any case, however, the side effects and dangers of new contraceptives need to be, and generally now are, systematically assessed by laboratory techniques and before human use and subsequently surveyed by epidemiological studies.

Mystical versus rational methods of birth control

There are two modes of approach to birth control: mystical methods (such as tying knots at bridal ceremonies, eating dead bees, and wearing amulets) have flourished in primitive societies, ancient and classical times, and the Middle Ages, and persist in folk practice today; and rational methods seek to influence known or surmised processes involved in reproduction. Rational methods subdivide into those that involve some particular behaviour only (nonappliance methods) and those requiring a special agent (appliance methods).

Nonappliance methods. Since ancient times, oral and anal intercourse, homosexuality, special postures, gestures merely suggestive of coitus, and a host of other techniques have been resorted to in order to achieve satisfaction but avoid conception. Soranus advocated holding the breath, and coughing, jumping, and sneezing after intercourse in order to expel semen; he also hypothesized infertile times in the menstrual cycle. Many peoples have also recognized that most, though not all, women do not conceive (because ovulation is suppressed) while suckling, and thus, as a means of birth control, suckling has been prolonged.

The so-called rhythm method requires sexual abstinence during the woman's "fertile period"—those days around the time of ovulation when conception is most likely to occur. The other days of her menstrual cycle are known as the "safe period." A "safe period" has been used in many societies, but until the 1920s there was not sufficient physiological understanding to determine when ovulation occurs in relation to menstruation. The methods now used entail recording, under medical guidance, dates of menstruation and the temperatures taken on daily awakening to ascertain the slight rise that occurs one to three days after ovulation. The "safest" period is after this has happened. Other safe days must be calculated in advance from the probable time of ovulation after menstruation. To do this, one must assume that the pattern is regular, which is not always the case. Even regular cycles can be altered, and temperature readings can be confused by pelvic inflammation, illness, emotional disturbance, climate, altitude, menopause, or conditions after pregnancy or miscarriage. Medication can sometimes be used to regularize cycles, but in at least 15 percent of women regularity cannot be achieved.

Coitus interruptus, withdrawal of the penis before ejaculation, has probably achieved more fertility control through the ages than any other method. Failure of the method relates to the timing of withdrawal and the deposit of some semen before the climax. It is criticized as unsatisfying to both partners and has been rejected in some Eastern cultures as unseemly. It is permitted to Muslims but forbidden to Orthodox Jews.

Coitus obstructus is full intercourse with the ejaculate suppressed by depressing the base of the urethra to force the semen into the bladder. Coitus reservatus (also called *Karezza*) is intercourse with ejaculation intentionally withheld.

Appliance methods

Condom. The condom, or sheath fitting over the penis, has long been used as protection, and as early as the 16th century the physician Gabriel Fallopius designed a medicated linen sheath for the glans or tip of the penis for the purpose of preventing venereal infection. By the 17th century, the condom was utilized as a contraceptive as well. Early condoms were generally made of animal gut, hemmed at one end, or fish membrane and were often inefficient. The marquise de Sévigné sarcastically described goldbeater's skin (intestinal membrane from cattle) as "armour against love, gossamer against infection." Casanova used condoms as contraceptives. Legend is confused on the origin of the term condom—one story telling of a man named Condom devising such a contraceptive for Charles II of England. Since the 1840s most condoms have been made of vulcanized rubber or, since the 1930s, of latex. At first they were usually washable but now are generally disposable and slightly lubricated. Efficient, convenient, but still disliked for its dulling of sensation, the condom fails mainly because of irregular use.

A comparable device, the barrier-spermicide "C-film," has been used in Hungary since 1968. A thin, translucent, pliable, water-soluble film four centimetres square, containing a highly active nontoxic spermicide, is placed over the moistened glans or in the vagina. It dissolves quickly and appears to make the cervical mucus impenetrable while destroying the sperm.

Methods per vaginum. Among the methods used by women, one of the oldest is "douching"—the practice of flushing out the vagina, generally with a liquid solution, after coitus—which is intended to impede the passage of spermatozoa or to remove them altogether. The Romans used oil and soft wool for this purpose, the Greeks vinegar. Charles Knowlton recommended various substances, including alum, hemlock, green tea, zinc, sugar of lead, and baking soda; other 19th-century writers advocated quinine, tannin, opium, prussic acid, iodine, strychnine,

alcohol, and carbolic acid. But no matter what type of solution is used, the method has low effectiveness.

Also ancient in origin are "spermicides," sperm-destroying and sperm-impeding substances prepared in the form of aerosol foams, jellies, creams, soluble suppositories, and foaming tablets, which are inserted into the vagina before each act of intercourse (often by means of a slender plastic applicator). In ancient times one ingredient was often a sticky substance such as honey or olive oil; the Egyptians also used crocodile dung, and the Jews used onion or peppermint juice. Spermicidal creams and jellies are used with a diaphragm or condom. Though, when used alone, some are theoretically in the upper range of effectiveness, as a group they protect only for short periods and are not generally reliable.

A number of other devices may also be placed in the vagina to cover the cervix, or neck of the uterus, and thus to prevent fertilization by blocking the passage of sperm to the ovum. An effective early method, subsequently promoted by neo-Malthusians, was the vaginal tampon or sponge (generally used in conjunction with a spermicide). Similar practices were known even earlier: Casanova reported inserting half a lemon in the vagina; the Japanese once used disks of bamboo tissue paper. In 1823 a German physician, F.A. Wilde, started taking wax impressions of the cervix and making caps of metal and subsequently of crepe rubber to fit; these were the first true caps. They were made to be inserted and changed regularly by a physician. Although today a physician or trained nurse is still required to fit the cap properly and give instruction in its use, latex cervical caps are available in several sizes and can be inserted by the user. In contrast to caps, diaphragms are larger in size and consist of latex or soft rubber mounted on a spring metal rim; like caps, however, they are placed in the vagina in front of the cervix and, carefully used, have a high rate of effectiveness. They were first produced in 1880 by W.P.J. Mensinga, professor of anatomy at Breslau, and because they were promoted by Dutch neo-Malthusians, they became known as the "Dutch caps." First made of vulcanized rubber in three sizes, they now appear in latex in 21 sizes. Highest protection is achieved when the diaphragm is used in combination with spermicidal jelly or cream.

To be included within this category are various means of preventing intercourse altogether—such as chastity belts (any of various belted devices to prevent access to the vagina) and infibulation (tying together the prepuce or labia with clasps or stitches). The former was used in medieval times and the latter in ancient Rome. Of minor importance (but of ancient usage) is artificial retroversion of the uterus—that is, turning the uterus backward on its axis so that the cervix and vagina no longer connect.

Intrauterine devices (IUD's). In the 19th century, physicians sometimes inserted intracervical devices (such as a stem pessary, collar buttons, or wishbone) into the cervical canal to be changed and inspected at intervals. About 1920 silkworm gut loops attached to a silver wire to aid removal were used; it was feared, however, that the silver link provided a route for infections. To avoid this, a German, E. Gräfenburg, designed various intrauterine devices—first a star of silkworm gut tied with silver wire, later a coiled silver wire ring. Although he excluded patients with pelvic inflammation and used aseptic procedures with good results, the American Medical Association reported 17 deaths and 176 serious conditions when the method was used by other physicians, and it was discredited.

From 1959 on, however, new reports and research on intrauterine devices (IUD's) made of silver, stainless steel, and molded plastics that caused no corrosion brought promising results. Within five years, a variety of such devices had been developed and subjected to intensive tests. When they were skillfully inserted and retained, their safety and effectiveness were found to be considerable. Molded in a number of simple shapes such as spirals, loops, and circles, they are about 20 to 30 millimetres in diameter.

The IUD is inserted into the uterine cavity in a simple medical procedure and may generally be left in place until a pregnancy is desired. The IUD's mode of action is not yet clear. Substantial research evidence indicates, however, that it does not interfere with ovulation but may prevent implantation, and that if a conception persists the fetus is not damaged. Some women experience cramping or bleeding after IUD insertions, but these side effects usually subside or can be controlled by medication. In some 25 percent of women the device will not remain in place or must be removed. Because the successful insertion of an IUD gives lengthy protection, the method has been promoted in densely populated nations of the developing world. Adverse side effects needing medical attention, as well as failure rates, however, make it less successful than was at first hoped.

Oral contraceptives. There have always been potions that it was hoped would prevent conception without inhibiting the enjoyment and spontaneity of coitus. Some had purely symbolic content—such as drinking water that had been used for washing a dead person. Some—such as infusions of willow bark, plantains, walnut leaves, saffron, potions of gunpowder, water in which smiths had quenched their forceps, and pills of oil and quicksilver—were intended to induce physiological change. Some herbal medicines may have had some effect: tribeswomen in central Paraguay took extracts of *Stevia rebaudiana*, now found to affect the fertility of rats; the barbasco root used in Mexico provides a basic ingredient of pills today. Many recipes, however, were not only ineffectual but harmful, and Soranus, St. Jerome, and 19th-century writers warned against them.

Although oral contraception on a scientific basis was forecast as early as the mid-19th century, the first effective "birth control pills" achieving physiological suppression of ovulation were not successfully developed until the 1950s. In 1955 Gregory Pincus, a research biologist at the Worcester Foundation for Experimental Biology (Shrewsbury, Massachusetts), assisted by the American pharmaceutical firm of G.D. Searle, found a group of orally effective compounds. In large-scale field studies conducted in Puerto Rico and Haiti the pills were found effective and acceptable.

The pill

The pills contain hormonelike substances that enter the bloodstream and set up a chain reaction of the nervous system that inhibits the production of ova (thus reproducing the biochemical action by which ovulation is stopped naturally during pregnancy). Despite early side effects such as nausea, dizziness, and headache, bleeding and spotting, and weight gain among some users, which can generally be controlled, oral contraceptives were found to be acceptable as well as effective. Further research has yielded improved compounds that seem to have reduced these difficulties. The pills, available only by prescription and under the supervision of a physician, are not recommended for use by women with any of a number of medical tendencies such as vascular, thromboembolic, liver, or diabetic disorders, or cancer.

Research suggests that there may be several hazards in the use of birth control pills. There appears to be a possible relation between their use and cancer of the breast and uterus. There is some evidence of increased hypertension, abnormal glucose tolerance, and other biochemical changes. There is a slight possibility of genetic damage to the ovarian egg. The pills can aggravate such allergies as asthma, eczema, and migraine and such other conditions as alopecia, psoriasis, epilepsy, multiple sclerosis and otosclerosis, and porphyria. The worst hazard seems to be a ninefold increase in thromboembolic disorders (involving clotting of blood or plasma). The publication of such findings has led to increased anxiety about the use of the drugs. Nevertheless, such dangers—or those also arising from the use of IUD's—may be less frequent than serious complications of unwanted pregnancies.

Sterilization. Permanent contraceptive sterilization by means of castration of men or hysterectomy and ovariectomy in women has been largely replaced by surgery that leaves the sex glands intact but severs or obstructs the

tubes through which the sperm or ova pass to accomplish fertilization. Known as tubal sterilization in the female and vasectomy in the male, this form of sterilization impairs neither sexual appetites nor performance. Although the operation is generally irreversible, fertility may sometimes be restored spontaneously or by subsequent surgery. Satisfactory pharmacological means of sterilization have not yet been found.

Sterilization can present various social and psychological problems. Voluntary sterilization, for instance, is rarely defined in law or is defined inadequately, and thus personnel performing such operations may risk being objects of civil or criminal action. The person accepting sterilization may subsequently experience regret and mental distress. Compulsory sterilization for eugenic reasons is legal in some countries, but implementation of the law usually presents problems. Nevertheless, voluntary sterilization is being promoted increasingly in the United States and the United Kingdom, as well as in Asia, where India has a major sterilization program.

Induced abortion. Abortion is the termination of pregnancy before the fetus has attained the ability to live independently. A fetus is usually considered viable when weighing 1,000 grams or more and after 20 to 28 weeks of pregnancy. (Medical and legal definitions vary as to the required number of weeks.) Induced or artificial abortion is a major birth control method, to be distinguished from spontaneous or accidental abortion, popularly known as miscarriage.

Methods used to induce abortion depend on the woman's condition and the duration of pregnancy. If possible, during the first 12 weeks, there is surgery consisting of dilation of the cervix and evacuation of the uterus by some means of scraping, suction, or vacuuming. After the first 12 weeks the size of the fetus and placenta usually demands a vaginal or abdominal hysterotomy (surgical incision of the uterus). Various chemical measures for emptying the uterus are also possible and may be combined with surgery. Safe and reliable oral abortifacients have yet to be found, but encouraging experiments are being carried out.

Although most religions have condemned induced abortion, the application of severe criminal sanctions to deter its practice became common only in the 19th century; induced abortion was usually made illegal but was sometimes permitted or tolerated to preserve the life of the mother. The first important departure from the 19th-century pattern came in the U.S.S.R. in 1920, when the post-revolutionary government authorized abortion at the request of the mother; in 1936 another decree restricted legal abortion practice, but in 1955 abortion on request was restored. Since the late 1940s a movement to legalize abortion on all or some grounds gained impetus, nourished by widespread support for women's rights, by official concern about rising birthrates and a rapidly expanding world population, and by unhappiness about very high maternal death rates associated with illegal abortions. First Japan and some of the eastern European countries authorized abortion at the request of the mother. The Scandinavian countries and Swiss cantons followed with rather more restrictive grounds and procedures for authorization. Great Britain, Haiti, and some states of the United States liberalized the laws during the late 1960s, though greater restrictions were imposed in Romania, Hungary, and East Germany. In Asian countries other than Japan and China, abortion is generally not covered by legislation, though this is under discussion in India. In different countries the grounds for abortion vary: they may be for preservation of the life of the mother, for other strictly medical reasons, for eugenic or some social reasons, or simply "on demand," without restriction; of course, there are no grounds where it is wholly banned. Where laws are liberalized, abortions tend to increase steeply, at least at first. The proportion of pregnancies ending in induced abortion, legal and illegal, is often very high; for example, in The Netherlands and West Germany it is estimated at 25 percent, in France 50 percent, and in Japan over 50 percent.

The move to legalize abortion

Legal abortion for private or social reasons, as granted by doctors and official committees or boards and carried out in hospitals or approved centres, is usually allowed only during the first three months of pregnancy; and some countries do not permit a second induced abortion within six months of the first. Nevertheless, some countries have machinery for appeal against refusal. And a woman refused legal means may turn to illegal ones; in Yugoslavia, for instance, it was found that 58 percent of those refused legal abortion resorted to illegal abortion. Criminal abortion is hazardous and is not wholly displaced by legal abortion, even under the most liberal laws. Mortality in criminal cases is estimated at 35 to 94 per 100,000; in legal, but nonmedical, cases performed in the first three months, it is about 1.2 per 100,000 (though it rises to about 40 per 100,000 in legal cases of all kinds). After abortion the likelihood of abnormal pregnancies, premature births, illness in the woman, or even sterility is increased. Of legal abortees a high proportion are married women; and of criminal abortees the largest proportion are the very young, the unmarried, previous abortees, and wives pregnant at marriage.

Characteristics of legal and illegal abortion

Abortion can be followed by feelings of guilt, disturbed sexual relations, and psychologically induced illness. Studies show a high proportion of abortees to be maladjusted; in a study in Yugoslavia only 24 percent were considered well balanced. In cases in which legal abortion has been denied, on the other hand, the children may suffer; one study revealed that children born after refused requests for abortion showed a high incidence of delinquency, social maladjustment, educational failure, and need for psychiatric help. For purposes of birth control, medical opinion strongly favours contraception over abortion.

Infanticide. Infanticide, once an important method of fertility control, was common in classical times and is practiced in some primitive or isolated cultures even today. The Christian emperor Constantine of Rome legislated against it in the 4th century AD, but with poverty, lack of facilities for preventing conception, and condemnation of illegitimacy, it continued in Europe, despite punitive laws, into the 19th century. With the spread of contraception and legal abortion, it is now rare and is generally associated with puerperal disorders or with parents' mistreatment of their children (the "battered baby" syndrome).

Although there are arguments for euthanasia for disabled babies who survive birth, infanticide is now generally illegal.

Abstinence and ceremonials. Both abstinence and late marriage are used by some individuals and members of religious groups whose conscience forbids contraception and abortion. Some governments promote such means as population curbs.

Some customs, ceremonials, and rites have a recognized contraceptive element; for example, the male pubertal rite of subincision (splitting the underside of the penis) among Australian aborigines reduces fertility, and there are cultures forbidding intercourse in child marriage or during menstruation, lactation, and periods of religious celebration.

Possible future methods. Because it is unlikely that a single contraceptive method can be universally applied, the goal of birth control technology is to develop a variety of simple, effective, inexpensive, and harmless new methods to meet the needs of all people of all cultures and faiths. Contraceptive research seeks new "appliance" and "nonappliance" techniques and improvements of existing ones in order to control or interrupt the sequence of events leading to pregnancy.

Basic research into reproductive physiology has begun to identify possible new approaches to controlling fertility. Formerly, birth control research was unfashionable and neglected; medical and scientific personnel were frequently hostile or indifferent, and money and facilities were not forthcoming. But with the acceptance of birth control, such research is now intensified. First, there is the research designed to improve present oral and other

methods in order to achieve long-term action (by oral dose, injection, or implants). Second, there is research dealing with the role of the glands and the central nervous system in all stages of reproduction. This research may lead to means of inhibiting glandular secretion, controlling the production and transport of ova and spermatozoa, or intervening in fertilization or placenta formation. To influence processes such as these, many agents and combinations of agents are being investigated. The chief problems are still the dangers of partial control, the maintenance of control, toxicity, and unwanted side effects.

SOCIAL AND PSYCHOLOGICAL ASPECTS OF BIRTH CONTROL

Throughout history and among most cultures, power and prosperity have been associated with growing populations. Social and economic status and advancement of families often depended on numbers of offspring. With high mortality from disease, war, and other natural hazards, the survival of society as a whole and of families was generally best served by pronatalist attitudes and institutions. Not infrequently, however, limitation of reproduction has been motivated by the contrary need to maintain or improve health and living standards. This happened when, with temporary freedom from war or epidemics, population rose and methods of cultivation could not provide enough food, work, or housing—for instance, in the Greek city-states, in medieval Europe prior to the 14th-century decimating plague called the Black Death, and in 19th-century industrial cities favoured by the control of disease. There have always been innumerable reasons why some individuals and groups should wish to control their fertility.

Population problems and birth control

The abiding personal, ethical, and economic reasons for birth control have been intensified in recent decades by the so-called population explosion. After World War II the dramatic lowering of death rates through mass public health measures resulted in the doubling of the growth rate of the world's population in about 15 years. It was less than 1,000,000,000 in the year 1800; it is now more than 3,500,000,000 and by the end of the 20th century could be twice that number. Furthermore, the most rapid population increases are occurring mainly in the countries with the lowest per capita economic production—those that have the greatest need to raise production and living standards but are least able to keep pace economically with rapid population growth. Many of these developing nations are in Asia and Latin America, and contain 70 percent of the world's population. To help solve this problem, birth control has been advocated in order to bring population growth rates to levels at which agricultural, industrial, and social developments can not only maintain but improve the quality of life. But developed countries are also experiencing problems of population imbalance, though less acute; and in most of them, birth control by one means or another is common. The major social factors affecting the objectives and practice of birth control are religious and ideological beliefs, biological urges, cultural and familial patterns, the health and status of women, the pressures of national class or group interests, ambition, education, occupational patterns, living standards, housing, and so on.

Social and ethical issues of induced abortion

Special moral and social questions attach to abortion. Those who object to abortion on ethical grounds begin with the premise that, except where the mother's life is at stake, there is no rational basis for distinguishing between the newborn infant and the fetus: the fetus grows, changes, and even reacts to its environment in the mother's womb; the infant is in every sense only a potential member of society, just as the fetus is. Proponents of abortion, on the other hand, make somewhat the following arguments: prior to the fourth month of pregnancy at least, the fetus has acquired so few of the characteristics commonly identified as human that most people do not equate destruction of the fetus with murder; population control demands (because contraceptive techniques will never be perfect) that abortion be available to those mothers who wish to terminate a pregnancy for good cause; it is inefficient, and socially unwise, to impose criminal sanction against behaviour acceptable to a significant body of opinion; and, finally, only if women are given complete and sure control of births can their complete emancipation be assured.

Religious attitudes and beliefs. The major religions of today, influenced by the condition of the times in which they took root, support marriage and reproduction and have been fearful of measures like birth control that might affect marital stability. They have all recognized the power of the sexual urge and have sought to direct and control it, some more fearfully than others. Birth control has seemed irrelevant or antagonistic to reproduction and to spiritual goals as they have been understood, and the churches' slow processes of evaluating new knowledge and other circumstances have retarded acceptance of it. Militant religious groups have swayed governments on the issue of birth control and inadvertently inspired the growth of independent services. In the West, religious acceptance of birth control came only when sexual pleasure and physical union were accepted as important to marriage and when problems of overpopulation were recognized. The newer secular ideologies of humanism and socialism were concerned not with sexual morality but with individual freedom, well-being, and justice; the control of fertility was accepted as an individual right and means to prosperity.

Religions are now generally agreed on the responsibility of parents, but grounds for control and methods are still disputed. Furthermore, although religious observance has declined, its precepts, sanctions, and attendant emotional reactions of fear, guilt, and shame, which have permeated social custom, continue often to exert influence.

Judaism. Historically, Jewish doctrines on marriage and procreation have been related to national ambition and struggle for survival; survival itself was identified with a close and disciplined community in which the individual was perpetuated through family and name. Celibacy has had little place in Judaism; there is an obligation to have children, though love and companionship are deemed equally important in marriage. The seed has traditionally been considered viable; thus, coitus interruptus (onanism) was banned as "spilling the seed," though abortion is allowed if the mother's life is threatened. There is a long tradition of the use of sterilizing potions, vaginal tampons, and even abstinence during famines. Orthodox sections condemn male methods of birth control and those interfering with spontaneity, but for the mother's health certain female methods are allowed, after consultation with medical and rabbinic authorities. Reformed and Conservative branches of Judaism, however, urge proper education in birth control as the means of enhancing spiritual values in marriage and achieving the welfare of mankind. Female methods, subject to medical considerations, are acceptable, and a high proportion of Jewish couples use birth control.

Early Christianity. In the early church, formed in a time of revulsion against the prevailing sexual excesses of the Roman Empire, celibacy was considered superior to marriage because the Second Coming of Christ was thought to be close at hand; it was not that reproduction was no longer needed, but that spiritual perfection was considered to be impeded by worldly distractions. While self-discipline and the denial of appetites were emphasized over the whole range of human behaviour, coitus as the vehicle of original sin was particularly restricted and came to be associated with guilt, shame, and uncleanness. Its primary rationale was childbearing, which was not to be frustrated. Such feelings still have force to inhibit the use of some birth control measures.

Eastern Orthodoxy. Although indulgence in sex is considered a handicap to spirituality in the Eastern Orthodox Church, parenthood is a duty, and economic pressures must ideally be met by frugality and by social aid for large families. Traditionally, only abstinence is permitted, because interference with any phase of reproduction is forbidden and the killing of sperm is considered no dif-

ferent from abortion and infanticide. However, the church, while considering the use of contraception to be the result of failure in spiritual focus, has not sought to hinder the distribution of contraceptives.

Roman Catholicism. Roman Catholic doctrine on birth control stems, in particular, from the teachings of St. Augustine, St. Thomas Aquinas, and legalistic and scholastic elements within the church, who held that procreation was the natural result of coitus and the primary purpose of marriage and that contraception was therefore a frustration of natural law. Throughout most of the history of the church, however, there have been a few theologians who have taken a more sympathetic view of sexual pleasure in marriage; and this concept, together with that of avoiding children because of poverty, gained ground by the 19th century, when the use of contraceptives began to be widespread.

During the 19th century there developed the idea that birth control by "natural" means—particularly the rhythm method—was not a positive exclusion of procreation and was therefore to be regarded as morally licit if properly used. Formal approval of the rhythm method was first given by Pope Pius XI in his 1930 encyclical *Casti Connubii.* It was repeated in 1951 by Pope Pius XII, who specified that Catholics might practice the rhythm method for a number of medical, eugenic, economic, and social reasons. Other methods, as well as abortion and sterilization, however, were still rejected. In 1958 he forbade the use of oral contraceptives or anovulants except for some therapeutic purposes.

A number of Catholic theologians, doctors, and laymen had begun to question whether coitus reservatus and the rhythm method were the only moral ways of family planning. Some claimed that oral contraceptives could be morally used, since they postpone ovulation without interfering with the sexual act. Finally, some sought full acceptance of contraception and contraceptives.

The debate among Roman Catholic theologians

Of the many reasons for the growing uncertainty among Catholic moralists about birth control, two reasons were prominent. First, increasing emphasis was being placed upon the "secondary" end of marriage—mutual love and fulfillment. This was the result of various factors, such as a better insight into the nature of interpersonal relations, the changing status of women, a concern for health, the pressures of increasing population, the spread of higher education, and the acceptance of contraception by other denominations and its widespread use. Second, many moralists felt that in the past undue emphasis had been placed on the physical element of the sexual act and that instead of being subordinated to man's total well-being, the biological aspect had acquired an undeserved value.

Against this background, leading theologians concluded that the entire problem required intensive reappraisal. To study the question from all possible angles, Pope John XXIII in 1963 appointed a commission of theologians, gynecologists, psychologists, demographers, and married couples. While the commission continued its deliberations, the Vatican Council in 1965 approved its "Pastoral Constitution on the Church in the World of Today." Although the council did not dispute previous bans on contraceptives, the constitution opened the door to future change by eliminating the distinction between "primary" and "secondary" purposes of marriage. Thus it placed the fostering of conjugal love on the same plane of importance as the procreation and education of children. It also established the primacy of individual conscience.

The international commission appointed in 1963 reported to Pope Paul VI in 1966, but its recommendations were not made public until April 1967, through an unauthorized press "leak." The majority, it was noted, urged the pope to define doctrine so that chemical and mechanical means of birth control would be morally licit. The minority recommended no change in the interpretation of teachings. In July 1968 Pope Paul VI delivered his encyclical *Humanae Vitae* ("Of Human Life"), in which he declined the advice of the commission and firmly restated the traditional view.

Humanae Vitae

The pope noted the social and economic difficulties caused by rapid population growth, but, he said, chemical and mechanical contraception are not permissible means of coping with these problems. He urged that, instead of sponsoring fertility control programs, governments encourage social and economic progress, and though noting the personal difficulties imposed on couples using the rhythm method, he said that rigorous self-discipline required to use this technique may enhance rather than harm the purity and value of conjugal love. He repeated Pope Pius XII's plea that medical science help make the rhythm method more reliable but yielded no ground to demands that the traditional views on birth control be modified. Following the traditional natural law position, he declared illicit "every action which, either in anticipation of the conjugal act or in its accomplishment, or in the development of its natural consequences, proposes, whether as an end or as a means, to render procreation impossible," including abortion and sterilization as well as birth control methods other than rhythm and coitus interruptus. The teaching in the encyclical carried the authority of the pope but was not infallible. It set off widespread controversy and a further polarization of Catholic views. Dutch bishops, for example, viewed the pronouncement as only "one of many factors" to be considered in making decisions on child spacing and family size, along with "mutual love" and "social circumstances." It is now widely accepted that individual conscience must be the final guide, though discussion of the issue continues.

Protestantism. Martin Luther and John Calvin held an Augustinian view of coitus even stricter than that of the Roman Catholic Church of their time, but they gave marriage a status equal to celibacy and did not consider children necessarily the primary motive of marriage and coitus. While their view of sex placed Protestantism in opposition to contraception, the emphasis on other aspects of marriage eventually aided acceptance of the concept of birth control. Contraception was accepted by some Protestant clergy by the end of the 18th century, though general consensus came only in the 1930s. Since then, most Protestant churches have evolved a concept of responsible parenthood that strongly sanctions the use of contraception within marriage. The shift from opposition to support of family limitation is exemplified by the Lambeth Conference of Anglican bishops, which specifically condemned contraception in 1908 and 1920, cautiously approved it in 1930 in cases in which there was a clearly felt moral obligation to limit or avoid parenthood, and finally in 1958 approved it strongly by declaring, "The responsibility for deciding upon the number and frequency of children has been laid by God upon the consciences of parents everywhere. . . . The *means* of family planning are in large measure matters of clinical and aesthetic choice, [provided] they [are] admissible to the Christian conscience" (Proceedings of the 1958 Lambeth Conference, Bishops of the Anglican Communion). In short, Christians might use the gifts of science for proper ends. The Lambeth Conference also joined the question of birth control to larger social and global population questions, particularly in developing countries; but it did not impose legislation on individuals, asserting that the family does not exist for the sake of society.

Methodists were early acceptors of birth control, and the Methodist Conference in 1939 considered the aim of contraception to be "the healthiest family in the healthiest possible way." In 1931 the U.S. Federal Council of Churches ruled that careful and restrained use of contraceptives by married people was valid and moral, and in 1961 the National Council of Churches in the United States affirmed that "The general Protestant conviction is that motives, rather than methods, form the primary moral issue, provided the methods are limited to the prevention of contraception" (National Council of Churches policy declaration, 1961). Eventually the World Council of Churches, through the Commission of the Churches on International Affairs, committed itself to a policy of cooperation with the United Nations in demographic

The modern Protestant position

tasks; in 1966 it stated that responsible parenthood must be accepted as an integral part of the ethic of today.

Islām. Islāmic marital and sexual morality has roots in both Judaism and Christianity. While the Qur'ānic advocation is to marry and generate, there is no clear objection to birth control; and because common sense may be applied where there is no Qur'ānic prohibition, liberal interpretation has been possible. Birth control was early advocated by the Prophet's friend Hazrat ibn As, in order to avoid poverty. Though there was disagreement among the disciples of the Prophet, permission for coitus interruptus has been attributed to the scholars among them and to subsequent scholars. A medieval theologian, al-Ghazālī, said that contraception by means of withdrawal was justified to protect one's property, to preserve the health and beauty of one's wife, and to preclude worries about overlarge families. Muslim doctors like ar-Rāzī and Avicenna in the 10th century described many contraceptives and offered medical reasons for avoiding childbirth. A more recent Islāmic *fatwā* (pronouncement) was made by the grand mufti of Egypt in 1937: "It is permissible for either husband or wife, by mutual consent, to take any measures to prevent semen entering the uterus, in order to prevent conception." In 1960 the Turkish government obtained a *fatwā* permitting coitus interruptus if the proper raising of children was made impossible by social conditions. Therapeutic abortion was accepted on the basis of the Qur'ānic precept that "necessities overrule prohibitions." There is, however, no clear consensus: although a *fatwā* in Jordan in 1964 ruled that a government birth control policy was binding on individuals, other authorities resisted limitation of family size and legislative action.

Hinduism and Buddhism. Among Hindus, the begetting of a son is regarded as a primary religious obligation —both to continue the family and to facilitate the salvation of one's father and forebears. According to doctrine, women were created to bring children into the world, and marriage ceremonies stress the obligation to produce many sons.

In Buddhism, religious doctrine does not directly stress procreation, since the essence of this religion is to break away from worldly passions in pursuit of serene detachment. The tradition of high fertility among Buddhists appears to be supported mainly by cultural mores rather than religious doctrine.

On the control of fertility, Hinduism and Buddhism both lack either specific prohibitions or obligations in the modern sense. Doctrinal opposition to bodily injury has been a religious deterrent to infanticide and abortion. And the general fatalism of both faiths, as embraced in the various concepts of *karma*, has tended to restrain direct interference with fertility.

At the same time, there has been enough doctrinal latitude in Eastern religions so that modern spokesmen have not found it too difficult to construct a theological foundation for the use of contraception as a means of family planning. As the Indian philosopher and statesman S. Radhakrishnan expressed it to the Third International Conference on Planned Parenthood at Bombay in 1952, "If the purpose is not wrong, there is no ethical or spiritual harm done, and it is the purpose which determines the use or abuse of these modern inventions."

Effects of economic conditions and social status

Social influences. In modern societies providing economic opportunity and social mobility there are far more incentives to birth control. Men have ambitions for social and economic position, higher living standards, and education, and parents desire that their children should fare better than they themselves in this world. Such individual fulfillment probably has a better chance of success if income is concentrated on fewer children. In poorer societies, on the other hand, or in poorer segments of affluent societies, men generally lack much confidence that they can alter their adverse circumstances, or they fear disappointment; in any case the motivation for contraception is low. Furthermore, birth control is not highly valued when infant mortality is high, when there is dependence on family or child labour, or when aggrandizement is achieved by marriage alliances or the socioeconomic distribution of sons and daughters.

For individuals there may be a variety of reasons for avoiding or neglecting contraception. Women in traditional or impoverished cultures are often pressured to believe that bearing children is their raison d'être, and the males, feeling fatalistic or ineffectual in relation to the world, tend to believe that fathering a string of children is a demonstration of manliness and power. Furthermore, men who desire submissive wives can fear that contraception tends to liberate women. Conversely, men are more likely to accept birth control when they see their husbandly role as good friends rather than good lovers and when women's status in the family and society is relatively high.

The problem of usable methods

General motivation is not the only determinant of birth control, however. Method is also important. Since contraception is essentially a voluntary procedure, the individual or couple must be motivated to use the method. Thus, for instance, the absence of privacy in most homes, and the lack of medical guidance, make techniques such as the diaphragm unsuitable in preindustrial societies. The expense of condoms usually puts them beyond the reach of the poor. And while the rhythm method involves no "devices," it does involve relatively sophisticated use of calendars and measurements of time and temperature that are alien to many cultures and difficult to introduce to barely literate populations. The newer intrauterine contraceptives (IUD's), however, show substantial promise in helping curb population growth, because their use requires only a single insertion for longtime protection against pregnancy and requires only momentary medical attention and occasional checkups.

With increased investment in contraceptive research, the perfection of other simple new methods is anticipated. Meanwhile, educational efforts under government auspices are seeking to increase motivation for fertility control in a growing number of nations. (See also POPULATION.)

ning methods may be found in *Studies in Family Planning*, a quarterly of the Population Council of New York.

(E.E.N.D./Ed.)

Birth Defects and Congenital Disorders

The term birth defect includes both abnormalities of structure and deficiencies of function that are present at the time of birth. These defects may be inherited (genetic), or they may be the result of an accident encountered by the child while in the mother's womb.

Congenital disorders include birth defects but also include diseases, such as syphilis, that can attack the child before birth and damage structures already formed. Among infections possibly only rubella (German measles) affects the embryo during its period of development, producing true malformations.

When a defect develops

The unborn human infant acquires its essential form, and its organs and tissues are all laid down and defined, within the first eight weeks after conception. This is the period during which the child is often, but not always, described as an embryo; only afterward is it called a fetus. After the first eight weeks there is differentiation and growth, and some anomalies may arise, especially of the brain, eye, and inner ear; but all gross disturbances of form will already have occurred. The distinction between embryo and fetus is useful if it emphasizes the early period of development critical in the production of congenital defects. Many biochemical defects may not be manifest until the metabolism is separated at birth from that of the mother; all such defects, however, have their inception in an earlier failure to develop some enzyme system.

CAUSES AND INCIDENCE OF CONGENITAL DEFECTS

Causes. Grossly malformed children have at different times and in different cultures inspired either awe or revulsion. They have been regarded as the playthings of the gods, and some gods have been modelled on human or animal malformations. The defects have been regarded as signs and portents or as punishment for sin. The ancient belief that they are produced by maternal emotional impressions or shock still lingers today. In its more absurd form it is expressed by such things as the belief that if a mother is frightened by a frog or a rabbit, the child in consequence will lack the top of its head or may have a harelip. There is no evidence in favour of such beliefs. Nor is there evidence that maternal emotional stress or anxiety contributes in any nonspecific way to the production of malformations.

It must be emphasized that birth defects do not all have the same basis, and it is even possible for apparently identical defects in different individuals to be due to different causes. Though the basis of most defects is still uncertain, almost all are due to genetic factors, environmental influences, or a combination of these two. Genetic factors must include not only inherited familial defects but also spontaneous genetic mutations and chromosomal anomalies arising during division of the cells.

Genetic factors

Some birth defects can be recognized as the direct outcome of Mendelian dominant or recessive inheritance. Two genes at the same location—these genes are called alleles—on a set of two chromosomes—homologous chromosomes—represent alternative characteristics, such as yellowness or greenness of peas. In dominant inheritance only one of the alleles need be for the characteristic; in recessive inheritance the pair of alleles must be identical: that is, if one of the two genes for colour of peas is for yellow and one is for green, the yellow is inherited; if both are for green—a recessive trait—greenness is inherited. Such direct inheritance may be modified by the environment; the manifestation of most of these defects may be modified in such a way that the pattern of Mendelian inheritance is obscured—some defects may be difficult to recognize in individual cases, and large and detailed pedigrees may be necessary to determine patterns of their recurrence. A high incidence of defects occurring in the offspring of cousin marriages may point to recessive inheritance of conditions rare in the community. The skeletal anomalies of achondroplasia (abnormal conversion of cartilage into bone with resultant dwarfism) and osteogenesis imperfecta (a disease marked by fragility of the bones) exemplify defects with dominant inheritance. Albinism (absence of pigment in skin, hair, and eyes), microcephaly (possession of an abnormally small or imperfectly developed brain), and many inborn errors of metabolism are determined by recessive inheritance.

Such a relatively simple pattern of inheritance fails to explain many common anomalies, such as harelip (with or without cleft palate) and congenital dislocation of the hip, and yet these conditions do show some tendency to recur in families. It is thought possible that several sets of alleles—polygenic inheritance—may be involved, in which each defect would represent the summation of the operation of these several independent sets of alleles; and only when these come together, as they are more likely to do in offspring of kindred, does the defect appear. This pattern of inheritance is difficult to prove, but from mathematical study of many families, supporting evidence is accumulating. When the pattern operates, the occurrence of two defective children increases the probability of a third, in contrast to the constant ratio of risk when only one set of alleles is involved. A severe form of any anomaly, or an anomaly present in the sex in which it does not usually occur, carries a higher risk to members of the family. The relative risk of the anomaly within a kindred is proportionately greater for those anomalies that are rare in the community. In many other anomalies, such as heart defects, complete obstruction or narrowing of the gut, defects of the brain and of the kidneys, bladder, and urinary passages, there is little or no increased incidence in particular families, and polygenic inheritance appears an inadequate explanation.

In chromosomal defects, there is defective sharing of the chromosomes among the cells, usually during division of the sex cells; this results in a gross genetic error. Such gross genetic disturbances probably account for 25 to 30 percent of early abortions; but few affected offspring apart from those with Down's syndrome (also called mongolism) survive to show birth defects. In inherited conditions, such as achondroplasia and the blood disease hemophilia, the death rate before reproduction is so high that the gene concerned would be eliminated if it were not renewed by spontaneous mutation. In achondroplasia only one out of five individuals receives the dominant gene from the family. In the other four it appears as a spontaneous mutation. If a mutant, dominant gene produces a condition so severe that the affected individuals fail to reproduce, the condition cannot be recognized. This is probably a rare occurrence, but it cannot be proven or disproven. By increasing the mutation rate, nuclear and other high-energy radiation can increase the incidence of congenital defects.

Environmental factors

The association of fetal anomalies with maternal rubella (German measles) infections and more recently with thalidomide has focussed attention on the possible effects of environmental factors. These had been extensively studied in free-swimming embryos, but the mammalian embryo was thought to be protected within the uterus. The incidence of fetal malformations due to maternal German measles varies in different epidemics and with the stage of the pregnancy at which the infection occurs. The greatest number of defects result when the infection occurs between the fifth and eighth week following the last menstrual period, but even then only rarely do as many as 20 percent of the infections cause defects. Even in epidemic periods the disease can be the cause of only 2 or 3 percent of all congenital defects. Such defects as deafness and cataracts result from infections during the fetal period; in earlier infections cardiovascular anomalies predominate. Thalidomide tends to involve the arms and legs. These are shortened, intermediate segments are missing, and the hands and feet are deformed. The embryo exposed to radiation may suffer damage to cells most actively dividing at that time, but this is very rarely the cause of human malformations. Despite observations

in experimental animals, it is doubtful that shortage of oxygen or nutrient substance produces defects in man. When an abnormality is produced in an animal by drugs or other agents, the incidence and nature of the abnormality are often dependent on the species and strain of animal used; and the effect of the agent may be to cause a pre-existing and latent genetic defect to become manifest rather than to act directly on the embryo and cause the defect.

The embryo floats cushioned in amniotic fluid and shielded in the maternal uterus, and it is extremely doubtful that physical injury ever determines a congenital defect. If the amniotic fluid is scanty near the end of the pregnancy, the fetus may be molded by continued pressure within or upon the uterus. Ears may be distorted or limbs bowed, but these defects of later fetal life often correct themselves.

A genetic factor can only express itself in a suitable environment. Much of the environment of the developing embryo is dependent on the operation of other genetic factors, and this is in part the basis of polygenic inheritance. Unknown and presumably chemical influences from the mother do, however, operate. Variations in the implantation and subsequent development of the placenta must also be important. Even when genetic factors are established, the genetically identical eggs of "identical" (monozygotic) twins may produce one affected and one unaffected child. This conditioning of the genetic inheritance by the environment is of the greatest importance. Its future understanding provides the best hope of limiting the occurrence of some abnormalities, in some cases by preventing the unmasking of harmful genetic factors by drugs, toxic agents, and maternal deficiencies. Unfortunately little is yet known of this interaction.

Interplay of environmental and genetic factors

Incidence. The incidence of birth defects depends on what is classified as a defect. About 20 percent of all babies born dead, or dying in the first week of life, die because of some serious malformation. This is about six per thousand births. Significant malformations will usually be detectable in the first two weeks of life in just under 20 per thousand total births. By the age of five years, another five or six per thousand will have been recognized. When serious metabolic errors such as fibrocystic disease of the pancreas and defects undetected or appearing later are added, a figure of 30 per thousand births is probably a conservative estimate for significant birth defects. If all classifiable structural anomalies found on careful dissection are included, nearly half the population will show some anomaly and, if all local tissue malformations such as skin blemishes and moles are included, there will be few unaffected.

Some conditions, such as anencephaly (the absence of all or most of the brain), account for up to 4 percent of stillbirths and early neonatal deaths in Ireland and western Britain but may have an incidence as low as one-twentieth of this elsewhere. There is wide variation in the incidence of different defects in different racial groups. It is much less certain that the total incidence of congenital defects varies significantly.

Offspring with severe malformations do not survive the embryonic period, and all but a few chromosomal defects are eliminated as early abortions. Most defects represent a local failure of growth often allied to a failure of differentiation. This can include a failure to canalize a passage or failure of a septum (thin dividing wall) or ridge to fuse. When there is imbalance in the constituents present in an area, the part may be enlarged, and the useful functioning tissue reduced. Failure to differentiate and arrange cells properly is often also local, with an imbalance in their proportion in tissues and organs. Such areas of faulty development may range from skin nevi ("birthmarks") to totally malformed kidneys and disorganized brains. Cells not taking part in normal development may later proliferate, forming aggressive and malignant tumours (embryomas) or tumours, especially in testes and ovaries, that show a mixture of elements of the various embryonic layers (teratomas). Whether areas once formed degenerate or fail to grow because of disturbed blood supply or some degenerative disturbance is uncertain.

General nature of defects

DEFECTS OF THE DIFFERENT BODY SYSTEMS

Musculoskeletal systems. Achondroplasia and osteogenesis imperfecta are among the more important general disturbances. In achondroplasia there is an inherited defect in long bones that develop through cartilage, and the arms and legs are stunted. There are also deformities of the chest and skull. About 80 percent of infants with achondroplasia die soon after birth, but those that survive are strong and sturdy dwarfs with unimpaired intellect. In osteogenesis imperfecta (brittle bones) there is an inherited and obscure defect of bony tissue, and bones may be broken even before birth. Multiple fractures occur on the slightest injury until puberty, after which there is a progressive improvement.

A great variety of local anomalies occur. Congenital dislocation of the hip and the talipes equinovarus form of clubfoot, in which the foot is extended and turned inward, show strong familial incidence. Fusion and webbing together of the digits of the hands and feet (syndactyly) or the presence of extra digits (polydactyly) are often inherited but are often variable in their form even in the same kindred. Imperfect extremities include hemimelia, in which hands and feet are imperfect or deformed, and phocomelia, in which defects in the long bones result in attachment of hands and feet, often also imperfectly developed, close to the body like the flippers of a seal. Apart from the numerous cases resulting from thalidomide, phocomelia is rare, and there is considerable detailed variation.

Cervical ribs, or additional tiny ribs arising from the lower neck vertebrae, are common anomalies that are unrecognized except in a few individuals in later life, when, probably because of changes in posture, the cervical ribs may press on nerves going to the arm and produce pain and other symptoms. Other anomalies may be complex; thus in cleidocranial dysostosis—"imperfect development of collarbones and skull"—the clavicles, or collarbones, are absent or rudimentary, there are complex deformities of the skull, and teeth are absent or poorly developed.

Central nervous system. A most important defect involves the spine and allows protrusion of the membranes of the spinal cord in the midline of the back (meningocele) or, worse, exposes the spinal cord itself in the floor of the defect (myelomeningocele or myelocele). The defect may be associated with anencephaly. The defect of the cord sometimes extends the whole length of the vertebral column. When nerves and especially when cord structures protrude, attempts at repair nearly always result in some loss of control of the lower part of the body. Often, when only the cord seems to be involved and for reasons that are still debatable, the ventricles, or cavities, normally present within the brain dilate (hydrocephalus). The head enlarges, and, with thinning of the cerebral cortex (outer layer of the brain), there is variable impairment of brain function. Congenital hydrocephalus may also result from a defect that significantly narrows the passage between the ventricles.

Defects in spinal cord and brain

Many complex anomalies of the brain can occur, often with deformities of the folds or convolutions (gyri) of its surface. Small and large gyri (microgyria and macrogyria) occur. They may be absent (agyria), reduced (oligogyria), or increased (polygyria) in number, and multiple areas of imbalance between nerve cells and supporting elements (tuberous sclerosis) may occur. Sometimes there is an overall reduction in brain size (microcephaly), often associated with a disturbed gyral pattern; this is usually inherited as a Mendelian recessive. Such anomalies will be found in only a minority of those with mental defects and with spastic and other disturbances; debate continues on what proportion of these defects result from less evident developmental errors and how many from damage done by lack of oxygen and by other deficiencies or by physical injury at birth.

Sense organs. Congenital deafness may be due to a maternal infection with German measles (rubella) or to

inheritance. Both rubella and genetic factors can also produce cataracts. Small eyes (microphthalmia) and absence of eyes (anophthalmia) may be associated with grave brain defects but can exist alone. Injury by rubella and infection with the protozoan *Toxoplasma gondii* within the uterus may produce small eyes. The organs of smell and taste are very rarely disturbed and usually only with associated complex brain anomalies. Congenital indifference to pain must depend on a rare defect at a high level in the brain.

Digestive tract. Anomalies of the digestive tract occur at all levels. Harelip, especially when combined with cleft palate, creates a serious feeding difficulty in early infancy; it is due to a failure of structures that are growing forward to form the nose and mouth to unite. A break in the continuity of the esophagus (esophageal atresia) is almost always further complicated by an opening between the esophagus and the trachea. Spasm and a thickened ring of muscle at the exit from the stomach (hypertrophic pyloric stenosis), appearing and progressing in the first month after birth, may cause persistent vomiting. It is five times more common in boys than in girls and tends to occur in more than one member of a family. The incidence may be as great as five per thousand boys.

Defects in the bowel

A segment of intestine, usually near the anus, may lack nerve cells and networks concerned with peristaltic movements and may act as an obstruction, leading to intermittent but progressive constipation and gross dilation of the intestine above the defect (Hirschsprung's disease). As in hypertrophic pyloric stenosis, there is a high familial incidence. A stenosis or area of structural narrowing may occur anywhere in the alimentary canal; the passageway, or lumen, may be totally occluded. Parts of the bowel may be duplicated, usually forming cystlike structures leading to obstruction. Atresia (lack of an opening to the outside) of the anus is often due only to a thin membrane, but fistulas or narrow passages from the obstructed bowel may open into the urethra, the vagina, and the area between the vagina and the anus. Less often the rectum ends at a higher level. Here again there may be fistulas and even wider openings into the urinary tract; rarely, the arrangement may approach the common excretory cloaca of lower animals.

In cystic fibrosis of the pancreas there is an abnormality of mucus secretion affecting the whole body in varying degrees. In intrauterine life, abnormal secretions in the bowel and the lack of pancreatic enzymes to digest protein may result in a mass of material in the bowel that distends and blocks it (meconium ileus). In infancy there can be deficiency of digestive secretions and, often, disturbed fat absorption. Thick viscid secretions in the bronchi later lead to emphysema (overdistention of the lungs because of dilation of the air sacs) and repeated lung infections. This occurs in about one in a thousand births and is inherited as a Mendelian recessive.

Cardiovascular system. A multitude of anomalies exist, and some are discussed elsewhere. The essential consideration is whether or not abnormal openings between cavities exist. Such shunts may allow oxygenated blood from the lungs to mix with venous blood from the body. This occurs in small defects of the septa, or dividing walls, of the heart, and in a ductus arteriosus (shunt between the pulmonary artery and the aorta) that fails to close. More serious are anomalies in which blood returning from the body mixes with oxygenated blood from the lungs, producing cyanosis (blueness of skin due to inadequate oxygen supply). Extreme cyanosis, or blue baby disease, occurs in the tetralogy of Fallot—an interrelated set of defects in which there is a wider defect of the septum and obstruction to the outlet from the right ventricle to the lungs—and in other complex anomalies. In less serious imperfections, however, there may be no admixture of blood; sometimes, as in transposition of the heart to the right side, which may or may not be associated with a similar transposition of the abdominal viscera, anomalies cause no circulatory impairment.

Blood. Defects of the blood might be used to illustrate inherited or inborn metabolic anomalies. The life and shape of the red blood cell depend on enzyme systems, which may be defective. The hemoglobin that the cell carries may exist in numerous variant forms. These variants are usually less useful and even harmful, but some have probably had survival value. Thus the hemoglobin of the sickle cell trait and sickle cell anemia increases resistance to malaria. Many defects are so widespread in populations that they can scarcely be regarded as abnormal.

Excretory system. Absence of one kidney may occur in one in a thousand. There is enlargement of the other, and the condition is usually unsuspected. There is a high association with conditions such as, in females, a bicornuate uterus (a uterus with two partially united compartments) and vaginal atresia (lack of a channel in the vagina) and, in males, with absence of a testicle. Absence of both kidneys is fatal soon after birth and is accompanied by defects in the sexual organs and defective lung development. Disorganized development of one or both kidneys is often associated with renal (kidney) cysts and abnormal structures. The poorly developed kidneys with cysts in the newborn infant differ from the inherited cystic kidneys that develop in later life. The ureters and the bladder itself may be dilated, either behind an obstruction (for which congenital folds of mucous membrane in the urethra may be responsible) or without visible obstruction—the so-called megalo-ureter. Gross distention of the urinary passages is sometimes associated with the absence of abdominal muscles. In all these conditions there is a serious risk of kidney infection.

Kidney defects

In ectopia vesicae (displacement of the bladder), a serious defect, the bladder lies open on the lower part of the abdominal wall with the ureters discharging there. This urinary defect presents a long-term problem in surgical management. In the male a lesser degree of the anomaly is epispadias, in which the urethra opens on the abdominal side of the penis rather than at the tip; bladder control is absent. Openings on the opposite side of the penis, in hypospadias, are entirely different, since bladder control is retained.

Reproductive system. The anomalies of hypospadias and epispadias affect the reproductive system as well as the excretory system. In the female a lack of an opening in the vagina or in the cervix will allow mucus from the cervix (hydrocolpos) and later blood from the uterus (hematocolpos) to accumulate and progressively enlarge the uterus.

In pseudohermaphrodites the sex organs are so developed that they appear not to correspond to the gonads (testes or ovaries) present. In female infants a congenital defect, manifest before birth and inherited as a recessive, disturbs the production of adrenal hydrocortisone and results in overproduction of the male sex hormone. In consequence the clitoris enlarges and at birth may resemble a penis with hypospadias. The vagina appears to open into the urethra and is not visible, and the labial folds resemble the scrotum. The condition is progressive after birth, but both it and the associated salt imbalance respond dramatically to treatment with cortisone. Somewhat similar sex organs may be produced by steroids, often progesterone, given for threatened abortion but also exerting a male hormonal influence.

Pseudohermaphrodites and true hermaphrodites

Persons with a wide range of abnormalities have been described as male pseudohermaphrodites. The group includes persons with hypospadias and undescended testes, those with a clitoris and a vagina ending in a mass connected to testes, and persons with an imperfect uterus, a single fallopian tube, and no sex gland on that side. The correct management of all these anomalies demands most expert care.

In a true hermaphrodite both ovarian and testicular tissues are present on either one or both sides. The arrangement of other genital structures is extremely variable in the hundred or so reported cases, and the whole problem is extremely complex.

Respiratory system. Cleft palate, an excessively small lower jaw, and esophageal atresia (imperfectly developed

passageway in the esophagus) with an opening between esophagus and trachea all cause respiratory difficulty. A defect in the diaphragm allowing abdominal contents to enter the chest is an important cause of failure of respiration in the newborn. Anomalies of the lungs range from absence of one or both lungs to insignificant variation in the size and shape of the lobes.

Endocrine system. Anomalies of the ductless glands are rare. Deficiency of the thyroid will, soon after birth, produce signs of cretinism with slow metabolism, coarse skin, and mental retardation. Overdevelopment of the adrenal cortex affects metabolism of the cortical hormones with disturbance of genital development and often of salt balance.

Skin. In albinism there is inability to produce melanin pigment, and the resulting white skin and hair and sometimes red eyes and intolerance to light are due to a metabolic defect inherited as a Mendelian recessive. It occurs in both white and coloured races and varies greatly in degree of severity. Many rare skin diseases that well illustrate Mendelian inheritance have been studied. The dry, scaly skin of ichthyosis occurs in different forms, illustrating different patterns of inheritance. Birthmarks, such as port wine stains and strawberry nevi (small pigmented areas on the skin), are a local and abnormal development of blood vessels. These and pigmented moles are so common that they are often not regarded as malformations.

CONDITIONS ARISING FROM CHROMOSOMAL DEFECTS

During division of the sex cells the number of chromosomes is halved, one of each pair going to each cell. It sometimes happens that both chromosomes of a pair go to one sex cell (nondisjunction). When two sex cells unite, there can then be not two paired chromosomes but three. The cell is then called trisomic. The unpaired chromosome may be fused with another chromosome and can then be carried through to succeeding generations. When neither chromosome of a pair goes to a germ cell, the zygote or fertilized egg is short of a chromosome and has one chromosome unpaired. This is called a monosomic anomaly. More complex anomalies occur but disrupt development so early that abortion occurs. This happens also with trisomies of all but a few small chromosomes and with all monosomies except those involving the sex chromosomes.

Monosomy and trisomy

Turner's syndrome. In a form of monosomy called Turner's syndrome, only one female sex chromosome (X-chromosome) is usually present, but more complex arrangements can occur. The external genitalia are feminine but remain infantile after puberty. The ovaries are rudimentary and do not contain eggs, body growth is impaired, there is often a distinctive webbing of the neck, and there is a characteristic facial appearance.

Klinefelter syndrome. In the Klinefelter syndrome the genitalia are normal and masculine before puberty. Later development is usually retarded, enlargement of the breast often occurs by the 20th year, and the incidence of mental retardation is increased. Sperm are absent from the testes. The number of female (X) chromosomes is increased, usually giving the pattern XXY. Other patterns —XXXY, XXXXY, and XXYY—which occur much less frequently—raise interesting problems as to the time at which separation of the chromosome pairs fails. The Klinefelter syndrome may have an incidence as high as one in 500 males.

Down's syndrome (mongolism). This is the only numerically important example of a trisomy involving autosomal (nonsex) chromosomes, and it has an incidence of one to two per thousand. Babies with this defect are small and have distinctive arrangement of skin folds around the eye, which is not unlike that of the Mongolian race; short fingers with incurved little finger; and diagnostically useful abnormalities in the skin creases of the palm of the hand. These children are retarded in physical and mental development and often have more serious anomalies such as congenital heart lesions and intestinal atresia (imperforate intestine). When the extra chromosome becomes fused with another chromosome, the anomaly may recur in other members of the family. If the mother of the child is young, chromosome studies of the parents are advisable. The defect is most common among mothers aged 35 or more; in these instances the defect is usually not familial.

Biscay, Bay of

Noted for its rough seas, squalls, and storms, the Bay of Biscay, a roughly triangular-shaped extension of the North Atlantic Ocean, is bounded on the east by the west coast of France south of Île d'Ouessant (Ushant, off the western tip of Brittany) and on the south by the north coast of Spain out to Cabo (Cape) Ortegal at the extreme northwest. The name is a corruption of the Spanish Golfo de Vizcaya (after the province of Vizcaya, around Bilbao), which is restricted to the angle between the two countries. The French name is Golfe de Gascogne. The sea is crisscrossed by important shipping routes and, since prehistoric times, has witnessed the movements of maritime people along the fringe of Atlantic Europe.

Its hypothetical boundary with the Atlantic extends about 357 miles from Île d'Ouessant to Cabo Ortegal. The area of the bay is about 86,000 square miles (223,000 square kilometres), and its maximum depth, a little south of its centre, is 15,525 feet.

Physiography. The continental shelf is up to about 100 miles (160 kilometres) wide off Brittany but narrows to less than 40 miles off the Spanish shore. The edge of the shelf and the continental slope are dissected by numerous submarine canyons of which that of Cap Breton, in the southeastern corner of the bay, is one of the largest. The bottom sediments are largely sand and mud.

Beyond the continental slope lies the Biscay Abyssal Plain, with depths of about 15,000 feet, which occupies about half the area of the bay. Much of it has very flat topography. The principal rivers flowing into the bay are the Loire, the Adour, and the Dordogne and Garonne, which form the Gironde Estuary.

Geological history

The continental shelf and slope and the abyssal plain are underlain by thick sediments of Mesozoic and Tertiary age (*i.e.*, formed between about 225,000,000 and 2,500,000 years ago) that appear to form a seaward continuation of rocks of similar age in the Aquitaine Basin of southwestern France. The shelves are believed to have been formed by sedimentation keeping pace with subsidence, and the French shelf has subsided by about 10,000 feet since Lower Cretaceous time (about 136,000,000 years ago). The shelf areas are underlain by continental crust, but the abyssal area is underlain by thinner oceanic crust, the boundary between the two being a faulted zone beneath the continental slope. It has been suggested that the abyssal part of the bay was formed by the anticlockwise rotation (drift) of Spain relative to France, leaving a triangular gap in which oceanic crust was formed as the gap opened. The hypothesis has received some support from paleomagnetic data and has been popular with workers attempting to reconstruct the geometric fit of the continents prior to the formation of the Atlantic Ocean. Since the hypothesis envisages the beginning of the rotation in the Late Cretaceous, however, it is rendered more difficult to accept by the probability that Mesozoic and Tertiary sediments exist beneath the abyssal plain and by the proved existence of Early Mesozoic and earlier rocks beneath Aquitaine. The rotation, if it occurred, must have been of much earlier date.

Currents, tides, and salinity. Surface currents are influenced by the clockwise circulation in the North Atlantic that produces a clockwise circulation in the bay. This pattern is frequently disturbed by wind, so that, on the shipping route across the mouth of the bay, currents in any direction may be encountered. Westerly gales in winter give rise to an eastward-flowing current along the north coast of Spain, which reaches five miles per hour. The main outflow of water is believed to be a subsurface current flowing westward off the north coast of Spain.

The range of mean spring tides is about 20 feet on the French coast at the northern end of the bay near Île d'Ouessant, decreasing southward to about 12 feet in the southeastern angle near Biarritz. Strong westerly winds increase the normal height of tide by several feet. Easterly winds depress the tidal levels.

Salinity of surface waters is about 35 parts per thousand, slightly higher than average ocean water. This is the result of the northward spread of hypersaline water leaving the Mediterranean through the Strait of Gibraltar.

Climate. The Bay of Biscay is noted among sailors for rough seas. The frequency of gales is in fact less than in more northerly parts of the eastern Atlantic, but they can be severe and may exceed 70 miles per hour. Squalls are also a hazard to navigation and may occur at any time of year. The north coast of Spain is noteworthy for dangerous squalls and capricious winds. The climate on shore is maritime, with mild winters and cool summers.

Principal ports

Economic activity. The principal ports are Brest, Nantes, La Rochelle, Bordeaux, and Bayonne in France, and Bilbao, Santander, Gijón, and Avilés in Spain; none are able to take large vessels. Resorts include La Baule, Biarritz, and Saint-Jean-de-Luz, all on the French coast. Fishing is a principal industry. Catches include sardines, tuna, anchovies, hake, cod, bream, and crustaceans, including lobster. Oyster culture is practiced in shallow lagoons and estuaries along the French coast. Offshore drilling has taken place off the Aquitaine coast in the hope of finding possible future sources of petroleum and natural gas.

BIBLIOGRAPHY. Recent geological and geophysical work is described by L. MONTADERT *et al.*, "The Continental Margin in the Bay of Biscay," in *Report of the Institute of Geological Sciences*, no. 70/15, pp. 43–74 (1971). Sediments and recent history of the French continental shelf are discussed by G. BOILLOT *et al.*, "Morphology, Sediments and Quaternary History of the Continental Shelf between the Straits of Dover and Cape Finisterre," *ibid.*, pp. 75–90. There is no comprehensive work on oceanography and climate, but the general background is given by R.W. FAIRBRIDGE, ARNOLD GORDON, and ERIC OLAUSSEN, "Atlantic Ocean," in R.W. FAIRBRIDGE (ed.), *The Encyclopedia of Oceanography*, pp. 56–85 (1966); and some information on tides, currents, and climate in GREAT BRITAIN, HYDROGRAPHIC OFFICE, *Bay of Biscay Pilot*, 4th ed. (1956).

Bismarck, Otto von

Otto von Bismarck, the Prussian statesman who founded and became first chancellor of the German Empire, was born on April 1, 1815, at Schönhausen in Brandenburg. His father, Ferdinand von Bismarck-Schönhausen, was a Junker landowner who had served in the Prussian Army; his mother, Wilhelmine Mencken, was the daughter of an untitled bureaucrat who had risen high under Frederick William III. The contrast between his parents did much to cause the conflict in Bismarck's own nature. In physical appearance and avowed tastes he was a Junker: powerfully built, devoted to country pursuits, and with an enormous appetite for food and drink. Mentally and emotionally, however, he was sophisticated and highly bred, sensitive to the point of hysteria, with a subtle intellect and a gift of expression that put him in the highest class of German writers.

LIFE

Early years. Bismarck went to school in Berlin, living with his mother and developing a romantic nostalgia for the family estates, which he seldom visited. He read law first at Göttingen University and then at Berlin; he was a disorderly student, though he passed his examination. He then entered the Prussian service and became a judicial administrator at Aachen. There he was drawn into the international society that stopped at the spa on the way to other watering places; and at one time absented himself without leave for some months in order to follow across Germany an English girl with whom he had fallen in love. The adventure came to nothing and the criticism of his official superiors drove Bismarck to resign from the service at the age of 24. He declared, "I will play music as I like it or none at all." The family estates were running into difficulties, and Bismarck took over the management of them from his father and to some extent from his elder brother.

Bismarck. 1880.
Achiv fur Kunst und Geschichte

Under his mother's influence, Bismarck as a youth had been a deist, indifferent to Christianity. In the country, he came to know his Pietist neighbour Adolf von Thadden and was deeply affected by the death of Thadden's daughter Marie. Soon after he fell in love with another girl of this Pietist circle, Johanna von Puttkamer, whom he married in July 1847. To win her hand Bismarck avowed his own conversion, though he was inclined to lay down to God the conditions on which he would acknowledge his existence.

Early career. In 1847 Bismarck became a member of the United Diet, the quasi-representative body that Frederick William IV summoned in order to authorize a loan for the building of a railway to East Prussia. Bismarck stood out as the provocative spokesman of absolutism and reaction, dismissing the mildest liberal measures with contempt. The Diet demanded that it should be summoned regularly; when the King refused this it rejected the railway loan and was prorogued. Before it could meet again the Revolution of 1848 swept Germany, and Frederick William IV himself capitulated to the revolution in Berlin on March 18. Bismarck wished to organize a military repression and civil war. When the King pleaded that he had been unable to sleep for worry, Bismarck replied, "A king must be able to sleep." He attempted to force the King's abdication and suggested to Princess Augusta, wife of the King's brother William, that her husband, too, should withdraw in favour of his young son, who would then become the helpless figurehead of the reaction. Augusta indignantly refused and remained the mortal enemy of Bismarck throughout her life. In later years he launched the version that Augusta had made the proposal to him and that he had rejected it out of loyalty to the King—one of many instances in which he put the best appearance on failure and sought to mislead posterity.

The 1848 revolution

Bismarck was in eclipse so long as liberalism prevailed in Germany. He was elected neither to the National Assembly at Frankfurt nor to the first Prussian Parliament at Berlin. In October the army occupied Berlin, and Frederick William IV issued a more monarchist constitution.

Bismarck was elected to the new Second Chamber. In April 1849 the Frankfurt National Assembly offered the imperial crown to Frederick William. He refused it; and Bismarck was one of the few who welcomed this refusal. Frederick William next attempted to gain the leadership of northern Germany with the cooperation of the princes. This challenge to Austria was opposed by Bismarck, and when open conflict seemed to be approaching in October 1850, he advocated return to Austro-Prussian cooperation in German affairs. He welcomed enthusiastically the Prussian surrender at Olmütz (now Olomouc, Czechoslovakia), when Frederick William's schemes were abandoned, and praised Austria as "a German power that is fortunate enough to rule over foreign peoples." He hoped that, with the defeat of the revolution, Prince Metternich's "system" with its Holy Alliance of Austria, Russia, and Prussia would be restored. These views made him an obvious choice to represent Prussia at the federal Diet at Frankfurt. He arrived there on May 11, 1851, renewing a career in the service of the state that was to last without interruption for 39 years.

Prussian representative at Frankfurt

Bismarck went to Frankfurt as the leading advocate of cooperation with Austria in German affairs. Within a fortnight, his outlook was revolutionized, and he became convinced that the Austrian statesmen would never treat Prussia as an equal. The men who had defeated the revolution in Austria no longer thought in Metternich's cautious terms. They believed that they could hold the revolution in check without any assistance from their former conservative partners Russia and Prussia. But if the challenge came from Austria, Bismarck was not slow to take it up. He disputed every formal sign of Austria's leadership, though Austria was in fact "the presiding power" at the Diet by virtue of the federal act; and he carried on a relentless personal feud with successive Austrian representatives. Hitherto only the Austrian had smoked at meetings. Now Bismarck, too, pulled out his cigar case. Such trivialities were to reshape the destinies of central Europe. Bismarck soon came to speak with contempt of Frederick William IV and of Otto von Manteuffel, his foreign minister. He believed that they were sacrificing Prussia's greatness to their romantic conception of conservative solidarity. In his opinion "the Holy Alliance was dead," and Prussia should follow a policy of self-centred realism. It should claim the headship of Germany and make alliances with foreign powers against Austria in order to achieve it; it should even ally itself with "the revolution."

During the Crimean War (1853–56) Bismarck feared that Prussia would support Austria or even join the Western powers in war against Russia. He reached the conviction that the Balkans and the lower Danube, however vital to Austria, were no concern of Prussia's, and this view did much to shape his later policy. At the end of the war he believed that Russia and France would soon come together in a "revisionist" alliance—Russia to undo the results of the Crimean War, France to expel Austria from Italy—and he urged that Prussia should make a third in this restless combination. He overrated the dynamism of both Russia and France and insisted that Prussia could gain the headship of Germany only as part of a general European upheaval. His greatest state paper dismissed as impossible the limited reordering of German affairs that he himself carried through 14 years later.

Bismarck grew increasingly critical of Prussia's official policy in his last years at Frankfurt. He was over 40 and seemed to have achieved nothing. In 1858 Frederick William IV became insane, and his brother William took his place as regent. This began the short-lived "new era," when Prussian policy took a liberal turn. Bismarck seemed out of place at Frankfurt with his reactionary reputation, and early in 1859 he was sent as ambassador to St. Petersburg—"put in cold storage" was his own phrase.

In January 1861 Frederick William IV died and the prince regent became King William I. A soldier by training and profession, he wished to increase the army in order to be able to train all those liable to military service. This increase would, in addition, enable him to cut down the *Landwehr*, or militia, which Prussian conservatives regarded as a dangerously democratic institution. The liberal majority in the Prussian Parliament was ready to increase the grant for the army, but they defended the *Landwehr* and sought to reduce the period of military service from three to two years. In 1860 Parliament authorized the increased grant for one year only. Albrecht von Roon, the minister of war, at once organized new regiments, implying that the grant was permanent. In November 1861 a general election strengthened the more advanced liberals, who were now organized as the German Progressive Party. Roon urged William to make Bismarck prime minister, but the King was alarmed by Bismarck's advocacy of alliance with France and his plans for sweeping away the German princes.

Ambassador at St. Petersburg and Paris

In March 1862 Bismarck was recalled from St. Petersburg. He expected to be made prime minister (minister president); but though William was running into increasing difficulties with the Chamber of Deputies, he still shrank from an open breach of the constitution, and Bismarck on his side would not take office until the King could be forced to accept a revolutionary foreign policy. He was therefore sent as ambassador to Paris. There he and Napoleon III dangled before each other the idea of alliance against Austria.

Appointment as prime minister. Meanwhile events in Berlin had reached a crisis. The Chamber of Deputies would authorize the increased military expenditure only if the period of service was reduced to two years. On September 17 the ministers, including Roon, agreed to this compromise; it was rejected by William, and Roon swung around to his support. Immediately after the meeting of the council Roon sent to Bismarck the famous telegram, "Periculum in mora. Dépêchez-vous" ("There is danger in delay. Hurry up"), meaning that the King's reluctance had been broken. On Sept. 22, 1862, Bismarck arrived in Berlin and was at once made prime minister. It was an uneasy partnership. William wished to defend his independent conduct of military affairs but still rejected an adventurous foreign policy; Bismarck encouraged the domestic conflict in order that the King should be dependent on him and then be drawn into a foreign policy by no means to his taste.

The constitution laid down that the budget must be agreed upon by the Chamber of Deputies, the upper house, and the king. Bismarck argued that if one of the three rejected the budget there was "a gap in the constitution," and that the government must collect the existing taxes (and of course spend them) until agreement was reached. This theory served to promote a conflict. He told the Chamber in his first speech, "The great questions of our day cannot be solved by speeches and majority votes—that was the great mistake of 1848 and 1849—but by blood and iron." Time and again the liberal majority offered a compromise, but Bismarck knew that this would destroy his hold over the King and always evaded it. Dissolution failed to shake the liberal majority; this, too, was an advantage for Bismarck, for a conservative Chamber would have made him unnecessary.

Bismarck's main interest lay elsewhere—in foreign policy. He had long announced his intention of settling the German question. When he took office a conflict had already started on Austrian initiative. The Austrians proposed to the federal Diet a delegate conference at Frankfurt to strengthen the confederation. Bismarck answered by proposing the direct election of a German Parliament, and he asked the French government what it would do "if things grew hot in Germany." Napoleon III was in a conservative mood and gave a timorous answer. In February 1863 the Diet rejected the Austrian proposal and the alarm blew over.

The Polish revolt

Russia and France had worked together with increasing intimacy since the end of the Crimean War. This intimacy was disturbed by a revolt in the part of Poland ruled by Russia, which broke out in January 1863. Napoleon III tried to turn his back on this embarrassing affair and pretended that it was a question of Russian domestic

politics. Bismarck, however, sent Count Gustav von Alvensleben to conclude a convention with Russia (Feb. 8, 1863), for cooperation against the Polish insurgents. Bismarck always regarded Polish national ambitions as the greatest threat to Prussia's existence, and his motive in proposing the Alvensleben Convention was principally to silence the advocates of concession to Poland at the Russian court. Certainly the convention did not win Russian gratitude: Prince A.M. Gorchakov, the chief minister, resented the implication that Russia was in any need of help. Moreover, Napoleon III, who was impotent to act against Russia, thought of making a demonstration in favour of Poland by threatening Prussia; and at the beginning of March, Bismarck had to ask Gorchakov to allow him to withdraw the convention. Far from being a great stroke of policy, the convention was an impulsive gesture against the Poles that led Bismarck into a position of some danger: he had almost put Prussia as a hostage between Russia and France.

Meeting of the German princes at Frankfurt

In August 1863 the emperor Francis Joseph I invited the German princes to a meeting at Frankfurt to discuss the reform of the confederation. It was the high-water mark of the Austrian attempt to unite Germany by agreement. Its principal element was a "directory" of princes. Bismarck might have been willing to compromise with Austria at the expense of the princes; he would certainly not give the princes authority over Prussia. William I was tempted to attend the Frankfurt meeting, especially when King John of Saxony brought an invitation in person. Bismarck threw all his weight on the other side. It was his first struggle for ascendancy over William, and he won it, though at great strain. When the argument was over, Bismarck smashed a large jug of water on the ground and broke into hysterical sobs. William's refusal wrecked the Frankfurt meeting. Though the princes approved the Austrian proposals, they added the proviso that Prussia must approve them too. The princes had, in fact, no interest in German unity and welcomed the conflict between Austria and Prussia as giving them an easy excuse.

In answer to the Austrian policy of working with the princes, Bismarck emphasized his friendship with Russia and with France. In the autumn of 1863 he concluded a commercial treaty with France and imposed this treaty on the Zollverein, the German customs union, which Prussia controlled. There was no room for Austria in this arrangement, and the economic division of Germany was thus made final, even while the political confederation still existed.

War over Schleswig-Holstein

In November 1863 Frederick VII, the last Danish king of the male line, died, and therewith the Schleswig-Holstein question, which had played a vital part in the German Revolution of 1848, was renewed. The two duchies, Schleswig and Holstein, were in union with Denmark; Holstein alone was a member of the German confederation, though there was also a German majority in southern Schleswig. In 1848 the German liberals had attempted to "liberate" the two duchies with the assistance of the Prussian Army but had been defeated by the protests of the great powers, and the Treaty of London (1852) had reaffirmed personal union. The Danes had subsequently tried to extend their constitution to include the two duchies, and German national sentiment countered by supporting a rival claimant to the duchies, the Duke of Augustenburg. Bismarck had no interest in creating another petty German state, particularly on Prussia's border; on the other hand, he would not let Austria steal a march on him by appealing to German national feeling.

Johann Bernhard von Rechberg-Rothenlöwen, the Austrian foreign minister, was a conservative who hated German liberalism and therefore fell in with Bismarck's plans. On Jan. 16, 1864, he signed a treaty of alliance for war against Denmark, not to liberate the duchies but to enforce personal union as laid down by the Treaty of London; German nationalism was repudiated. The Danes were soon defeated and Schleswig overrun. A conference of the great powers then met to try to save the settlement of 1852, but the coalition of non-German powers no longer existed. On May 28 Austria and Prussia repudiated the Treaty of London and were able to renew the war against Denmark without intervention or serious protest from any foreign power. In August Denmark made peace, ceding the duchies to Prussia and Austria jointly (the definitive treaty was signed at Vienna on Oct. 30, 1864). Later in August, Bismarck and William visited Francis Joseph at Schönbrunn. Rechberg was willing to surrender the duchies to Prussia but asked in return for a guarantee of Venetia and help in recovering Lombardy from Italy; Francis Joseph also wanted compensation in German territory. The terms were logical enough, but they were too high for Bismarck. He might compromise with Austria; he would hardly go to war with Italy, and perhaps France as well, for Austria's sake. Austria and Prussia therefore agreed to rule the duchies jointly until something turned up that would make a lasting solution possible.

Conflict with Austria

Bismarck still hoped to reach an agreement with the Austrians when their difficulties increased elsewhere—either in Italy or the Near East. Instead they concentrated on German affairs and put forward the claim of the duke of Augustenburg to the duchies. On May 29, 1865, a Prussian Crown Council discussed whether to meet the Austrian challenge by war. The generals favoured war; Bismarck insisted on alliance with France and an appeal to German nationalism if war was decided on. He said: "If war against Austria in alliance is struck out of the vocabulary of diplomacy, it is impossible for Prussia to have a policy." This idea was still too revolutionary for William, and compromise followed once more. By the Convention of Gastein (Aug. 14, 1865), Austria was given the administration of Holstein, Prussia of Schleswig. Bismarck, rewarded with the Prussian title of Count von Bismarck-Schönhausen (September 1865), soon moved again toward an alliance. In October he visited Napoleon III at Biarritz. Hitherto he had assumed that Napoleon would repeat in Germany the policy that he had followed with Count Camillo di Cavour in Italy: he would join in the war against Austria and expect to receive a territorial reward for his assistance. At Biarritz Napoleon made it clear that he planned to remain neutral and that his reward should be the cession of Venetia to Italy. The Biarritz bargain was negative: Bismarck would not guarantee Venetia to Austria, and Napoleon would not give Austria support.

After promising not to defend Venetia, it was an easy development to promise it to Italy. This was the essential clause of the alliance with Italy, which Bismarck signed on April 8, 1866; in return Italy promised to join in war against Austria if it broke out in the next three months. In May there was a last attempt at compromise, organized by the brothers Anton and Ludwig von Gablenz—one a Prussian, the other an Austrian general. Bismarck would have been satisfied with the military headship of northern Germany. Austria was still unyielding and at the beginning of June repudiated the alliance with Prussia by bringing the question of the duchies before the Diet. Prussian troops invaded Holstein, and when a majority of the Diet condemned Prussia, Bismarck declared the German confederation at an end (June 14). War followed against Austria and those German states that took the Austrian side.

Two Prussian armies invaded Bohemia, and on July 3 the Austrians were decisively defeated at Sadowa, near Königgrätz (Sadova, near Hradec Králové). They appealed for French help, but Napoleon III would only mediate. A believer in the national principle, he sympathized with the Prussian purpose and himself urged Bismarck to annex the whole of northern Germany. Bismarck's real struggle was with his own king. William had been gradually taught to believe that the Austrians were the aggressors, and he wished to punish them by annexing some of their territory. Bismarck got his way only after a bitter dispute, in which he called the Crown Prince to his aid. By the preliminary peace of Nikolsburg (July 26), he excluded Austria altogether from Germany, instead of di-

viding Germany between Prussian and Austrian zones at the line of the Main, as he had proposed before the war broke out. The southern German states were to have "an international independent existence." Bismarck's moderation in 1866 has been much praised, and certainly he wished to preserve Austria as a great power—"we shall need its strength in future for ourselves." But Austria remained intent on revenge until the events of 1870 made it impossible. Moreover, in preserving Austria, Bismarck saddled himself and his successors with "the Austrian problem." The War of 1866 defeated the empire that Metternich had served, but within a few years Bismarck re-created the conservative system of Metternich in a modified form.

A general election took place in Prussia on the day of the Battle of Sadowa (Königgrätz). The Progressive Party was much weakened and soon afterward split. The majority formed a new party, the National Liberals, that would support Bismarck in exchange for concessions in home affairs. He agreed to admit that he had acted illegally in collecting the taxes without parliamentary authorization, and the Diet passed an act of indemnity.

All the states north of the Main that had fought against Prussia in 1866 were annexed except Saxony; the others had to join a federation under Prussian control. The King of Prussia became its president and commander in chief. Bismarck set up a Bundestag elected by universal suffrage, but he did not propose to allow it any say in the military budget, which was to be written into the constitution; nor was there to be a responsible ministry—the real decisions were to be taken by a federal council composed of delegates from the states. The National Liberals revolted against this sham, and Bismarck met them halfway, perhaps with one eye on liberal feeling in southern Germany. The chancellor became a responsible minister, though the only one, and the military budget was authorized only until the end of 1871. Then, after further dispute, Bismarck agreed in 1874 to authorization only for seven years (the Septennate), and this produced a crisis every seven years while he remained in office.

Bismarck and the National Liberals made a genuine compromise. Certainly the chancellor was appointed by the king, or emperor, as the prime minister had been in 18th-century England; but neither Bismarck nor his successors ever infringed the constitution, though Bismarck was often tempted to do so. There was in imperial Germany a true rule of law, and the will of the people could have prevailed if they had known what to will. The Bundestag won the essential point of any constitution: it controlled supply for the military forces, though it could exercise this control only every seven years instead of annually, as in a fully liberal country.

Conflict with France: the Luxembourg crisis

At the time of making peace with Austria, the French ministers—though not Napoleon himself—demanded compensation for Prussia's aggrandizement. Bismarck answered with vague talk of Belgium, but when the French asked for an alliance and the cession of German territory on the left bank of the Rhine he evaded them. In September 1866, Napoleon III, who was wiser than his advisers, declared himself content with the new order in Germany, but French public opinion insisted on some concrete satisfaction. Luxembourg seemed the solution. It had been a member of the old confederation and was garrisoned by Prussian troops, but it was ruled by the King of The Netherlands, and Bismarck did not claim it for his new federation. Indeed he advised Napoleon III to buy it from the King of The Netherlands. The French dallied over these negotiations, and the German public began to protest against the loss of this "old German land." Bismarck himself joined in the protest (April 1, 1867), though finally he accepted compromise at an international conference: the Prussian garrison was withdrawn and Luxembourg was neutralized instead of being annexed to France.

The Luxembourg crisis is one of the most disputed episodes in Bismarck's career. Some writers have seen in it a trap by which he meant to involve France in war; others claim that he was surprised by the strength of German feeling and had to go along with it. Certainly the crisis put an end to all hopes of a Franco-Prussian alliance, such as Bismarck had often discussed. On the other hand, although Bismarck regarded war with Austria as one of the only two possible alternatives before 1866, he does not seem to have worked deliberately for war with France in the same way. Even in 1869 he suggested that France might acquire Belgium in return for the addition of the southern German states to the federation.

These states were the point about which Bismarck's policy revolved. In 1866 his renunciation of them had been genuine: he did not want to add Roman Catholic states to a predominantly Protestant federation. But he counted on their liberalism to keep them from alliance with either France or Austria. Instead the liberal parties in southern Germany lost ground to clericalists who were strongly anti-Prussian. Bismarck was faced with a dilemma. If he rallied the southern liberals by proposals of unification, this would strengthen liberalism throughout Germany; if he did nothing, Austrian and even French troops might soon be on the Main. His solution was to prepare for unification by increasing the prestige of the Prussian monarchy.

One device to achieve this was the proposal, which he put forward unsuccessfully early in 1870, to give the king of Prussia the title of German emperor. Another was to encourage members of the House of Hohenzollern to accept any vacant thrones that might be offered them. In 1866 Prince Charles of Hohenzollern-Sigmaringen went to Romania on Bismarck's advice to become prince and later king of that country. In 1869 his brother Leopold was offered the throne of Spain, vacant after a revolution in 1868. Though Bismarck later established the version that he had no connection with this offer, there is, in fact, no doubt that he repeatedly urged it on the Spaniards until they wore down Leopold's reluctance in June 1870. This does not imply that the Hohenzollern candidature was intended to provoke a war with France. France was to be presented with a *fait accompli*, and Leopold was to become king before the French learned of it.

Franco-German War

On July 3 the news leaked out prematurely. The French government demanded Leopold's withdrawal, and William, who had always disliked the affair, seconded them. On July 12 Leopold withdrew. Bismarck, though taken by surprise, had wished to reject the French demands and to score a victory of prestige, if not actually to provoke a war. Instead he seemed to have been humiliated. At the last minute he turned the humiliation against the French. He transformed a message that William sent him from Ems from a surrender into a defiance, and the French declared war a week later. Bismarck soon claimed that he had caused the war by means of this "Ems telegram," but it is likely that the Bonapartists, who dominated Napoleon III, would have insisted on war in any case.

The war of 1870, unlike the war against Austria, had no practical purpose; Bismarck asked nothing of France except to be left alone. But from the beginning of the war he accepted the military proposal to annex Alsace-Lorraine. The generals urged the strategical advantage; Bismarck thought rather of giving German national feeling some concrete symbol of victory, and, as well, he was glad to have some cause for lasting estrangement between France and the German liberals. Later he regretted this estrangement and assured the French that he had been opposed to the annexation of Metz. There is no contemporary evidence of this. His diplomacy during the war was limited to preventing the French from finding allies or provoking a European mediation. He was successful and in February 1871 imposed upon them an indemnity of 5,000,000,000 francs, as well as the loss of the territory. This became the Treaty of Frankfurt in May 1871.

The German Empire

All the southern German states joined the war against France, but they were still reluctant to enter an empire controlled by Prussia. It would have been easy to drive them on by evoking popular feeling, but Bismarck was determined that Germany should not be made by demo-

cratic means—it must be made by the princes, not by the Bundestag. He gave some political concessions to the southern German states and, more effectively, bribed the king of Bavaria with large sums from his secret fund. The Bundestag merely asked William to deign to accept the imperial crown; the actual offer was made by the princes, and William I was proclaimed German emperor on Jan. 18, 1871. Two things stand out in this supreme achievement of Bismarck's life. Germany was made without the German people, almost against them: though Germany was technically united, 8,000,000 German Austrians were excluded from the German national state.

Imperial chancellor: Prince von Bismarck. Nevertheless, Bismarck was the hero of the German people in 1871, and he was created Prince von Bismarck (March 21, 1871) and appointed imperial chancellor. The National Liberals acted almost as a government party in the Reichstag. Bismarck discussed every legislative measure with their leaders before introducing it and left the conduct of measures through the Reichstag to them. In addition, the conservatives also split, and one section, the Free Conservatives, accepted liberal measures so long as Bismarck advocated them. Between 1871 and 1878 Bismarck had a majority in the Reichstag, almost in the Western parliamentary sense; and he carried through fundamental changes, comparable with the work of the Revolution in France or of the Benthamites in England. Germany was given a common currency and a central bank. A single code of commercial and civil law was created, and a high court of justice set up at Leipzig. The tangle of medieval survivals was swept away in less than a decade, and Germany became the most modern and liberal of states, so far as laws could make it so.

Distrust of political Roman Catholicism was common doctrine among liberals in the 19th century. Bismarck shared this distrust, and it grew stronger in 1871 when a confessional party, the Centre, gained 58 seats in the Reichstag. Though the Centre claimed to defend strictly Roman Catholic interests, it drew its support from all the elements that had opposed Bismarck's work; for instance, Protestant Hanoverians supported it, while Bavarian nationalists, though Roman Catholic, did not. Bismarck regarded the empire as his own creation, and he branded any opponent of his as a *Reichsfeind* (enemy of the empire). He believed, too, that unity was most easily created if there was some object to attack, and the Centre provided that object when Germany had no foreign enemies. He said of Ludwig Windthorst, leader of the Centre, "Everyone needs somebody to love and somebody to hate. I have my wife to love and Windthorst to hate."

The struggle began over the state control of education. When the Roman Catholics claimed the right to choose and license their own teachers, Bismarck attacked the teaching orders and then insisted that the state should train and license priests. Priests and bishops were imprisoned and sees were left vacant. By 1876, when the struggle reached its height, Bismarck seemed to have committed himself irrevocably to the liberals; even the Prussian conservatives, though Protestant, were turning against him. It was the climax of the liberal era.

Bismarck assumed in 1871 that, with the defeat of France, a long period of peace would follow. The only danger seemed to be the French desire for revenge. Hence he encouraged republicanism in France in order to create an ideological gulf between the republic and the two eastern empires. With these empires he revived the conservative partnership of the Holy Alliance in a new form. This was the League of the Three Emperors, or Dreikaiserbund, constituted in 1873. Impressive in title, it was never more than a vague expression of monarchical solidarity in fact. The league implied that the three empires, and especially Russia and Austria-Hungary, would settle their disputes peacefully. In reality it held together only so long as there were no disputes.

League of the Three Emperors

Its weakness was shown in 1875, even before the Eastern question raised its head. Bismarck was on bad terms with the French government, whom he accused of patronizing the German Roman Catholics; in addition, he was offended at the reorganization of their army. In April a German newspaper published, on Bismarck's instructions, an article entitled "Is War in Sight?" Probably he wished only to shake the French nerve and to underline the Centre's association with the "foreign enemy." The French, however, raised the alarm and appealed to the great powers. Austria-Hungary did not respond—the first open symbol of Vienna's new dependence on Berlin. Both Russia and Great Britain protested in Berlin, and Bismarck had to repudiate his own words. The Eastern crisis, which began in July 1875, raised more serious difficulties. Germany had no direct interests in the Near East, and during the Crimean War Bismarck had been the most emphatic advocate of neutrality, even to the extent of refusing Russian diplomatic support. But then the main conflict had been between Russia and the western powers. Now France kept an attitude of reserve; Great Britain took the lead against Russia, and Austria-Hungary showed an increasing inclination to go over to the British side. Bismarck, at first, followed the French example and turned his back on the crisis. In December 1876 he declared that the whole of the Near East "was not worth the bones of a Pomeranian grenadier." His only concern was to keep Russia and Austria-Hungary on good terms, and he succeeded until the autumn of 1876. Then the Russians foresaw that they would be driven to war against Turkey for the sake of the Balkan Slavs; and they appealed to Bismarck to keep Austria-Hungary neutral, as they claimed (with some exaggeration) to have kept that monarchy neutral in 1870. Bismarck refused: he would not allow either Russia or Austria-Hungary to be destroyed as a great power.

The crisis reached its height in March 1878 when the Russians abandoned their moderate plans and imposed the Treaty of San Stefano on the Turks. Great Britain threatened war; Austria-Hungary would not promise peace. Bismarck acted as "honest broker" and brought Russia and Great Britain to a compromise. He could rightly claim to be the main architect of the peaceful settlement between them, which was confirmed by the Congress of Berlin (June 1878). He presided and this seemed to symbolize his paramount position as mediator between the great powers. All the same, the Congress of Berlin marked the turning point in Bismarck's diplomacy. Hitherto he had believed that Germany could secure peace by keeping out of the combinations of the great powers; after 1878, he tried to achieve the same aim by having a finger in every pie.

The Austro-German Alliance

The Eastern crisis of 1875–78 destroyed Bismarck's faith in monarchical solidarity. In addition it made him regard Russia as too unstable to make a reliable ally. He decided, with great reluctance, to commit himself to the defense of Austria-Hungary. William held out against the alliance with Austria-Hungary until Bismarck forced his hand by threatening his resignation and that of all the Prussian ministers. The alliance followed logically enough from Bismarck's policy in 1866. Then he had refused to destroy the Habsburg monarchy; now, therefore, he had to guarantee it against foreign danger. At the same time he still hoped to keep out of Austria-Hungary's Balkan adventures. The alliance was limited to a direct attack by Russia, and Bismarck even made out that it brought advantage to Russia, in that Austria-Hungary would no longer be tempted to work with Great Britain. He said to the Russian ambassador, "I wanted to dig a ditch between her and the western powers."

The alliance was something of a conjuring trick: it preserved Austria-Hungary without supporting Austro-Hungarian policies. But suppose Austria-Hungary should take the risk of an aggressive Balkan policy, of which Germany disapproved? This was the insoluble problem that Bismarck left to his successors. Previously alliances had only been concluded as preparation for a war or on its outbreak; now Bismarck tried to make international relations rigid. He himself regretted this later and advised his successors not to take their treaty obligations literally; every treaty, he said, contains the unwritten clause, *rebus sic stantibus* ("unless circumstances change").

The Austro-German alliance was signed on Oct. 7, 1879. It marked the beginning of a new period of conservatism in Bismarck's foreign policy. The same change had already taken place in his policy at home. Until 1877 he continued to work with the National Liberals. Then fiscal, economic, and political factors turned him against them. The existing taxes did not cover the cost of the armed forces, and the deficit had to be met by "matricular contributions" from the states. Bismarck wished to escape this dependence; on the other hand, he did not wish to increase the power of the Reichstag by introducing direct taxation in the empire. Indirect taxes were voted for an indefinite period; therefore, once granted, the Reichstag would have no more control over the military expenditure than the Prussian Parliament had had after 1862. The National Liberals foresaw this danger and they would agree to more indirect taxation only if they received "constitutional guarantees." In December 1877 Bismarck invited Rudolf von Bennigsen, the leader of the National Liberals, to become a Prussian minister and virtually his deputy. Bennigsen insisted that the invitation must be extended to two other National Liberals. Bismarck had planned to take Bennigsen prisoner. Instead the National Liberals threatened to turn Bismarck into the figurehead of a parliamentary ministry. He broke off the negotiations and on Feb. 22, 1878, announced his intention (never in fact achieved) of introducing a tobacco monopoly. This was his first breach with the National Liberal policy, and it ended the plan of giving the German Empire a parliamentary ministry.

Breach with the National Liberals

The breach with the National Liberals soon widened. In June 1878 an attempt was made to assassinate William I. Bismarck at once dissolved the Reichstag and launched an anti-Socialist campaign designed to hit the National Liberals on the rebound. They either had to renounce their liberal principles or be branded as the supporters of assassins. They lost 30 seats in the election and then tried to get back into Bismarck's favour by voting for the anti-Socialist bill after all. He was, however, intent on destroying them as a political force. In March 1879 he made his peace with Windthorst, the Centre leader, and at once began to undo the measures against the Roman Catholics, despite his early boast that he would never "go to Canossa" (where the emperor Henry IV submitted to the pope in 1077). His basic reason for the *Kulturkampf* (his conflict with Roman Catholicism) had been to create some target for national resentment. Now the Socialists filled the role even better. Furthermore, the Centre drew its main strength from the peasant farmers of western Germany. They sympathized neither with liberalism nor —what was more important—with free trade. Reconciliation with the Centre was the preliminary to protection, and this was the essential change that took place in Bismarck's policy in 1879.

The initial impulse was the decline in agricultural prices that hit all Europe at the end of the decade. Bismarck was determined to maintain the predominance of the agrarian classes—primarily of the Prussian Junkers, but also of the land workers who were supposed to make the best soldiers. Agrarian protection could not be carried by itself. Bismarck also introduced tariffs on manufactured goods, particularly on iron and steel. This satisfied the great industrialists of western Germany, who were henceforth ready to accept the Junker landowners as partners. The return to protection was more than a change of policy. Hitherto protection had been the defensive weapon of backward countries. Germany, the most progressive industrial nation, took it up for aggressive purposes.

Protection completed the estrangement of the National Liberals. They had always cared more for laissez-faire than for individual freedom, and Bismarck challenged them at their most sensitive point. In 1880 the party split, the more advanced members gradually drawing toward the Progressives. The National Liberal remnant became purely an interest group representing the needs of heavy industry.

Bismarck's manoeuvre was not altogether successful. He had destroyed the National Liberal majority without putting anything else in its place. The remaining National Liberals were in a minority even when the two conservative groups joined them. In fact the Centre held the decisive position, and it could defeat Bismarck's measures if it voted with the Progressives and the Social Democrats. His Reichstag policy between 1879 and 1890 all turned on this point: he had no solid party on which to rely, yet would not accept the open partnership with the Centre that was the only alternative. Hence he had to invent alarm cries, imaginary panics with which to stampede the electorate. The "social peril" had been the cry of 1878; it failed to work satisfactorily in 1881. Bismarck had to call in, first, colonial disputes in 1884 and then foreign dangers in 1887. Both were risky expedients that could not be repeated, and in 1890 Bismarck found himself once more without a majority.

Social security

Bismarck did not rely only on repression to defeat the Social Democrats. He was the first statesman in Europe to devise a comprehensive scheme of social security, offering the worker insurance against accident, sickness, and old age. This Bismarckian "socialism" later became a model for every other country in Europe. It represented in part the paternalist function of the state that Bismarck, as a conservative, had always held. But no doubt its prime function was as a weapon against the Social Democrats. It is commonly held that it failed of this purpose. The Social Democrats continued to increase despite both persecution and state insurance. Bismarck himself confessed in 1890 that he had failed and wished to establish a military dictatorship in order to crush the Social Democrats. But in a deeper sense he succeeded. The Social Democrats ceased to be a revolutionary party, and, when a mortal crisis came in 1918, they preserved the empire as Bismarck had created it. This was his last and most unexpected achievement.

Bismarck had not meant to commit himself exclusively to Austria-Hungary when he made the alliance of 1879. Rather he desired to renew good relations with Russia on a conservative basis. This was not difficult. The Russians asked only for security in the Near East, and the Austrians gave up hope of alliance with Great Britain when the Liberals came to power there in 1880. The League of the Three Emperors was renewed (June 1881). This was both a conservative partnership, echoing the phrases of the Holy Alliance, and a pact of practical cooperation in the Near East, guaranteeing Russia security at the Straits. Austria-Hungary assented to the league unwillingly; Vienna had a deep distrust of Russia that could never be surmounted and would have preferred an anti-Russian alliance with Italy and Great Britain. Bismarck, to satisfy the Austrians, agreed to a Triple Alliance with Italy (May 1882). This gave Austria-Hungary a guarantee at least of Italian neutrality in the event of war with Russia; in exchange Bismarck had to promise to defend Italy against France. This system of alliances—further extended to Romania in 1883—was strictly defensive and aimed at preserving the general peace of Europe. But, like the earlier League of the Three Emperors, it depended on Russia and Austria-Hungary remaining pacific and conservative in the Balkans, and it threatened to break down when new difficulties occurred there in 1885.

Colonial ventures

Bismarck's colonial ventures were closely related to his other policies. He had always repudiated interest in colonies. Pointing to Russia and France, with Germany in the middle, he said, "Here is my map of Africa." In 1884, however, he flung himself into colonial disputes with Great Britain and in the course of a single year acquired for Germany the Cameroons, South West Africa, East Africa, and part of New Guinea. His motives have been much debated. He certainly had close connections with the great trading firms of Hamburg and welcomed an occasion to estrange them from England and English liberal ideas. Moreover, he needed a cry with which to fight the election of 1884, and hostility to England seemed as good as any. He himself, as he grew older, clung ever more persistently to office. The old Emperor could not last much longer, and Bismarck feared that when the Crown Prince succeeded a liberal ministry

would be set up. He was constantly on the watch for this imaginary "German Gladstone ministry" and sought to drive out of public life anyone who might qualify as a member of it. But the Crown Prince could not himself be driven out; therefore he had to be isolated and preparations had to be made to discredit him. Since he had an English wife, England had to be presented as hostile to Germany.

Colonial ambitions also served the needs of Bismarck's foreign policy. He made a determined effort to be reconciled to France while the Eastern question was quiescent. He would not, of course, return Alsace-Lorraine, though he made misleading apologies for the annexation, but he offered to support the French anywhere else in the world. They suspected, however, that he was pushing them into conflict with Great Britain, and to lull these suspicions Bismarck trumped up disputes of his own with the British in order to be able to convince the French that he had common interests with them. This policy had a certain success so long as Jules Ferry, the great advocate of colonial expansion, was prime minister in France. But even Ferry did not intend a permanent reconciliation with Germany, though he used Bismarck's cooperation to further his colonial plans, and the policy broke down altogether when he fell from power on March 31, 1885. Bismarck then patched up his disputes with Great Britain and soon repudiated all interest in colonies. In 1889 he declared, "I am not a colonial man."

The army bill

The calm that had followed the Congress of Berlin was broken in 1886. In the Near East a new crisis was caused by the unification of Bulgaria. In France Georges Boulanger appeared as the leader of a patriotic movement agitating for revenge. Bismarck used this crisis both to strengthen his position in the Reichstag and to give his foreign "system" a new form. The Septennate, passed in 1880, was running out. Bismarck exaggerated the danger from France in order to justify an increased grant; moreover, by emphasizing the French danger, he could distract attention from Russia, which was his real anxiety. Finally he hoped to secure a new Reichstag more favourable to himself and thus get additional security against the accession of the Crown Prince. The parties in the Reichstag, including even the Progressives, were ready to agree to the proposed army increases but would grant them only for three years. This gave Bismarck the excuse for a conflict, which he deliberately provoked. In November 1886 the Reichstag authorized the army bill for three years only. It was at once dissolved. Bismarck persuaded the Conservatives, the Free Conservatives, and the National Liberals to form an electoral cartel on a so-called patriotic basis. Even Bennigsen, who had retired from politics in despair, was induced to return in order to defend the national cause. These tactics were successful. The Progressives lost half their seats, although the Centre was not shaken. The army grant was duly passed for seven years, and Bismarck had a Reichstag ready to support him in anything. As soon as the election was over, Bismarck minimized the danger from France and worked to remove the tension that he himself had largely created.

The Reinsurance Treaty

Bismarck's real anxiety was not an attack from France, which Germany could easily defeat, but a conflict between Russia and Austria-Hungary in the Near East. He urged the two countries to partition the Balkans, but Austria-Hungary would never agree to this. Bismarck was determined not to fight a war for Austria-Hungary's Balkan interests, let alone for the preservation of Turkey. He therefore provided Vienna with other allies who would bear the responsibility for him. In 1879 he had worked to separate Austria-Hungary from Great Britain; now he worked to bring them together. The two Mediterranean agreements (March and December 1887) between Austria-Hungary, Great Britain, and Italy were made under his auspices. By them the three powers agreed to maintain the status quo, particularly in the eastern Mediterranean.

Yet at the same time Bismarck himself made a secret agreement with Russia that deprived this coalition of much of its effect. The League of the Three Emperors, renewed for three years in 1884, ran out in 1887. The Russians, on bad terms with Austria-Hungary, would not renew it again. They suggested a new agreement with Germany alone. Bismarck accepted this, but revealed to them the Austro-German treaty of 1879, by which he would have to aid Austria-Hungary if Russia attacked it. The Russians countered by refusing to remain neutral if Germany attacked France. With these two exceptions, a treaty promising neutrality in the event of war was concluded in June 1887. This "Reinsurance" Treaty had a further clause by which Germany promised Russia diplomatic support in Bulgaria and at the Straits—the points on which the powers of the Mediterranean agreements were combined against Russia.

The Reinsurance Treaty may have made the Russians feel less isolated in the Near East and so deterred them from any violent impulse, but there is no good evidence that the Russians ever contemplated war there in 1887. Bismarck later made a much greater claim: the Reinsurance Treaty, he insisted, had kept Russia away from France, and the failure to renew it in 1890 caused the Franco-Russian alliance. This was an unjustified exaggeration. The Russians had little confidence in German policy even after the treaty, and it was the French who held back from alliance in 1887. Bismarck's economic policy itself helped to defeat his diplomacy. The rising German tariffs on Russian grain estranged the great Russian landowners, and when Bismarck closed the German market to Russian bonds in November 1887, he drove the Russians to look to Paris for money instead.

Frederick III

In March 1888 there came the catastrophe that Bismarck had long dreaded: William I died, and the Crown Prince succeeded as Frederick III. The liberal era seemed to have arrived. But the new emperor was already a dying man, and Bismarck had taken his precautions. Frederick III and his wife were surrounded by Bismarck's creatures, who cut them off from contact with the remaining liberal politicians. Bismarck remained securely in office. Only one reactionary minister, Robert von Puttkamer, was dismissed. Yet Bismarck was not satisfied. He launched a violent press campaign against Alexander of Battenberg, the former prince of Bulgaria, in the quite unfounded belief that the Emperor was planning to make him chancellor. Bismarck even appealed to the Russian government, though in vain, to threaten war if Alexander were nominated. These pathological alarms were ended only on June 15 when Frederick III died.

William II and Bismarck's fall

Bismarck had taken no precautions to make the new ruler, William II, amenable; on the contrary, he had encouraged him in subordination, as a preliminary to playing him off against his father. Still, Bismarck's position seemed unshakable. He had no political rivals, and in 1886 had made his son Herbert (born 1849; Count von Bismarck-Schönhausen from 1871) secretary of state in order to gain unchecked control of foreign affairs. Herbert had all his father's violence without his skill and encouraged him in the worst courses. Bismarck set out to take William II prisoner, as he had taken William I prisoner in 1862. His only method of governing was to raise the cry "the *Reich* in danger," and he intended to provoke a crisis so grave that a dictatorship would have to be set up, with himself as dictator and William II as a helpless puppet. But William II was a more skillful politician than his grandfather, and he understood the new Germany better than Bismarck. He was not prepared to be estranged from the mass of his subjects; he believed, not altogether wrongly, that the Social Democrats would cease to be dangerous if they were treated with conciliation. He preached a policy of social reform, including factory legislation and recognition of the trade unions. In his own words, he wanted to be a *roi des gueux* ("beggars' king"). He also advocated a demagogic foreign policy. He repudiated Bismarck's cautious policy of keeping Russian friendship and refusing to support Austria-Hungary. Instead he wanted alliance with Great Britain, unrestricted backing of Austria-Hungary, and a large-scale promotion of German economic interests in the Near East. Bismarck did not openly oppose this policy.

The crisis centred on the anti-Socialist laws, which were due to expire in 1890. The Conservatives wished to renew them without alteration; the National Liberals demanded a slight modification. Bismarck made no attempt to reconcile them. In fact, as he admitted, he wanted the bill to be rejected and then "the waves would mount higher and higher until a catastrophe occurred." The National Liberals insisted on their amendment. The Conservatives thereupon voted against the bill as a whole, and it was defeated with the aid of the radical and Social Democratic opposition on Jan. 25, 1890. The Reichstag was at once dissolved. The general election of February 20 brought defeat to the Bismarckian parties. The Progressives, the Social Democrats, and the Centre together had a strong majority. Bismarck welcomed the crisis. He proposed to carry out a coup d'etat. The German princes, who had made the empire, should now declare that it was dissolved and a new constitution should be drafted, abolishing universal suffrage and reducing the powers of the Reichstag. William II refused to follow this path; he would not, he said, stain the first years of his reign with the blood of his subjects. Bismarck attempted to isolate the Emperor. He revived a royal order of 1852, which forbade the ministers to advise the Emperor except in the presence of the prime minister, and he appealed to the ministers to threaten a joint resignation, as they had done in 1879. But times had changed. Bismarck was old, William young, and the ministers had their careers before them. Only Herbert Bismarck stood by his father.

Resignation

At the last moment Bismarck tried to turn foreign policy to his advantage. He claimed that the Russians were willing to renew the Reinsurance Treaty only if he remained in office. William II refused to be taken prisoner. On March 18 he demanded Bismarck's resignation. Bismarck drafted a letter of resignation, emphasizing only the differences in foreign policy and blaming William for the estrangement from Russia. He arranged that this letter should be published on the day of his death.

Last years. No one but Herbert went with Bismarck into retirement. Bismarck was an implacable foe. He never forgave an injury, even an imaginary one, and refused to use the personal title of duke of Lauenburg that the Emperor conferred on him when he retired. His last years were devoted solely to discrediting William, though the Emperor made many efforts at reconciliation. Bismarck used every weapon in this last campaign. In a speech at Leipzig in 1892, he criticized imperial influence and urged the German people to make the empire more democratic, although he had spent his life thwarting their democratic wishes. This demagogic appeal did not work. The German masses rightly regarded Bismarck as their enemy, and the left-wing parties even managed to prevent an address of congratulation to Bismarck from the Reichstag on his 80th birthday in 1895. Bismarck then swung back to the extreme right and ended up, as he had begun, as a violent Junker. He emphasized his claim that he had built and maintained good relations with Russia that his successors had destroyed. In 1896 he even published the text of the Reinsurance Treaty—a breach of official secrecy for which any lesser man would have been prosecuted.

His main energy in these last years went into the composition of his *Reflections and Reminiscences* (*Gedanken und Erinnerungen*), a work of great literary genius though of doubtful historical value. He increased the drama of every event and always presented himself in a favourable light. Bismarck died at Friedrichsruh on July 30, 1898, about three years after the death of his wife. He carried his feud with William II to the grave, for the inscription on his tombstone, which he devised himself, read: "A True German Servant of the Emperor William I."

Herbert Bismarck had entered the Reichstag in 1893, where he acted as a member of the extreme right. He advocated high agrarian protection and alliance with Russia, opposed colonial expansion, and became increasingly anti-British. During the South African War he was one of the most obdurate pro-Boers. He died in 1904 and with his death the challenge of the "Bismarckians" to William II came to an end.

ASSESSMENT

Bismarck was a political genius of the highest rank, but he lacked one essential quality of the constructive statesman: he had no faith in the future. The revolutions of 1848 convinced him that the old order could not be preserved unchanged, and all his later policy was shaped by this conviction. He went with the modern forces of liberalism and democracy solely to draw their sting. Like Metternich he regarded them as evil; unlike Metternich he turned them to his own purposes. He is sometimes compared with the leaders of the English governing classes, who under Sir Robert Peel also made a compromise with liberalism and democracy. But there was a basic difference. In England there was a genuine compromise, in Germany only a trick. The German people were defrauded, given a shadow instead of the substance.

Greatness in foreign policy

Bismarck was at his greatest in foreign policy. There he understood, as no one else did, "the art of the possible." He never aspired to dominate Europe; he was content to balance between the great powers. Though he had no moral objection to war, he preferred to get his way by diplomacy and went to war only for limited aims when it was necessary to his policy. The system of alliances that he built up was designed to secure the peace of Europe, and he played the powers off against each other with matchless skill. In fact, though no believer in eternal peace, he was the principal architect of the halcyon age that gave Europe 26 years of peace after the Congress of Berlin.

In domestic affairs his record is less inspiring. He had a lust for power that grew on him with the years. He wanted Prussia to be supreme in Germany. He wanted the king to be supreme in Prussia; but most of all he wanted to be supreme over the king. His boasted loyalty to the crown vanished as soon as William II showed signs of independence, but he was equally ruthless, though more subtle, with William I. He spoke contemptuously of the old Emperor's intelligence and did not shrink from the most unscrupulous tricks in order to keep his hold. His suspicion of possible rivals was unbounded, and he persecuted them out of public life one after the other. In his latter years all his energies went into the search for the "German Gladstone cabinet," which he was convinced was being prepared against him, a search all the more degrading in that this cabinet was always a creation of his imagination. He battered down any politician who dared to cross him even in trifles and refused to allow the Reichstag to pay a posthumous tribute to Eduard Lasker, a sincere National Liberal who had done much for the empire but had shown some independence. Yet Bismarck himself changed course whenever it suited him. He repudiated old friends and old policies without scruple and often showed the disloyalty that he denounced in others. He lived in the age of democracy and German power, and he devoted his life to making these two forces as harmless as possible. Despite his ringing, self-confident phrases, he was at heart a despairing conservative, caring only for the past, dreading the future, and trying to retard its arrival. Gladstone said of him, "He made Germany great and Germans small."

BIBLIOGRAPHY. There is no standard biography of Bismarck even in German. The more recent works in English include ERICH EYCK, *Bismarck and the German Empire*, 2nd ed. (1964), which is in part the belated revenge of a German Liberal; A.J.P. TAYLOR, *Bismarck: The Man and the Statesman* (1955), largely an expansion of the present article; and WERNER RICHTER, *Bismarck* (1962; Eng. trans., 1964). The first two volumes of Bismarck's autobiography were translated as *Reflections and Reminiscences* (1968), and the third volume has not been translated. There is a full discussion of books on Bismarck in G.P. GOOCH, "The Study of Bismarck," in *Studies in German History* (1948, reprinted 1969).

Bivalvia

The Bivalvia, known commonly as bivalves, constitute one of the major classes of the invertebrate phylum Mollusca. The group is characterized by a bivalved shell, *i.e.*, one with two separate sections; oysters, mussels, cockles, scallops, and clams are typical members. The bivalve shell is compressed toward the closure line between the valves, which are connected by an elastic ligament (valves and ligament jointly constituting the shell); with but few exceptions, the animal is entirely enclosed within the shell. Valves and ligament are secreted by the mantle (a fleshy or membranous outgrowth of the outer body wall) and are equivalent to the univalve shell of a snail. The two valves are usually bilaterally symmetrical, *i.e.*, they are mirror images of one another. Enclosure of the head with consequent withdrawal of the mouth from contact with the bottom, or other solid surface, has resulted in the evolutionary loss of the head. The mantle margins are responsible for sensory functions. Feeding is by the labial palps (lips), or, more usually, by large paired gills (ctenidia); a water current is created by cilia (*i.e.*, tiny hairlike structures). Minute organic particles in the water are retained in the lattice work of the ctenidia.

GENERAL FEATURES

Distribution and size range. Most bivalves are marine, occurring in all latitudes and at all ocean depths. Many species occur in freshwater. The size of bivalves ranges from that of certain Condylocardia—*i.e.*, about one millimetre (about .04 inch) long—to the giant clam of the South Pacific, *Tridacna gigas*, which may be over 120 centimetres (about four feet) long and weigh up to 300 kilograms (about 700 pounds).

Economic importance. No group of aquatic invertebrates is of greater economic importance than the bivalves. The animals have been used as food, and their shells have been used as objects of barter, as tools, and as ornaments from the earliest recorded times; they continue to be so used by primitive peoples. Generally, all bivalves—with the possible exception of the thorny oyster, *Spondylus*—are edible, although there is occasional danger from poison accumulated by the animals during so-called red tides, in which swarms of organisms known as dinoflagellates (usually *Gonyaulax*) are taken in with the normal planktonic food (microscopic plants and animals). In polluted areas, typhoid bacilli may be similarly accumulated without harm to the bivalve.

The most important edible bivalves are oysters of the genera *Ostrea* and *Crassostrea*. *Ostrea* includes the European flat oyster, *O. edulis*, and the small olympic oyster, *C. lurida*, of the Pacific. *Crassostrea* includes the American, Portuguese, and Japanese oysters, *C. virginica*, *C. angulata*, and *C. gigas*, respectively—all have been, or are, cultivated. *O. edulis* was cultivated in Roman times; in Japan, *C. gigas* has been cultivated at least since the 18th century. The common mussel (*Mytilus edulis*) is now widely cultivated in Europe, north of La Rochelle, on the Bay of Biscay, in France, where it is grown on stakes interwoven with brushwood—a method that originated in the 13th century. In northwestern Spain, where *Mytilus* is cultivated on a large scale, the mussels are grown on ropes suspended from floats. In the United States various species of oysters are cultivated; the soft-shell clam *Mya arenaria*, the hard-shell clam *Mercenaria* (*Venus*) *mercenaria*, and other clams are also cultivated on both the Atlantic and Pacific coasts. The scallops (*Pecten* and *Chlamys*) are also highly prized as food. The extent to which prehistoric man depended on bivalves has been indicated by discoveries of large man-made scrap piles composed almost exclusively of bivalve shells. Although bivalves of the genera *Pinctada* and *Pteria*, the source of pearls, have been collected by divers in many tropical seas since early times, many pearl-oyster fisheries have been discontinued since the commercial development in Japan of methods for artificial stimulation of pearl formation. In artificial stimulation, small beads (made from the shells of freshwater bivalves) are enclosed in a small bag of mantle (shell-forming) tissue and, by a simple operation, are introduced into the reproductive region of the body of living pearl oysters (*Pinctada*). In most cases the tissue graft survives, and layers of nacreous (mother-of-pearl) material are laid down, forming what is—apart from the centre—a true pearl. The oysters are kept in baskets slung from rafts in sheltered waters in which phytoplanktonic (*i.e.*, microscopic chlorophyll-containing organisms) food is abundant. This procedure is now the basis of a large industry in the shallow waters off the east coast of Japan and elsewhere in tropical regions in which species of *Pteria* are used. Smaller, less regular pearls are also obtained from various freshwater bivalves of the family Unionidae.

Oyster cultivation

The large gold-lip pearl shell (*Pinctada maxima*) is a source of mother-of-pearl, taken from the nacreous inner layer of the shell. The windowpane shell (*Placuna placenta*), common in the Indian Ocean and the west Pacific Ocean and living free on the surface of mud, has long been collected for its flat translucent valves, which are used for glazing windows. In the Philippine Islands, the shells are made into lampshades, trays, bowls, and other articles for export.

Damage by bivalves

Wooden boats, wharves, and other timber structures exposed to seawater require protection from attacks of various species of shipworms (Teredinidae). *Teredo navalis*, the best known, was once a serious menace in The Netherlands, where dikes were built partly of wood. The use of other materials and the development of modern methods of protecting timber, usually involving poisonous impregnations, have largely removed this danger. Piddocks (Pholadidae), the date mussels (*Lithophaga*), and other bivalves are able to bore into rock and sometimes damage man-made concrete structures in the sea.

NATURAL HISTORY

Reproduction and life cycle. Most bivalves are of separate sexes; *i.e.*, an animal is either male or female. The paired gonads open primitively into the pericardium, a membranous sac surrounding the heart. In most cases, however, the gonoducts (*i.e.*, the tubes leading from the gonads) open separately, and the eggs or sperm pass into renal (kidney) ducts before being discharged into the water. The eggs are usually small. Large eggs occur in cases of direct development (*i.e.*, without a larval stage); and in cases where development occurs within the gills (*e.g.*, marine species of Carditacea and Erycinacea, some species of *Teredo*, in freshwater species of Sphaeriacea and Unionacea).

Hermaphroditism (*i.e.*, a state in which functional re-

productive organs of both sexes occur in the same individual) takes various forms; the gonad may be divided into separate ovary and testis, as in certain scallops (most scallops have separate sexes), or sperm-producing follicles and egg-producing follicles may occur among one another in the gonad, as in the Tridacnidae. All such animals, which are represented in many superfamilies, are known as simultaneous hermaphrodites. Other bivalves known as consecutive hermaphrodites, because they alternate sexual roles, usually function first as males; there are exceptions, however, in which the initial phase is female. In the former type there may be a period of simultaneous hermaphroditism during which both types of gametes, or sex cells, are produced—*e.g.*, in the common *Mercenaria mercenaria* and the woodboring *Bankia setacea*. Rhythmical consecutive hermaphroditism occurs in the European flat oyster, *Ostrea edulis*, which usually is first male then female and continues to alternate from one sex to the other at a rate conditioned by the water temperature. It functions as male and female in alternate years in waters around Great Britain, but functions in both capacities in one season in the Mediterranean. This type of hermaphroditism occurs in all species of *Ostrea* in which the eggs are incubated and then must pass out the inhalant chamber, against the flow of water, and through the gills after spawning. *Teredo navalis* also alternates in sex, but its life-span is usually too brief to permit more than one change. In oysters of the genus *Crassostrea* (including common American, Portuguese, and Japanese species), in which both egg and sperm are freely discharged, most spawn first as males; later, the proportion of sexes becomes about equal; among the older individuals there are more females. Most bivalves appear to be true males or females, never changing sex.

Veliger larvae

In the majority of marine species and in the freshwater Dreissenacea, following the initial embryonic stages, a trochophore larva (*i.e.*, a free-swimming form) and then a veliger larva (which has the beginnings of a shell, mantle, and foot) develop. The latter also has the characteristic ciliated velum, or sail, which can be drawn within the already functional bivalve shell. The veliger larva swims by means of the long cilia around the velum, with the hinge beneath. Small cilia around the base of the velum carry food particles—microscopic plants—to the mouth. When the larva permanently attaches itself to the substrate (*i.e.*, any solid surface), radical changes in form occur. These changes may be delayed if the larva does not immediately find an appropriate surface. During this process the velum is lost by partial conversion into the labial palps. Several structures develop: the foot, which is used by the oyster for temporary crawling; the byssus gland, which is used for temporary attachment of the larva and then usually lost; and the first gill filaments. The fully adult form and habit are then assumed.

Notable exceptions to this course of development occur in the Protobranchia (*e.g.*, *Nucula*, *Yoldia*), in which the large velum, consisting of rows of large ciliated cells, gives the larva a barrel-like appearance; direct development occurs in protobranchs either within or outside the mantle cavity (*i.e.*, the space between the mantle and the body). In the freshwater Unionidae, the glochidium, or larva, with a toothed bivalve shell, is stimulated by shade to attach itself to the gills or fins of a passing fish; here it becomes encysted and temporarily parasitic, until it eventually escapes by rupture of its cyst, emerging as a free-living adult. The so-called haustorius larva of the Mutelidae is still further modified; that of the African *Mutela bourguignati*, for example, develops a filament

which it uses to attach itself to the fins of the cyprinid fish, *Barbus altianalis radcliffi*. The bivalve form gradually develops as the animal feeds parasitically. Sexual dimorphism (*i.e.*, secondary differences in form between male and female) is rare. In the protobranch *Nucula delphinodonta*, the female carries a brood chamber plastered on the outside of the posterior, or rear, end of the shell. In the Carditacea (*Thecalia* and *Milneria*) the shell of the female is modified as a brood pouch. The initial male phase of the wood borer *Xylophaga dorsalis* possesses a sperm-retaining organ that is absent in the later female phase. There is similar evidence of a secondary sexual organ in males of the septibranch *Cuspidaria*. In the freshwater Lamsilinae, the development of a marsupium, a structure for the containment of early embryos, from the gills results in a change in the shape of the female shell.

Behaviour and ecology. Compression of the valves toward one another has affected the foot, which, in contrast to the creeping organ probably possessed by primitive mollusks and certainly by existing snails and chitons (Polyplacophora), has become well adapted for penetration into and movement through soft substrates. By virtue of the lateral compression of shell and foot and the ability of these structures to collect suspended or deposited material (by means of water currents created by action of cilia on the gill filaments), the bivalves may be regarded as the most successful of all infaunal (*i.e.*, burrowing into the sea bottom) animals that feed by means of cilia. Many (*e.g.*, mussels), however, have secondarily become attached to a hard surface either by horny byssus threads secreted by a gland at the base of the foot or as a result of cementation by one valve (*e.g.*, edible oysters) to a surface. In this way, bivalves have also become important constituents of the epifauna (the animals, collectively, living on the surface of the sea bottom).

Attachment of sessile forms

From both infaunal and epifaunal origins, bivalves have become adapted for rock boring. Other bivalves are highly efficient wood borers, notably the shipworms (Teredinidae), which both bore into and digest wood. There are also instances of commensalism (*i.e.*, close association between two organisms in which one derives an advantage and the other is unaffected), for example, in the Erycinacea, and one example of parasitism. Although usually slow moving through soft substances or permanently attached by byssus threads or cementation, certain bivalves, notably certain scallops (Pectinidae) and species of *Lima* and *Solemya*, can swim for short distances.

Nucula, *Mactra*, and *Poromya* are infaunal. (*Nucula* is disposed parallel to the surface, the others are vertical.) This is the primitive habit of the Bivalvia—that is, unattached and slow moving. Changes in external form involving the relationship between the mantle–shell unit and the combined mass of foot and viscera (visceropedal mass), however, have permitted alteration in habit and the exploitation of different surfaces. Deep burrowers occur in the superfamily Tellinacea, in which the siphonal tubes (which draw in and expel water) are not united; the inhalant one is extensile and searches over the surface for organic deposits that are actively drawn in (*e.g.*, *Tellina*, *Abra*, *Macoma*, *Scrobicularia*). The animal may be up to 15 centimetres (about six inches) below the surface, in some cases lying on one side. Such tellinaceans are deposit feeders, as distinct from suspension feeders. Tellinaceans are largely successful because their tubular-shelled, vertically disposed bivalves are capable of extremely rapid upward and downward movement through soft sand or mud. The siphons are very short but the foot is enlarged to form an efficient organ for vertical movement. Other types of deep burrowing bivalves are the gapers—*e.g.*, species of *Mya*, *Lutraria*, and *Panope*; each belongs to a different superfamily, but the fused siphons of all are elongated. The animal penetrates deeper as it grows larger and may attain depths to 60 centimetres (about two feet)—*e.g.*, the geoduck *Panope generosa*. The siphons contract when the animal is exposed or endangered.

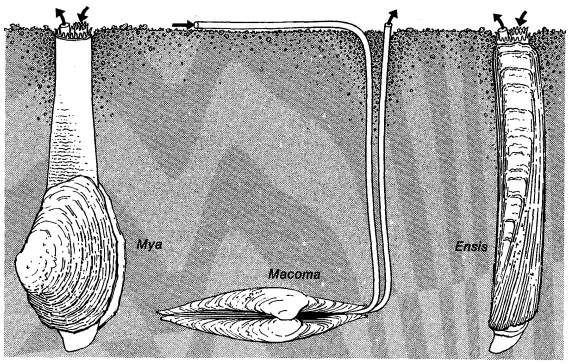

Figure 2: Deep-burrowing bivalves.

Mussels maintain themselves most effectively on an exposed rocky surface. At the enlarged posterior end the inhalant opening is raised clear of the bottom. This condition, which is always associated with byssal attachment, appears sporadically throughout the Bivalvia. It is present in the related Pinnidae, or fan shells, including the genera *Pinna* and *Atrina*, which live vertically embedded in soft material (a return to a fixed infaunal life); in the freshwater Dreissenacea (freshwater mussels superficially like the marine *Mytilus*); and members of other groups including *Cardita suborbicularis* (Carditacea).

Byssal attachment is fully retained in the pearl oysters and in the greatly modified saddle oysters (Anomiacea); it is also retained in some scallops, but many of these (species of *Pecten*, *Amussium*, *Chlamys*) become free and, horizontally disposed, are able to swim hinge hindmost. They also execute sudden escape movements with hinge foremost, water being suddenly ejected between the shell valves. If placed on the left side they can also turn over. These swimming movements appear to represent developments of mechanisms evolved in connection with cleansing action in the mantle cavity.

Other Pectinidae, for example, the Pacific rock scallop, *Hinnites*, and particularly the tropical thorny oysters, *Spondylus*, become cemented to a surface by way of the mantle and shell. The foot is retained to aid in cleansing the mantle cavity except in the Ostreidae and the Plicatulidae, which apparently became cemented at a more remote period in their evolutionary history and so have lost all trace of the foot.

Although most widespread among members of the somewhat miscellaneous order Anisomyaria, monomyarianism (*i.e.*, reduction to one adductor muscle for closing the valves) occurs elsewhere, notably in some freshwater Etheriidae and in the Tridacnidae. All members of the former (a family of the Unionacea) are adapted for life in rushing water; one South American genus of this group, *Acostea*, which attaches by either valve, becomes monomyarian by loss of its anterior adductor muscle during growth of the already reduced anterior regions. Monomyarianism has been attained in a unique manner in the tropical Tridacnidae. All species are attached by a massive byssus, although this is lost in the adult giant clam, which remains relatively fixed by virtue of its great weight. The structure of the tridacnids is unique; the hinge and ligament have moved from middorsal (as in *Cardium*) to midventral, lying beside the aperture through which the byssus passes. The free margins of the valves, now on the upper surface, are separated by greatly extended siphonal tissues. Originally (as in *Cardium*) confined to the posterior end, these margins are pulled out, occupying the entire upper surface; they are also laterally extended so that their scalloped margins extend, when expanded, over the edges of the shell. A long, broad expanse of highly pigmented tissue is thus exposed to sunlight, which is intense because the tridacnids are confined to shallow midtropical waters, usually on coral reefs. The movement of the mantle in relation to the visceropedal mass—which itself is little affected apart from the reduction of the anterior retractor of the foot and byssus—is explained by the presence in the exposed siphonal tissues of large populations of unicellular algae (zooxanthellae), which form a substantial portion of the

animals' food; the usual feeding and digestive organs are retained, however. Possibly the additional source of nutrition explains the exceptional size of the giant species, *Tridacna deresa* and *T. gigas*. One consequence of the turning movement of the mantle is the loss of the anterior adductor and the increased size and central position of the posterior adductor. *Lima* and *Tridacna* are the only vertically disposed monomyarians.

Cementation to a surface also occurs in other groups and may not always occur in monomyarians. In Etheriidae, cementation (by either valve) occurs in the genus *Etheria*. *Myochama* and *Cleidothaerus* (Pandoracea) are cemented by the right valves, but species of the largely tropical Chamidae are cemented by either valve. Here the shell grows in a turning movement involving a splitting of the ligament from the anterior end. The process of cementation influences the form of the mantle and shell, but not that of the visceropedal mass—a conclusive demonstration of the fundamental difference between their growth processes.

Locomotion. As noted, the laterally compressed foot is an efficient organ for penetration of soft materials. It is extended by the pressure of blood contained within extensive sinuses, or hemocoeles (*i.e.*, spongy tissues) under the control of various muscles. These muscles include persisting members of certain shell muscles present in the primitive mollusks and retained in that form in *Neopilina*.

Burrowing

Burrowing takes place by a series of digging cycles. First, the foot is extended and used as a probe with the siphons open. The siphons then close while the adductor muscles contract. This closure and contraction has the dual effect of compressing the water in the mantle cavity as well as the blood in the hemocoeles. The former leaves the shell by the only remaining opening, the pedal gape (through which the foot is extended), thereby loosening the substrate in that region. Blood is forced into the tip of the foot, which dilates to form an anchor; the pedal, or foot, retractors contract, pulling the animal forward; the adductors then relax, and the siphons reopen either permanently or during a brief resting period prior to the beginning of the next digging cycle.

The swimming movements of the scallops (Pectinidae) involve jet propulsion. *Lima hians* also swims, partly by the aid of long, vertically disposed tentacles.

FORM AND FUNCTION

Structural features. The Bivalvia consist of an inner body made up of a dorsal (*i.e.*, on the upper side) visceral mass and a ventral (*i.e.*, on the lower side) muscular foot, the two constituting the visceropedal mass, which is completely enclosed within a mantle, or pallium, that secretes the shell. The foot and the mantle margins can be protruded, and in most bivalves all tissues can be withdrawn within the protection of the shell. The internal cavity formed by the overhang of the mantle lobes constitutes the mantle cavity, which extends on either side of and behind the visceropedal mass.

There is much greater variety of habit in the Bivalvia than might at first appear. Members of the two major subdivisions, Protobranchia and Lamellibranchia, exemplify wide differences in habits while exhibiting little difference in outward form.

Gill structure

The protobranchs, so named because of the relatively simple structure of the gills, or ctenidia, have many undoubtedly primitive characters and have, if shell form is a reliable indication, remained unchanged since the Early Paleozoic Era (570,000,000 years ago). The rounded, nutlike shell of *Nucula* is bilaterally symmetrical (*i.e.*, the right and left valves are similar); they are also largely symmetrical anteroposteriorly. This results from reduction of the anterior region consequent to the loss of the head. The two adductor muscles are of similar size (isomyarian), and the two pairs of anterior and posterior pedal (foot) retractor muscles, slightly more centrally placed, are similarly symmetrical. Although laterally compressed as it protrudes to cut through a substance, the margins of the large foot open out widely to grip the surface as the pedal muscles contract, thus drawing the shell forward. The gills have a central axis with alternately placed filaments extending outward on either side, the axis being attached to the roof of the mantle cavity by a membrane. As in the gills of the most primitive existing gastropods (snails and slugs), lateral cilia on the opposed faces of the filaments create an upward respiratory current. Water is drawn anteriorly into a ventral inhalant chamber and passes between the gill filaments into the smaller, dorsal exhalant chamber; into the latter open the anus and the reno- (kidney) reproductive pore, and all of their products thus are discharged posteriorly by way of the exhalant current. Adjacent filaments are united by ciliary junctions. Particles filtered out as the current passes through the gill are collected on frontal cilia and may contribute to the food supply.

The largest organs in the mantle cavity are the labial palps, enlarged upper and lower lips concealing the mouth, which lies in the midline behind the anterior adductor. Only bivalves possess labial palps, and, in *Nucula*, they may be regarded as indicating the manner in which—during the evolution of the bivalves—the mouth maintained contact with the environment as it was gradually enclosed by the mantle and shell. The outer palp on each side bears an elongated, extensile proboscis with a ciliated groove on its inner face. The proboscis extends outside the shell and actively collects organic deposits from the material in which *Nucula* superficially burrows. This material is passed between the inner grooved faces of the opposed palp lamellae and exposed to the sorting action of complex ciliated tracts, which control the type of material that enters the mouth. Excess material is ejected onto the mantle surface, where it collects in mucus-laden masses known as pseudofeces. This material is periodically expelled by sudden contractions of the adductor muscles. These are divided into a catch muscle for sustained contraction and a quick muscle for periodic sudden contractions.

Pseudofeces

The form of the shell in *Spisula*, one of the commonest of sand-burrowing lamellibranch bivalves, and about twice the size of *Nucula*, is similar to that of the smaller bivalve. It also is equivalve (*i.e.*, the two valves are similar), equilateral (anteroposteriorly symmetrical), and isomyarian; the gills are very large, extending the length of the mantle cavity from the anterior adductor and consisting of many more filaments than in *Nucula*. Water is drawn past the filaments by the action of cilia. All intercepted particles are conveyed by oralward currents between the palps. Gills are the sole means of feeding; the palps are concerned with food selection. Pseudofeces collect in the inhalant cavity in *Spisula* and are rejected as in *Nucula*. Here, as in the great majority of lamellibranchs (and in some protobranchs), the inhalant as well as the exhalant current enters posteriorly. This permits the animals to burrow, anterior end downward; water is both drawn in and expelled from the posterior end. In *Spisula*, both openings lie at the end of a short united, retractable siphon formed by posterior extension of the mantle margins. An important distinction from *Nucula* is the fusion of the mantle margins, separating the ventral, inhalant opening from the dorsal, exhalant opening.

Poromya, a representative of the small group, the septibranchs (which are usually subsumed under the subclass Lamellibranchia), is similar in form to the protobranchs and lamellibranchs. It is equivalve, largely equilateral and isomyarian, and has a well-developed foot and anterior and posterior retractors. It is different in that the gills are replaced by a septal partition. This structure is slung like a hammock across the mantle cavity and attached by muscles at either end. It is connected laterally with the mantle wall and internally with the sides of the foot (or posterior to this with the other half of the septum). This septum is pierced in two places on each side by a small ciliated lattice through which water flows upward. Dead or motionless animals, small crustaceans, and worms, are drawn into the mantle cavity and pushed into the large mouth by muscular action of small, nonciliated, palps. No mechanism is needed for expulsion of waste particles. Unlike other bivalves, the septibranchs are carnivorous (*i.e.*, they feed on living animals), the gut being suitably modified. The stomach forms a crushing gizzard.

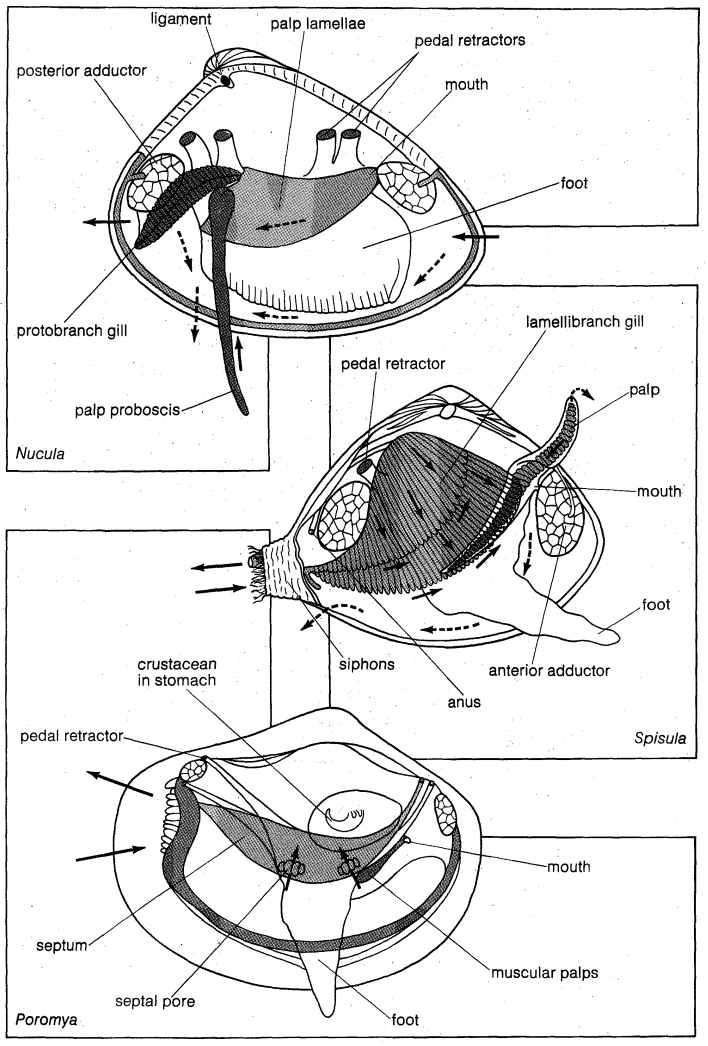

Figure 3: Internal views of *Nucula*, a protobranch; *Spisula*, a lamellibranch; and *Poromya*, a septibranch. Solid arrows indicate position of inhalant and exhalant water currents; broken arrows, currents collecting excess material (pseudofeces).

Change in shell form in *Nucula*, *Mactra*, and *Poromya* is a consequence of changes in rates of growth around the mantle margin. If these are more or less equally diminished on either side of the midventral region, then the rounded to oval shell found in *Nucula*, *Spisula*, and *Poromya* is produced. If growth gradients are higher at the two ends than in the middle, then an elongated shell is formed, with the hinge in the middle of the dorsal surface, as in the jackknife clam *Tagelus* (Tellinacea). More often only the posterior end is extended, with the hinge very near the anterior end as in the well-known razor shells, species of *Siliqua*, *Solen*, and *Ensis* (Solenacea). *Tagelus* is equilateral, but the razor shells are not.

Significance of the byssal attachment

The appearance of a byssus in some adult forms may be an instance of neoteny or paedogenesis, *i.e.*, the retention of larval characters. Such attachment in the postlarval stage is widespread—indeed, probably universal among bivalves. By the persistence of the byssal attachment the Bivalvia are able to colonize hard surfaces—that is, to become epifaunal instead of infaunal.

Such permanent attachment may have profound effects on form, hence, on habit. Throughout the evolutionary changes that have occurred, the foot and the byssus it secretes represent a fixed point in relation to which the mantle and shell and the anterior and posterior regions of the visceropedal mass may alter in their proportions. With the valves vertically disposed, the first effect of byssal attachment is a flattening of their ventral margins, for example, in attached ark shells (Arcacea) and in the mussels (*e.g.*, *Modiolus*, *Mytilus*). The ventral intake of water at the posterior end is affected by this flattening, with its accompanying pressure against a hard surface. In attached species of *Arca*, the problem is met by anterior as well as posterior intake of water. The shell remains equilateral with adductors of similar size, and the hinge line is parallel to the ventral surface. But in the mussels (Mytilidae) there is great posterior enlargement of the mantle and shell and of the visceropedal mass; there is also a corresponding anterior reduction. The shell is not equilateral, and the hinge line is inclined at an angle of up to 45°. A heteromyarian condition results: the anterior adductor is reduced and the posterior one enlarged. The anterior pedal (largely byssal) retractor muscle is also reduced and the posterior ones enlarged. The resultant bivalve is secured by radiating byssal threads, planted by movements of the elongated foot.

Further change along these lines leads to greater anterior reduction and loss of the anterior adductor. Bivalves with this monomyarian condition are horizontally disposed, all but the Ostreidae lying on the right side and —in species in which the byssus is retained as it is in the pearl oyster (*Pinctada*)—with the hinge line at right angles to the ventral surface. The anterior part of the mantle and shell and the anterior region of the visceropedal mass are confined to the small area between the centre of the hinge line and midline of the reduced and now very anteriorly placed foot. There is bilateral asymmetry, the lower valve being the more concave. The mantle and shell, and to a large extent the visceropedal mass also, become reorganized around the central adductor muscle so that bivalves such as *Pecten* acquire a secondary radial symmetry. They may be considered equilateral with the hinge line dorsal and the middle of the free margin of the valves ventral; but the foot, where it persists, indicates the morphological midventral point.

The mantle lobes secrete the calcareous valves; the mantle isthmus secretes the elastic ligament. Growth occurs at the margin. The mantle has three marginal folds; the outer is concerned with shell secretion, the middle—which carries tentacles and occasionally eyes (in scallops)—is sensory, and the innermost is muscular, controlling the inflow of water created by cilia on the gills.

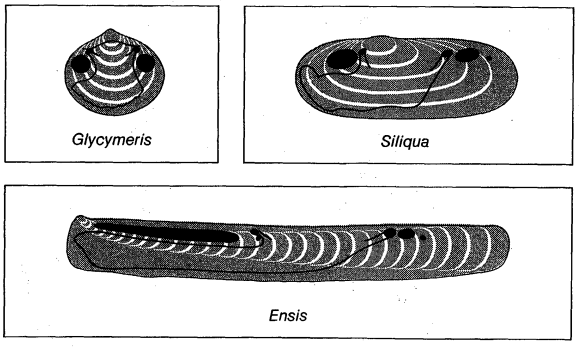

Figure 4: Representative bivalves, *Glycymeris*, *Siliqua*, and *Ensis*, showing direction of marginal growth and muscle attachments.

Shell layers

The shell has three layers. The superficial periostracum —a horny outer coating on the valve—is secreted by the inner surface of the outer mantle fold. The outer calcareous layer is formed by the outer surface of this fold, and the inner calcareous layer is formed by the general surface of the mantle. Usually this layer is bounded by a so-called pallial line where the pallial, or orbital, muscles are attached to the shell. Only this inner calcareous layer can thicken with age. The ligament consists of corresponding layers, but the innermost two are uncalcified, and the periostracum is often worn off.

The periostracum largely consists of protein; similarly, the other layers have a matrix of protein (conchiolin) impregnated with crystals of calcium carbonate that may be deposited in one of three forms: calcite, aragonite, or vaterite. Both the organic matrix and the crystalline calcium carbonate are formed in the extrapallial fluid, which lies between the mantle and the inner surface of the shell.

In this fluid are determined the pattern of the matrix and the nature of the crystal growth. Shell structure varies, but generally the outer layer is of prism-shaped sections, the inner in leaflike sections or layers. In the latter, nacre is formed if the crystals are of aragonite, calcitostracum if the crystals are of calcite.

The mid-dorsal hinge consists of elastic ligament, the opening thrust of which operates against the closing action of the contracting adductor muscles; sometimes the ligament is lost. In addition, there are usually teeth that interlock to ensure close approximation of the valves when closed. The teeth, with the corresponding sockets on the other valve, are secreted by a thin layer of mantle below the mantle isthmus, which forms the pallial crest and separates the calcareous surfaces throughout life. Various types of dentition occur and are of major taxonomic value, especially in fossil shells.

Functional features. *Circulation.* The heart, enclosed in the so-called pericardium, consists of one muscular ventricle with an auricle opening into it on each side. Blood enters the auricles by way of vessels from the gills and is driven into anterior and posterior vessels (aortae) by contractions of the ventricle. The blood then enters cavities called sinuses and usually returns to the heart by way of either the gills or the kidneys. There are no capillaries. Except in a few species in which the oxygen-carrying pigment hemoglobin occurs, there is no respiratory pigment. The blood corpuscles are amoeboid (*i.e.*, move by means of temporary extensions of the body known as pseudopodia), and some possess digestive powers.

Respiration and feeding. Blood flows through spaces within the gill filaments in the direction opposite to the upward flow of water between the filaments. In *Nucula* and similar protobranch bivalves, the gills retain an almost exclusively respiratory function. The palp proboscides are the feeding organs. In all lamellibranch bivalves the enlarged gills become, as in *Spisula*, the exclusive organs of feeding. There is great variation in the form of the gill filaments and in the arrangement of ciliary tracts upon them. Special straining cilia, the laterofrontals, are developed between the lateral cilia responsible for the formation of the water current and the frontal cilia now concerned with food collection and its passage, mixed with mucus, to the palps and mouth.

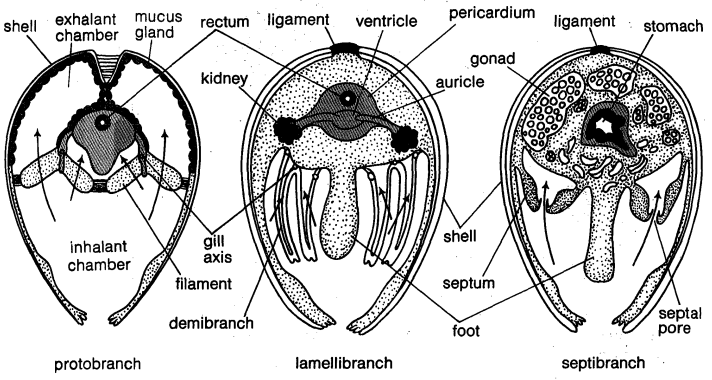

Figure 5: Transverse sections through bodies of a protobranch, a lamellibranch, and a septibranch. Arrows indicate direction of respiratory (and feeding) current in protobranch and lamellibranch; in septibranch they indicate ciliary-produced current through septal pores, which are closed when septum is drawn upward.

The lamellibranch ctenidium may be filibranch (W-shaped in cross section, with long filaments) or eulamellibranch (W-shaped in cross section and with two well-developed adductor muscles). In the former, adjacent filaments are connected by ciliary junctions (as in the protobranch condition), but in the eulamellibranch gill these are firmly united by tissue junctions of great complexity. Both types of gill are highly efficient in the collection of finely divided plant life. Their respiratory role is of minor importance. This is evident in the septibranchs, in which respiration must take place through the mantle surface. But the respiratory needs of these slowly moving, often attached bivalves are slight.

Digestion. The mouth leads by way of a short esophagus into a stomach, which communicates by ciliated ducts with the surrounding mass of digestive diverticula (formerly hepatopancreas or digestive gland). Associated with the midgut is a sac containing the crystalline style. The head of the style bears against the gastric shield, a hardened area of the stomach wall and the only nonciliated surface in the gut. Rotation of the style helps to draw food into the stomach and to mix it; in addition, it slowly dissolves, liberating enzymes (biological catalysts) that digest starch, cellulose, and possibly fats. The diverticula may secrete some digestive enzymes. Elaborate ciliated sorting areas permit only finer particles and digested material to pass into the digestive diverticula for absorption or intracellular (*i.e.*, within the cells) digestion. Larger particles are conveyed by way of a deep groove into the coiled midgut, which passes dorsally into the hindgut, or rectum. The anus opens on the hindface of the posterior adductor. Food absorption occurs only in the extensive tubules of the digestive diverticula; the function of the midgut and hindgut is to consolidate the feces into firm pellets that will not foul the exhalant chamber. In the septibranchs, in which this procedure is unnecessary, the midgut is straight.

Digestive enzymes

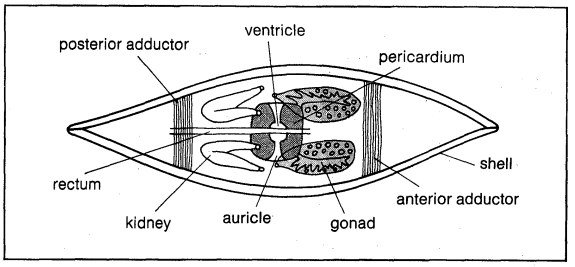

Figure 6: Pericardial (coelomic) complex in typical eulamellibranch bivalve.

Excretion. The kidneys, or organs of Bojanus, which open internally into the pericardium and externally into the exhalant chamber, consist of looped, usually branched tubes. Fluid forced through the walls of the heart into the pericardium flows through them and receives wastes. The kidneys may be united, as in the Tridacnidae, in which they are also greatly enlarged. Most bivalves also possess pericardial glands, which consist of excretory tissue lining the outer surface of the auricles or extending into the mantle (Keber's glands); in both cases these glands discharge into the pericardium.

Nervous system and sense organs. The nervous system is simple. The primitive molluscan system of four pairs of ganglia (*i.e.*, nerve centres)—cerebral, pleural (pallial), pedal, and visceral—occurs only in protobranchs such as *Nucula;* in all other bivalves, the two first ganglia unite, forming the cerebropleural ganglia, which lie above the esophagus. The pedal ganglia are in the foot, and the visceral ganglia are on the underside of the posterior adductor. Connective nerves unite the ganglia, and nerves extend through the body and into the siphons. In Pectinidae (scallops), which have the anterior regions of the body reduced, the cerebropleural and pedal ganglia are displaced in the direction of the visceral ganglia; the latter are enlarged to form a kind of visceral brain, a development even more evident in *Lima.*

With the loss of the head and the general inactivity of the bivalves, sense organs are poorly developed. Organs responding to the stimuli of vibration and gravity (otocysts) occur in the foot, except in the Ostreidae, which cement themselves to a surface and in which the foot is lost. In cemented bivalves that retain the foot, the otocysts persist. Vestigial (degenerate) eyes occur at the anterior end of the ctenidia in some primitive genera, but well developed pallial eyes are present around the siphonal openings in the cockles (Cardiacea). In the Pectinidae they are very numerous around the mantle margins. They are just as numerous and just as well developed in byssally attached forms (*Pedum*) and cemented forms (*Spondylus*) as in free-swimming forms (*Pecten,*

Sight

Chlamys). The pallial eyes are situated on the middle fold of the mantle margin. Bivalves without eyes also react to light, indicating the presence of photosensitive cells or else the direct effect of light on the nervous system. The numerous tentacles on the middle mantle fold are sensitive to chemical substances.

EVOLUTION AND CLASSIFICATION

Evolution. Existing Mollusca consist of a number of well defined classes that do not form an ascending series in terms of evolutionary development but rather have evolved radially from a common ancestral condition. From consideration of common structures, a primitive mollusk has been postulated from which existing classes, as diverse in external appearance and habit as gastropods, bivalves, and cephalopods, can be derived. The precise characteristics of this hypothetical animal have been questioned since the discovery of the first living monoplacophoran, *Neopilina galatheae*, with its possible, although by no means certain, indication of a primitive segmentation. This, however, is more of a concern of the origins of the Mollusca; for the Bivalvia there is no reason to alter previous postulates that the class arose from somewhat limpet-like animals with an anterior head and a ventral foot (the head foot) and above this the concentrated viscera covered with a mantle that secreted a domelike shell. A posterior mantle cavity housed one pair of gills with associated pallial organs. A series of paired shell muscles connected the foot with the shell, which initially was not calcified.

Classification. No satisfactory system of classification of bivalves has so far been devised. Paleontologists are concerned with the microstructure of the shell and with the hinge teeth and ligament. Neontologists (*i.e.*, specialists in recent, or nonfossil, forms) must also take into account organ systems, such as gills, palps, stomach, and the nature and extent of mantle fusion. Many superfamilies of the Bivalvia have persisted with remarkably little change since the Early Paleozoic (which began 570,000,000 years ago) and later ones from the Mesozoic (which began 225,000,000 years ago) and much that has been discovered about living bivalves appears applicable to their remote ancestors.

Distinguishing taxonomic features. The classification of the Bivalvia is based on the types of dentition, gill structure, and stomach form; also on the structure and degree of fusion of the mantle and on the structure of the valve.

Annotated classification.

CLASS BIVALVIA

Two calcareous valves joined by a noncalcareous ligament; mostly marine, some live in brackish water or freshwater; internally and externally symmetrical; head is rudimentary; two symmetrical gills used for respiration and feeding; locomotion usually by means of a well developed foot; some forms are sessile (*i.e.*, permanently fixed and nonmoving) being cemented or else attached to substrate by byssal threads. About 15,000 species.

Subclass Protobranchia

Gills with 2 divergent rows of flat, short filaments; shallow burrowers.

Order Nuculacea

Dentition taxodont (*i.e.*, with numerous similar teeth along hinge area); feed by means of palp proboscides.

Order Solemyidae

Hinge teeth reduced; feed by means of gills.

Subclass Lamellibranchia

Gills lamellibranch (*i.e.*, shaped like thin plates) or septibranch (reduced to horizontal muscular septa, or membranes).

Order Taxodonta

Taxodont dentition; gills filibranch (*i.e.*, w-shaped in cross section, with long filaments attached to each other by cilia); byssally attached or shallow burrowers.

Order Anisomyaria

Heteromyarian (*i.e.*, anterior adductor muscle reduced) or monomyarian (*i.e.*, without anterior adductor muscle); primitively byssally attached, some becoming free or cemented; hinge teeth reduced, secondary or absent; includes mussels, pearl oysters, scallops, saddle oysters, edible oysters.

Order Schizodonta

Hinge teeth few and divergent.

Order Heterodonta

Cardinal teeth (those near the anterior end of the hinge) and lateral teeth (comprising ridge below hinge area) well developed; eulamellibranch (*i.e.*, gills w-shaped in cross section); basically shallow burrowers, includes cockles, giant clams, tellins, and venerids.

Order Desmodonta

Teeth small or absent; mostly deep burrowers or borers; includes razor clams, carnivorous septibranchs.

Critical appraisal. The most important classification based on the characters of modern bivalves (of greatest concern here) is that of one authority, who divided the class into four orders: Protobranchia, Filibranchia, Eulamellibranchia, and Septibranchia. Later the Pseudobranchia were added to include groups that lay indeterminately between the Filibranchia and Eulamellibranchia.

It has been suggested that bivalves evolved along three branches, normal, sedentary, and burrowing or boring. This view persists despite the fact that the bivalve form must initially have evolved in relation to the exploitation of the infaunal habit with byssal attachment there persisting, where it persisted at all, only for temporary attachment in soft substrates.

Classification is satisfactory only at the level of superfamilies as these have been defined by some authorities. There is a remarkable degree of adaptive radiation within many of these. They exhibit many common features concerning the nature and extent of mantle fusion involving the mode of formation of the siphons and the manner in which the ligament is formed. There is evidence that might unite the primitive eulamellibranch Carditacea and Astartacea into one superfamily, which possibly might be considered an order; however, so far as living bivalves are concerned, there is no urgency in producing a definitive classification.

The position is different for fossil groups, however, since some classification schemes are based on both paleontological and neontological criteria. One, for example, involves arrangement of the superfamilies under 15 orders, which are grouped under five subclasses. But there is strong argument for grouping the superfamilies into no more than five orders.

Bizet, Georges

The most naturally gifted and original of all French composers of the mid-19th century and universally remembered for his opera *Carmen*, Georges Bizet was also the composer of many other works hardly inferior in quality. During his short life he was handicapped by the French public's exclusively operatic tastes in music; and, when he died at the age of 36, he had only just begun to achieve the wholly individual style and the dramatic power that show fitfully in his earlier music.

Bizet.
The Bettmann Archive

Bizet was born in Paris on October 25, 1838, and baptized Georges, though his registered names were Alexandre-César-Léopold. His father was a singing teacher and his mother a gifted amateur pianist; the boy's musical talents declared themselves so early and so unmistakably that he was admitted to the Paris Conservatoire before he had completed his tenth year. There, his teachers included the accomplished composers Charles Gounod and Fromental Halévy, and he quickly won a succession of prizes, culminating in the Prix de Rome, awarded for his cantata *Clovis et Clotilde* in 1857. This prize carried with it a five-year state pension, two years of which musicians were bound to spend at the French Academy in Rome.

The Prix de Rome

Bizet had already shown a gift for composition far superior to that of a merely precocious boy. His first stage work, the one-act operetta *Le Docteur miracle*, performed in Paris in 1857, is marked simply by high spirits and an easy mastery of the operetta idiom of the day. His *Symphony in C Major*, however, written in 1855 but subsequently lost and not discovered and performed until 1935, will bear easy comparison with any of the works written at the same age of 17 by either Mozart or Felix Mendelssohn. Flowing and resourceful counterpoint, orchestral expertise, and a happy blend of the Viennese classical style with French melody give the symphony a high place in Bizet's output.

The young composer was already aware of his gifts and of the danger inherent in his facility. "I want to do nothing *chic*," he wrote from Rome, "I want to have *ideas* before beginning a piece, and that is not how I worked in Paris." In Rome he set himself to study Robert Schumann, Carl Maria von Weber, Mendelssohn, and Gounod, who was regarded as more than half a German composer by the admirers of the fashionable French composer Daniel Auber.

> Mozart's music affects me too deeply and makes me really unwell. Certain things by Rossini have the same effect; but oddly enough Beethoven and Meyerbeer never go so far as that. As for Haydn, he has sent me to sleep for some time past.

Instead of spending his statutory third year in Germany, he chose to stay on in Rome, where he collected impressions that were eventually collected to form a second C major symphony (*Roma*), first performed in 1869. An Italian-text opera, *Don Procopio*, written at this time, shows Donizetti's style, and the ode *Vasco de Gama* is largely modelled on Gounod and Meyerbeer.

When Bizet returned to Paris in the autumn of 1860, he was accompanied by his friend Ernest Guiraud, who was to be responsible for popularizing Bizet's work after his death. In spite of very decided opinions, Bizet was still very immature in his outlook on life (youthfully cynical, for instance, in his attitude toward women) and was plagued by an artistic conscience that accused him of preferring the facilely charming in music to the truly great. He was even ashamed of his admiration for the operas of his Italian contemporary Giuseppe Verdi and longed for the faith and vision of the typical Romantic artist, which he could never achieve. "I should write better music," he wrote in October 1866 to his friend and pupil Edmond Galabert, "if I believed a lot of things which are not true." In fact the skepticism and materialism of the dominant Positivist philosophy persistently troubled Bizet; it may well have been an inability to reconcile his intelligence with his emotions that caused him to embark on so many operatic projects that he never brought to a conclusion. The kind of drama demanded by the French operatic public of the day could very seldom engage his whole personality. The weaknesses in the first two operas that he completed after his return to Paris are a result not so much of the composer's excessive regard for public taste as of his flagging interest in the drama. Neither *Les Pêcheurs de perles* (*The Pearl Fishers;* first performed 1863) nor *La Jolie Fille de Perth* (1867; *The Fair Maid of Perth*) had a libretto capable of eliciting or focussing the latent musical and dramatic powers that Bizet eventually proved to possess. The chief interest of *Les Pêcheurs de perles* lies in its exotic Oriental setting and the choral writing, which is more individual than that of the lyrical music, over which Gounod still casts a long shadow. Although *La Jolie Fille de Perth* bears only a skeletal resemblance to Sir Walter Scott's novel, the characterization is stronger (the gypsy Mab and the "Danse bohémienne" anticipate *Carmen*), and even such conventional features as the night patrol, the drinking chorus, the ballroom scene, and the heroine's madness exhibit a freshness and elegance of language that raise the work unmistakably above the general level of French opera of the day.

Return to Paris

Although warmly acknowledged by Berlioz, Gounod, Saint-Saëns, and Liszt, Bizet was still obliged during these years to undertake the musical hackwork that only the most successful French composers were able to avoid. Stories of his moodiness and readiness to pick a quarrel suggest a profound inner uncertainty, and the cynicism and vulnerability of adolescence hardly yielded to a mature emotional attitude of life until his marriage, on June 3, 1869, to Geneviève Halévy, the daughter of the composer of the opera *La Juive* (1835; *The Jewess*). Between his engagement in 1867 and his marriage, Bizet was himself aware of undergoing "an extraordinary change . . . both as artist and man. I am purifying myself and becoming better." Adverse criticism of certain features of *La Jolie Fille de Perth* prompted him to break once and for all with "the school of *flonflons*, trills and falsehoods" and to concentrate his attention on the two elements that had always been the strongest features of his music—the creation of exotic atmosphere and the concern with dramatic truth. The first of these was brilliantly exemplified in the one-act *Djamileh* (1872), original enough to be accused of "exceeding even Richard Wagner in bizarrerie and strangeness"; and the second in the incidental music for Alphonse Daudet's play *L'Arlésienne* (1872), which is marked by a delicacy and tenderness quite new to his music. Besides the happiness of his marriage, which was crowned by the birth of a son in July of this same year, his letters show that he was deeply stirred by the events of the Franco-Prussian War, and, during the siege of Paris, he served in the national guard.

Effect of Bizet's marriage

First production of *Carmen*

It was in the first flush of this new emotional maturity, but with the ardour and enthusiasm of youth still unshadowed, that he wrote his masterpiece, *Carmen*, based on a story by the contemporary French author Prosper Mérimée. The realism of the work, which caused a scandal when it was first produced in 1875, was to inaugurate a new chapter in the history of opera; and the combination of brilliant local colour and directness of emotional impact with fastidious workmanship and a wealth of melody have made this opera a favourite with musicians and public alike. The philosopher Friedrich Nietzsche regarded it as the type of "Mediterranean" music that was the antidote to Wagner's Teutonic sound. The scandal caused by *Carmen* was only beginning to yield to enthusiastic admiration when, on June 3, 1875, Bizet died suddenly at his home in Bougival, on the Seine River near Paris.

MAJOR WORKS

OPERAS: Eight published operas, including *Les Pêcheurs de perles* (first performed 1863); *Carmen* (1875).

ORCHESTRAL WORKS: *Symphony in C major* (composed 1855); *Petite Suite*, arranged from *Jeux d'enfants* (1871); suite, *L'Arlésienne* (1872).

INCIDENTAL MUSIC: Incidental music for Daudet's *L'Arlésienne* (1872).

PIANO MUSIC: *Jeux d'enfants*, twelve pieces for piano duet (1871); *Variations chromatiques de concert* (1868).

SONGS: Thirty-seven published songs, including "Chanson d'avril" (?1866); "Berceuse" (1868).

BIBLIOGRAPHY. WINTON B. DEAN, *Bizet* (1948), a short, but extremely thorough study of the composer and his work, with useful background information; MINA K. CURTISS, *Bizet and His World* (1959), a fascinating re-creation of Bizet as a man and of his position in his family and among his contemporaries, based on correspondence and documents that only became available after 1950.

(M.Du P.C.)

Black Muslims

The Black Muslims (officially titled the Nation of Islam) are a quasi-religious, black nationalist organization among Afro-Americans. Based in Chicago, Illinois, the Nation of Islam was led, almost from its inception, by Elijah Muhammad, reverently called by his followers "The Honorable Elijah Muhammad, Holy Prophet and Messenger of Allah." To his followers he was divinely chosen and inspired to unite black Americans under Islam for their ultimate emancipation from white rule.

NATURE AND SIGNIFICANCE

Elijah Muhammad fulfilled a traditional desire among less advantaged black Americans, going back to slave days, for a messiah who will set them free [see also NEGRO CULTS (IN THE UNITED STATES)]. This messianic impulse, common among politically and socially oppressed groups, is one of the reasons the Nation of Islam has gained such popularity among black Americans, many of whom see their situation as similar to biblical accounts of the Egyptian bondage of the children of Israel and their eventual divine deliverance. Muslims believe all black Americans are chosen as members of the "ancient tribe of Shabazz, . . . the lost-found Nation of Islam in the wilderness of North America."

At first the leaders of the Nation of Islam placed its antecedents in what they believed to be "Arabian civilization," the highest development of which was reached in Egypt. Since the 1960s, however, and the emergence during that decade of independent black African nations, their organization gradually begun to centre around Africa.

In its ideology the Nation of Islam is political; its proclaimed objective is an "Afro-American homeland" and a forthcoming "Black Nation." In practice, however, it shuns anything political, because it holds that Allah himself (who is both a religious and political leader) will bring about the New World and the New Islam—the religion of the "Black Nation." While it awaits the advent of this New World, Elijah Muhammad, the Messenger of Allah, acted as its political and religious leader.

Elijah Muhammad made his appeal primarily to urban, lower class American blacks, who were, for the most part, poorly educated migrants from rural areas of the South. Northern-born Muslims were generally better educated, though college graduates comprised only a small percentage of the movement's followers. During the early 1960s Malcolm X succeeded in attracting more college graduates to the Nation of Islam, though its additional appeal to this group was also based on the movement's shift in emphasis from a political to a more social orientation.

Before 1935 membership in the Nation was very small; its meetings were usually held in homes or rented places. Exact data on membership is difficult to secure since the figures are kept secret. The two largest memberships are at Mosque (formerly called Temple) No. 27 in Los Angeles and Mosque No. 7 in New York City. Total membership was estimated in the early 1960s at between 10,000 and 25,000. There were then between 5,000 and 15,000 registered followers, at least 50,000 believers, and a larger number of sympathizers. With the recent rise in popularity of nationalistic ideas among black Americans, however, the Nation of Islam has become more and more popular, and its membership has probably increased far beyond these early estimates. One 1970 source records claims of a membership of from 100,000 to 750,000.

EARLY HISTORY AND BACKGROUND

Noble Drew Ali's Moorish-American Science Temple

The origins of the Nation of Islam are found in the religious tradition of Noble Drew Ali's Moorish Science Temple of America (established 1913). It also embodies the secular tradition of Marcus Garvey's Universal Negro Improvement Association (founded 1914). Elijah Muhammad was himself a member of both these organizations. The philosophy of the Moorish Science Temple was based on the assertion that American blacks are "Asiatics" and, specifically, Moors whose forebears inhabited Morocco before they were enslaved in North America. In 1929, after Noble Drew Ali's death, the leadership of the movement was assumed by W.D. Fard, who reportedly claimed that he was Noble Drew Ali reincarnated. In 1930 a split developed in the movement. The faction that called itself the Moors remained faithful to the teachings of Noble Drew Ali and still exists as a small group; the other faction followed W.D. Fard, and later Elijah Muhammad, to become the Nation of Islam.

Leadership of W.D. Fard. W.D. Fard became prominent in the black nationalist movement upon the death of Prophet Noble Drew Ali. In 1930, he founded a temple in Detroit. He "proclaimed that his mission was to secure 'freedom, justice, and equality' for his 'uncle' living in the 'wilderness of North America, surrounded and robbed completely by the caveman.' " (From Arna Bontemps and Jack Conroy, *They Seek a City;* Doubleday, Doran & Co., Inc., 1945.) W.D. Fard used various names: Walli Farrad, Professor Ford, Farrad Mohammed, F. Mohammed Ali, Wallace Fard Muhammad, and even God (Allah). He is said to have peddled silks and raincoats from door to door in Chicago. After organizing the Detroit temple he gradually receded into the background, finally disappearing and leaving no trace.

Development and expansion. Fard's mysterious disappearance led some of his followers to believe that he was, truly, the "Supreme Ruler of the Universe," or "God, Allah." Not all his followers, however, believed in his divinity, and a divisive controversy developed. One result was the founding of the Chicago branch of the Nation of Islam in 1933. The Chicago Temple, led by Elijah Muhammad, severed all connection with the parent group. The nucleus of the present Nation of Islam was Elijah Muhammad, his mother, his wife, and his six children. They constituted the early membership of his first temple, which became Mosque No. 1 in Detroit.

IDEOLOGY

Social and racial aspects. The Nation of Islam insists that knowledge of one's own identity—one's self, nation, religion, and God—is indispensable to a creative life for the individual and for the group and is the true

meaning of heaven. The members believe that consciousness of self and identity remain incomplete unless complemented by knowledge of one's "enemy." The enemy of the Nation of Islam is the Caucasian race, specifically the American white man, held responsible for the moral and material conditions of black Americans. The enemy also is the disastrous effects on blacks of the white man's claim to cultural, moral, and spiritual superiority—the myth of white supremacy.

Religious aspects. Elijah Muhammad proclaimed that his mission on earth was to deliver this message to the "so-called American Negroes," who until the coming of Master Wallace Fard Muhammad had no knowledge of themselves or of their enemy. Muhammad's concern was with organizing blacks so that they may return to their own religion and their own kind in fulfillment of the covenant that he believes Allah made with their "patriarch," Abraham of the Old Testament.

W.D. Fard Muhammad is the God of the Black Muslims. He is known to his followers as "Allah (God) in the Person of Master W.F. Muhammad, to Whom all Praise is due, the Great Mahdi or Messiah, as the Christians say." He is also "the Son of Man and the Saviour." According to Muhammad's account, "Allah came to us from the Holy City Mecca, on July 4, 1930." Prophet Fard, the Mahdi or Saviour, is also believed to be the God of the Black Nation prophesied in the Bible (Rev: 18:1).

Although W.D. Fard is considered to be a black man and God, he was also said to be a very fair-skinned Arab. Nonetheless, the Black Muslims assign to him all the attributes of God. He is referred to as the "Creator of Heaven and Earth, Most Wise, All Knowing, Most Merciful, All Powerful, Finder and Life-Giver, Master of the Day of Judgment." Muhammad's followers pray to him and implore his help in everything. One of the criticisms by orthodox Muslims of Muhammad's followers is that they worship W.D. Fard rather than Allāh (God) of the "true" Islām. They contend that even the Prophet Muḥammad, founder of the religion of Islām, was merely a prophet and never claimed to be God (Allāh).

Economic aspects. The Nation of Islam stresses the importance of economic self-sufficiency for racial advancement, continuing Garvey's belief that economic self-determination was fundamental to the realization of the political objectives of black nationalism. In an "Economic Blue Print for the Black Man," Muhammad advises his followers, thus: "(1) Recognize the necessity for unity and group operation (activities). (2) Pool your resources; physically as well as financially. (3) Stop wanton criticisms of everything that is black-owned and black-operated. (4) Keep in mind—*Jealousy Destroys From Within.* (5) Observe the operations of the White Man. He is successful. He makes no excuses for his failures. He works hard—in a collective manner. You do the same. . . ."

Political or apolitical aspects. The leader of the Nation of Islam categorically stated that it is not a political movement and that the answers to the problems of black Americans do not lie in politics and the vote. Black Muslims do not participate in local or national politics. According to Muhammad, the American government is unjust and corrupt in the eyes of Allah, and therefore it is sinful for righteous Muslims to participate in its affairs. He claimed that Allah enjoins his followers not to vote. Although Elijah preached the need for a homeland for American blacks, he had no political program for the establishment of a national home.

Members of the Nation also believe that Allah forbids them to bear arms or do violence to anyone whom he has not ordered to be killed. Muhammad himself and many of his followers were arrested and jailed for refusing to serve in the armed forces. Politically and socially they have shown a tendency to isolate themselves from the American black community and from the larger American community.

The national principle is the ideological basis upon which the Nation of Islam is organized. Elijah claimed that "Allah in the Person of Master Wallace Fard Muhammad" explained to him the history and significance of the "Black Nation." The "Black Nation" consists of the entire world population of the "black, yellow, and red races." He distinguishes the Nation of Islam from the Black Nation in that the Nation of Islam is a chosen people within the "Black Nation," elected by Allah as his special instrument for the redemption of the entire Black Nation.

INSTITUTIONS AND PRACTICES

> The organization of the Nation and the symbols of authority suggest to the members a form of "private" government where they seek freedom, justice and equality, among themselves rather than in the larger American community. Consequently, members feel that they belong, both to a nation and a government of their own. . . . The nation has its own flag and its own corps of private police who maintain discipline within the [organization]. (From E.U. Essien-Udom, *Black Nationalism: A Search for an Identity in America;* University of Chicago Press, 1962.)

The Nation is oligarchic and highly disciplined.

Organizational structure. Authority in all matters of ideology, theology, and policy resided solely in Elijah Muhammad. He was the only leader of the Nation. National officers consist of two Supreme Captains—one male, the other female—and a National Secretary. The male Supreme Captain was Elijah Muhammad's son-in-law and the female his daughter.

Temples. The basic organizational unit is the temple or mosque. Each mosque is autonomous. Mosques are theoretically equal, and each through its minister has direct access to Elijah Muhammad. He formerly appointed all his national officers and ministers. In later years, however, due to Muhammad's ill health, much of this authority was assumed by the National Officers. The most important officers of a mosque, after the Ministers, are the Captains, Secretary, Treasurer, and the Investigator. Mosque captains are assisted by officers ranked as first, second, and third lieutenants.

Organizations. Within each mosque there is a men's organization, the Fruits of Islam (FOI), and a women's organization, the Muslim Girls Training and General Civilization Class (MGT-GCC). Only members of the Fruits of Islam and the Muslim Girls Training classes are eligible to become officers of a mosque. The FOI is described as a "military" organization but members neither bear arms nor have military objectives. It does have some features characteristic of military training in its organization, discipline, and ranking officers. Members of the FOI enjoy a certain amount of prestige and regard themselves as protectors of the interest of the Nation and especially of the dignity of black womanhood. Officers include the Captain, First, Second, and Third Lieutenants.

Fruits of Islam and women's programs

According to members of the Nation, the Muslim Girls Training and General Civilization Class (MGT-GCC) is "the name given to the training of women and girls in North America how to keep house, sew, cook, and in general, how to act at home and abroad." The MGT-GCC is organized along the same lines as the FOI. Among the women, hygiene and personal cleanliness are emphasized. The women are taught reading and writing (especially those who did not receive formal education), history, and domestic science—which includes sewing, cooking, housekeeping, and child care. In general, both the FOI and MGT-GCC serve the adult education and initiation polices of the Nation. Members of these organizations are considered servants of the Nation.

Finance. The income of the Nation is kept secret. Some of its sources of income are known, however. These sources include contributions by members and by other interested individuals. Most of the funds come from voluntary contributions of members. Each member is required to pay a percentage of his income into the central treasury of the mosque. This fee is called duty. Additional funds are derived from public functions such as bazaars, dinners, and collections at public meetings. Another source of income is from sale of the Nation's weekly newspaper, *Muhammad Speaks Newspaper.*

National Convention. Each year a national convention, called the Muslim Annual Convention, is held on February 27. Members of all the mosques attend these

conventions, and some of the meetings are open to the press and the general public. During the convention business meetings are held and members and officials of the various mosques renew old acquaintances. There are no debates on the reports given at these conventions, nor any decisions made by the delegates. The business of the Nation is conducted behind the scenes. Ministers and other mosque leaders meet in conferences with the Messenger and with the Supreme Captains.

Membership. Theoretically, black people—and all red, yellow, or brown peoples—are eligible for membership in the Nation of Islam. Various methods are used to recruit new members. It is the duty of every Muslim to invite nonmembers to the mosque meeting. Offers of jobs, free meals, and dinners at Muslims' homes are also used to attract prospective members. Many new members are gained through both the Nation's newspaper *Muhammad Speaks* and weekly radio broadcasts that can be heard in every major city in the United States. Motion pictures are occasionally shown portraying the businesses and educational activities of the Muslims, and of Elijah's or other member's visits to Africa and the Middle East. Public rallies are another means of recruiting new members.

Recruitment of members

Initiation. Initiation of new members is aimed at facilitating their withdrawal from society, reorienting their values, and maintaining discipline, cohesion, loyalty, and enthusiasm in the movement. A new member is taught to believe that his nationality is "Muslim" or "Asiatic." He is made to change his "slave name" and submit himself totally to the will of Allah and Elijah Muhammad. Lessons designed to give the initiate such new perspectives and values facilitate the aims of the movement.

Discipline. Muslims disapprove of undisciplined, spontaneous impulses. The pursuit of a "righteous" life, as prescribed by the "Laws of Islam" and by Muhammad's directives, is seen as the major purpose of individual existence. These laws and directives prohibit the following: extramarital sexual relations; use of alcohol, tobacco, and narcotics; indulging in such activities as gambling, dancing, movie going, dating, sports, long vacations from work, sleeping more than is necessary to health, quarrelling between husband and wife, lying, stealing, discourtesy (especially toward women), and insubordination to civil authority, except on the ground of religious obligation. Maintaining personal habits of cleanliness and keeping fastidious homes are moral duties. The eating of pork, corn bread, collard greens, and other foods traditional among American blacks is forbidden. Violation of any of these or other rules is punished immediately by suspension from the movement for periods ranging from 30 days to 7 years. The most important sanctions that appear to regulate the behaviour of Muslims are loss of membership and fear of Allah's chastisement.

Religious ceremony and ritual. There is virtually no religious ceremony or ritual at mosque meetings, except the prayers said at the opening and closing of meetings; also there are usually verses read from the Qur'ān (Islāmic scripture) and the Bible during the minister's lecture. Members are required to study Muslim procedures for prayer, to practice them, and to say daily prayers. Elijah's followers do not worship in accordance with the prescribed traditions of Eastern Muslims. Their meetings are devoted to lectures. All persons entering a mosque for meetings, including members, officers, and visitors, are searched. Men are searched by FOI members, women by MGT members. Male and female visitors sit separately at all temple functions.

Symbols

All Muslim mosques have symbols that are used by the Ministers during the lectures. The main symbol consists of an American flag and a tree with a black man hanging from a branch, which appears on a blackboard. This symbolizes justice under the American flag. Opposite the tree is a cross, another symbol of oppression, suffering, and death. Below the cross appears the word Christianity. In the upper right hand corner the flag of the Nation of Islam is painted: the moon and stars in white, against a red background that represents the sun. The letters I.F.J. & E. are inscribed on the flag and stand for Islam (Peace), Freedom, Justice, and Equality. Directly opposite the word Christianity is inscribed Islam. Between the two flags and the names of the two religions is a large question mark with the question: "Which one Will Survive the War of Armageddon?"

Members of the Nation of Islam hold a spiritual reunion every year on February 26, the birthday of the Great Mahdi (Allah in the person of Master Wallace Fard Muhammad). Most Muslims worship at their local Mosques, but many make the "pilgrimage" to Chicago, the American Mecca. February 26 is a day of worship, contemplation, and rejoicing. Gifts and greeting cards are exchanged.

Business enterprise. Economic self-sufficiency is one of the major doctrines of the Nation. Habits of thrift and hard work are expected of members. In addition to businesses owned and operated by the various Mosques, individual members are encouraged to start businesses. Most of these businesses are small enterprises. The Nation also owns several farms, and increasingly large sums are spent in buying farmlands in the South. A major project for which the Nation has been collecting funds for several years is a multimillion dollar Islamic Center in Chicago.

Education. The Nation of Islam has always maintained a day school. The first school, called the University of Islam, was established in Detroit in 1932, the second in Chicago in 1934. Both schools have been in continuous operation since. The University of Islam in Chicago provides an elementary and secondary school curriculum and is approved by the Board of Education of Illinois. Boys and girls receive instruction in the same building but in separate classrooms, except in kindergarten and the first grade. Successful graduates have gained admission to accredited colleges and universities. Until early 1959 no tuition was charged at the University of Islam. At that time very nominal fees were introduced. Facilities at the University of Islam serve also for adult education classes that include Arabic, along with basic reading, writing, and mathematics.

Communications. Today, the Nation of Islam publishes a national weekly tabloid newspaper, *Muhammad Speaks*, which features, mainly, news of various mosques and of members. It also carries news items pertaining to the conditions of black Americans and of African and Asian countries. During the Nigerian civil war (1967–70) it was the most consistently profederalist newspaper in the United States. Each issue uses a great deal of space for the editorials of Elijah Muhammad and a documented outline entitled "What The Muslims Want" and "What the Muslims Believe." Muhammad or one of his ministers can be heard on radio stations in every major city in the United States and Canada.

NATION OF ISLAM VIS-A-VIS OTHERS

The reaction of other black Americans and leaders of civil rights groups to the Nation has been mixed. Some civil rights leaders have publicly denounced it. They generally agree with white critics that the Nation is a "black supremacy" movement. Other black Americans and leaders, however, do not appear to be as disturbed by the Nation as are "respectable Negroes." Muslims are considered merely another facet of the black community. They are generally looked upon with respect by members of the black masses, although this respect is often mingled with incredulity. The general reaction among whites who are aware of the Nation of Islam is, to say the least, unfavourable. Many have described it as a "Black Supremacy Movement," and as "anti-American," "anti-Semitic," and "anti-Christian."

The U.S. Senate Internal Security Subcommittee and the House Un-American Activities Committee have both investigated the movement. It has also been listed by the Federal Bureau of Investigation (FBI) as a movement dangerous to the security of the United States. Even though local police frequently invade mosques and harass members of the Nation, no direct conflict of any major proportions has occurred between the Muslims and federal authorities. Movements of its members are closely ob-

served by FBI agents, however. No constitutional issue has yet arisen with regard to the legitimacy of the Nation's existence.

Elijah Muhammad recognized Muslims from the Middle East, Asia, and Africa, but he believed that many Muslims living in America have forsaken the teachings of Islam. In turn, many orthodox Muslims criticized Muhammad for his racist doctrines. They state that to teach racial hatred and supremacy "is against the Qur'ān and the Prophet." In addition, Eastern Muslims claim that Muhammad's ministers teach more from the Bible than from the holy Qur'ān.

Malcolm X

The ejection of Malcolm X, one of the Nation's leading ministers, in 1964 caused a temporary setback in the popularity and prestige of the organization. Before this time the Nation's membership had grown to its highest level, due primarily to the popularity of Malcolm X. In addition, college students and middle class blacks were becoming members or sympathizers. With the assassination of Malcolm X in February 1965, the Nation of Islam lost some of its influence as a nationalist group because of the suspicion that the Muslims had some connection with his death.

In recent years, as a part of the growing nationalist tendency in black communities, the Nation did begin to reacquire some of its former popularity, but it has not regained the importance it had during the years 1960–64 under Malcolm X. The Nation once more seems to be reverting to the status of a religious cult, though with increased emphasis on economic activities.

SUMMARY AND PROSPECTS

The Nation of Islam provides for its members a community with common religious, cultural, and economic interests. Through years of persistent effort it has made a genuine contribution to both the material and spiritual rehabilitation of thousands of alienated and socially despised blacks. Significantly, it stimulated and fostered the spread of "black power" consciousness, the increasing demand among black Americans for community control, and the upsurge of group pride. Through its economic activities, the Nation may well show the way to the emergence of some form of "co-operative capitalism" among black Americans. This, rather than "black supremacy" or political action, may well become its most important contribution. Whether the Nation of Islam can survive the lifetime of its aging leader and maintain its present cohesion remain in question.

Black Sea

The roughly oval-shaped Black Sea (Chernoye More in Russian; spelled Chernoje More in the transliteration system of the Akademiya Nauk) occupies a great basin, strategically situated at the southeastern extremity of Europe but connected to the distant waters of the Atlantic Ocean by the Bosporus (which emerges from its southwestern corner), the Sea of Marmara, the Dardanelles, the Aegean Sea, and the Mediterranean Sea. The famous peninsula of the Crimea thrusts into the sea from the north, and just to its east the narrow Kerch Strait (Kerchensky Proliv) gives onto the smaller Sea of Azov. The Black Sea coastline is otherwise fairly regular. The maximum east–west extent of the sea is 733 miles (1,180 kilometres), while the shortest distance between the tip of the Crimea and the Kerempe Burmi Cape to the south is 163 miles (263 kilometres). The water surface area is 162,280 square miles (420,300 square kilometres), almost the size of Sweden or Morocco, and the total volume of water is 131,000 cubic miles (547,000 cubic kilometres), with a maximum depth of more than 7,250 feet (2,210 metres) in the south central sector. The shores of the Black Sea lie within the territory of the Soviet Union (on the north and east), Turkey (on the south), and Bulgaria and Romania (on the west).

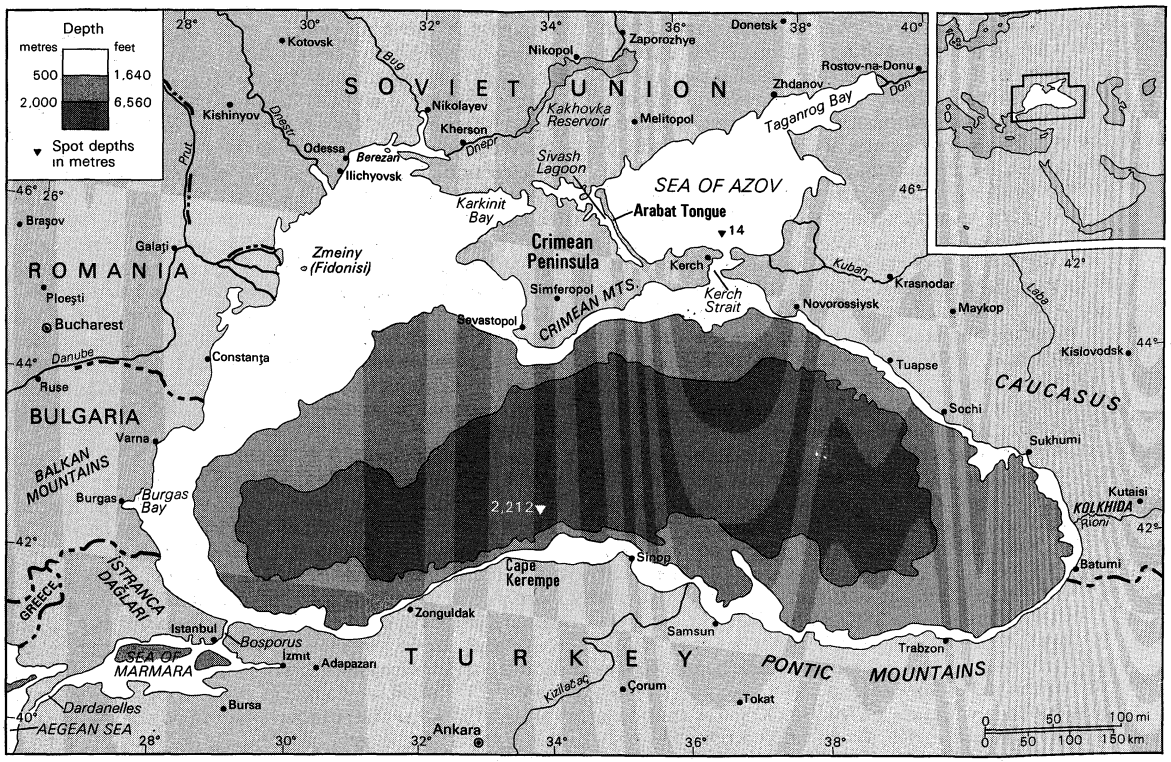
In ancient Greek myths, the sea—then on the fringe of the Mediterranean world—was named Pontus Axeinus, meaning inhospitable. Later explorations made the region more familiar, and, as colonies were established along the shores of a sea the Greeks came to know as more hospitable and friendly, its name was changed to Pontus Euxinus, the opposite of the earlier designation. It was across its waters that Jason and the Argonauts set out, according to legend, to find the Golden Fleece in the land of Colchis, a kingdom at the sea's eastern tip (now the Georgian S.S.R.), which, according to some accounts, was possibly inhabited by a black race. Yet the Turks, when they came to control the lands beyond the sea's southern shores, encountered only the sudden storms whipped up on its waters and reverted to a designation reflecting the inhospitable aspect of what they now termed the Kara Dengiz, or Black Sea.

The naming of the sea

To scientists the Black Sea is a remarkable feature because its lower levels are, to all intents and purposes, almost "dead"—not as a result of modern pollution but because of continued weak ventilation of the deep layers.

To the nations of the region, the Black Sea has been of immense strategic importance over the centuries; the advent of more settled conditions has brought its economic importance to the fore. (For further information on human geography of the Black Sea and its shores, see the articles on the nations of the region; for a related physical feature, see AZOV, SEA OF; for information on the deltas of rivers flowing into the Black Sea, see the articles DANUBE RIVER; DNESTR RIVER; DNEPR RIVER; and DON RIVER.)

Topography. *The shoreline.* In the east and south, the great mountain ranges of the Caucasus and the Pontic Mountains encircle the Black Sea in a pincer-like grip around the Kolkhida structural depression, now filled with riverborne sediments, at the sea's eastern tip. The whole region has little coastal lowland, with only the deltas of a few rivers slowly pushing out to sea. Farther west, near the Bosporus outlet, the shoreline relief, although still steep, moderates somewhat. In the southwest the smooth contours marking spurs of the Istranca (Dağları in Turkey; Strandzha in Bulgaria) ranges become northward more jagged. Farther north, in the Burgaz Bay area, low mountains emerge where the Balkan Mountains of Bulgaria extend eastward. Continuing northward, a flatter plateau region gives way to the great Danube Delta, which thrusts its mass out into the sea. Northwestern and northern shores are low and furrowed by numerous ravines and river valleys, the mouths of which are often impeded by sandy spits. The moun-



The Black Sea and associated bodies of water.

tains of the southern Crimea form the only precipitous cliff areas.

The submarine relief. The Black Sea contains but three small islands: Zmeiny (Fidonisi), Berezan, and Kefken Adasi. The submarine relief may be visualized as a series of concentric and occasionally asymmetrical rings. Beyond the shoreline a shallow shelf zone occupies about a quarter of the entire area. It is broadest in the west and at the head of Kerch Strait but elsewhere forms a rim about 6–7 miles wide, and the depth of the edge is usually less than 330–360 feet. It gives way at its edge to a slope, broken by submarine valleys and very steep in its upper parts. Between the ports of Sinop and Samsun (in the central southern sector), the coastline is paralleled by a rugged range of underwater mountains extending for nearly 100 miles. The hollow forming the basin's core covers about a third of the total area and is completely featureless flat plain, with depths increasing evenly toward the centre to a little over 7,200 feet, with the axis of maximum depth displaced toward the Turkish coast, where the maximum depth of about 7,257 feet (2,212 metres) has been recorded.

Geological background. *Rock types.* Underlying rocks reflect the regional diversity of both type and age. The ancient Precambrian rocks of the southern tip of the structural block known as the Russian (or East-European) Platform, dating from at least 570,000,000 years ago, appear in the northwest. The associated Skifsky Platform has a deep cover of sedimentary rocks that were laid later. The deepwater depression, considered by some geologists as a geosyncline (or vast downwarp), has unique significance in the structure of the Earth's crust. The centre of the depression is made up of sedimentary and basaltic crustal layers respectively with a granite layer thrust between them at the periphery. Seafloor deposits generally change from coarse pebbles and gravel at the periphery to fine silts at the centre of the basin, although the progression is by no means regular.

Variety of rock ages and types

Geological history. Much of the geological history of the Black Sea remains to be clarified, but it seems clear that it is a residual basin of the ancient Tethys Sea, dating from about 250,000,000 to 60–40,000,000 years ago. The present form of the Black Sea probably emerged at the end of the Paleocene Period, about 40,000,000 years ago, when structural upheavals in Asia Minor split off the Caspian Basin from the Mediterranean. The newly created Black Sea Basin became gradually isolated from the ocean, and its salinity was reduced; at that time the Crimea and the Caucasus were probably islands.

By the upper Miocene, about 25,000,000 years ago, the Black Sea flowed into a chain of sea lakes but gradually became separated from the Caspian region. As mountains—the Pontic, Caucasian, Crimean (Krymskye), and Carpathians—rose all around, outwashed sediments filled the basin. Further earth movements and changes in sea level associated with Ice Age glaciers then occurred and led to intermittent connections with the Mediterranean. During the last of the great glaciations the freshwater Lake Novoevksinsky was formed, and 6,000 to 8,000 years ago the present connection with the Mediterranean Sea was made. Strong earthquakes—for example, the Crimean earthquake of 1927—remain associated with the area.

Climate. On the whole, the Black Sea climate is mild, with cool summers, warm autumns, short winters, and prolonged springs, with the southern Crimea and the southeastern shores enjoying the best conditions. Conditions over the water are affected by the surrounding terrain, especially that of the dry plains of the northwest. In winter, spurs of the Siberian anticyclone (clear, dry, high-pressure air mass) create a strong current of cold air, and the northwestern Black Sea cools down considerably, with regular ice formation. The eastern portion, sheltered from cold air by the Caucasus, is milder. The winter invasion of polar continental air (which prevails for an average of 185 days annually) is accompanied by strong northeast winds, a rapid temperature drop, and frequent precipitation, with the air becoming warm and moist after passing over the milder eastern portions of the sea. Tropical air from the Mediterranean regions (87 days affected on average) is always warm and moist. Occasionally, winds that have travelled from the Atlantic across eastern Europe bring rain and sharp squalls.

The average January air temperature in the central portion of the sea is about 46° F (8° C) and decreases to 36–37° F (2–3° C) to the west. Spring air temperature everywhere approaches 61° F (16° C), rising to about 75° F (24° C) in the summer. Absolute minimums approach −22° F (−30° C) during the winter frosts in the northwest, while the Crimea may enjoy 99° F (37° C) in sum-

mer. Winds are strongest everywhere in the winter, with the cruel northeasterlies reaching hurricane force in the coastal region of Novorossiysk, just to the east of the Kerch Strait, and gale force on the sea itself. A noteworthy feature of the southern Crimean area is the occurrence of foehn winds—currents of hot, dry air dropping down from the mountains.

Periodicity in water temperatures

The hydrological system. The temperature of the Black Sea's upper layer has a marked yearly periodicity. In winter, water temperature ranges from 31° F (−0.5° C) in the northwest and about 43° F (6° C) generally, down to water depths of 230–260 feet; lower down, the water gets warmer, reaching 48.4° F (9.1° C) at the very bottom. In spring and summer, the upper levels warm up to an August peak of 79° F (26° C) and even higher near the shores; at middle levels (about 160 feet deep), a cold layer remains at 45° F (7° C), and the depths do not change from their winter levels.

Salinity of the Black Sea is almost half that of the oceans and is on average just under 22 parts per thousand (‰). Salinity varies from 17‰ on the surface to 22.3‰ in the depths and is, of course, greatly reduced near the major river mouths. A 20‰ salinity is recorded at a depth of 260 feet in the central waters, at 575 feet near the southern shores, and at 650 feet near the northern coast. Salinity increases to 38‰ at the Bosporus, where waters from the Sea of Marmara intrude. In composition, as opposed to degree, the salt of the Black Sea is almost the same as that of the oceans.

A most important feature of the Black Sea is that oxygen is dissolved (and a rich sea life made possible) only in the upper water levels. Below a depth of only 510 feet at the centre but below twice this depth near the edge, there is no oxygen, for the sea has been contaminated by hydrogen sulfide, forming a saturated, gloomy, "dead" zone frequented only by adapted bacteria.

Currents in the Black Sea are wind generated, with the main current running around counterclockwise, its branches forming gyres and sometimes large closed rotations. The current is relatively slow on the surface, except where shallow submarine relief may cause local speed-ups, but its speed is a mere inch or so a second in the depths. Flows in the Bosporus are complex, with surface Black Sea water going out and deep, saltier water coming in from the Sea of Marmara. Surface winds are an important complicating factor, especially in the shallow sill, or threshold. This situation also holds for flows to and from the Sea of Azov through the Kerch Strait.

Complex water flowage in the Bosporus

The overall water balance of the sea results from a combination of the factors of precipitation (55 cubic miles per year), inflow from the continental mass (74) and the Sea of Azov (6), surface evaporation (86), and exit through the Bosporus (50). The water level each year, therefore, varies slightly according to factors influencing any one or more of these components. Tides are virtually nonexistent, their range being exceeded by the foot or so variation induced by seiches (the changes resulting from rapid atmospheric pressure movements).

Vertical intermixing of water, except at or near the wind-whipped surface, is limited because of the compact and hence stratified nature of the sea. It has been estimated that 130 years are required to bring water in a cycle from depth to surface, although there is some limited sea-bottom turbulence caused by the warmth of the Earth's crust, and by chemical reactions in the seabed.

Plant and animal life. The Black Sea derives a Mediterranean genetic heritage from a series of invasions from that area and has Caspian elements dominant in freshwater estuaries and river mouths. In some zones, it has a rich biological productivity; and its offshoot, the Sea of Azov, is the richest in the world in this respect.

All the main groups of micro-organisms (which are predominant by a biomass, or total size, one and a half times larger than that of the groups of phytoplankton and zooplankton combined) are found in the sea. Most of them occur in a thin surface layer, with a few anaerobic bacteria in the hydrogen sulfide zone, which is otherwise lifeless. The tiny phytoplankton number some 350 species; compared to numbers in the Mediterranean, the zooplankton are even poorer, with but 80 species, including jellyfish. In coastal areas, there are eggs and larvae of invertebrates and fish. The diffusion of sea-bottom plants and animals (benthos) is four or five times poorer than in the Mediterranean, again because of the effects of the hydrogen sulfide layer. In the shallow northwest section, there is a notable extensive field of the water plant known as phillophora, whose approximately 10,000,000-ton accumulation rivals that of the Sargasso Sea. Oysters and mollusks have commercial significance in this region. The wood-boring teredo mollusk, however, is very destructive of wooden ships and structures.

There are about 180 species of fish, a fifth of them of commercial importance. The famous sturgeons are most important, followed by herring, khamsa, sprat, gray mullet, and others, including the Black Sea shark. There is some seasonal migration of fish, notably through the Bosporus.

Human utilization. The Black Sea is an important year-round transportation artery, linking the eastern European nations with world markets. Odessa, the historic Ukrainian city, together with the nearby new Soviet port of Ilichyovsk account for half the sea's freight turnover; the Soviet Black Sea fleet accounts for half that nation's sea transportation. Novorossiysk and to a lesser extent the ports of Tuapse and Batumi farther to the east specialize in petroleum. In Bulgaria, Burgas is the main export centre and Varna the main import hub. Constanţa, in Romania, connects oil-bearing regions with foreign markets. In Turkey, Istanbul is the main port, while the Danube acts as a huge trade artery for the Balkan countries.

Fish constitute the most widely used biological resource of the Black Sea, and the Soviet Union takes up fully two-thirds of the total catch. One conservationist measure has been the banning of dolphin fishing by Soviet authorities since 1966: formerly, 80,000 of these gentle creatures were being killed annually. Anti-pollution measures include restrictions on oil tankers and on the disposal of industrial wastes.

Finally, the magnificent climate and mineral springs of the regions around the Black Sea have made it the Soviet Union's major recreational and recuperative centre, with the Crimea the most important region. The Golden Sands region of Bulgaria and the Mamaia region of Romania have also attracted an increasing number of tourists, many from foreign countries, in recent decades.

Blackstone, Sir William

One of the most famous of English jurists, William Blackstone was also a judge, member of Parliament, and university administrator. Blackstone's lectures at Oxford established English law, hitherto studied only in the Inns of Court, as a subject of university study alongside civil and canon law. His *Commentaries on the Laws of England*, a literary masterpiece based on his lectures, was the first complete description of English law ever written. It achieved immediate renown, shaped the future of legal education both in England and America, and is today a legal classic.

Education and early academic career. Blackstone was born in Cheapside, London, on July 10, 1723. He was the fourth and posthumous son of Charles Blackstone, a silk merchant of moderate means, and his wife Mary, daughter of Lovelace Bigg of Chilton Foliat, Wiltshire. His mother died when Blackstone was 12. He was educated by his uncle Thomas Bigg, a London surgeon, first at the Charterhouse (1730–38) and then at Pembroke College, Oxford, where he read not only the classics, but logic and mathematics. Everything that he wrote shows a wide knowledge of literature and an allusive and elegant literary style.

In 1741 he became a student at the Middle Temple (Inn of Court). In 1743 he was elected a member of All Souls College, Oxford; a year later he became a fellow, and by 1746 he had become a barrister. His practice was not very successful, but in college affairs he at once proved himself an active and efficient man of business, zealous for order and improvement. His greatest service was to hasten the completion and furnishing of the Codrington Library, which was finished in the summer of 1751. His persistence also brought about the building of the Wharton rooms adjoining the library. These were clearly congenial tasks: in the summer of 1743 Blackstone had written a treatise, *Elements of Architecture*, that he revised and expanded in 1746 and 1747.

In 1750 Blackstone took the degree of Doctor of Civil Law. In July 1753 he decided to retire from his practice and concentrate on the teaching of academic law and legal work in and around Oxford. He had been recorder of Wallingford since 1749 and assessor (that is, judge) of the Chancellor's Court since 1751.

Lectures on the common law

Blackstone had developed a great interest in common law, and in 1753 he began to lecture in that subject. These were the first lectures on English law ever delivered in a university. He stated his aims in a notice of his lectures dated June 23, 1753:

> It is proposed to lay down a general and comprehensive Plan of the Laws of England; to deduce their History; to enforce and illustrate their leading Rules and fundamental Principles; and to compare them with the Laws of Nature and of other Nations.

In 1756 he published *An Analysis of the Laws of England*, a synopsis of his lectures for the guidance of his pupils.

In October 1758 Blackstone was elected first holder of a chair (the Vinerian professorship) of common law. His lectures formed the basis of his *Commentaries*, which were published between 1765 and 1769. In this Oxford period of Blackstone's life he did the university another great service: appointed delegate of the university press in 1755, he rapidly achieved important reforms both in its administration and in its methods of printing. His edition (1759) of the *Magna Carta* and the *Charter of the Forest* is an example of the reformed typography. The edition led in February 1761 to his election as a fellow of the Society of Antiquaries; he read papers to the society in 1762 and 1775.

Public life. For several years Blackstone combined academic life in Oxford with increasingly active public life in London. In 1759 he resigned the office of assessor of the Chancellor's Court and in 1761 became a bencher (lecturer and supervisor) of the Middle Temple. In March 1761 he was elected member of Parliament for Hindon, in Wiltshire, on the recommendation of William Petty Fitzmaurice, 1st marquess of Lansdowne, but with no great enthusiasm on his own part. In May 1761 he married Sarah, daughter of James Clitherow of Boston House, Brentford, and bought Priory Place, Wallingford. Marriage lost him his fellowship at All Souls, but in July he was appointed principal of New Inn Hall, a medieval hall that survived until 1887, when it was annexed to Balliol College. In 1763 he became solicitor general to the queen. By this time it could not have been easy, even for a man of Blackstone's tireless industry, to combine his public life in London with his Oxford life. His decision to leave academic life came after the rejection of his proposal to convert New Inn Hall into a specialized college of common law. In 1766 Blackstone resigned both his chair and his headship of the hall.

Parliamentary career

Blackstone sat in the House of Commons for nine years as member of Parliament for Hindon (1761–68) and for Westbury (1768–70). He was not a zealous politician. He described himself as "amid the Rage of contending Parties, a Man of Moderation." But Blackstone had exhibited some previous interest in politics, for in 1751 he had taken part in a campaign to elect a country Tory, Sir Roger Newdigate, as member of Parliament for Oxford University, and in 1754 he had supported the old Tory interest in the Oxfordshire election. Blackstone was not a particularly successful politician and spoke mainly on legal and constitutional questions. The most conspicuous of these were the repeal of the Stamp Act (1766), which Blackstone opposed, and the Middlesex election of 1769, when he supported the expulsion of the political reformer John Wilkes from the House of Commons. On May 8, 1769, Blackstone gave his "unbiassed opinion" that Wilkes was disqualified from sitting in the House. This opinion was attacked as being inconsistent with the *Commentaries*. But the attack was based on genuine or pretended misunderstanding of Blackstone's position, for he did not, as he explained in 1770, maintain that expulsion from the House automatically conferred incapacity for election.

In 1770 Blackstone refused the office of solicitor general but accepted that of judge of the Common Pleas and was knighted. He was now at the height of his fame. Little is known about his extracurricular activities in the last ten years of his life. He probably had more leisure than ever before. He spent it at Wallingford, where he played a prominent part in the making of two new turnpike roads and in the repair of St. Peter's Church. The church spire, completed in 1777, was built at his expense. He urged that convicts be put to work in penitentiaries instead of being transported and helped draft the Hard Labour Bill that became law in 1779. Blackstone described this reform as "a species of Punishment in which Terror, Benevolence, and Reformation are . . . happily blended together." Toward the end of the 1770s his health failed; he died on February 14, 1780, and was buried, by his wish, in St. Peter's Church.

Assessment. Blackstone was a good judge but a better commentator. The *Commentaries* is a systematic, clear, and elegant description of the state of English law in the middle of the 18th century. It had an immediate and outstanding success. In England and America the *Commentaries* became the basis of university legal education.

Criticisms of Blackstone's views

Contemporary criticism of the *Commentaries* was directed not against the book as a whole but against particular points. His treatment of dissent was particularly criticized. Blackstone, in response, made some alterations in wording but did not change his view that dissent remained, in law, a crime. The most damaging criticism came near the end of Blackstone's life and had its greatest effect after his death. This was the philosopher Jeremy Bentham's attack on him as an "enemy of reformation."

Bentham's attack began with the anonymous publication, in 1776, of *A Fragment on Government*. It was directed against Blackstone's introduction, in which he treats government, sovereignty, and law in general. It was basically the attack of a dogmatic legal reformer upon a historical expositor of the law. Blackstone's conduct at Oxford showed that he was a defender neither of

the status quo nor of vested interests. In the House of Commons he had promoted an important reform in the law relating to the administration of assets, and in the *Commentaries* he criticized other existing laws, including the game laws, the Poor Law, and the laws of inheritance. He certainly believed that the constitution was "wisely contrived," but he was aware that it had faults. Passages in the *Commentaries* could well have been quoted in favour of parliamentary reform—the statement that there might be "a more complete representation of the people," and the disapproval of influence and of rotten boroughs, for example. But it would be absurd to expect the *Commentaries* to be primarily a plea for reform. Its purpose, like that of the lectures it is based on, is to explain and describe. Blackstone's description of the law as it existed was accurate and comprehensive and was of great use to those who wished to reform it. His description of the constitution was much more in keeping with the facts than some of his critics allowed; his statement of the sovereignty of Parliament and his recognition of the implications of sovereignty went beyond those of all predecessors.

Bentham's picture of Blackstone as an arch conservative was influential because it fitted in with the climate of early-19th-century English legal reformers. In America, where Bentham and Utilitarianism never attained much popularity, Blackstone's reputation suffered no eclipse, but in England it was, for a time, clouded. It was restored, after the middle of the 19th century, by the rise of a group of jurists who, like Blackstone, believed history to be necessary to the understanding of law.

Blake, William

Poet, painter, engraver, and visionary, William Blake created a new, simple, and emotionally direct mode of thought and expression in the arts about 1790 and is now seen to have possessed a mind of outstanding originality and power. Yet he was ignored by the public of his day; poets and designers who did know him called him mad because he was single-minded and unworldly; he lived on the edge of poverty, and died in neglect. Only in recent times, more than 100 years after his death, has the breadth of his invention both in poetry and in painting been recognized. In addition, it is now clear that Blake had another imaginative gift: he saw with prophetic vision into the future, to the state of man in modern society.

William Blake was born in London on November 28, 1757. He was the second of five children. His father was a hosier, with a household typical of a modest shopkeeper in the late 18th century. The family lived and had their shop (which Blake's older brother later inherited) in a respectable area near Piccadilly. Although Blake's parents were Nonconformists—Protestant dissenters from the Church of England—they had the boy christened on December 11 at St. James's Church in Piccadilly. Blake did not go to school, but he learned from his mother and read widely even as a boy. Personal teaching was always to mean much to him, and he probably taught his younger brother Robert to read, and, when he married, he taught his wife.

London then was a small central city surrounded by villages and fields with market gardens. Blake was brought up in the denser part of London, and this makes his background different from that of most English poets before him, who grew up in the countryside. He walked to the villages outside London and in later life recalled the pleasure of these solitary rambles. On one of them, to Peckham Rye, before he was ten years old, he had a vision in which he saw a tree full of angels; when he told the story at home he found that his mother was kinder about it than his father.

Blake all his life had a strongly visual mind: whatever he imagined, he also saw. The accounts of those who watched him in his middle age draw imaginary personages make it plain that he had what is now called eidetic imagery—*i.e.*, the rare ability to see mental images as if they are suspended outside the head, so that they can be inspected like solid figures by shifting one's gaze from one side to the other. When Blake talked of his visions, he meant images he saw so vividly that they seemed to fill his outer rather than his inner eye. His poetry is everywhere charged and lit up with the almost physical presence of these images.

Blake, watercolour portrait by John Linnell (1792–1882). In the National Portrait Gallery, London.

Training in the visual arts. At the age of ten, Blake was sent to a good drawing school, and he wanted to become a painter. His father apprenticed him to an engraver—much as today a father in a like case might urge his son to become a commercial artist. He was first taken to a fashionable engraver, William Ryland, but he did not like the man's face which, he is supposed to have said, "looks as if he will live to be hanged." Even if he did not use exactly those words, the young Blake proved to be a shrewd judge of faces, and Ryland was hanged for forgery 12 years later.

Apprenticeship

A more humdrum engraver, James Basire, was found to take Blake as an apprentice, at the age of 14, for the usual seven years. In a professional sense, the choice of Basire was not happy because the dry and formal manner of engraving that Blake learned from him was already going out of fashion and later made Blake unfashionable as an engraver. Yet to a young, bright mind like Blake's, untutored and open, working for Basire was a kind of education. At the time, Basire was making a record of the monuments in Westminster Abbey, and in the long hours Blake spent drawing in the Abbey, he acquired a sense of the presence of history and its heroes.

When Blake completed his apprenticeship in 1779, he enrolled as a student in the Royal Academy. He was an unhappy student; he took a strong dislike to Sir Joshua

Reynolds, who was president of the academy, and he felt that his talents were being wasted in the setting of the academy. He made his living by engraving for publishers and painting watercolours. By this time, after

Friendship with England's new intellectuals

1778, he had become friendly with a number of people who belonged to a new intellectual class then growing in England. Unorthodox in their religious views, some of them, such as John Flaxman, a fellow artist, had joined the mystical sect of Swedenborg; but most of them were Unitarians and rationalists like Joseph Priestley. Their politics were liberal and sometimes even republican. They thought that the actions of their government against the American Colonies, both before and after the Revolution, were tyrannical. They were much concerned with education, but not as it was traditionally practiced in the endowed schools (in which the chief justice, Lord Eldon, ruled as late as 1805 that modern languages were not admissible subjects). The schools which they supported were the so-called dissenting academies, in which the sons of manufacturers in the north of England were for the first time taught contemporary subjects, including science. Their outlook was, then, practical, modern, and Quakerish; and they despised the establishment as a fortress of out-of-date privilege.

Blake met some of these people regularly at the house of the Rev. Anthony Mathew and his learned wife, and later, when revolutionary fervour ran high, at the house of Joseph Johnson, a radical publisher. They were the only people who ever took an interest in getting Blake's poems into print. Blake had begun to write poetry when still a boy; and Mathew and his wife, with help from John Flaxman, in 1783 published a small book of these poems under the title *Poetical Sketches By W.B.* The poems are described in the preface as "the production of untutored youth, commenced in his twelfth, and occasionally resumed by the author till his twentieth year."

Blake married Catherine Sophia Boucher on August 18, 1782, and they set up house near Leicester Square. Though she was illiterate and signed the register with a cross, Blake's loving tutelage made her into a companion with whom he could read Milton's *Paradise Lost* (naked in the garden, to represent Eden) and who would share the work of printing and colouring the books of his poems that he thereafter engraved himself. In 1784 his father died, and William Blake moved next door to his

Career as an engraver

boyhood home and opened a printshop with a fellow engraver, James Parker, who had been with him at Basire's. At the same time he brought his younger brother, Robert, to live with them. Blake and his wife never had children, and Robert long took the place of a child in Blake's thought. After Robert died in 1787, Blake often saw him in his dreams. The death of his brother and the failure of the printshop in the same year always hung together in Blake's memory.

Nevertheless, Blake seems to have been able to make a fair living as an engraver in those years and to win the regard of a small group of artists—chiefly John Flaxman and Henry Fuseli—who respected his direct and single-minded way of doing whatever he set his hand to. In 1784 he had begun to write poetry again, in the form of a satire called *An Island in the Moon*, which he did not finish; but snatches from it began to form some of the themes for poems that he would put together in 1789 in *Songs of Innocence*. Blake engraved the text himself on small copperplates by a method of his own, with his own decorations, and printed and coloured them by hand. There are some grounds for believing that earlier, at Mrs. Mathew's, he had sung some of his poems to tunes of his own creation.

Songs of Innocence and Songs of Experience. *Songs of Innocence* and its sequel *Songs of Experience*, which Blake added in 1794, were epoch-making works, though they had no impact at all when Blake printed them. They were virtually unread and unknown until at least 50 years after Blake died. Nonetheless, they were as formative for the culture of the 20th century in Europe and America as the Bible and *The Pilgrim's Progress* had been for an earlier age.

It is not clear why *Songs of Innocence* did not touch off the romantic storm that was to come so soon after, when Wordsworth and Coleridge published the *Lyrical Ballads* in 1798. One obvious explanation is that Blake's books were not sold or reviewed in the ordinary way. But there would seem to be more to his neglect than either the mechanics of publication or his other eccentricities. Blake's failure to fire his contemporaries on the one hand and his striking power to fire the 20th century on the other are more than matters of the form and scope of romantic poetry. It is Blake's insight into the dilemmas of civilized city life and into the hierarchies of power among warring states and industrial societies that left his contemporaries cold and seems to speak so directly to today.

The *Songs of Innocence* and *Songs of Experience* were written on the simple model of Charles Wesley's hymns and the moral verses of Isaac Watts and other respectable Nonconformists. But Blake's works reverse the roles of those didactic fables; in them it is not the poet who instructs the child, but the child who teaches the poet. In *Songs of Innocence* the child recounts the pleasures of a life in nature; in *Songs of Experience* the reader is shown children trapped and bewildered in the prisons of state and church.

Blake was 35 or more when he engraved the *Songs of Experience;* he had turned out, after all, not to be a precocious poet; and his outlook, though it had been foreshadowed in earlier work, was not fully formed until he was past 30. In part this is because his outlook was complex and coupled elements that more often than not are found on opposite sides of an argument.

Intellectual temperament

In the first place, Blake was a revolutionary. He was 18 when the Declaration of Independence inspired not only Americans but idealists everywhere in Europe. He was 22, and was present, when a rioting crowd expressed its general hatred of authority by burning Newgate Prison on June 6, 1780. Blake sympathized with the French Revolution in 1789, raged against the attacks on Tom Paine in 1798, and in 1801 still dreamed "that France & England will henceforth be as One Country."

Second, Blake belonged by temperament and sympathy to a Puritan tradition that took the Sermon on the Mount literally as its "Everlasting Gospel"—a name Blake was to use for the fragments of a long poem that he worked on around 1818. Blake was therefore opposed to private property, to any established church, to formal government and the laws of his time, to the machinery of war or any other kind of machinery which, in his phrase, keeps men working to "polish brass & iron hour after hour, laborious task, kept ignorant of its use."

Third, Blake did not distinguish between political and religious dissent. As he grew older, and particularly after a short attempt to live away from London, he increasingly used the language of religion. But what he wrote about was always human and social justice, and he identified state and church equally as prisons in which their subjects suffered physically and spiritually together. Both are identified in his books with the Old Testament Yahweh, so that Blake's form of Christianity was in fact the so-called gnostic heresy which elevated Jesus against Yahweh. Blake's combination of political radicalism with Christian Nonconformity is still an important element in the politics of the left in England.

Fourth, Blake was unusually perceptive in realizing that mechanical labour can reduce man to the status of an animal in a mill and in seeing that industry might produce the same result if it is directed only toward economic gain. Blake had worked endless hours to earn a living as an engraver in the difficult times from 1793 onward, and the experience had sharpened his vision of the threat of industrial exploitation to modern society. He was a man of remarkable character: intelligent and acute in observation, with a sweeping, imaginative grasp of the implications of his own experience, entirely upright in what he said and did, and with an unforced, natural acceptance of the remarkable gifts of language and design that he was endowed with.

From 1789 to 1794 Blake was writing for *Songs of Experience* lyrical poems of the kind he had put into *Songs*

of Innocence. Though the mood of the later is different from that of the earlier work and is bitter, the manner is the same. The disillusion of the *Songs of Experience* was a part of a general despondency among liberals in England in those years during which the increasingly violent French Revolution lost public sympathy and became a bogey.

Narrative poems. Between 1790 and 1793, Blake also wrote a book in prose, *The Marriage of Heaven and Hell.* He chose the title deliberately to contradict the Swedenborgian division between the two symbolic states, which did not seem to him to go beyond conventional theology. This remarkable book of fewer than 30 pages includes a series of "Proverbs of Hell," which spell out in simple images the themes that Blake was developing at the same time in the *Songs of Experience.* One of the most searching and troubling of these is the theme of "The Tyger": *i.e.*, the understanding that energy, enthusiasm, commitment, and a willingness to fight for a cause are all parts of the divine scheme and do not necessarily contradict the harmony of nature as it is expressed in the meekness of other creatures. In *Songs of Innocence,* the symbol of Christ had been the lamb; after *Songs of Experience,* Blake's thought returned constantly to more active symbols such as the tiger—a creature who has been designed by God to express himself fiercely. So "The Proverbs of Hell" say "The wrath of the lion is the wisdom of God," and "The tygers of wrath are wiser than the horses of instruction." In such opinions Blake tried to heal and even to turn upside down the division between the good or angelic and the bad or Satanic. In this period, the word devil was a mark of approbation in Blake and the word angel a mark of disrespect, for the climate of reaction then settled in England had made "angel" a synonym for "hypocrite" in Blake's eyes.

Composition of *The Marriage of Heaven and Hell*

During this time Blake began to write a different kind of poetry, one which is not lyrical in manner but has instead a narrative form in long, unrhymed lines with the rhythm of the King James Version of the Old Testament. Blake later used this "prophetic" manner in all his long poems, and it has come to be taken as his personal style. An early work in this style was the poem, *The French Revolution,* which was to have been printed by Joseph Johnson, who was then publishing the works of the radicals, Paine, Mary Wollstonecraft, and William Godwin. The book, however, was not issued, and the single copy that survives, dated 1791, is evidently a proof. There is no trace of six other parts that are implied by the title page. The poem is more directly political than anything else that Blake wrote, and it may be that Johnson did not issue it for the same reason that made him in 1791 turn over the second part of Paine's *Rights of Man* to another publisher (who was in fact prosecuted for it). Prosecution for sedition had become a constant threat to authors, printers, and booksellers in England and imposed an effective though silent censorship.

Narrative form of *The French Revolution*

Blake continued to engrave a number of books himself that voice his opposition to those who feared every kind of change. For a time he harked back to themes from the American Revolution. But from 1795 the world of his books becomes imaginary, and the wars that rage in them between authority and liberation are fables, written in a symbolism in which even the names of the protagonists are inventions.

The atmosphere of England at war with France was difficult for Blake: he was out of sympathy with the turn in public opinion, and in London he was surely known as an opponent of the government. Further, the inflation and economic depression of the war years hit Blake hard because he depended for his livelihood on designing and engraving, which in such times were luxury crafts with failing prospects. Blake and his wife had moved to a more modest part of London: south of the Thames. In 1796 a bookseller commissioned Blake to illustrate the *Night Thoughts* of Edward Young, and the first part was printed in 1797 but was a failure. Though the economic crisis was in part to blame, it is also clear that Blake, though he was acknowledged by his friends to be a highly original artist, was neither a man to the public taste nor one who could compromise with it. He scraped along from this time with the help of patronage from Thomas Butts, a Swedenborgian who bought drawings and small paintings from him for nearly 30 years.

In 1800 John Flaxman found work for Blake with William Hayley, a man of letters and of some means, who lived near Felpham on the Sussex coast. When the work seemed likely to grow, Blake moved to Felpham to be near Hayley. It was the only time in his life that he left London, and he stayed away for three years. Blake recognized the move as a watershed in his life: he wrote to Thomas Butts soon after he got to Felpham that "in future I am the determined advocate of Religion & Humility, the two bands of Society." Like Flaxman, Hayley was a well-wisher and a political liberal but not connected with the radical groups in London, and the move assured Blake's livelihood, gave him a friendly patron who did not think his ideas outrageous, and—quite as important—removed him from his more revolutionary friends and their persecutors in London.

Association with Hayley

The arrangement seemed idyllic, but it was one that could hardly last. Blake was not a man who could settle down in servility to Hayley, whose flat poetry and elevated sentiments became in his mind an insult to his own talent. There were small disagreements and growing friction. The country was lonely and the cottage damp, and Mrs. Blake had rheumatism. Above all, Blake could not stand what he called "the meer drudgery" of the work he was asked to do by Hayley, while his own art was neglected: several passionate letters to Thomas Butts and to his older brother are eloquent about this. Blake decided that he must move back to London, and he made plans to do so in the summer of 1803.

His stay at Felpham was, however, to end more dramatically. On the morning of August 12, 1803, a private in a troop of dragoons stationed in the village came into the cottage garden and seemed to Blake to behave offensively. Although Blake was a small man and not far short of 50, he summarily threw the soldier out of the garden. Thereupon the soldier swore a complaint, supported by a second soldier, that Blake had made seditious statements about the King, the army, and the country and had assaulted him. Blake had to post bail of £250, and, on January 11, 1804, had to stand trial. He had by that time gone back to live in London and was convinced that the soldier had been sent by informers from there. Hayley stood by Blake throughout, and some of the villagers gave evidence for him. In the end, he was found not guilty, and nothing more was heard of the matter except that Blake put the soldier into his last book, *Jerusalem,* as a peculiarly devious figure of treachery.

From this time, in 1804, Blake worked at his two longest books: *Milton,* which he finished in 1808 or a little later, and *Jerusalem,* which he finished only in 1820. The vision of an ideal of human life that they offer is the same as in the *Songs of Innocence* and *Songs of Experience:* man must free himself from conventional authority, including the hidden conventions that rule family life, the hierarchies of seniority, sex, and status, and the anxiety to conform to the usual canons of success. A good society, which Blake calls the New Jerusalem, cannot be achieved by political and social reforms alone. There must be universal grace of spirit, a sense of human dignity, and a flow of respect between person and person before life can be lived in a way that is true to human nature and the natural world.

Themes of *Milton* and *Jerusalem*

A new theme now appears in the long, prophetic poems, which, as they describe the work of building the New Jerusalem, refer more often to other forms of labour, and particularly to labour at the forge and the loom. These symbols of male and female occupations, which have many overtones in Blake's philosophy of the natural world, did not crop up in his poems much before 1800; and it must be supposed that Blake had only recently begun to hear about the new industries in the north of England. Though Blake never went north of London, many of the landscapes he describes and the place names he uses come from the north; and he was evidently an acute listener and reader.

In passages about male and female labour, Blake set forth a penetrating vision of the Industrial Revolution as it entered the life of the poor: the smoke, the noise, the stupefying drudgery, the estrangement from all that is individual in a man's life. The most powerful lines on this theme stand at the beginning of *Milton*, where Blake asks whether Jerusalem was built "among these dark Satanic Mills." The word mill in Blake's usage does not yet mean a factory but a mechanism, such as an arrangement of gear wheels or other machinery. But the spirit in which the line is sung and quoted nowadays is right. With grave foresight, Blake saw in his mind's eye that men were being chained economically to machines, and he knew prophetically what damage these abuses would work, physically and spiritually.

Last exhibition

Last years. In 1809 Blake made a last effort to put his work before the public and held an exhibition of 16 paintings and watercolour drawings. One of the paintings shown was based on Chaucer's Canterbury pilgrims; it may have prompted Blake to mount the exhibition because he felt he had been cheated by a fellow artist, Thomas Stothard, who had been commissioned to make a rival painting of the same subject. Blake wrote a thoughtful and pugnacious *Descriptive Catalogue* for the exhibition, but only a few people attended, among them Charles Lamb.

Blake found it difficult to get work now, and the engravings that can be identified as his from this period are often hack jobs. He was almost forgotten, even by those well read in poetry. In 1824 Charles Lamb did not even know that he was still alive. About 1818, however, some young painters who shared his religious seriousness (they called themselves "The Ancients") began to cultivate Blake. One of them, John Linnell, in 1821 commissioned him to make drawings for the Book of Job and later to engrave them; and in 1825 commissioned him to make watercolour drawings for Dante's *Divine Comedy*. In his 60s, Blake thus, for the first time, found a following and support for the imaginative work that he had longed to do all his life. As a result, it was in his last years that he produced his most assured and beautiful designs. It must be added, however, that when his engravings from Job were published in 1826, the book once again failed.

Toward the end of his life Blake suffered much from gallstones and wrote no more, though marginal notes he made here and there had his old ironic flash of contempt for state institutions and pious conformity. He still coloured copies of his books in bed, and that is how he died in a room off the Strand in his 70th year, on August 12, 1827. He was buried in an unmarked grave in Bunhill Fields.

Long after his death Blake was appreciated only by fellow artists and poets. Dante Gabriel Rossetti, himself a painter and a poet, bought a sketchbook in which Blake had also written drafts and versions of poems (among them "The Everlasting Gospel") from an attendant at the British Museum in 1847 for ten shillings. He lent it to Blake's first biographer, Alexander Gilchrist, in 1861 and to Swinburne for his long *Critical Essay* on Blake in 1868. William Butler Yeats helped to prepare and annotate a major edition of Blake's works in 1893. In 1920 T.S. Eliot included in *The Sacred Wood* an essay on Blake that made his name familiar to a new reading public after World War I. The centenary of his death in 1927 was marked by a number of articles and books, and thus became the turning point at which William Blake's modern reputation was established.

MAJOR WORKS

ILLUMINATED BOOKS: Relief etching on copperplates afterward tinted with watercolours—*There Is No Natural Religion*, 2 series, 19 small plates (unfinished); *All Religions Are One*, 10 small plates (*c.* 1788), prose aphorisms; *Songs of Innocence*, 31 plates (1789), lyrical poems; *The Book of Thel*, 8 plates (1789), allegorical narrative poem; *The Marriage of Heaven and Hell*, 27 plates (1793), prose manifestos, including "The Proverbs of Hell," paradoxical aphorisms, and "A Song of Liberty"; *Visions of the Daughters of Albion*, 11 plates (1793), and *America: A Prophecy*, 18 plates (1793), symbolical political poems: *Europe: A Prophecy*, 18 plates (1794), historical and political parable; *Songs of Innocence and of Experience, shewing the Two Contrary States of the Human Soul*, 54 plates (1794–*c.* 1801); *The Book of Urizen*, 28 plates (1794), in early copies *The First Book of Urizen*, first book of Blake's cosmic epic, or "Bible of Hell"; *The Book of Ahania*, 6 plates (1795), second book of the cosmic epic; *The Book of Los*, 5 plates (1795), retelling the myth of Urizen from Los's viewpoint; *The Song of Los*, 8 plates (1795), continues the myth of Urizen; *Milton: A Poem in 2 Books*, 50 plates (1804–08), epic poem, including the lyric popularly but erroneously known as "Jerusalem"; *Jerusalem*, 100 plates (*c.* 1804–*c.* 1820), epic poem.

OTHER WRITINGS (POETRY): *Poetical Sketches by W. B.* (1783); *Tiriel* (written *c.* 1789, first printed 1874), first of the so-called prophetic books; *Vala or the Four Zoas*, (1795–*c.*1804, printed 1925 unfinished), includes 9 full-page drawings and many marginal illustrations; *The Everlasting Gospel* (*c.* 1818, printed 1925 unfinished). A notebook used by Blake as a commonplace book (*c.* 1793–1810), and later called the Rossetti Manuscript (first printed in full, 1957), contains lyrical poems, epigrams, and fragments; a manuscript of *c.* 1803 (later called the Pickering Manuscript) contains 10 poems printed 1905, among them "The Smile," "The Golden Net," "The Mental Traveller," The Land of Dreams," "The Crystal Cabinet," and "Auguries of Innocence." (PROSE): *A Descriptive Catalogue* (1809), for an exhibition of Blake's watercolours and drawings—art criticism and aesthetic theory; *Public Address*, a critical essay (written *c.* 1810, printed 1925); *A Vision of the Last Judgement* (written *c.* 1810, printed 1925), essay on a lost tempera print given its present title by Dante Gabriel Rossetti; aesthetic theory and criticism.

COLOUR PRINTS OR MONOTYPES: "The Ancient of Days" (1794; Whitworth Art Gallery, University of Manchester, England); a series of 12 large prints of "Historical and Poetical Subjects" (1795; Tate Gallery, London), including "Elohim Creating Adam" (called by Blake "God Creating Adam"), "God Calling Adam," "The Lazar House," "Nebuchadnezzar," "Hecate," "Pity," "Newton," and "Good and Evil Angels Struggling for Possession of a Child"; "Glad Day" (after 1800; British Museum), from a drawing of 1780 (Victoria and Albert Museum, London).

ILLUSTRATIONS (BIBLICAL): Two series for the whole Bible, one in tempera or fresco (1799–1800; 37 paintings); the other in watercolour (*c.* 1800–05; more than 80 paintings—some lost). The tempera series includes "Bathsheba at the Bath" (Tate Gallery), "The Nativity" (Sydney Morse Collection), "The Procession from Calvary" (Tate Gallery), and "Christ the Mediator" (George Goyder Collection); the watercolour series includes "Jacob's Ladder" (British Museum), "David and Goliath" (Museum of Fine Arts, Boston), "The Stoning of Achan" (Tate Gallery), "The Soldiers Casting Lots for Christ's Raiment" (Fitzwilliam Museum, Cambridge, Cambridgeshire), "Christ in the Sepulchre" (Sydney Morse Collection), and "The Red Dragon and the Woman Clothed with the Sun" (Brooklyn Museum, Brooklyn, N.Y.). *The Book of Job*, 22 watercolour paintings (*c.* 1818–21, engraved 1823–25). (FOR MILTON'S POEMS): Two series of watercolour illustrations: for *Paradise Lost* (1808; Museum of Fine Arts, Boston), including "The Downfall of the Rebel Angels," "God Creating Eve," "Adam and Eve Asleep," "The Temptation of Eve," and "The Prophecy of the Crucifixion"; and for "L'Allegro" and "Il Penseroso" (*c.* 1818; Pierpont Morgan Library, New York). (FOR DANTE'S DIVINE COMEDY): 102 watercolours (1825–27), including "Inscription over Hell-Gate" (Tate Gallery), "Antaeus" (National Gallery, Melbourne), "The Simoniac Pope" (Tate Gallery), "The Circle of the Lustful" (City Museum and Art Gallery, Birmingham, England), "Lucia Carrying Dante in his Sleep" (Fogg Art Museum, Harvard University), "Beatrice Addressing Dante from the Car" (Tate Gallery), and "Dante and Virgil with SS. Peter, James and John" (British Museum). (OTHER ILLUSTRATIONS): Designs for engravings for a translation of G.A. Bürger's *Leonora* (1796); 12 designs for engravings for Robert Blair's poem *The Grave* (1805); watercolour (fresco) of *The Canterbury Pilgrims* (1808; Pollok House Collection, Glasgow; engraved 1810); wood engravings for R.J. Thornton's *Pastorals of Virgil*, the First Eclogue (1820–21).

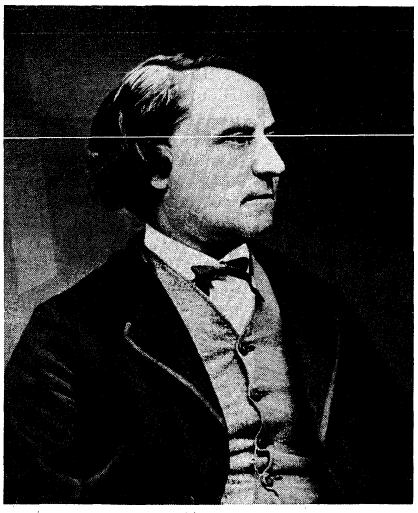
Blanc, Louis

Louis Blanc was a French utopian socialist of the mid-19th century whose writings had a powerful influence on radical thought. He proposed that the government provide jobs for workers and the social ideal: "from each according to his ability, to each according to his needs."

H. Roger-Viollet



Blanc.

Journalism. Jean-Joseph-Charles-Louis Blanc was born on October 29, 1811, in Madrid, where his father was inspector general of finances in the Spanish regime of Joseph Bonaparte. When that regime collapsed in 1813, the Blancs returned to France. Louis studied at schools in Rodez and Paris. He became a tutor in the family of a wealthy industrialist in northern France who employed more than 600 workers; there he came in contact with liberal political circles and found employment on a Republican newspaper. In 1837 he became a member of a committee for electoral reform directed by leaders of the opposition to King Louis-Philippe. In 1839, at the age of 26, he founded the *Revue du Progrès.* It was in this newspaper that his most important work, "L'Organisation du travail" ("The Organization of Labour"), appeared serially in 1839. The principles laid down in that essay, which first brought him to public attention, formed the basis of his subsequent career.

Blanc's theory of socialism

Blanc believed that the competitive capitalism then developing in France tended to stunt the human personality, pitting one man against another and driving the weaker to the wall. The first step toward a better society would be to guarantee work for everyone. This could be done by establishing "social workshops" financed by the state. These workshops, controlled by the workers themselves, would gradually take over most production until finally a socialist society would come into being. Blanc did not believe in human equality. But he did not agree with the followers of the socialist Saint-Simon, who held that workers should be paid according to their performance; he argued that justice would be satisfied only "when each one in accordance with the law written in some shape in his organization by God Himself, produces according to his faculties and consumes according to his wants."

Politics. In 1843 Blanc joined the committee of *La Réforme,* the journal of the extreme left-wing Republicans. In 1847 he became prominent in the so-called banquets campaign for electoral reform, holding large audiences with his oratory. The culminating banquet, arranged to take place in Paris on February 22, 1848, was banned, but a riot on the following day led to an insurrection and the fall of the monarchy. Blanc became a member of the provisional government of the Second Republic. On February 25, 1848, following a motion by Blanc, the government undertook "to guarantee the livelihood of the workers by work" and "to guarantee work for every citizen." But the government was divided. For the majority the revolution represented a political change in which a monarchy with a restricted franchise was to be replaced by a free democratic republic based upon universal suffrage; for the minority, including Blanc, it also heralded a social and economic transformation.

Although Blanc and his friends were a minority in the government, they had many supporters in the streets; and their colleagues made important concessions to their ideas by reducing working hours, proclaiming the right to work, appointing Blanc chairman of a permanent commission to investigate labour problems, and establishing national workshops to relieve the more acute unemployment. The national workshops were a travesty of those envisaged by Blanc; they were established by his opponents to discredit him and become little more than a gigantic system of outdoor relief. Meanwhile, unemployment grew from 6,100 on March 7 to 118,310 on June 15. The celebrated Luxembourg Commission, of which Blanc had been made chairman, became an arbiter in trade disputes and a centre of socialist propaganda; it was unable, however, to win acceptance of its recommendations for the reorganization of labour and industry.

Exile. Blanc was forced to flee to England after the workers unsuccessfully revolted in June 1848. He did not return to France until the fall of the Second Empire of Louis-Napoleon in 1870. He supported himself during his exile by teaching and lecturing; he wrote a history of the Revolution of 1848 and a history of the French Revolution as well and also a series of books on British political and social conditions; and he carried on polemics with other political exiles.

When he returned to France after 22 years, he was still a famous man. He was elected a deputy to the National Assembly, receiving more votes than Victor Hugo. He refused to join in the revolutionary commune that seized control of Paris in the spring of 1871, but after the commune was crushed he sought to obtain a political amnesty for the communards. He remained a man of the left, although without much following. One of his last speeches in 1881 was in support of a proposal to reduce the length of the working day. He died at Cannes on December 6, 1882.

BIBLIOGRAPHY. Louis Blanc's principal works are *Histoire de dix ans, 1830–1840,* 5 vol. (1841–44; Eng. trans., *The History of Ten Years, 1830–1840,* 2 vol., 1844–45, reprinted 1969), an attack on the government and person of King Louis-Philippe; and *Histoire de la Révolution française,* 12 vol. (1847–62), a political, economic, and social interpretation. *Historical Revelations: Inscribed to Lord Normanby* (1858, reprinted 1971), was written in English during his exile and concerns the revolution of 1848. *Lettres sur l'Angleterre,* 2 vol. (1865; Eng. trans., *Letters on England,* 2 vol., 1866), contains the author's observations on economic, poli-

tical, and social life in England. After Blanc's death, some friends collected in *Discours politiques, 1847 à 1881* (1882), the most important speeches of his long life. The earliest biography, written just after his death, was LOUIS FIAUX, *Louis Blanc* (1883), in French. The most important general study is EDOUARD RENARD, *Louis Blanc, sa vie, son oeuvre, une jeunesse pauvre* (1928). PAUL KELLER, *Louis Blanc und die Revolution von 1848* (1926); and P. VERLINDE, *L'Oeuvre économique de Louis Blanc* (1940), are narrower in scope. JEAN VIDALENC, *Louis Blanc, 1811–1822* (1948), is a short biography (in French), using the older studies and written for the centenary of the revolution of 1848.

(J.Vi.)

Blanche of Castile

The wife of Louis VIII, the mother of Louis IX (St. Louis), and twice regent of France, Blanche of Castile contributed much to the unification of French territories.

She was born in 1188 in Palencia, Spain, the daughter of Alfonso VIII of Castile and Eleanor, the daughter of Henry II of England. Her grandmother Eleanor of Aquitaine, Queen of England, travelled to Spain to take the 11-year-old Blanche to France, where a marriage treaty was concluded with Louis, the young son of King Philip II Augustus. This politically motivated marriage had been arranged by Blanche's uncle, King John of England, and was celebrated in 1200 at Portsmouth, Hampshire. It represented only a brief truce in the struggle between England and France for control over certain French territories.

Marriage to Louis

Blanche, who became French through marriage, was gradually to become French in spirit as well. Although she did not cease to be concerned for her family, among them her uncle John and his allies, her brother-in-law Ferrand of Portugal and her cousin Otto of Brunswick (later Holy Roman Emperor Otto IV), she rejoiced at the French victory over Otto and the English at Bouvines in 1214, marking the first stage of French unification, a goal for which she was constantly to strive. In the same year, she gave birth to Louis, the future king of France.

Upon John of England's death, Blanche boldly tried to seize the English throne: in 1216 Louis of France invaded England on her behalf. The English stood firm against him, and John's nine-year-old son was finally crowned Henry III.

A devout Catholic, Blanche soon became involved in what she sincerely believed to be a holy war against the heretical Cathari, a sect founded on the belief that good and evil had two separate creators, which was flourishing throughout southern France. Her husband, who became Louis VIII in 1223, took part in a crusade against the Cathari but suffered a fatal attack of dysentery upon returning to the north of France in 1226. In accordance with her husband's will, Blanche became both guardian of the 12-year-old Louis and regent of France. She zealously pressed to have Louis crowned immediately, and the coronation took place at Reims three weeks after Louis VIII's death.

Regent of France

Her most pressing problem was to deal with a rebellion of the great barons, organized by Philip Hurepel, the illegitimate son of King Philip II Augustus, and supported by King Henry III of England. In the face of such adversity, Blanche showed herself by turns a delicate diplomat, a clever negotiator, and a strong leader. Dressed in white, on a white palfrey draped in the same colour, she rode into battle at the head of her troops. After an attempted abduction of the young King, Blanche did not hesitate to replace rebel noble associates with commoners if she thought it necessary. She also created the local militias that served the kingdom so well.

Blanche was gradually able to subdue the revolt, established a new truce with England, and, in 1229, pacified the south of France by signing the Treaty of Paris with Raymond VII, Count of Toulouse. France then entered an era of peace and domestic stability, which saw the construction of many cathedrals throughout the country.

On only one occasion did Blanche fail to exhibit diplomatic conduct. In 1229 a dispute between an innkeeper and some students took place in the Latin Quarter in Paris. The police were summoned, and the students were beaten and thrown into the Seine; such intervention in the Latin Quarter, however, was contrary to the prerogatives granted to the university, and the faculty and students threatened to strike if the university's privileges were not respected. Badly advised, Blanche held firm, but the university closed its doors, and the faculty and students left Paris for the provinces and abroad. It was to take four years and the intervention of the pope before the university would return to Paris with new prerogatives, this time granted by Blanche herself.

Although Louis IX came of age on April 25, 1236, Blanche remained at his side as his most loyal and steadfast supporter. Discreet and efficient in public affairs, she lacked tact with regard to her son's private life. Although Blanche herself had chosen Margaret of Provence to be Louis's wife, she treated Margaret with great severity. In 1244, after Louis recovered from a serious illness, he and his wife, much against Blanche's wishes, made a vow to go on a crusade against the Muslims. They embarked in 1248 and once again the kingdom was entrusted to Blanche.

Informed of Louis's defeat at al-Manṣūrah, Egypt, and subsequent imprisonment, Blanche herself went to seek his ransom and that of the French Army. She petitioned her parents, her allies, and the pope himself for funds and supplies, but interest in the crusade had dwindled.

Last years

Although weakened by a heart ailment, Blanche did not neglect her obligations as a regent. Continuing to preside over council meetings, she signed laws and watched over the poor of Paris. When some of the poor were mistreated by the cathedral chapter, she herself rode, as formerly, to open the gates to their prison. On her way to the Abbey of the Lys, one of her favourite retreats, Blanche suffered an attack of the heart ailment that was to take her life. She was returned to the palace of the Louvre, dressed in a nun's habit, and laid on a bed of hay. There, after begging forgiveness of all and having received the last sacraments, she died on November 12, 1252. She was buried at Maubuisson Abbey and her heart taken to the Abbey of the Lys.

Louis IX was in Jaffa when he learned of his mother's death. The news distressed him greatly, for he was aware that he had lost not only an incomparable parent but also the strongest supporter of his kingship.

BIBLIOGRAPHY. JEAN DE JOINVILLE, *Histoire de Saint Louis* (Natalis de Wailly edition, 1874); and GUILLAUME DE NANGIS, *Chronique latine . . .*, 2 vol. (Géraud edition, 1843), two works contemporary of Blanche's reign, supply interesting opinions on her actions. The language used is sometimes archaic and difficult to comprehend. T. NISARD, *Histoire de la reine Blanche, mère de Saint Louis* (1851); and J.S. DOINEL, *Histoire de Blanche de Castille* (1870), are dated, but still remain quite interesting. ELIE BERGER, *Histoire de Blanche de Castile, reine de France* (1895), is still the most complete study; YETTE JEANDET, *Blanche de Castille, reine de l'unité française* (1965), the most recent biography. See also MARGARET WALLE LABARGE, *Life of Louis IX of France* (1968).

(Y. J.)

Blanqui, Auguste

The personification of revolutionary Communism in France, more remarkable for his revolutionary strategy than for originality of doctrine, Louis-Auguste Blanqui, the French Socialist, quickly became a legendary figure, a sort of martyr to the revolutionary cause. He spent, in fact, more than 33 of his 75 years incarcerated in nearly 30 different prisons. His disciples, the Blanquists, played an important role in the history of the workers' movement even after his death.

In relation to other Socialists, Blanqui cannot be considered either an economist or a philosopher. He was essentially a theoretician of revolution and a practitioner of insurrection. He thought that the taking of power could be the act only of a small minority. Blanqui's main idea was that there could be no Socialist transformation of society without a temporary dictatorship that would first disarm the bourgeoisie, confiscate the wealth of the church and of the large property holders, and bring the great industrial and commercial enterprises under state

control. The next stage would be to establish industrial- and agricultural-production associations and develop education so as to render the people capable of organizing the country's economy to their own benefit.

Blanqui was born on February 1, 1805, in the little town of Puget-Théniers in the French Maritime Alps, where his father, Dominique Blanqui, was acting as subprefect. In 1818 he joined his elder brother, Adolphe, the future liberal economist, in Paris and studied both law and medicine until 1824. From 1827 he began taking part in the student demonstrations against the restored Bourbon monarchy, but he was disappointed by the Revolution of July 1830, which established the bourgeois monarchy of Louis-Philippe. Blanqui then began his true political career. A member of the Société des Amis du Peuple (Society of the Friends of the People), he was pursued and twice imprisoned (1831 and 1836). In these years he was much influenced by the doctrines of Filippo Buonarroti, who in 1796 had been involved in the abortive rising against the Directory government by François Noël (Gracchus) Babeuf's Société des Égaux (Society of Equals). He studied the popular insurrections of the French Revolutionary period and became increasingly convinced of the inevitability of class struggle, in which he regarded the rich as the aggressors. Blanqui was thereafter convinced that in order to establish a popular government it was absolutely necessary first to build up heavily disciplined groups of conspirators. His taste for secret societies stemmed from this conviction; he organized first the Société des Familles (Society of Families) and then the Société des Saisons (Society of the Seasons). The latter society's disastrous attempt at insurrection on May 12, 1839, was the classic prototype of the Blanquist surprise attack. Five hundred armed revolutionaries took the Hôtel de Ville (City Hall) of Paris, but, isolated from the rest of the population, they were easily defeated after two days of fighting. Blanqui escaped but was later arrested. His death sentence was commuted to life imprisonment, and he was sent to the island of Mont-Saint-Michel off the Normandy coast. After four years of solitary confinement, he was believed to be dying and was granted a formal pardon; but he was not able to leave the prison hospital at Tours until just before the Revolution of 1848.

The Blanquist insurrection of 1839

This revolution was a decisive experience for Blanqui. Returning to Paris, he founded the Société Républicaine Centrale (Central Republican Society) and urged the provisional government that had formed after Louis-Philippe's fall to pursue more Socialistic policies. Although he took an active part in the organization of workers' demonstrations, he was convinced that the people were not ready for the universal suffrage that the provisional government proposed, and he demanded the postponement of the impending elections. The election results confirmed Blanqui's apprehensions: the conservatives constituted the majority of the Constituent Assembly. Blanqui was sentenced to ten years' imprisonment for having participated, on May 15, in a popular demonstration of which he had in fact disapproved. Released in 1859, he again organized secret societies and was rearrested in 1861, remaining in prison until he escaped to Belgium in 1865. Great changes occurred in France while the man they had begun to call *l'enfermé* ("the locked-up one") was able to take no part in events. The Parisian workers were defeated on the barricades of June 1848. Louis-Napoleon executed his coup d'etat of December 2, 1851, and became, as Napoleon III, hereditary emperor of the French the following year. An unprecedented industrial growth created conditions suited for the development of a modern workers' movement. Consideration of these changes led Blanqui to study and write about political economy and Socialism; most of these works were published after his death under the title *Critique sociale*. After 1865 Blanqui often went clandestinely from Brussels to Paris, where the first Blanquist groups were being organized among students and, later, among workers. He also wrote *Instruction pour une prise d'armes* (1867–68; "Instruction for a Taking Up of Arms"), a kind of manual for urban guerrilla warfare. When the first defeats of the French Army in the Franco-German War of 1870 began to threaten Napoleon III's position, Blanqui returned to Paris. On September 4, 1870, two days after Napoleon III's surrender to the Germans, there was a bloodless revolution in Paris, as a result of which the Third Republic was proclaimed and a provisional government was formed. In this action the Blanquist groups took some part. With the German armies advancing on Paris, Blanqui showed himself a patriot as well as a revolutionary, founding both a club and a newspaper of the same extremely Jacobin name: *La Patrie en danger* ("Our Country in Danger"). He invited Parisians to unite against Germany and support the government, and he showed considerable military skill in indicating what measures should be taken for the defense of Paris. He very soon became convinced that the provisional government, fearing the populace, was failing to take adequate defense measures. Consequently, the Blanquists twice unsuccessfully attempted to overthrow the government (October 31, 1870; January 22, 1871). After the capitulation of Paris and the elections of February 8, 1871, which were won by conservatives, Blanqui retired to the country, where he was arrested on March 17 for his part in the revolt of October 31. The day after Blanqui's arrest the insurrection called the Paris Commune occurred, and the Blanquists played a very important role in it. Blanqui himself was elected president of the Commune, but the government of Adolphe Thiers refused to release him from prison. Eventually the Commune capitulated, and, in the struggle for amnesty for its adherents, Blanqui became a kind of symbol. Still in prison, he was elected deputy for Bordeaux in April 1879. His election was invalidated, but he was pardoned and set free. For two years, in spite of his advanced age, he continued as a journalist and an ardent campaign speaker in favour of Socialism. On the eve of a meeting, he was struck by apoplexy and died a few days later, on January 1, 1881. Shortly afterward, a rapproachement between the Marxists and the Blanquists resulted in the founding in 1881 of the Comité Révolutionnaire Central (Central Revolutionary Committee) and in 1898 of the Parti Socialiste Révolutionnaire (Revolutionary Socialist Party).

Revolution of September 4, 1870

Bleeding and Blood Clotting

The evolution of the high-pressure blood circulation of the vertebrate animals has brought with it the risk of serious bleeding after even slight injury. Mechanisms to prevent bleeding—hemostatic mechanisms—are therefore essential to survival; and they have, in fact, evolved in parallel with the circulatory systems. In mammals, in which greater blood pressures and greater physical activity have increased the hazard, hemostatic processes are more complex and efficient than those of their amphibian ancestors. It is the mammalian, and particularly the human, system that is described in this article.

Components of hemostatic mechanism

The hemostatic mechanism has three main components, blood clotting, aggregation (collecting together) of platelets, and contraction of blood vessels, all depending on integrated and interdependent reactions. In man, defects in any of these may occur, resulting in persistent bleeding from slight injuries, or there may be overactivity, causing formation of blood clots (thrombosis) in major vessels. An understanding of hemostasis is thus of practical importance; but, though much is known, many questions are still unanswered.

When a vessel is breached, blood escapes for as long as the breach remains open and the pressure within the vessel exceeds that outside. Flow can, therefore, be stopped by closing the breach or by equalizing the pressure. The breach can be closed by contraction of the vessel wall or by the formation of a solid plug. Pressure can be equalized by a rise in external pressure due to blood trapped in the tissues (the mass of blood is called a hematoma); or by a fall in the intravascular pressure—the pressure within the vessel—caused by constriction of a supply vessel; or it may be equalized by a diversion of flow through dilated bypass vessels; or by a fall in general blood pressure, as in fainting or shock. The timing and relative importance of these events vary with the scale of the injury. Bleeding from the smallest vessels can be stopped by platelet plugs (see below); from larger ones, the cooperation of blood clotting is needed; in still larger vessels, contraction becomes of paramount importance, and the severe drop in pressure associated with shock is the last line of defense.

HEMOSTASIS

Visible events in hemostasis. Hemostasis can be studied in such vascular membranes as the hamster cheek pouch. These can be viewed with the microscope, filmed by high-speed photography, and examined by means of electron microscopy. The vessels seen are arterioles, the smallest arteries, and venules, the smallest veins, connected by capillaries, the smallest of all blood vessels. The flow through these of red and white cells and platelets is clearly visible, and these cells normally have no tendency to adhere to each other or to the lining (endothelium) of the vessels. An injury too slight to rupture a vessel may still bring about a hemostatic reaction. After the pressure of a blunt point, there may be partial vascular contraction and platelet adhesion in successive layers at the point of injury. A mass is formed that grows until it almost blocks the vessel; then it usually breaks down and re-forms, the cycle being repeated perhaps many times. Upon examination, these masses are found to consist of apparently unchanged platelets, without fibrin or other cells, and even these slight injuries are found to cause shedding of some endothelial cells and exposure of deeper tissues to which the platelets adhere.

Clot formation

If the vessel is cut so that blood escapes, the reaction is different. In muscular vessels there may be immediate contraction, but usually this is insufficient to prevent bleeding. Then a mass forms in the breach and finally stops the flow. This mass is formed of platelets in which there is a loss of granules and a closer compaction; and, between the platelets, there are bundles of fibrin fibres. These changes occur mainly near damaged collagen, the fibrous protein found in connective tissue. A day later, more fibrin can be seen, and the platelets have degenerated into an amorphous mass. Then the fibrin itself begins to be dissolved by a specific enzyme, plasmin, and is replaced by a permanent framework of new collagen and blood vessels, and healing is complete.

Platelets and their aggregation. Mammalian platelets are nonnucleated cells, roughly a third the size of red blood cells, produced by the bone marrow cells called megakaryocytes; there are about 250,000 platelets per cubic millimetre of blood. They carry enzymes and adenosine triphosphate (see below), and the vasoconstrictive substances epinephrine and 5-hydroxytryptamine. They also contain platelet factor 3, a substance active in blood clotting, and a contractile protein (thrombosthenin) that allows platelets to extend and retract long footlike projections called pseudopodia.

Platelets adhere strongly to surfaces other than that of the lining of blood vessels, such as collagen, glass, metals, and fabrics. Adherent platelets themselves become adhesive for other platelets, so that, in a flow system, a mass is built up. The propagation of this adhesiveness from one layer to the next is probably due to a mechanism causing the breakdown of internal adenosine triphosphate (ATP) to adenosine diphosphate (ADP) and the release of the latter at the platelet surface. ADP causes platelet adhesion, possibly by bonding with calcium and a plasma protein, and it also promotes the release of more ADP from the platelet interior; thus, a chain reaction captures more platelets. The process is limited by two factors. The adhesion is mechanically unable to withstand the shear forces imposed by blood flow on masses of more than a certain size, and ADP is also broken down within a few minutes by plasma enzymes. This type of aggregation is temporary and reversible.

Action of thrombin

With vascular rupture and contact of the blood with tissues outside the vessel, a new factor is introduced. This is thrombin, an enzyme produced by activation of the clotting system. Thrombin causes more permanent platelet aggregation than does ADP alone. Platelets exposed to thrombin lose their granules and release not only ADP but also platelet factor 3, which accelerates the production of more thrombin. Thrombin also attacks the precursor of fibrin—fibrinogen—trapped between platelets, to form fibrin, which consolidates the mass in a manner analogous to that of steel rods in concrete.

Blood coagulation. It is a familiar experience that shed blood soon clots. This dramatic physical change has attracted much biological interest and entire schools of investigators. Because it can be studied in the test tube, and blood can be broken up into active components that can be recombined in endless permutations, there is an enormous amount of experimental data and speculation, filling scores of books and thousands of scientific papers. Only an outline of current theory can be presented here.

Fibrin and the thrombin–fibrinogen reaction. The clotting of blood is due to the sudden appearance of fibres that entangle the blood cells. Clumps of platelets adhere to the intersections with pseudopodia extending along the fibres, and it is a normal platelet function to cause retraction of the fibrin by an active shortening of the pseudopodia. During this clot retraction, the fluid in the clot (serum) is squeezed out, leaving a solid mass of cells and fibrin. Fibrin is a tough, polymerized protein—that is, it is a complex protein made up of repeating units—and electron microscopy reveals its molecular orientation. It is formed from fibrinogen, a soluble protein of high molecular weight that is produced by the liver. Fibrinogen is converted to fibrin by thrombin, an esterase that splits the fibrinogen molecule to form one major fragment (fibrin monomer—the substance in its simple, unpolymerized form) and several smaller fragments. The monomer molecules then link together (polymerize) to form long fibres. Later, additional bonding between the units of the polymer is promoted by an enzyme known as fibrin-stabilizing factor, or factor XIII.

Thrombin does not exist in the normal circulation but is generated from a precursor, prothrombin. This is a rather stable protein formed in the liver by a process requiring vitamin K, any deficiency of this vitamin depressing production of prothrombin and of certain other clotting factors. Prothrombin is adsorbed by such inorganic gels as aluminum hydroxide, $Al(OH)_3$, or bari-

um sulfate, $BaSO_4$, a property much used in separation processes.

Activation of prothrombin. There are two physiologically relevant ways in which prothrombin can be activated. One is contact of the blood with foreign surfaces; the other is the addition of damaged tissue cells or their extracts. Contact produces clotting in four or five minutes; tissue extracts, in 12 or 15 seconds. To most workers during the first half of the twentieth century, the tissue reaction seemed the more important. A theory developed in the early 1900s postulated that the tissues release a factor ("thrombokinase" or "thromboplastin") at an injury site that activates prothrombin. Calcium is also required; and citrates and oxalates that remove ionized calcium suppress clotting until more calcium is added and are much used as anticoagulants. This theory of clotting, involving four factors and two products, is illustrated in Figure 1.

The four-factor theory was generally accepted for nearly 50 years. Then the wide use of the "prothrombin-time test" showed that other factors must be involved. In this test, tissue extract (now called thromboplastin) is added with calcium to citrated plasma (plasma—blood minus its cells—treated with citrate to prevent coagulation) and the clotting time is recorded. By the four-factor theory, because thromboplastin and calcium are in excess, and fibrinogen is seldom inadequate, a lengthening of the clotting time represents a deficiency of prothrombin. This test was useful in detecting the vitamin K deficiency of liver disease (because vitamin K is required in the manufacture of prothrombin by the liver) and in certain other situations involving vitamin K. But in some cases a lengthening of the "prothrombin" time was found not to be due to prothrombin deficiency. In one case studied, the investigator found that prothrombin-free normal plasma added to the patient's blood corrected a "prothrombin" defect, and he was able to isolate from this plasma a normal factor required for prothrombin activation that was deficient in the patient. He called this "factor V," the fifth clotting factor. By similar methods, two other factors were later discovered. As there was considerable terminological confusion at this time, an international committee ruled that each clotting factor should be identified by a Roman numeral. For chronological reasons, the factors newly recognized as concerned in the activation of prothrombin by thromboplastin became factors V, VII, and X.

Identification of clotting factors

These discoveries did not at first alter the basis of the four-factor theory; they only added accelerators to the first-stage reaction. The nature of thromboplastin itself remains obscure. It is now thought to be a mixture of substances that are active as catalysts of certain clotting reactions and another substance, known as "tissue factor," that is the true initiator of clotting by this pathway.

Contact-activated system. Preoccupation with the activity of tissue extracts distracted attention from the surface-contact reaction. Activating surfaces include glass, metals, fabrics, plastics, skin, muscle, connective tissue, and certain fatty acids. Inactive surfaces include some oils, waxes, resins, silicones, a few plastics, and endothelium, the most inert surface of all. The physicochemical properties that determine activity are not known, and neither water wettability nor surface electric charge seems to be significant. The problem is important; modern surgery requires a perfectly inactive material to make substitutes—prostheses—for heart valves and sections of blood vessel and to allow filtration of waste products from the blood outside the body.

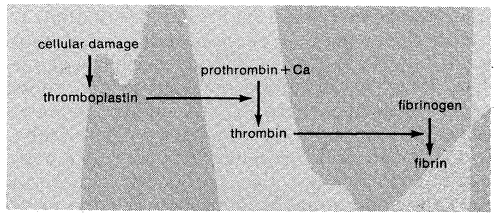

Figure 1: The classical (four-factor) theory of blood clotting.

The physiological importance of this contact system was revealed by a study of hemophilia, in which the blood clots normally with thromboplastin but abnormally in glass. The tissue-activated system in hemophilia is, therefore, apparently normal, and yet serious bleeding occurs from trivial injuries. It had long been known that a small proportion of normal plasma added to hemophilic blood corrects the clotting defect in glass, and that normal blood transfusion improves hemostasis in the patient. Investigation of this effect showed that after contact and a delay phase of three or four minutes, normal blood generates a prothrombin activator as powerful as thromboplastin. A normal factor required for this reaction was identified, and there was shown to be a deficiency of this factor in hemophilia. The element became known as factor VIII. Further investigation revealed three other necessary factors, designated IX, XI, and XII. A substance supplied by the platelets was also required. This substance is identified as phospholipid in Figure 2.

Deficiency of factor VIII in hemophilia

From R. MacFarlane, *International Review of Experimental Pathology* (1968); Academic Press

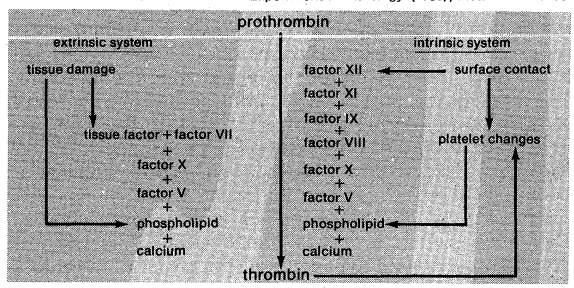

Figure 2: The clotting factors concerned in the activation of prothrombin (see text).

Thus, the factors required for prothrombin activation by the tissue-activated (extrinsic) and the contact-activated (intrinsic) systems are as shown in Figure 3. The question immediately posed is the function of this multiplicity of factors. Simultaneous interaction is improbable, and most workers agree on sequential reactions between pairs of factors. It was shown by one investigator that factor XII is the factor first activated by surface contact, becoming an enzyme that activates factor XI. Other work established the probable reaction sequence XII, XI, IX, VIII, and X, with subsequent reactions common to both extrinsic and intrinsic systems.

From R. MacFarlane, *International Review of Experimental Pathology* (1968); Academic Press

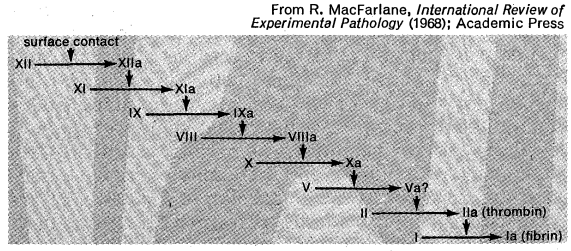

Figure 3: An enzyme cascade postulated as the basis of the intrinsic clotting system. Factor V may accelerate the action of factor Xa instead of forming an activator (Va) itself.

As regards the reactions between these factors, there is evidence that, in some factors, the activating substance is an enzyme that splits the factor X molecule to form another enzyme (Xa), which activates prothrombin (factor II) in the presence of factor V, calcium, and phospholipid. Factor X appears to be activated in this way also by both the tissue- and the contact-activated clotting systems. Thrombin was already known to be an enzyme; activated factors XII and XI have enzyme activity, and there is indirect evidence of enzyme action in other instances. On this admittedly incomplete basis, it was proposed in 1964 that the clotting mechanism might be a cascade of proenzyme enzyme transformations (Figure 3), the product of each stage activating the next. Later experiments have modified this generalization. Factor V

does not appear to be in the sequence but to act as a co-factor for the activation of prothrombin by Xa.

The extrinsic (tissue) system also activates factor X and provides an alternative pathway of more importance in nonmammalian vertebrates in which the intrinsic system with its probably greater amplification has not been developed.

From R. MacFarlane, *International Review of Experimental Pathology* (1968); Academic Press

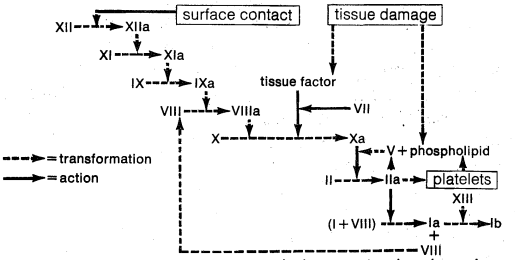

Figure 4: A scheme for the coagulation mechanism based on the cascade principle. The extrinsic and intrinsic pathways both act on factor X. Factors VII and V are shown as accelerators.

A current scheme of coagulation is shown in Figure 4. This illustrates "positive feedback" effects of thrombin, which increases the reactivity of factors VIII and V and releases platelet factor 3.

The sequential theory outlined is not accepted by all authorities. One authority considers that factors VII, IX, and X are not separate plasma entities but derivatives of the prothrombin complex formed, together with thrombin, during the process of activation. But these derivatives themselves catalyze prothrombin activation, and it is recognized that one of them ("autoprothrombin III," or factor X) is itself activated to form an enzyme ("autoprothrombin C," or Xa) that activates "prethrombin" to thrombin (Figure 5). This theory explains the otherwise

From W. Seegers, *Annual Review of Physiology* (1969); Annual Reviews, Inc. Vol. 31, p. 280

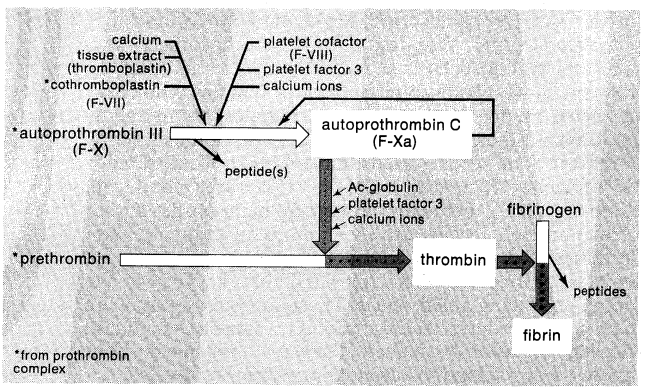

Figure 5: Basic chemical reactions: formation of autoprothrombin C, thrombin, and fibrin.

strange similarity in the properties and origin of factors VII, IX, X, and prothrombin; but it does not assign a precise function for several factors, a deficiency of which causes known clotting defects.

Inhibition of clotting. Systems involving enzyme self-activation—autocatalysis—could, if not checked, become totally activated by the most trivial stimulus. In the case of blood clotting, this could mean intravascular coagulation and immediate death; but there are inhibitory systems that destroy every activated clotting factor within a few seconds in the bloodstream so that only at sites of local production does clotting normally take place. Six different factors are described as inhibiting thrombin alone, the most important being antithrombin III, a plasma protein that combines with thrombin to form an inert complex. This action is greatly enhanced by heparin, a substance formed by certain connective tissue cells called mast cells. Activated factor X may be inactivated by the same mechanism. Thrombin itself inhibits its own production; when its concentration is sufficiently high, it destroys factor VIII.

Effect of plasmin

Another anticoagulant effect is the fibrinolytic (fibrin-splitting) action of the enzyme plasmin. Its physiological function is the removal of old fibrin at injury sites and any that may be deposited in normal vessels. The fibrinolytic and clotting mechanisms have striking similarities. Plasmin is derived from plasminogen, an inert protein precursor that can be activated by tissue factors (called lysokinases) or by contact through factor XII. An activator, urokinase, is also released by blood-vessel lining and is present in normal urine. Certain bacteria produce plasminogen activators, the streptokinase of hemolytic streptococci being the most potent. Plasmin is rapidly destroyed in the bloodstream and normally acts only when taken up by fibrin.

Vascular function. The most obvious hemostatic vascular reaction is constriction after injury. This is of great importance in large arteries, in which clotting and platelet adhesion would be unable to arrest bleeding. The survival, despite delayed surgical aid, of some persons who have lost limbs in accidents is due to constriction of their main arteries. The stimulus for contraction is not known precisely. In the capillaries, contraction has been considered to be impossible because of the absence of muscle cells from their walls, but recent studies with the electron microscope show possibly contractile elements in endothelial cells, and capillary function may have to be reassessed.

Other vascular reactions to injury have only a subsidiary hemostatic effect. Dilation of undamaged vessels in the vicinity of an injury provides an alternative pathway for the bloodstream. It is probably caused by the release of vasodilator substances, such as histamines, from damaged tissues. Another reaction is an increase in vascular permeability that allows plasma to escape through the vessel wall. This raises the tissue fluid pressure and also thickens the blood remaining in the vessel. Dilation also is caused by the action of bradykinin, a substance released from its precursor by an enzyme that is itself activated by contact through factor XII, or by tissue factors.

The relationships of these systems to hemostasis are shown in Figure 6 (below).

HEMOSTATIC DEFECTS AND ABNORMAL BLEEDING

In man, hemostatic failure may result from inherited or acquired defects in any of the clotting or platelet functions described. The usual consequence is persistent bleeding from injuries that would normally give little trouble. Some persons may bleed more easily than normal, perhaps even spontaneously, as a result of an increased fragility of the blood vessels. This fragility is not itself a hemostatic defect but is often associated with one.

Patterns of bleeding

Abnormal bleeding follows a pattern defined by the underlying defect. Platelet abnormalities are associated with spontaneous bleeding from the membranes of the nose, mouth, and gastrointestinal and urogenital tracts.

From R. MacFarlane, *International Review of Experimental Pathology* (1968); Academic Press

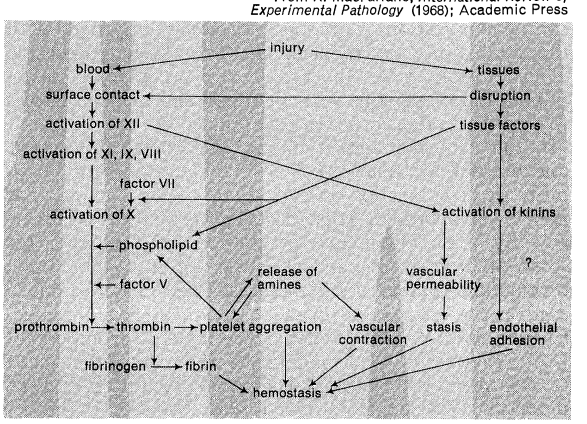

Figure 6: A comprehensive schema of hemostasis.

There is also purpura (small hemorrhages in the skin); and these hemorrhages can be produced by moderate pressure. Needle punctures in the skin also bleed longer than the normal few minutes, as in the "bleeding-time test." Massive tissue hemorrhages are rare, and the bleeding from extensive injuries, such as at operation sites, is often controllable by usual methods.

Blood clotting defects produce a different picture. Spontaneous bleeding and purpura are rare, and the effects of the bleeding-time test and of application of moderate pressure are normal. Bleeding from larger injuries, however, may be uncontrollable by any but specific replacement therapy; before this became available, many such persons died of hemorrhage following minor injury or such operations as a tooth extraction. The most characteristic feature of such defects, as typified by hemophilia, is the occurrence of massive and crippling hemorrhages into joints and muscles and bleeding into body cavities.

Vascular defects causing abnormal bleeding are rare. Groups of dilated capillaries in the skin and mucous membranes (telangiectases) may occur as an inherited or acquired condition, and these may bleed persistently if injured. There may be a capillary abnormality in von Willebrand's disease (see below). In the Ehlers-Danlos syndrome, there is an increased fragility of even major vessels, which are easily ruptured. In most cases of increased capillary fragility, there is also a platelet defect, quantitative or qualitative. This may suggest that platelets have a function in maintaining vascular integrity or that agents damaging platelets also damage vessels.

Diagnosis. The diagnosis of hemostatic defects depends on clinical and laboratory data. Investigation of the affected person's family background is important because many of these conditions are inherited. The personal history reveals the type of bleeding and the possible effects of drugs, chemicals, allergy, infection, or metabolic or dietary abnormalities. Examination reveals visible hemorrhages or vascular lesions, and the effects of internal bleeding. Clinical tests include the pressure and bleeding-time tests, already mentioned, and the collection of blood samples for laboratory testing. This includes the counting and examination of the platelets and tests for functions such as adhesiveness, response to ADP, and clot retraction. Tests of clotting function include the coagulation time in glass, the prothrombin time, and a battery of investigations of the intrinsic clotting system. These allow a deficiency of any of the clotting factors described to be identified and a quantitative assessment of activity of individual factors to be made. Most cases of abnormal bleeding can, by these means, be traced to specific defects; and precise diagnosis often allows effective treatment.

Clinical and laboratory tests

Course and outlook. The hereditary hemorrhagic disorders are life-long afflictions, and treatment, however temporarily effective, cannot alter the basic abnormality. Eventually, it may be possible to transplant into the affected person some normal organ or tissue that will provide a permanent supply of a genetically deficient factor. Until then, treatment is mainly to relieve the effects, though some prevention of the effects is possible. Even so, the expectation of life has enormously improved with the availability of replacement (transfusion) therapy. This, in itself, raises the problem of an increase in the population of persons with these genetic defects; efforts to discourage their procreation are needed.

In the acquired and secondary disorders, the course and outlook are determined by the cause and the possibility of its correction and of repair of the damage that it may have caused. Total destruction of the bone marrow by toxic chemicals, irradiation, or leukemia (or some other form of cancer) causes a failure of platelet production that is usually irreparable. Lesser damage can be repaired if the drug or chemical is eliminated. Certain cases of platelet deficiency (called thrombocytopenia) may respond permanently to removal of the spleen or treatment with adrenal hormones. Acquired clotting defects may result from liver disease, cancer, or the development of anticoagulants or excessive fibrinolysis. Again, the course and outlook are determined by the underlying condition.

Therapy. Treatment may be to relieve or prevent the manifestations and may be local or general. Local treatment consists of the application to the site of bleeding of such coagulants as thrombin or Russell's viper venom, or such vasoconstrictors as epinephrine, and the use of devices to retain dressings with firm pressure and without movement. Hemostatic dressings may be of slowly soluable materials, such as gelatine sponge. Much can be done, particularly in dental work, by these means.

General treatment consists mainly of temporary replacement therapy by transfusion. In thrombocytopenia —deficiency of platelets—transfusions of platelet-rich plasma can be given; in clotting deficiencies concentrated preparations of the missing factor can be given that will restore hemostatic function to normal for hours or days and, with repetitions, will allow injuries to heal or operations to be performed. The use of factor VIII in this way has revolutionized the treatment of hemophilia.

Hemorrhagic disorders. The hemorrhagic disorders comprise many genetic abnormalities and disease syndromes, and only a brief mention of the more important ones is possible here.

Platelet disorders. Platelets may be deficient in numbers, as the result of some identifiable disease or of injury to the platelet-producing cells of the bone marrow (secondary thrombocytopenic purpura), or may be of unknown cause (idiopathic thrombocytopenia). The platelets may be normal in number but defective in function, as in Glanzmann's and von Willebrand's diseases, both inherited as simple dominants—that is, each of these diseases becomes manifest if inherited from one parent alone. In von Willebrand's disease there is also a moderate deficiency of factor VIII in most cases, and correction of this defect may greatly improve hemostasis.

Coagulation defects. Any clotting factor (except calcium and thromboplastin) may be deficient as a hereditary or acquired defect. The commonest and most important of the hereditary disorders is hemophilia, a deficiency of factor VIII due to an abnormal gene located on the X sex chromosome. (Males have an X and a Y sex chromosome; females, two X-chromosomes.) Abnormal bleeding occurs in males carrying this gene on their single X-chromosome but not in females who carry the gene on one X-chromosome; females, though they can transmit the condition, are themselves hemostatically normal if their second X-chromosome is normal. Factor IX deficiency (Christmas disease) is a rarer condition, clinically and genetically similar to hemophilia. Other hereditary deficiencies are even more infrequent. Data on these states are given in the Table. Rarely, specific inhibitors, particularly to factor VIII, may develop in the blood, producing a deficiency. These inhibitors may arise in persons who have received blood transfusions or blood fractions, or after pregnancy. They may disappear spontaneously or respond to adrenal hormone therapy.

Excessive fibrinolysis. Excessive breakdown of fibrin (fibrinolysis) may cause bleeding, clots being rapidly digested, the blood fibrinogen becoming depleted and anticoagulant products formed. This may occur in cases of cancer, particularly of the prostate. An acute form (defibrination syndrome) may occur in certain obstetrical conditions associated with placental disease, or in injuries or operations involving lung or brain tissue, in which tissue factor may gain access to the bloodstream. Besides fibrinogen, factors V and VIII are also depleted. Infusions of fibrinogen are effective in controlling bleeding, and destruction of fibrin can be reduced by injecting inhibitors of protein breakdown.

Vascular abnormalities. In purpura, there is an unexplained and abnormal fragility of the capillaries, resulting in pinpoint hemorrhages in the skin and mucous membranes. In von Willebrand's disease capillaries may be distorted and dilated. In both these conditions, platelet defects have also been described.

Defects in capillaries

In hemorrhagic telangiectasia, visible groups of enormously dilated capillaries occur in the skin and mucous membranes of the mouth, nose, and gastrointestinal and

Recognized Coagulation Defects

deficient factor	hereditary defect		acquired defect
	probable inheritance	approximate incidence per million	
II (prothrombin)	not known	0.1	vitamin K deficiency liver disease
VII (proconvertin)	autosomal recessive	0.1	coumarin anticoagulant drugs
IX (Christmas factor; PTC)	sex-linked recessive (Christmas disease)	3–4	
X (Stuart-Prower factor)	autosomal recessive	0.1	
I (fibrinogen)	autosomal recessive	0.1	defibrination syndrome liver disease
V (proaccelerin)	autosomal recessive	0.1	defibrination syndrome
VIII (antihemophilic globulin)	sex-linked recessive (hemophilia)	30–40	defibrination syndrome circulating anticoagulant
XI (plasma thromboplastin antecedent)	autosomal dominant (PTA deficiency)	1	
XII (Hageman factor)	autosomal recessive (Hageman deficiency)	0.1	
XIII (fibrin stabilizing factor)	autosomal recessive	0.1	

respiratory tracts. The condition is inherited as a simple dominant, the lesions appearing in adult life and tending to bleed on the least provocation. Clotting and platelet functions are normal.

Thrombosis. Thrombosis, the formation of a blood clot that tends to plug in functionally normal blood vessels, is an important and increasing cause of death in Western societies. The causes of thrombosis are obscure. The commonest, and perhaps the most important cause, is a lesion that destroys the normal endothelial surface of a blood vessel. Platelets tend to adhere to such lesions, forming masses that, when reinforced by fibrin, may completely obstruct the blood flow. In arteries this obstruction may have disastrous consequences, as in coronary or cerebral vessels, or in a major artery of a limb or an organ. In veins the local results are less apparent, perhaps not detected, but, behind the original thrombus, the whole blood content of the vein may clot to form a large mass. This occurs most frequently in the leg veins and may be due to slowing of the blood flow during prolonged surgical operations or confinement to bed. The danger is that the clot may become detached and be swept into the pulmonary artery, causing fatal obstruction to the circulation. Other predisposing causes of thrombosis may be the increase in platelet numbers and adhesiveness and the increased coagulability of the blood that follows injury and blood loss.

The prevention and treatment of thrombosis aims at correcting these predisposing conditions. Specific treatment with anticoagulants includes the use of coumarin drugs, the injection of heparin, and the promotion of fibrinolysis by use of streptokinase or urokinase.

Blood, Human

Blood consists of specialized cells of several types suspended in a liquid medium, the plasma. It is well adapted for its role in the transport of many substances to and from the organs and tissues. The circulatory system provides the mechanism by which this vital function of the blood is achieved (see BLOOD CIRCULATION, HUMAN). The circulating blood continuously supplies oxygen, nutrient substances, and other materials necessary for the viability and activity of all of the cells of the body and carries away disposable cell products, including carbon dioxide and other waste materials. If blood flow ceases, death occurs within minutes because of the untoward effects of an unfavourable environment on highly susceptible cells. The relative constancy of the composition of the blood is made possible by the circulation, which conveys blood through the organs that regulate the concentration of its components. In the lungs blood acquires oxygen from the inspired air and releases carbon dioxide transported from the tissues. The kidneys remove excess water and dissolved waste products. Nutrient substances derived from food reach the bloodstream after absorption by the intestinal tract. Endocrine glands release their secretions into the blood, which transports these hormones (*e.g.*, insulin and thyroid hormone) to the tissues in which they exert their effects. Many substances are recycled through the blood; for example, iron released during the destruction of old red cells is conveyed by the plasma to sites of new red cell production where it is reutilized. Each of the numerous components of the blood is kept within appropriate concentration limits by an effective regulatory mechanism. In many instances feedback control systems are operative; thus a declining level of blood sugar leads to accelerated release of sugar into the blood so that a potentially hazardous depletion of blood sugar does not occur.

Unicellular organisms, primitive multicellular animals, and the early embryos of higher forms of life lack a circulatory system, and exchange of substances between cell and environment is accomplished by simple diffusion. In larger and more complex animals transport of adequate amounts of oxygen and other substances requires some type of blood circulation. The diffusion process then occurs between the body cells and the fluid derived from the blood, which by its constant motion maintains the constancy of the internal environment. Some simple animals, including small worms and mollusks, have blood that lacks an oxygen-binding substance analogous to hemoglobin; others are provided with pigments capable of transporting relatively large amounts of oxygen. In many invertebrates the blood pigment is dissolved in the plasma. Hemocyanin, a copper-containing protein chemically unlike hemoglobin, occurs in certain crabs and oth-

Types of blood

er lower animals. Hemocyanin is blue in colour when oxygenated and colourless when oxygen is removed. Some invertebrates have hemoglobin in solution in the plasma. In almost all vertebrates, including man, hemoglobin is contained exclusively within the corpuscles of the blood. The red cells of the lower vertebrates have a nucleus, are relatively large, and are often ovoid in shape; the cell contour is convex. In contrast, mammalian red cells lack a nucleus, are smaller, and have a biconcave shape. Red cells vary markedly in size among mammals; those of the goat are much smaller than those of man, but the goat compensates by having many more red cells per unit volume of blood. The concentration of hemoglobin inside of the red cell varies little between species (see BLOOD AND LYMPH).

Functions of the cells

The red cells permit the blood to carry sufficient oxygen to sustain life and to provide for the tremendous increase in oxygen requirement during physical exertion. Accordingly, they have an essential role in the transport function of the blood. In addition to the red cells, blood contains smaller numbers of cells of other types. The white blood cells, or leukocytes, are nucleated and larger than red cells. They are primarily concerned with defense mechanisms, preventing or coping with infection, and participating in the dissolution and removal of foreign material (phagocytosis). The smallest cells of the blood, the blood platelets, are nonnucleated. They are principally involved in maintaining the integrity of the vascular tree itself. They prevent leakage of blood from delicate capillaries, seal the walls of injured vessels, and contribute to the coagulation of the blood (see BLOOD DISEASES; BLEEDING AND BLOOD CLOTTING).

In the human embryo the primitive blood cells have their origin in the mesenchyme, the embryonic connective tissue, first appearing in the blood islands of the yolk sac. After the second month of intra-uterine life, red cell production occurs predominantly in the liver, where some white cell and platelet precursors also appear. At this time the spleen also is an active site of blood formation. In the fifth month blood formation begins in the newly developing bone marrow. At first white cell precursors predominate, but by the time of birth the bone marrow has become virtually the only source of red cells, white cells, and platelets. The lymphocytes are an exception; they arise from the thymus, spleen, and lymph nodes.

PROPERTIES AND FUNCTIONS

Properties. Blood is an opaque red fluid, freely flowing but more dense and more viscous than water. The characteristic colour is imparted by hemoglobin, a unique iron-containing protein. Hemoglobin brightens in colour when saturated with oxygen (oxyhemoglobin) and darkens when oxygen is removed (deoxyhemoglobin). For this reason, fully oxygenated blood from an artery is lighter in colour than the partially deoxygenated blood from a vein. The red cells constitute about 45 percent of the volume of the blood, and the remaining cells (the white cells and platelets) less than 1 percent. The fluid portion, the plasma, is a clear, slightly sticky, yellowish, proteinaceous liquid. After a fatty meal plasma transiently appears turbid. Within the body the blood is permanently fluid, and turbulent flow assures that cells and plasma are fairly homogeneously mixed. When blood is shed, physicochemical changes are initiated that cause the blood to coagulate (see BLEEDING AND BLOOD CLOTTING). The blood clot consists of microscopic strands of a complex protein, fibrin, forming a gel in which the blood cells are entrapped. The clot shrinks, or retracts, squeezing out an incoagulable yellowish fluid, the serum. An anticoagulant can be added to the shed blood to prevent the deposition of fibrin and to maintain the blood in a fluid state. When blood treated in this way is undisturbed, the cells gradually settle; the red cells go to the bottom, the white cells and platelets form a thin white layer (buffy coat) overlying the red cells, and the plasma appears in the upper portion of the container. The cells settle because they are denser than the plasma; specific gravity of the plasma is about 1.026, while that of red cells is about 1.093. The specific gravity of whole blood varies with the proportion of red cells that it contains; an average normal value is about 1.060. The rate at which red cells settle (sedimentation rate) is normally slow because of the small size of the red cells and their relatively large surface area. When red cells form aggregates like rolls or coins, or rouleaux, the surface–volume ratio is decreased and the sedimentation rate is accelerated. Separation of cells and plasma may be accomplished rapidly and completely by the use of a centrifuge, a device in which rapid rotation accelerates sedimentation by increasing gravitational forces. The relatively high viscosity of blood, as compared with water, is largely attributable to the suspended red cells. Viscosity increases disproportionately as the cell fraction increases. The viscous properties of blood differ from those of simple liquids in that the viscosity of blood is dependent on conditions of flow. Slowly flowing blood is more viscous than the same blood flowing through the same vessel at higher rates of flow.

Characteristics of shed blood

Separation of cells and plasma

The pH of blood is kept within narrow limits of variation at about 7.4, slightly on the alkaline side of neutrality (a pH of less than 7 indicates acidity, of more than 7 alkalinity). Venous blood is somewhat less alkaline (7.35) because of the higher carbon dioxide content. Constancy of pH is achieved by a system of efficient buffers in the blood and by the selective excretory functions of the lungs and kidneys. The rate and depth of respiration are controlled physiologically to maintain a normal tension of carbon dioxide in the blood, important in maintaining blood pH. The excretion of acid or alkaline urine by the kidneys is regulated by physiologic needs for sustaining the normal pH of the blood.

Blood volume and distribution

The total amount of blood varies with age, sex, weight, body build, and other factors, but a rough average figure for adults is about 7 to 8 percent of body weight. An average young man has a plasma volume of about 45 millilitres and a red cell volume of about 30 millilitres per kilogram of body weight. There is little variation in the blood volume of a healthy person over long periods, although each component of the blood is in a continuous state of flux. In particular, water moves in and out of the bloodstream with great rapidity, achieving a balance with the extravascular fluids (those outside the blood vessels) within minutes. The normal volume of blood provides such an adequate reserve that appreciable blood loss is well tolerated. Withdrawal of 500 millilitres (about a pint) of blood from normal blood donors is a harmless procedure. Blood volume is rapidly replaced after blood loss; within hours plasma volume is restored by movement of extravascular fluid into the circulation. Replacement of red cells is completed within several weeks. Tolerance to change in blood volume is made possible by the elasticity of the circulatory system. Only about 15 percent of the blood is contained in the relatively rigid arteries, while 70 percent is in the more distensible veins. The capillaries, which have a total cross-section area about 1,000 times greater than that of the aorta, contain only about 10 percent of the blood. The vast area of capillary membrane, through which water passes freely, would permit instantaneous loss of the plasma from the circulation were it not for the plasma proteins. In particular, the plasma albumin has the greatest functional significance in regulation of plasma volume. Capillary membranes are impermeable to albumin, the smallest in weight and highest in concentration of the plasma proteins. The osmotic effect of the plasma albumin retains fluid within the circulation, opposing the hydrostatic forces that tend to drive the fluid outward.

Maintaining stability of internal environment

Functions. Broadly conceived, the function of the blood is to maintain the constancy of the internal environment, an aspect of the precise biologic regulation called homeostasis. The circulating blood makes possible man's adaptability to changing conditions of life—his endurance of wide variations of climate and atmospheric pressure; his capacity to alter his physical activity; his tolerance of changing diet and fluid intake; his resistance to physical injury, chemical poisons, and infectious

agents. The blood has an almost unbelievably complex structure, and many components participate in its functional activities, often in an intricate and poorly understood way. Regulatory mechanisms with which the blood is involved include sensors that detect alterations in temperature, in pH, in oxygen tension, and in concentrations of the constituents of the blood. Effects of these stimuli are in some instances mediated via the nervous system or by the release of hormonal substances (chemical mediators). Some of the major functions of the blood are outlined in the paragraphs that follow.

Respiration. In terms of immediate urgency, the respiratory function of the blood is most vital. A continuous supply of oxygen is required by living cells, in particular those of the brain, and deprivation is followed in minutes by unconsciousness and death. A normal man at rest uses about 250 millilitres of oxygen per minute, a requirement increased manyfold during vigorous exertion. All of this is transported by the blood, most of it bound to the hemoglobin of the red cells. The minute blood vessels of the lungs bring the blood into close apposition with the pulmonary air spaces (alveoli), where the pressure of oxygen is relatively high.

Oxygen diffuses through the plasma and into the red cell, combining with hemoglobin, which is about 95 percent saturated with oxygen on leaving the lungs. One gram of hemoglobin can bind 1.35 millilitres of oxygen, and about 50 times as much oxygen is combined with hemoglobin as is dissolved in the plasma. In tissues where the oxygen tension is relatively low, oxygen diffuses out of the blood. Not all of the oxygen is removed, and the venous blood returning to the lungs is partially oxygenated. The added demand for oxygen during increased physical activity is met primarily by accelerated rate of blood flow, permitting more oxygen to be transported. In addition, a larger fraction of the oxygen combined with hemoglobin may be extracted by the tissues with high oxygen requirements.

Elimination of carbon dioxide

Carbon dioxide, a waste product of cellular metabolism, is transported by the blood in the opposite direction. Occurring in relatively high concentration in the tissues, it diffuses into the blood and is carried to the lungs for elimination by way of the expired air. Carbon dioxide is much more soluble than oxygen and readily diffuses into red cells. It reacts with water to form carbonic acid, a weak acid that at the alkaline pH of the blood appears principally as bicarbonate. Carbon dioxide also reacts with hemoglobin to form a carbamate compound, a substance that is significant in carbon dioxide transport within red cells. The tension of carbon dioxide in the arterial blood is regulated with extraordinary precision through a sensing mechanism in the brain that controls the respiratory movements. Carbon dioxide is an acidic substance, and increase in its concentration tends to lower the pH. This tendency is averted by the stimulus that causes increased depth and rate of breathing, a response that accelerates the loss of carbon dioxide. It is the tension of carbon dioxide and not of oxygen in the arterial blood that normally controls breathing. Inability to hold one's breath for more than a minute or so is the result of the rising tension of carbon dioxide, which produces the irresistible stimulus to breathe. Respiratory movements that ventilate the lungs sufficiently to maintain a normal tension of carbon dioxide are adequate under normal conditions to keep the blood fully oxygenated. Control of respiration is effective in regulating the uptake of oxygen and disposal of carbon dioxide, and in maintaining the constancy of blood pH.

Nutrition. Each substance required for the nutrition of every cell in the body is transported by the blood: the precursors of carbohydrates, proteins, and fats; minerals and salts; vitamins and other accessory food factors. These substances must all pass through the plasma on the way to the tissues in which they are utilized. The materials may enter the bloodstream from the gastrointestinal tract, or they may be released from stores within the body or become available from the breakdown of tissue. Turnover of substances carried by the blood may be rapid in relation to their concentration in plasma. Hundreds of grams of sugar (glucose) may be absorbed into the blood each day; yet the plasma concentration of glucose does not greatly exceed 100 milligrams (mg) per hundred millilitres (ml). All of the calcium in the skeleton and teeth has had to traverse the plasma, but the concentration of calcium in plasma is closely guarded at about 10 mg per 100 ml. The concentrations of many plasma constituents, including glucose and calcium, are carefully regulated, and deviations from the normal may have catastrophic effects. One of the regulators of the blood sugar is insulin, a hormone released into the blood from glandular cells in the pancreas. Ingestion of a carbohydrate meal is followed by increased production of insulin, which tends to keep the blood sugar from rising excessively. But an excess of insulin may severely reduce the blood sugar, causing a reaction that, if sufficiently severe, may include coma and even death. Glucose is transported in simple solution, but some substances require specific binding proteins (proteins with which the substances form temporary unions) to convey them through the plasma. Iron and copper, essential minerals, have special and necessary transport proteins. Nutrient substances may be taken up selectively by the tissues that require them. Growing bones utilize large amounts of calcium, and bone marrow removes iron from plasma for hemoglobin synthesis.

Excretion. The blood carries the waste products of cellular metabolism from their sites of release to the excretory organs. The removal of carbon dioxide in the lungs has been described. Water produced by the oxidation of foods or available from other sources in excess of needs is excreted by the kidneys as the solvent of the urine. Water derived from the blood also is lost from the body by evaporation from the skin and lungs and in small amounts from the gastrointestinal tract. The water content of the blood and of the body as a whole remains within a narrow range because of effective hormonal and other regulatory mechanisms that determine the urinary volume. The concentrations of physiologically important ions of the plasma, notably sodium, potassium, and chloride, are precisely controlled by their retention or selective removal as blood flows through the kidneys. Of special significance is the renal (kidney) control of acidity of the urine, a major factor in the maintenance of the normal pH of the blood. Urea, creatinine, and uric acid are nitrogen-containing products of metabolism that are transported by the blood and rapidly eliminated by the kidneys. The kidneys clear the blood of many other substances, including numerous drugs and chemicals that are taken into the body. In performing their excretory function, the kidneys have a major responsibility for maintaining the constancy of the composition of the blood. The liver is in part an excretory organ. Bilirubin (bile pigment) produced by the destruction of hemoglobin is conveyed by the plasma to the liver and is excreted through the biliary ducts into the intestinal tract. Other substances, including certain drugs, also are removed from the plasma by the liver.

Work of white cells, blood enzymes, and antibodies

Defense mechanisms. Cells of the blood and constituents of the plasma interact in complex ways to confer immunity to infectious agents, to resist or destroy invading organisms, to produce the inflammatory response, and to destroy and remove foreign materials and dead cells. The leukocytes (white blood cells, discussed later in this article) have a primary role in these reactions: granulocytes and monocytes phagocytize (ingest) bacteria and other organisms; they migrate to sites of infection or inflammation and to areas containing dead tissue; they participate in the enzymatic breakdown and removal of cellular debris; lymphocytes are concerned with the development of immunity and with acquired resistance to infections. Blood contains a number of substances that nonspecifically inhibit the growth of micro-organisms. One of these is lysozyme (muramidase), a bacteriocidal enzyme that occurs also in other body fluids, including the tears. Acquired resistance to specific micro-organisms is in part attributable to antibodies, plasma globulins that

are formed in response to the entry into the body of a foreign substance (antigen). Antibodies that have been induced by micro-organisms tend to prevent reinfection by the same organism and often confer a high degree of resistance. Cells and antibodies may cooperate in the destruction of invading bacteria; the antibody may attach to the organism and sensitize it so that it is more readily phagocytized. Involved in some of these reactions is complement, a group of protein components of plasma that participate in certain immunologic reactions. Micro-organisms and other cells sensitized by a specific antibody may be killed by complement.

Mechanisms to prevent blood loss

Hemostasis. The blood is contained under pressure in a vascular system that includes vast areas of thin and delicate capillary membranes. Even the bumps and knocks of everyday life are sufficient to disrupt some of these fragile vessels, and serious injury can be much more damaging. Loss of blood would be a constant threat to survival if it were not for protective mechanisms to prevent and to control bleeding. The platelets contribute to the resistance of capillaries, possibly because they actually fill chinks in vessel walls. In the absence of platelets capillaries become more fragile, permitting spontaneous loss of blood and increasing the tendency to form bruises after minor injury. Platelets immediately aggregate at the site of injury of a blood vessel, tending to seal the aperture. A blood clot, forming in the vessel around the clump of adherent platelets, further occludes the bleeding point. The coagulation mechanism involves a series of chemical reactions in which specific proteins and other constituents of the blood, including the platelets, play a part (see BLEEDING AND BLOOD CLOTTING). Plasma also is provided with a mechanism for dissolving clots after they have been formed. Plasmin is a proteolytic enzyme—a substance that causes breakdown of proteins—derived from an inert plasma precursor known as plasminogen. When clots are formed within blood vessels, activation of plasminogen to plasmin may lead to their removal.

Temperature regulation. Heat is produced in large amounts by physiological oxidative reactions, and the blood is essential both for its distribution and disposal. The circulation assures relative uniformity of temperature throughout the body and also carries the warm blood to the surface, where heat is lost to the external environment. A heat-regulating centre in the hypothalamus of the brain functions much like a thermostat. It is sensitive to changes in temperature of the blood flowing through it and, in response to the changes, gives off nerve impulses that control the calibre of the blood vessels in the skin and thus determine blood flow and skin temperature. A rise in skin temperature increases heat loss from the body surface. Heat is continuously lost by evaporation of water from the lungs and skin, but this loss can be greatly increased when more water is made available from the sweat glands. The activity of the sweat glands is controlled by the nervous system under direction of the temperature-regulating centre. Constancy of body temperature is achieved by control of the rate of heat loss by these mechanisms.

COMPONENTS

Plasma. The liquid portion of the blood, the plasma, is a solution of enormous complexity containing more than 90 percent water. Its major solute is a heterogeneous group of proteins constituting about 7 percent of the plasma by weight. Fatty substances (lipids) are present in several forms in suspension and in solution. Other constituents include salts, glucose, amino acids, vitamins, hormones, and waste products of metabolism.

Functions and distribution of water

Water. The water of the plasma is freely exchangeable with that of the body cells and extracellular fluids and is available to maintain the normal state of hydration of all tissues. Water is the largest single constituent of the body and is essential for the existence of every living cell. It forms both the solvent in which intracellular chemical reactions occur and the ambient fluid that provides the proper environment for the cells. More than half of the water is contained within the cells; the remainder makes up the extracellular fluid, of which most is outside of the blood vessels. The portion of the water that is contained in the plasma is relatively small but is the most dynamic in terms of flow and of turnover rates of its many solutes. The semipermeable membranes enclosing all tissue cells and forming the walls of the capillaries give free access to water, but limit the passage of many solutes. Water moves across these membranes to achieve osmotic equilibrium. The principal difference between plasma and the extracellular fluid of the tissues is the high protein content of plasma. Plasma protein exerts an osmotic effect by which water tends to move from the extravascular fluid into the blood. Movement of water across cell membranes is determined by the concentration of the electrolytes, especially sodium and potassium, within and outside of the cell. Since cell membranes are relatively impermeable to these ions, their osmotic effects regulate the distribution of water. Water is the source of sweat, tears, secretions of the respiratory and alimentary tracts, and the urine. In addition to its primary property as a solvent and suspending medium, water is of vital physiological significance in transfer of heat. Water has a high specific heat—*i.e.*, it can take up much heat without appreciable rise in temperature—and is ideally suited for its role in regulation of body temperature. The remarkable precision with which the water content of man is regulated is demonstrated by the day to day constancy of the weight of the body, of which about two-thirds is water. Compensatory mechanisms controlling water loss assure relative constancy of the body water, despite large variations in fluid intake. Deficiency of water gives rise to the sensation of thirst; satisfaction of this demand provides an adequate water intake. The kidneys regulate the amount of water lost from the body by varying the volume of the urine; important in this control mechanism is a hormone (antidiuretic hormone) secreted by the pituitary gland. The sensing mechanism seems to detect changes in osmotic pressure of the extracellular fluid. If the osmotic pressure rises, antidiuretic hormone is secreted in larger amount and acts on the kidney to restrict water loss in the urine.

Proteins. Proteins are complex chemical compounds occurring in all living organisms and forming essential constituents of every living cell. Chemically, they are large molecules formed of chains of amino acids, organic acids that contain both an acidic and a nitrogenous basic (amino) group. Chains (polypeptides) are formed by linkage of the acid group of one amino acid to the amino group of the next (peptide bond). The characteristics of a protein are determined by the number and types of amino acids and the sequence in which they are arranged.

When dietary protein is digested in the gastrointestinal tract, individual amino acids are released from the chains and are absorbed. The amino acids are transported through the plasma to all parts of the body, where they are taken up by cells and are assembled in specific ways to form proteins of many types. The plasma proteins are released into the blood from the cells in which they were synthesized. Much of the protein of plasma is produced in the liver. The major plasma protein is albumin, a relatively small molecule, the principal function of which is to retain water in the bloodstream by its osmotic effect. The amount of albumin in the blood is a determinant of the total volume of plasma. Depletion of albumin permits fluid to leave the circulation and to accumulate and cause swelling of soft tissues (edema). Albumin binds certain other substances that are transported in plasma and thus serves as a nonspecific carrier protein. Bilirubin, for example, is bound to albumin during its passage through the blood.

Globulins, fibrinogen, and fibrin

Albumin has physical properties that permit its separation from other plasma proteins, which as a group are called globulins. In fact, the globulins are a heterogeneous array of proteins of widely varying structure and function, only a few of which can be mentioned here. The immunoglobulins comprise the antibodies, each of which was produced in response to a specific antigen.

For example, administration of poliomyelitis vaccine is followed by the appearance in the plasma of antibodies that react with polio virus and effectively prevent that infection. Antibodies may be induced by many foreign substances in addition to micro-organisms; immunoglobulins are involved in some hypersensitive and allergic reactions.

Other plasma proteins are concerned with the coagulation of the blood. The framework of the clot is composed of fibrin, which is derived from a soluble plasma component known as fibrinogen. When a blood vessel is injured or blood is shed, fibrinogen undergoes a chemical change that causes its molecules to aggregate in a special way, forming strands and filaments. These join to produce a meshwork of fibrin in which the blood cells are trapped. The formation of the fibrin net is preceded by a complex series of poorly understood chemical reactions involving many other plasma proteins specifically concerned with the coagulation process. An enzyme, thrombin, is responsible for the conversion of fibrinogen to fibrin. Thrombin does not exist in circulating plasma but is derived from an inert plasma precursor, prothrombin, during the coagulation process. Serum, the fluid expressed from the blood clot, differs from plasma principally in that fibrinogen, prothrombin, and certain other procoagulant proteins have been altered or removed.

Thrombin, differentiation of plasma and serum

Many proteins are involved in a highly specific way with the transport function of the blood. Blood lipids are incorporated into protein molecules as lipoproteins, substances of great importance in lipid transport. Iron and copper are transported in plasma by unique metal-binding proteins (transferrin and ceruloplasmin, respectively). Vitamin B_{12}, an essential nutrient substance, is bound to a specific carrier protein. Although hemoglobin is not normally released into the plasma, a hemoglobin binding protein (haptoglobin) is available to transport hemoglobin should hemolysis (breakdown) of red cells occur.

Transport of fats

Lipids. The concentration of lipids in plasma varies, particularly in relation to meals, but ordinarily does not exceed one gram per hundred millilitres. The largest fraction consists of phospholipids, complex molecules containing phosphoric acid and a nitrogen base in addition to fatty acids and glycerol. Triglycerides, or simple fats, are molecules composed only of fatty acids and glycerol. Free fatty acids, lower in concentration than triglycerides, are responsible for a much larger transport of fat. Other lipids include cholesterol, a major fraction of the total plasma lipids. These substances exist in plasma combined with proteins of several types as lipoproteins. The largest lipid particles in the blood are known as chylomicrons and consist largely of triglycerides; after absorption from the intestine they pass through lymphatic channels and enter the bloodstream through the thoracic lymph duct. The other plasma lipids are derived from food or enter the plasma from tissue sites.

Other plasma components. Some plasma constituents occur in plasma in low concentration but have a high turnover rate and great physiological importance. Among these is glucose, the blood sugar. Glucose is absorbed from the gastrointestinal tract or may be released into the circulation from the liver. It provides a source of energy for tissue cells and is the only source for some, including the red blood cells. Glucose is conserved and utilized and not excreted. Amino acids also are so rapidly transported that the plasma level remains low, although they are required for all protein synthesis throughout the body. In contrast, urea, an end product of protein metabolism, is rapidly excreted by the kidneys. Other nitrogenous waste products—uric acid and creatinine—are similarly removed.

Glucose

Several inorganic materials are essential constituents of plasma, and each has special functional attributes. The predominant cation (positively charged ion) of the plasma is sodium, an ion that occurs within cells at a much lower concentration. Because of the effect of sodium on osmotic pressure and fluid movements, the amount of sodium in the body is an influential determinant of the total volume of extracellular fluid. Dietary sodium usually exceeds requirements, and the excess is excreted by the kidneys. The amount of sodium in plasma is controlled by the kidneys under the influence of a hormone (aldosterone) of the adrenal gland. Potassium, the principal intracellular cation, occurs in plasma at a much lower concentration than sodium. The renal excretion of potassium is influenced by aldosterone, which causes retention of sodium and loss of potassium. Calcium in plasma is in part bound to protein and in part ionized. Its concentration is under the control of two hormones: parathyroid hormone, which causes the level to rise, and calcitonin, which causes it to fall. Magnesium, like potassium, is a predominantly intracellular cation and occurs in plasma in low concentration. Variations in the concentrations of these cations may have profound effects on the nervous system, the muscles, and the heart, effects normally prevented by precise regulatory mechanisms. Iron, copper, and zinc are required in trace amounts for synthesis of essential enzymes; much more iron is needed in addition for production of hemoglobin and myoglobin, the oxygen-binding pigment of muscles. These metals occur in plasma in low concentrations. The principal anion (negatively charged ion) of plasma is chloride; sodium chloride is its major salt. Bicarbonate participates in the transport of carbon dioxide and in the regulation of pH. Phosphate also has a buffering effect on the pH of the blood and is vital for chemical reactions of cells and for the metabolism of calcium. Iodide is transported through plasma in trace amounts; it is avidly taken up by the thyroid gland, which incorporates it into thyroid hormone.

Sodium, potassium, other metals

Chloride and other anions, hormones

The hormones of all of the endocrine glands are secreted into the plasma and transported to their target organs, the organs in which they exert their effect. The plasma levels of these agents often reflect the functional activity of the glands that secrete them; in some instances measurements are possible though concentrations are extremely low. Among the many other constituents of plasma are numerous enzymes. Some of these appear simply to have escaped from tissue cells and have no functional significance in the blood. Others, like plasmin and thrombin, are derived from plasma precursors and have specific functions.

Red blood cells (erythrocytes). The red blood cells are highly specialized, well adapted for their primary function of transporting oxygen from the lungs to all of the body tissues. Rather uniform in size (about eight microns in diameter), red cells have the form of biconcave disks, a shape that provides a large surface to volume ratio. When blood is centrifuged to cause the cells to settle, the volume of packed red cells (hematocrit value) ranges between 42 and 54 percent of total volume in men and between 37 and 47 percent in women; values are somewhat lower in children. Normal red blood cells are fairly uniform in volume, so that the hematocrit value is determined largely by the number of red cells per unit of blood. The normal red cell count ranges between 4,000,000 and 6,000,000 per cubic millimetre. Hemoglobin constitutes about one-third of the weight of each red cell. The amount of hemoglobin in blood is related to the hematocrit value and to the red cell count, and in normal adults ranges between 14 and 18 grams per hundred millilitres. When fresh blood is examined with the microscope, red cells appear to be yellow-green disks with pale centres, containing no visible internal structures. They tend to adhere to each other like rolls of coins (rouleaux).

Size, shape, and volume of red cells

The red cell is enclosed in a thin membrane composed of chemically complex lipids, proteins, and carbohydrates in a highly organized structure. Extraordinary distortion of the erythrocyte occurs in its passage through minute blood vessels, many of which have a diameter less than that of the red cell. When the deforming stress is removed, the cell springs back to its original shape. The erythrocyte readily tolerates bending and folding; but if appreciable stretching of the membrane occurs, the cell is damaged or destroyed. The membrane is freely permeable to water, oxygen, carbon dioxide, glucose, urea, and certain other substances but is impermeable to hemoglobin. Within the cell the major cation is potassium; in con-

trast, in plasma and extracellular fluids the major cation is predominantly sodium. Relative impermeability of the membrane to sodium and potassium permits differences in concentration to be maintained. Because of the differential permeability of the membrane, red cells are subject to osmotic effects. When they are suspended in very dilute (hypotonic) solutions of sodium chloride, red cells take in water, which causes them to increase in volume and to become more spheroid; in concentrated salt solutions they lose water and shrink. In distilled water red cells continue to swell until they become spherical, whereupon they disrupt, releasing the dissolved hemoglobin into the surrounding fluid (hemolysis).

Breakdown of red cells

Hemolysis. When red cell membranes are damaged, hemoglobin and other dissolved contents may escape from the cells, leaving the membranous structures as "ghosts." This process, called hemolysis, is produced not only by the osmotic effects of water but by numerous other mechanisms. These include physical damage to red cells, as when blood is heated, is forced under great pressure through a small needle, or is subjected to freezing and thawing; chemical damage to red cells by agents such as bile salts, detergents, and certain snake venoms; and damage caused by immunologic reactions that may occur when antibodies attach to red cells in the presence of complement.

Blood groups. The membrane of the red cell has on its surface a group of agents that confer blood group specificity (*i.e.*, that differentiate blood cells into groups). Most blood group substances are composed of carbohydrate linked to protein, and it is the chemical structure of the carbohydrate portion that determines the specific blood type. Blood group substances are antigens capable of inducing the production of antibodies when injected into persons or animals lacking the antigen. Detection and recognition of the blood group antigens are accomplished by the use of serum containing these antibodies. Persons of blood group A do not have in their serum an antibody that reacts with the group A antigen, but they do have an antibody reacting with the red cells of persons of blood group B. By the use of serum samples, each containing one or more antibodies, a large number of red cell antigens can be identified. They include those of the important ABO and Rh systems (see BLOOD GROUPS). Normal persons have in their serum antibodies that react with the ABO antigens that they themselves lack. Antibodies reacting with other red cell antigens are not normally present in serum and appear only after the person has been sensitized, as by the administration of a transfusion of blood containing the antigen. Pregnant women may be sensitized to red cell antigens of the fetus, a phenomenon occurring most often with certain antigens of the Rh system. The blood groups are inherited characteristics and are useful in genetic studies and in the determination of paternity. The large number of different red cell antigens makes it extremely unlikely that persons other than identical twins will have the same array of blood group substances.

Hemoglobin. About 95 percent of the dry weight of the red cell consists of hemoglobin, the substance necessary for oxygen transport. Hemoglobin is a protein; a molecule contains four polypeptide chains, each chain consisting of more than 140 amino acids. To each chain is attached a chemical structure known as a heme group. Heme is composed of a ringlike organic compound known as a porphyrin to which an iron atom is attached. It is the iron atom that reversibly binds oxygen as the blood travels between the lungs and the tissues. There are four iron atoms in each molecule of hemoglobin, which, accordingly, can bind four atoms of oxygen. The complex porphyrin and protein structure may be considered to provide just the proper environment for the iron atom so that it binds and releases oxygen appropriately under physiological conditions.

Interaction of hemoglobin and oxygen

The affinity of hemoglobin for oxygen is so great that at the oxygen pressure in the lungs about 95 percent of the hemoglobin is saturated with oxygen. As the oxygen tension falls, as it does in the tissues, oxygen dissociates from hemoglobin and is available to move by diffusion through the red cell membrane and the plasma to sites where it is utilized. The proportion of hemoglobin saturated with oxygen is not directly proportional to the oxygen pressure. As the oxygen pressure declines, hemoglobin gives up its oxygen with disproportionate rapidity, so that the major fraction of the oxygen can be released with a relatively small drop in oxygen tension. The affinity of hemoglobin for oxygen is primarily determined by the structure of hemoglobin, but it is also influenced by other conditions within the red cell, in particular the pH. When the interior of the red cell becomes more acid, as it does when carbon dioxide diffuses into the cell, hemoglobin binds less oxygen. This phenomenon, known as the Bohr effect, is of physiologic importance. In the tissues, where carbon dioxide is taken up by red cells, affinity of the hemoglobin for oxygen is lessened and more is made available for the tissue cells. Other components of the red cell similarly affect oxygen binding by hemoglobin. Among these are certain organic phosphate compounds produced during the chemical breakdown of glucose, in particular 2,3-diphosphoglycerate. An increase in the concentration of this compound lessens the affinity of hemoglobin for oxygen. At high altitudes, where the atmospheric oxygen pressure is low, the concentration of 2,3-diphosphoglycerate in the red cell increases, lessening the affinity of the hemoglobin for oxygen and driving more oxygen into the tissues, where it is much needed. Acclimatization to high altitude is achieved in part by this mechanism.

Hemoglobin and carbon monoxide

Hemoglobin has a much higher affinity for carbon monoxide than for oxygen. Carbon monoxide produces its lethal effects by binding to hemoglobin and preventing oxygen transport. The oxygen-carrying function of hemoglobin can be disturbed in other ways. The iron of hemoglobin is normally in the reduced or ferrous state, both in oxyhemoglobin and deoxyhemoglobin. If the iron itself becomes oxidized to the ferric state, hemoglobin is changed to methemoglobin, a brown pigment incapable of transporting oxygen. The red cells contain enzymes capable of maintaining the iron in its normal state, but under abnormal conditions large amounts of methemoglobin may appear in the blood.

Sickle-cell anemia

Information of widely ranging importance has been derived from the study of the hemoglobin molecule. Discovery of the cause of sickle-cell anemia has led to major advances in understanding of genetics, molecular biology, and the mechanisms of disease. Persons who have sickle-cell anemia are Negroes with an inherited abnormality of the hemoglobin causing a serious and often fatal disease. Cause of the disease is the mutation of a single gene that determines the structure of one pair of the polypeptide chains of the hemoglobin molecule. Sickle hemoglobin differs from normal hemoglobin in that a single amino acid in one pair of the polypeptide chains has been replaced (glutamic acid by valine). This single intramolecular change so alters the properties of the hemoglobin molecule that anemia and other effects are produced. The entire structure of the hemoglobin molecule is known, and many other genetically determined abnormalities have been identified. Some of these also produce diseases of several types. Study of the effects of altered structure of hemoglobin on its properties has greatly broadened knowledge of the structure-function relationships of the hemoglobin molecule.

Red cell metabolism. Survival of the red cell in the circulation depends upon the continuous utilization of glucose for the production of energy. Two chemical pathways are employed, and both are essential for the normal life of the red cell. An extraordinary number of enzyme systems participate in these reactions and direct the energy evolved into appropriate uses. Red cells contain neither a nucleus nor RNA (ribonucleic acid, necessary for protein synthesis), so that cell division and production of new protein are impossible. Energy is not necessary for oxygen and carbon dioxide transport, which depends principally on the properties of hemoglobin. Energy is needed for another operation: There is a tendency for the extracellular cation, sodium, to leak into the red cell and

for potassium to leak out; energy is required to operate a pumping mechanism in the red cell membrane necessary to maintain the normal gradients (differences in concentrations) of these ions. Energy is also required to convert methemoglobin to oxyhemoglobin and to prevent the oxidation of other constituents of the red cell.

Erythropoiesis (production of red cells). Red cells are produced continuously in the marrow of certain bones. The principal sites are the marrow spaces of the skull, vertebrae, ribs, breastbone, and pelvis, and of the upper ends of the femurs and humeri. Within the bone marrow the red cell is derived from a primitive precursor or erythroblast, a nucleated cell in which there is no hemoglobin. Proliferation occurs as a result of several successive cell divisions. During maturation hemoglobin appears in the cell and the nucleus becomes progressively smaller. In a few days, the cell loses its nucleus and is then introduced into the bloodstream in the vascular channels of the marrow. Almost 1 percent of the red cells are generated each day, and the balance between red cell production and the removal of aging red cells from the circulation is precisely maintained. If blood is lost from the circulation, the erythropoietic activity of marrow increases until the normal number of circulating cells has been restored.

Nutrients needed for red cell production

In a normal adult the red cells of almost one pint of blood are produced by the bone marrow every week. A number of nutrient substances are required for this process. Some nutrients are the building blocks of which the red cells are composed. For example, amino acids are needed in abundance for the construction of the proteins of the red cell, in particular of hemoglobin. Iron is a component of hemoglobin, and without it hemoglobin cannot be synthesized. Approximately one-quarter of a gram of iron is needed for the production of a pint of blood. Other substances, required in trace amounts, are needed to catalyze the chemical reactions by which red cells are produced. Important among these are several vitamins, riboflavin, vitamin B_{12}, and folic acid, necessary for the maturation of the developing red cell; and pyridoxine (vitamin B_6), required for the synthesis of hemoglobin. The secretions of several endocrine glands influence red cell production. If there is an inadequate supply of thyroid hormone, erythropoiesis is retarded and anemia appears. The male sex hormone, testosterone, stimulates red cell production; for this reason, red cell counts of men are higher than those of women.

The capacity of the bone marrow to produce red cells is enormous. When stimulated to peak activity and when provided adequately with nutrient substances, the marrow can compensate for the loss of several pints of blood per week. Hemorrhage or accelerated destruction of red cells leads to enhanced marrow activity. The rate of erythropoiesis is sensitive to the oxygen tension of the arterial blood. When oxygen tension falls, more red cells are produced and the red cell count rises. For this reason, persons who live at high altitude have higher red cell counts than those who live at sea level. There is a small but significant difference between average red cell counts of persons living in New York City, at sea level pressure, and persons living in Denver, one mile above sea level, where the atmospheric pressure is lower. Natives of the Andes, living nearly three miles above sea level, have extremely high red cell counts.

The rate of production of erythrocytes is controlled by a hormone-like substance (erythropoietin) that is produced largely in the kidneys. When the circulating red cells decrease or when the oxygen transported by the blood diminishes, an unidentified sensor detects the change and the production of erythropoietin is increased. This substance is then transported through the plasma to the bone marrow, where it accelerates the production of red cells. The erythropoietin mechanism operates like a thermostat, increasing or decreasing the rate of red cell production in accordance with need. When a man who has lived at high altitude moves to a sea-level environment, production of erythropoietin is suppressed, the rate of red cell production declines, and the red cell count falls until the normal sea level value is achieved. When a normal person donates a pint of blood to the blood bank, the erythropoietin mechanism is activated, red cell production is enhanced, and within a few weeks the number of circulating red cells has been restored to the previous value. The precision of control is extraordinary, so that the number of new red cells produced quite accurately compensates for the number of cells lost or destroyed.

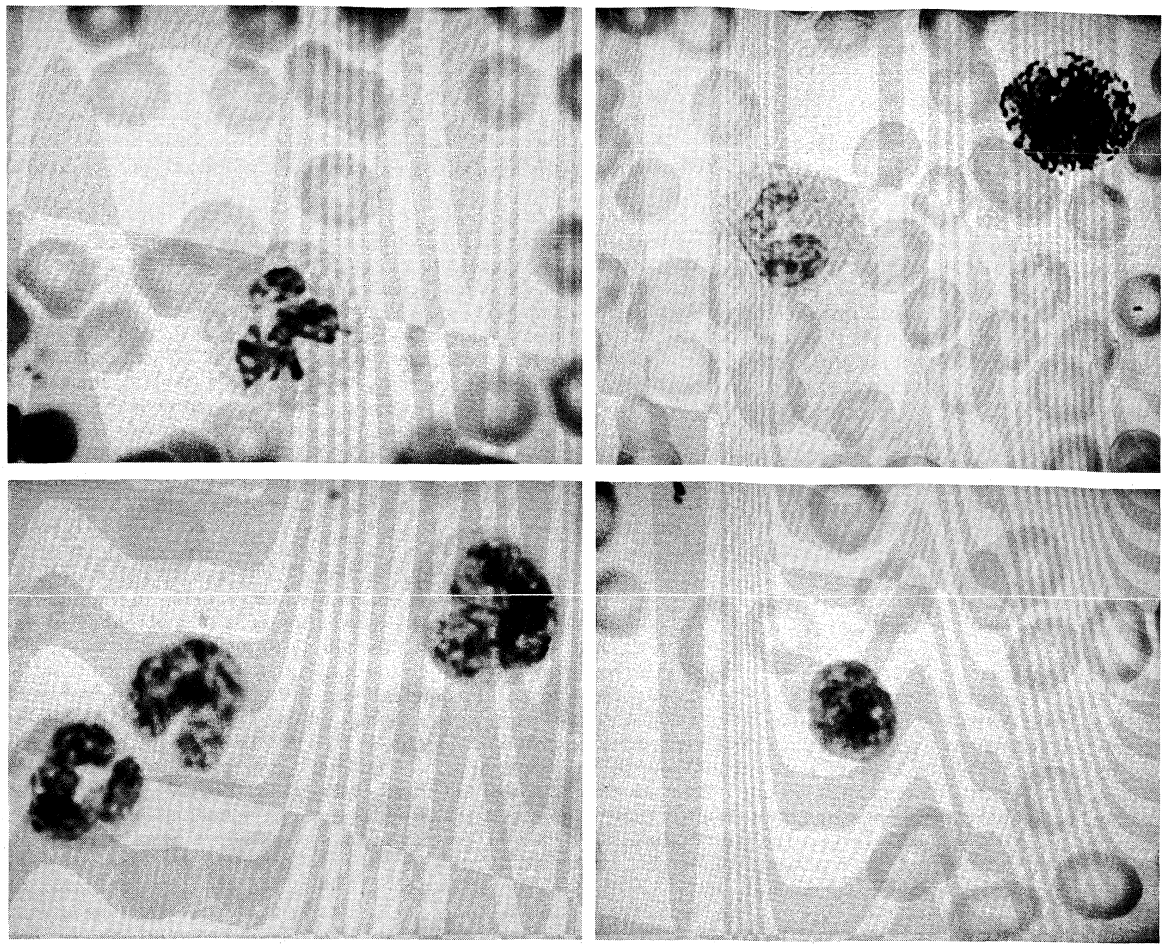
Removal of old and damaged red cells from circulation

Destruction of red cells. Red cells have a finite lifespan, on the average about 120 days. Although they utilize glucose to produce energy necessary for their survival, they are incapable of synthesizing protein; therefore reparative processes are not possible. As red cells age, wear and tear leads to loss of some of the protein, and the activity of some of the essential enzymes decreases. Chemical reactions necessary for survival of the cell are consequently impaired. The worn-out cells are removed from the circulation and rapidly destroyed. The normal process of destruction does not involve hemolysis with release of hemoglobin into the plasma. Instead, the entire red cell is engulfed by certain phagocytic cells that form a part of the lining of blood vessels, particularly in the spleen, liver, and bone marrow. These cells form a part of the reticuloendothelial system. Reticuloendothelial cells are also found in the lymph nodes, in the intestinal tract, and as free-wandering cells or macrophages. As a group they have the ability to ingest not only other cells but also many other microscopic particles including certain dyes and colloids. Within the reticuloendothelial cells erythrocytes are destroyed with remarkable rapidity. Protein, including that of the hemoglobin, is broken down, and the component amino acids are transported through the plasma to be utilized in the synthesis of new proteins. The iron removed from hemoglobin passes back into the plasma and is transported to the bone marrow, where it may be utilized promptly in the synthesis of hemoglobin in newly forming red cells. Iron not necessary for this purpose is stored within the reticuloendothelial cells but is available for release and reutilization whenever it is required. In the breakdown of red cells there is no loss to the body of either protein or iron, virtually all of which is conserved and reutilized. In contrast, the porphyrin ring structure of hemoglobin, to which iron was attached, undergoes a chemical change by which it is converted to bilirubin, a yellow pigment. Bilirubin released from reticuloendothelial cells after the destruction of erythrocytes is conveyed through the plasma to the liver, where it is extracted and secreted as bile pigment. The amount of bilirubin produced and secreted into the bile is determined by the amount of hemoglobin destroyed.

Disposal of products of red cell destruction

White blood cells (leukocytes). White cells, unlike erythrocytes, are nucleated and independently motile. Highly differentiated for their specialized functions, they do not undergo mitosis (ordinary cell division) in the bloodstream, but some retain the capability of cell division. As a group they are concerned with defense mechanisms and reparative activity. The number of leukocytes in normal blood ranges between 4,500 and 11,000 per cubic millimetre. Fluctuations occur during the day; lower values are obtained during rest and higher values during exercise. Violent physical exertion may cause the count to exceed 20,000 per cubic millimetre. Most of the leukocytes are outside of the circulation, and the few in the bloodstream are in transit from one site to another. As living cells, their survival depends on their continuous production of energy. The chemical pathways utilized are more complex than those of the red cells and are similar to those of other tissue cells. Leukocytes, containing a nucleus and able to produce RNA, can synthesize protein. They comprise three classes of cells, each unique as to structure and function, and designated granulocytes, monocytes, and lymphocytes.

Granulocytes. Most numerous of the white cells are the granulocytes, cells larger than red cells, having a multilobed nucleus and containing large numbers of cytoplasmic granules (*i.e.*, granules in the cell substance outside the nucleus). There are three types of granulocytes: neutrophils, eosinophils, and basophils. They are identi-



Types of white blood cells with red blood cells in background.

C. Lockard Conley

fied by the colour of the granules when the cells are stained with a compound dye. The granules of the neutrophil are pink, those of the eosinophil are red, and those of the basophil are blue black. About 60 percent of the white cells are neutrophils, while the eosinophils and basophils together comprise no more than 3 percent.

Neutrophils

The neutrophilic granulocytes are cells of fairly uniform size with a diameter between 12 and 15 microns. When examined in fresh blood that has not been allowed to dry, they display marked activity characterized by amoeboid motion: they extend long projections called pseudopods into which their granules flow and in this way rapidly advance along a surface. The nucleus consists of two to five lobes joined together by hairlike filaments. Within the body the neutrophils migrate to areas of infection or tissue injury. The attractive force that determines the direction of motion is known as chemotaxis and is attributed to substances liberated at sites of tissue damage. Neutrophils are actively phagocytic: they engulf bacteria and other fine particles and they may destroy living microorganisms. The granules of the neutrophil are microscopic packets of potent enzymes capable of digesting many types of cellular materials. When a bacterium is engulfed by a neutrophil, it is encased in a membranous sphere or vacuole. The granules empty their contents into the minute compartment containing the infectious organism. As this phenomenon occurs, the granules of the neutrophil are depleted (degranulation). Digestion of the invading organism is accomplished by the enzymes that surround it, and the organism is destroyed. Enzymes of the granulocyte are important not only in the elimination of micro-organisms but also in the removal of dead cells in areas in which tissue has been injured. Granulocytes, themselves, may be destroyed during the process.

Eosinophils and basophils, origins of granulocytes

Eosinophils, like neutrophils, are motile and actively phagocytic. They tend to be involved in tissue reactions in which there are antigen-antibody interactions. Less certain information is available about the specific function of the basophils.

The origin of all of the granulocytes is the bone marrow, and there is evidence that cells from which they arise, called stem cells, are the same line of cells as that which gives rise to the red cell precursors. The earliest cell recognizable as a precursor of the granulocytes is a myeloblast, extremely different in appearance from the mature cell. Granulocytic cells in various stages of development form the major component of the blood-forming cells within the bone marrow. The marrow contains a large reserve of mature granulocytes that can be released into the circulation when needed; it is thought to contain about a dozen times more mature granulocytes than are present in the blood. Within the circulation the neutrophils are not uniformly distributed in the blood but tend to concentrate along the membranes of the small blood vessels. Granulocytes needed to combat local infection may be derived from this "marginal pool" as well as from an increased output by the bone marrow. An equilibrium is normally maintained between the number of cells entering and leaving the blood. Granulocytes remain in the circulation for only a few hours, and after leaving it they do not return. A small number of these cells are found in the various secretions of the body, and many are removed by the reticuloendothelial system. Vast numbers may accumulate at sites of inflammation. From the time of their emergence from the bloodstream to the time of their loss or destruction the granulocytes are distributed through tissue spaces in numbers much larger than their number in the circulation.

Equilibrium between cells entering and leaving blood stream

The relative constancy of the granulocyte count in the blood implies that some control mechanism exists. Factors of hormonal nature, perhaps comparable to erythropoietin, probably influence the rate at which granulocytes are produced as well as the rate at which they are released from the bone marrow into the circulation. Definitive information about these control mechanisms is not yet available.

Characteristics and functions of monocytes

Monocytes. The largest cells of the blood are the monocytes, which make up on the average about 7 percent of the leukocytes. The nucleus is relatively big and tends to be indented or folded rather than multilobed. The cytoplasm contains large numbers of fine granules, which often appear to be more numerous near the cell membrane. Monocytes are actively motile and phagocytic. They are capable of ingesting infectious agents as well as red cells and other large particles, but they cannot replace the function of the neutrophils in the removal and destruction of bacteria. Closely related to the phagocytic cells of the reticuloendothelial system, they are considered to be scavengers and may enter areas of inflamed tissue later than the granulocytes. Often they are found at sites of chronic infections. Most of the available information about the origin and migrations of monocytes has been obtained from the study of animals. Few monocytes or cells identifiable as precursors of monocytes are seen in human bone marrow, but in the mouse there is evidence that monocytes have a marrow origin. The large phagocytic cells of the tissues, the macrophages, appear to have their origin from the blood monocytes.

Lymphocytes. About 30 percent of the white cells of the blood are lymphocytes. They have a single round nucleus and few if any granules in the cytoplasm. Most lymphocytes are small, only slightly larger then erythrocytes, with a nucleus that occupies most of the cell. Some are larger and have more abundant cytoplasm that stains blue. Lymphocytes are sluggishly motile, and their paths of migration outside of the bloodstream are very different from those of granulocytes and monocytes. Lymphocytes are found in large numbers in the lymph nodes, spleen, thymus, tonsils, and lymphoid tissue of the gastrointestinal tract. They enter the circulation through lymphatic channels that drain principally into the thoracic lymph duct, which has a connection with the venous system. Unlike other blood cells, some lymphocytes may leave and re-enter the circulation, surviving for about a year or more. The principal paths of recirculating lymphocytes are through the spleen or lymph nodes. Lymphocytes freely leave the blood to enter lymphoid tissue, passing barriers that prevent the passage of other blood cells. When stimulated by antigen and certain other agents, some lymphocytes "transform" to immature cells capable of cell division.

Functions and types of lymphocytes

The lymphocytes are concerned with vital defense mechanisms pertaining to acquired immunity to foreign cells and antigens. They are responsible for immunologic reactions to invading organisms and to foreign cells such as those of a transplanted organ or a cancer. In addition, they are involved in immunologic reactions to foreign proteins and other antigens not necessarily derived from living cells. Two classes of lymphocytes are recognized, indistinguishable by the usual microscopic examination. One class, represented by a small fraction of the blood lymphocytes, is capable of producing immunoglobulins, including various types of antibodies. These cells, when appropriately stimulated by a particular antigen, synthesize the corresponding antibody. The other class of lymphocytes, which includes most of those in the blood, is concerned with cell-mediated immunity. These are the lymphocytes that participate in the rejection of transplanted tissues and are involved in certain types of allergy.

In birds the differentiation of these two classes of lymphocytes is known to be dependent upon two organs. The cells capable of producing antibody have differentiated under the influence of lymphoid tissue in an outpouching of the gastrointestinal tract known as the bursa of Fabricius. Lymphocytes concerned with cell-mediated immune reactions have acquired their properties as the result of an influence of the thymus (see below). Lymphoid cells in various parts of the body have the properties of one or the other class. Whether a comparable relationship exists in man is uncertain, although there is abundant evidence of the role of the human thymus in immunologic reactions, and lymphoid tissue is plentiful in the gastrointestinal tract.

Thymus, rejection of foreign tissues

The thymus is a small organ lying behind the breastbone in the upper portion of the chest. It is relatively large at birth, begins to regress after puberty, and may be represented only by a fibrous cord in the elderly. During embryonic life, lymphocytes appear in the thymus before they are found elsewhere in the body. The effect of the thymus on the differentiation of lymphocytes begins before birth, and lymphocytes leaving the thymus populate lymphoid tissue elsewhere. Removal of the thymus from certain animals at the time of birth prevents the development of normal immunologic responses. The manner in which the thymus induces the differentiation of lymphocytes is unknown.

A primary function of the lymphocytes is to permit the body to distinguish its own tissues from material of foreign origin. If skin is removed from one part of the body and transplanted to another area of the same person, it will adhere and survive. On the other hand, if skin from one person is transplanted to another (other than an identical twin) the graft will be rejected. This is the result of an important protective mechanism that prevents the proliferation of foreign cells within the host, but it is also the mechanism that makes organ transplantation difficult. Rejection of a tissue graft is largely accomplished by cell-mediated immunity; lymphocytes migrate to the area of the graft and cause its destruction. Cell-mediated immunity is involved in other reactions including the tuberculin reaction: when persons who have had tuberculosis have an extract of the tubercle bacillus injected into their skin, a "positive" response occurs, an inflammatory reaction at the site of injection. The "positive" reaction is mediated by cells previously "sensitized" by the tuberculous infection; antibody is not involved. On the other hand, when a person has been infected or immunized with polio virus, antibodies are produced that are detectable in the serum. The ability to acquire immunity to foreign substances is called immunologic competence. Immunologic competence begins to develop during embryonic life, is incomplete at the time of birth, but is fully established soon after birth. If an antigen is introduced into the body before immunologic competence has been established, the individual will not subsequently develop immunologic reactions to it and is said to be tolerant to that antigen.

Tuberculin reaction, immunologic competence, immune tolerance

Study of immunologic competence and immune tolerance has been accelerated by interest in organ transplantation. Success of kidney transplants has been improved by increased knowledge about donor selection and techniques for suppressing the immune responses of the recipient. Comparable success has not yet been achieved with heart transplants.

Platelets (thrombocytes). The blood platelets are the smallest cells of the blood, averaging about two microns in diameter. Although much more numerous (150,000 to 300,000 per cubic millimetre) than the white cells, they occupy a much smaller fraction of the volume of the blood because of their relatively minute size. Like the red cells they lack a nucleus and are incapable of cell division, but they have a more complex metabolism and internal structure than have the red cells. When seen in fresh blood they appear spheroid, but they have a remarkable tendency to extrude hairlike filaments from their membranes. They adhere to each other, but not to red cells and white cells. In stained preparations of dried blood, platelets have a central granular area, the granulomere, and a peripheral, more clear area, the hyalomere. The granules contain substances important for the activity of platelets.

The function of the platelets is related to hemostasis, the prevention and control of bleeding. When the endo-

thelial surface (lining) of a blood vessel is injured, platelets in large numbers immediately attach to the injured surface and to each other, forming a tenaciously adherent mass of platelets. The mechanism of this reaction is not clearly understood, but platelets have an intrinsic "stickiness"; they tend to adhere to foreign surfaces and to collagen, an important component of normal connective tissue. The effect of the platelet response is to terminate bleeding and to form the site of the developing blood clot or "thrombus." If platelets are absent, this important defense reaction cannot occur, and protracted bleeding from small wounds (prolonged "bleeding time") results. The normal resistance of capillary membranes to leakage of red cells is dependent upon platelets. Severe deficiency of platelets reduces the resistance of the capillary walls, and abnormal bleeding from the capillaries occurs, either spontaneously or as the result of minor injury. Platelets also contribute substances essential for the normal coagulation of the blood, and they cause the shrinking, or "retraction," of a clot after it has been formed.

Effect of thrombin

Platelets are uniquely susceptible to the enzymatic action of thrombin, the substance responsible for converting fibrinogen to fibrin. Thrombin causes platelets to aggregate and to undergo irreversible structural and biochemical changes during which their survival as living cells is terminated. When a blood clot is formed by the action of thrombin, platelets display remarkable distortions of their membrane and extrude bulbous and threadlike pseudopods. The newly forming fibrin strands appear to become attached to the platelet filaments. The platelets subsequently draw together, causing the retraction of the clot. Platelets contain a contractile protein, thrombosthenin, which undoubtedly plays an important part in this phenomenon. On exposure to thrombin and certain other agents, the platelets release through their membranes some of their contents, including potassium and the substances that participate in the coagulation of the blood. Adenine diphosphate, one of the substances released, appears to be important in causing platelet aggregation. Platelets are capable of removing from the plasma and storing in high concentration certain chemical agents, including serotonin, a substance that causes constriction of small blood vessels. Serotonin is rapidly released when platelets aggregate and probably plays a part in control of bleeding by reducing the size of injured vessels.

Platelets are formed in the bone marrow by segmentation of the cytoplasm (the cell substance other than the nucleus) of giant cells known as megakaryocytes, the largest cells of the marrow: during differentiation in the marrow the megakaryocyte becomes large, and multiple nuclei appear; the abundant granular cytoplasm of the megakaryocyte divides into many little segments that break off and are released as platelets into the circulating blood. After about ten days in the circulation, platelets are removed and destroyed. There are no reserve stores of platelets except in the spleen, in which platelets occur in higher concentration than in the peripheral blood. Some platelets are consumed in exerting their hemostatic effects, and others, reaching the end of their life-span, are removed by reticuloendothelial cells. The rate of platelet production is controlled, but not so precisely as the control of red cell production. A hormone-like substance, thrombopoietin, as yet unidentified, is believed to be the chemical mediator that regulates the number of platelets in the blood by controlling the rate of platelet production.

EXAMINATION OF THE BLOOD IN THE LABORATORY

Physicians rely upon the clinical laboratory to obtain measurements of many constituents of the blood, information useful or necessary for the detection and recognition of disease. Some tests, such as one to detect anemia, are so regularly performed as a part of the health examination that they are considered routine. Hemoglobin is a highly coloured pigment that interferes with the passage of a beam of light. To measure hemoglobin concentration, blood is accurately diluted and the red cells broken down to yield a clear red solution. A photoelectric instrument is employed to measure the absorbance of transmitted light, from which hemoglobin concentration can be calculated. Hemoglobin is a relatively unstable pigment, and the best methods to measure it employ chemicals to form hemoglobin derivatives, in particular cyanmethemoglobin, with which more accurate measurements can be made. Changes in the hemoglobin concentration of the blood are not necessarily directly paralleled by changes in the red cell count and the hematocrit value, because the size and hemoglobin concentration of red cells may change in disease. Therefore, measurements of the red cell count and hematocrit value may provide additional useful information. Red cells can be counted visually with the use of a microscope. Highly diluted blood is introduced into a "counting chamber," a device in which a film of fluid of precisely controlled thickness is superimposed upon an accurately ruled grid, permitting the enumeration of cells in a predetermined volume of diluted blood. The method is laborious and imprecise and has been largely abandoned in favour of electronic particle counters that make possible extremely accurate red cell counts within a few seconds. The hematocrit value is obtained, after centrifuging blood in a tube of uniform diameter, by measuring the percentage of the blood column that is occupied by the packed red cells; an anticoagulant is required to prevent clotting during the test procedure. Variations in the leukocyte count beyond the normal range occur in many diseases. White cell counts can be performed with the counting chamber or with the electronic device; the blood is diluted and the red cells destroyed by hemolysis before the count is performed. Complex automated machines are available that simultaneously determine the hematocrit value, the hemoglobin concentration, and white cell and red cell counts. Only a tiny drop of blood is needed for the analyses, which are completed within a minute; results are printed out on a laboratory report that is sent to the doctor. Although expensive, the equipment increases the output of the laboratory and saves the technician valuable time.

Red cell count

Adequate examination of the blood cells requires that a thin film of blood be spread on a glass slide, stained with a special blood stain (Wright's stain), and examined under the microscope. Individual red cells, white cells, and platelets are examined, and the relative proportions of the several classes of white cells are tabulated. The information acquired may have important diagnostic implications. In iron deficiency anemia, for example, the red cells look paler than normal because they lack the normal amount of hemoglobin; in malaria the diagnosis is established by observing the malarial parasites within the red cells. In pneumonia and many infections the proportion of neutrophilic leukocytes is usually increased, while in others, such as whooping cough and measles, there is an increase in the proportion of lymphocytes.

Examination of individual cells

Chemical analyses are employed to measure many of the constituents of plasma. Often serum rather than plasma is used, since it can be obtained from clotted blood without the addition of an anticoagulant. Tests can be performed manually, with an individual procedure for each analysis. Quantitative determination of the amount of sugar in the blood is essential for the diagnosis of diabetes, a disease in which the blood sugar tends to be elevated. Nitrogenous waste products, in particular urea, tend to accumulate in patients with diseased kidneys that are unable to excrete these substances at a normal rate. An increase in the concentration of bilirubin in the serum often reflects a disorder of the liver and bile ducts, or an increased rate of destruction of hemoglobin. Measurements of these and many other serum constituents are so valuable in medical diagnosis that often multiple tests are performed. The autoanalyzer, a completely automated device, increases the number of procedures that can be performed in clinical laboratories. A dozen analyses may be made simultaneously by a single machine, employing a small amount of serum. The serum is automatically drawn from a test tube and is propelled through plastic tubing of small diameter. As the serum specimen

Chemical analyses

advances it is divided; appropriate reagents are added; chemical reactions occur with formation of a product that can be measured with a photoelectric instrument; and the result appears as a written tracing from which serum concentration of various substances can be read directly. The data acquired by the machine may be fed automatically into a computer and the numerical results printed on a form that is submitted to a physician. Many analyses are not performed routinely but are invaluable in special circumstances. In cases of suspected lead poisoning, for example, detection of an elevated level of lead in the blood may be diagnostic. Some analytical procedures have specific diagnostic usefulness. These include assays for certain hormones, including measurement of the thyroid hormone in the serum of patients suspected of having thyroid disease.

Immunologic reactions of blood

Other clinically important laboratory procedures are concerned with immunologic reactions of the blood. Careful determinations of the blood groups of the patient and of the blood donor, and cross matching of the cells of one with the serum of the other to ensure compatibility, are essential for the safe transfusion of blood. Determination of the Rh type of the pregnant woman is regularly performed and is necessary for the early detection of fetal-maternal incompatibility and for proper prevention or treatment of hemolytic disease of the newborn. The diagnosis of certain infectious diseases depends upon the demonstration of antibodies in the patient's serum. A serologic test is used routinely for the detection of syphilis.

Other procedures

Radioactive substances are used for special types of tests, including measurements of blood volume and estimation of the life-span of red cells. Many other kinds of blood examination yield useful results. Enzymes normally present in the muscle of the heart may be released into the blood when the heart is damaged by a coronary occlusion (obstruction of the coronary artery). Measurement of these enzymes in the serum is regularly performed to assist in diagnosis of this type of heart disease. Damage to the liver releases other enzymes, measurement of which aids in evaluation of the nature and severity of liver disease. Inherited abnormalities of proteins are increasingly recognized and identified by use of sophisticated methods. Accurate diagnosis of hemophilia and other bleeding disorders is made possible by investigations of the coagulation mechanism. Measurements of the concentration of certain vitamins in the blood provide the basis for diagnosis of some vitamin deficiencies. The number of potentially useful blood tests is so vast that they must be selected judiciously in the evaluation of the individual patient.

Blood and Lymph

The circulatory system, which contains blood and lymph, is an important connecting pathway; it permits a continuous integration among various tissues and organs of animals and facilitates contact with the environment outside the body. Blood is a cell-containing fluid that transports oxygen, water, carbon dioxide, products of metabolism, and internal secretions (*e.g.*, hormones). Blood is a tissue that is constantly circulating throughout animals, a means by which the constancy of the internal environment is maintained, and it is also the route by which the defenses against injury and disease may be quickly mobilized. Lymph is a fluid that is derived from the tissues of animal bodies and conveyed to the blood stream by lymphatic vessels.

This article compares blood and lymph in a number of living systems. For more specific information about blood in man, see BLOOD, HUMAN.

GENERAL FEATURES

Definitions. Blood in mammals may be defined as the red fluid that is pumped by the heart into arteries and returns to the heart in veins, following a complex but completely closed circular path. The red colour of mammalian blood is caused by hemoglobin, an oxygen-carrying protein in red cells (erythrocytes). Mature red blood cells of mammals, which contain no nuclear component, are disk shaped and float in a nearly colourless liquid called plasma. Plasma also contains white cells (leukocytes) and tiny bodies called platelets, which seal wounds. The grainy cytoplasmic component of one type of white cell, called granulocytes, constantly changes shape, engulfing and destroying unwanted particles. A nongranular type of white cell (lymphocytes) originates in mammalian lymphoid tissue (*e.g.*, spleen, lymph nodes) and has important immunological functions. Lymph, a rather colourless, sometimes milky liquid, drains from the tissues into lymph vessels, which converge into a thoracic duct, which empties into the blood. The above definitions of blood and lymph also apply (with modifications) to vertebrates other than mammals; *i.e.*, the red cells of other vertebrates contain nuclei but are red, except in the icefish, which has colourless blood. White cells vary in shape not only among vertebrates but even among mammals. The platelets of mammals resemble tiny disks of cytoplasm, but those of other vertebrates have nuclei.

Invertebrate animals have a great variety of liquids, cells, and modes of circulation. In insects, a heart pumps fluid, called hemolymph, through an open system to the tissues. In some worm species the fluid contains pigmented cells, but the fluid, called coelomatous fluid, does not circulate; in others the fluid circulates, but the cells may contain no pigment.

Perhaps blood should be defined by its functions, rather than by its appearance—when passing through skin, gills, or lungs, blood picks up oxygen from outside the body and loses carbon dioxide that was picked up in the metabolizing tissues; when passing through tissues, blood does the reverse and also picks up metabolized food, which maintains the cells of the body, and passes poisonous molecules and excess water to the kidneys for excretion.

Origin. How did the need for blood and lymph arise? Life probably originated in the oceans from molecules that accidentally developed an ability to reproduce, to form cells, and to evolve by reproducing many of the accidental changes (mutations) that occurred in their hereditary material. Most of the early cells must have developed certain deficiencies, and many survived only if they also developed the ability to depend on other cells, either as food sources or for transporting food, oxygen, and waste products.

Eventually, aggregations of specialized cells became organized into bodies whose inner cells lost contact with the outer world and with each other. An electronic system (the nervous system) and liquid systems of blood and lymph developed to provide communication among specialized body regions. In addition, as organs became complicated, both structurally and functionally, they developed a mechanism (hormones) for transmitting, receiving, and integrating information. A hormone is formed in one organ and transported in the blood to another site, where its major effect is exerted. An increase in blood sugar, for example, causes an increase in synthesis (in the pancreas) of the hormone insulin, which causes a decrease in blood sugar; an increase in the activity of the pituitary gland, in the brain, causes an increase in the activity of the adrenal glands, near the kidneys; and adrenal secretions in turn cause a decrease in pituitary activity. Mechanisms such as those provided by hormones enable a multicellular organism to outlive the individual cells comprising it; the removal of dead cells and of other particles too large to be transported by the blood to the kidneys for excretion is carried out by white cells.

Hormones

The blood has a mechanism that prevents its being emptied through wounds. Platelets in mammals and cells called thrombocytes in other vertebrates aggregate at a wound site, and, in the plasma near them, a clot, composed of a protein called fibrin, forms. Invertebrates may rely on the motion of cells to plug their wounds.

In the brief discussion of blood and lymph that follows, it may seem as if in species most alien to man the least sophisticated fluids exist; *i.e.*, fewer and less specialized proteins occur, as well as more primitive, all-purpose cells, but this may reflect limitations of knowledge.

PLASMA

Small molecules and the regulation of water content. Water molecules, which are the main component of body fluids, probably form clusters that break up rapidly except at water-repellent surfaces (*e.g.*, as provided by fats), where the clusters are more stable and icelike. The complex mixture of fatty and nonfatty structures in cell membranes, therefore, profoundly affects the behaviour of water and the substances dissolved in it. Although water itself and certain small molecules and ions (charged particles) pass through the membranes of all active cells, certain other molecules cannot; urea, an organic compound larger than most ions, however, apparently passes into cells by disrupting water clusters.

When two solutions containing different quantities of a substance are separated by a membrane that allows only water to pass (a semipermeable membrane), water flows through the membrane to the solution containing the most substance, in an attempt to equalize the concentrations on both sides of the membrane. When a cell is placed in water, therefore, it swells, because water passes into the cell through the membrane in response to the dissolved molecules and ions inside the cell; these particles are said to exert an internal pressure, called osmotic pressure, which may cause the cell to burst, or lyse (or, in the case of blood cells, hemolyse). If a cell is placed in a solution containing a higher concentration of a substance than that found in the cell, water leaves the cell through the membrane, and the cell assumes a wrinkled, or crenated, appearance. Living cells, including the blood cells in plasma, must expend metabolic energy to maintain an osmotic equilibrium.

Cell lysis

The salt concentrations in present-day seas are higher than those within cells. Invertebrate animals capable of regulating the water content of their circulating body fluids usually lower it to about two-thirds that of the surrounding ocean; aquatic mammals also are able to perform this physiological regulation. Other animals apparently need no such regulation. The body fluids of echinoderms, for example, resemble seawater; among crustaceans, the shore crab (*Carcinus*) regulates its water content, but the spider crab (*Maia*) does not. *Rhithropanopeus* is able to swell when it must molt; its eyestalks produce a hormone that prevents water inflow at other times. Animals that cannot regulate their water content and thus tolerate only a narrow range of salt concentrations (stenohaline animals) probably are restricted to oceanic life; animals that are able to regulate their water content (euryhaline animals) are free of this restriction. Mechanisms other than those involving a circulating body fluid, however, enable certain animals to regulate their water content; *e.g.*, some coelenterates and flatworms (Platyhelminthes), which live in freshwater, utilize a diffusely branched system to remove water.

Some cyclostomes (hagfish and lampreys), among the most primitive fishes, live in the ocean, are permeable to water, and regulate their osmotic pressure. Elasmobranch fishes (sharks and rays) maintain a blood osmotic pressure above that of seawater by retaining urea, which is excreted rapidly in other vertebrates by the kidneys. The advantages to marine animals of maintaining specific osmotic pressures are not well known. Saltwater fishes lose some regulatory ability in the cold; as a result, the concentration of salts in the plasma increases, so that it acts as an "antifreeze." Fishes in freshwater also may be affected by cold, but their plasma loses ions, which means that it freezes more easily.

The ability of an animal to retain salts when moving to freshwater may have been a prerequisite to the evolution of animals capable of retaining both salts and water on land. The urine of freshwater fishes contains a low concentration of salts. Amphibians and many crabs return to water when some as yet unknown mechanism senses the need for water to dilute body fluids. A specific region in the brain of amphibians produces a hormone similar to the antidiuretic hormone of man, which regulates water retention. Among reptiles, the evolutionary success of crocodiles over dinosaurs may be attributable to the development in crocodiles of a skin more impermeable to water; certain crocodiles, however, when dehydrated, return to the water, taking in more water through the skin than by drinking.

Although a sense of thirst is necessary in all animals living on land, the composition of their internal fluids may vary. Most of the osmotic pressure in the plasma of water-dwelling crustaceans, for example, is provided by salts; half of that in land-dwelling insects is provided by organic compounds called amino acids.

Regulation of ion content in man

The regulation of the content of ions in the plasma of vertebrates, especially mammals, appears increasingly complex at higher evolutionary levels; but perhaps man seems most complex because he has been studied most. The plasma concentrations of ions such as sodium, potassium, and calcium are regulated by hormones; but human emotional stress increases the activity of the adrenal glands, whose secretions affect the transport of sodium and potassium ions across cell membranes.

Glucose has relatively little effect on the osmotic pressure of plasma, but it is an important source of energy in cells; it must be available at all times, therefore, within controlled levels. Blood-glucose levels in vertebrates are regulated by two hormones formed in the pancreas, insulin and glucagon. Insulin, synthesized when plasma-glucose concentration increases, stimulates the liver to convert excess glucose into a storage compound, glycogen. Glucagon acts in the opposite way; *i.e.*, it increases abnormally low levels of plasma glucose. Among vertebrates, either hormone may dominate in maintaining the proper levels of plasma glucose, whose concentration is profoundly affected by feeding and by stress.

Because fatlike substances do not dissolve in water and force a specific arrangement of water molecules around them, they usually circulate surrounded by protein molecules, so that their water-hating (hydrophobic) areas do not come in contact with water in the plasma.

Proteins and their various roles. There are about 20 kinds of amino acids that link together in a specific order to form protein molecules. Each amino-acid sequence is determined by heredity; in turn, the sequence of amino acids determines the shape of each protein. A mosaic-like arrangement of amino acids with positive and negative charges may comprise most of the exposed parts of a protein molecule; other amino acids, which are hydrophobic, are found inside the coil-shaped molecule and thus do not come in contact with water surrounding it. The function of a protein molecule depends on its shape.

During evolution, a chance mutation may result in the replacement of one amino acid in a specific protein molecule by another. If the newly inserted amino acid destroys the function of the protein, an organism may die; on the other hand, the loss of a protein function by mutation may be compensated for by another mutation, either in the protein molecule itself or in some other one. If an animal survives a partial loss of function, the loss may be discovered if the animal becomes ill. Many proteins function as enzymes (biological catalysts); some enzymes (*e.g.*, several blood-clotting factors) have been shown to exist only because people born without them develop specific symptoms. Mutations that do not affect function can be discovered only by analyzing proteins whose sequences of amino acids have been established. The insulin of vertebrates, whose amino-acid sequence has been established, functions only if the two functional chains comprising the molecule are not altered; a mutation in the nonfunctional section that connects the chains does not inactivate the molecule.

Species-specific enzymes

Since an enzyme catalyzes a reaction involving a specific compound, it can be identified. An enzyme whose shape must change before it becomes active or a protein involved in the structure of an organism usually can be distinguished only by crude tests. Many active enzymes function efficiently only with molecules prepared from the same species. Although others (*e.g.*, insulin, blood-clotting Factor VIII) derived from one mammalian species will function if injected into another species, they act as antigens; *i.e.*, they stimulate formation of proteins called antibodies in the injected species. These enzymes, therefore, are recognized in the injected animal as foreign in composition, if not in function. The specificity of proteins for their own hosts has limited the understanding of their functions in species remote from man. Crude separation of plasma proteins carried out in mammals other than man show that proteins such as albumin and alpha, beta, and gamma globulins occur in them.

Albumin, a rather small protein that dissolves in water, comprises more than half the total proteins found in mammalian plasma, contributes to the blood osmotic pressure, and transports certain ions and fatty acids. Yet, humans born without it appear normal. The second most abundant protein in mammalian blood is a long, large molecule called fibrinogen. When blood clots, a series of enzyme interactions converts an inactive plasma enzyme (prothrombin) into an active enzyme (thrombin) that removes two pairs of amino-acid groups from each fibrinogen molecule to convert it into a molecule called a fibrin monomer. Molecules of the fibrin monomer then link together to form strands of fibrin, the visible clot. The remaining liquid, plasma lacking fibrinogen, is called serum. Fibrinogen, prothrombin, and many other proteins are formed in the liver. In animals other than mammals, some clotting enzymes, as well as the events that trigger their interactions, may be restricted to the cytoplasmic component of specific sensitive cells (see below *Thrombocytes and platelets*).

Gamma globulins are produced by plasma cells and lymphocytes that probably occur only in vertebrates. Some other globulins carry specific metal ions, which colour them—*e.g.*, mammalian transferrin, which carries iron, is brown, and ceruloplasmin, which carries copper, is blue. The most deeply coloured globulins have a specific slot in which they carry a flat molecule (heme) containing iron. In vertebrates, four globulin-heme moieties form one hemoglobin molecule in the red cells, where it remains until the cells die. Many polychaete worms have developed a similar protein; slight difference in the structure of its heme, however, makes it green in colour. A variety of polychaete blood proteins exists. The noncirculating coelomic fluid of some polychaetes contains hemoglobin; other polychaetes have two hemoglobins—one in the plasma and another in coelomic cells. Hemoglobin predominates in young *Serpula* polychaetes, green pigment (chlorocruorin) in older ones, and another polychaete, *Arenicola*, has a very large hemoglobin molecule. Hemocyanin, a large protein molecule that contains copper and turns blue when it takes up oxygen, occurs in many mollusks, where it may be the main plasma protein. All the pigment types mentioned pick up oxygen molecules easily and release them where they are needed. A change of shape in each hemoglobin subunit accompanies oxygen uptake or release and is transmitted to the other units in a way that facilitates the process (see COLORATION, BIOLOGICAL).

Hemoglobin

FORMED ELEMENTS

Red cells (erythrocytes). The hemoglobin in the plasma of some worms allows them to carry about ten times more oxygen than can an equal volume of seawater. The localization of hemoglobin in red cells increases this capacity another four times. The evolution of cells with such a singular function is traceable by arranging species in order of the increasing oxygen-carrying efficiency of their red cells. The mature red cells of mammals lack nuclei. Not only does a nucleus take space; it also requires oxygen; mammals, therefore, have the most efficient red cells, at least so far as oxygen-carrying ability is concerned. It thus is tempting to presume that, if no further evolutionary progress occurs, even though mutations continue, a maximum efficiency has been attained. Indeed, one can say that in the following aspects, evolution of red cells apparently stopped long ago: the total volume of red cells in proportion to the total volume of blood varies relatively little among mammalian species; in addition, all normal red cells have about the same high concentration of hemoglobin, above which the molecules would soon interfere with each other or even form crystals. On the other hand, the diameter of red cells varies greatly, ranging from less than 3 to more than 9 microns (1 micron is 0.001 millimetre). Both Indian and African elephants have large red cells (9.2 microns in diameter), but no clear relationship between red-cell size and total body size exists among other species. Red cells apparently became smaller as life on land developed or evolution in general progressed, but the relationship between red-cell size and evolutionary advancement is not clear. The supposedly primitive hagfish, for example, has red cells 26.4 microns long; those of the related lamprey are only 14.3 microns. The red cells of many sharks, about as large as those of some amphibians, are larger than those of many other fishes.

Evolution and red-cell size

The disk-shaped mature erythrocytes of most mammals have thick, rounded edges and lack nuclei. When such a cell is cut in half, both halves may assume a disk shape and resemble small red cells. Certain membrane components in the smallest red cells (two to four microns in diameter), which occur in ruminants such as cows, occur in a proportion different from that in other mammalian red cells. The fact that red cells are thin in the centre may increase their efficiency in gas transport. The efficiency of gas exchange and transport may be increased also by the fact that the shape of red cells can be distorted into cones, clubs, and dumbbells as they pass through the extremely narrow blood capillaries.

Perhaps red and white blood cells originate in the same cells in bone marrow. The need for red cells is conveyed in mammals by a protein (erythropoietin). The protein is formed by the action of a substance (erythrogenin), synthesized by the kidneys when they lack oxygen, on another molecule (erythropoietinogen), which is synthesized in the liver. A severe loss of red cells and the subsequent decrease in available oxygen is normally followed by a flood of young red cells, which still have nuclear material. The mature red cells of mammals contain many enzymes important for their maintenance and partly responsible for their death when they fail; the oldest cells, therefore, should die first, and they do in some mammals (*e.g.*, mouse, dog, and man); in other species, however, red-cell death may occur at any age in an apparently random manner. Although it has been suggested that red cells must pump out sodium ions and retain potassium ions to survive, dogs and some other mammals have about the same proportions of sodium and potassium ions in both red cells and surrounding plasma; yet their cells live no longer than do those of man. On the other hand, the less heat a vertebrate species produces, the longer its red cells live: turtle erythrocytes, for example, live longer than those of man; red cells of birds and mice have a shorter existence.

Extreme differences between sodium- and potassium-ion concentrations in erythrocytes exist in various species (see Table) and even within breeds in one species.

White cells. All poorly pigmented cells normally found floating in blood, hemolymph, or coelomic fluid may be called leukocytes, although those in the hemolymph and coelomic fluid of invertebrates are often called hemocytes and coelomocytes, respectively. White cells in hemolymph and coelomic fluid include cells that eat (phagocytize) foreign particles, as do the granulocytes of mammals; cells that recognize and chemically attack only specific foreign matter, as do the lymphocytes and plasma cells of mammals; and cells that clump together when disturbed, as do the thrombocytes. The distinctions among functions and blood-cell types of animals other than man, however, have not yet been clearly established.

Concentration of Potassium and Sodium Ions in Plasma and Red Cells of Certain Vertebrates

	potassium ions*		sodium ions*		percentage of red cells replaced per day
	red cells	plasma	red cells	plasma	
Man	95	4	19	138	1
Dog	8	4	97	143	1
Chicken	119	6	18	154	3

*Milli-equivalents per 1,000 millilitres.

A superficial resemblance exists among some mammalian blood cells and those of other animals. Some white cells of sea cucumbers (Holothuroidea), for example, resemble mammalian white blood cells called basophils; gastropod mollusks have cells that resemble lymphocytes and granular amoebocytes that resemble certain granulocytes of man (eosinophils); crustaceans have coelomocytes that clump around foreign cells and eat them; and insects have a multitude of hemocytes, some of which resemble human white cells while others do not. The evolution of insects and other arthropods diverged from that of man and other chordates so long ago that the blood cells of these two animal groups do not provide any evidence of a common ancestry. The most active white cells in insects, called plasmatocytes, can spread either over surfaces of parasites, forming membranous capsules, or over foreign particles; often they become granular. Hemocytes, most abundant in the last immature stage (larval instar) of insects, decrease in numbers during the nonfeeding stage called pupation, after which, in certain insects, new cells are formed. When a pupa is injured, hemocytes appear to seal the wound; actual clotting in insects, however, is initiated by cells called cystocytes (coagulocytes). When hemolymph flows from a wound, cystocytes enlarge, break down, and either turn the plasma around them cloudy or form threads around which the plasma jells. Other insect hemocytes show no identifiable activity.

Plasmatocytes

Echinoderms and worms also contain blood cells very different from those of man. Echinoderm groups differ in their types of blood cells; all, however, have phagocytes to eat foreign particles, and other hemocytes to repair damage and to seal wounds. Echinoderm blood cells probably form from stem cells (so-called lymphocytes); active movement of cells within the heartless hemal system may transport food throughout the body. Hemoglobin-containing cells occur in some burrowing echinoderms. The variety of cells in hemal and coelomic fluids among echinoderms and even within various areas of one individual possibly reflects a range of requirements totally different from those of man, so that there are no blood kinships between man and echinoderms. Among vertebrates, relationships are clearer; *e.g.*, fishes and amphibians have granulocytes, lymphocytes, and, probably, a type of white cell present in human blood and referred to as a monocyte.

Thrombocytes and platelets. The thrombocytes of fishes, amphibians, reptiles, and birds resemble the cells that aggregate at wounds in invertebrates; in vertebrates, however, the plasma apparently has more responsibility in the clotting process. Since no thrombin (an enzyme involved in clotting) forms when thrombocytes are removed from the plasma of fishes, these cells, which break down on contact with a wound, must liberate substances that convert plasma prothrombin (an enzyme precursor) to thrombin, which then converts plasma fibrinogen into fibrin strands (a clot). In contrast to other vertebrates, the plasma of mammals contains an inactive protein, Factor XII, also called the Hageman factor. Mammalian Factor XII, upon contact with some hard foreign surface, becomes an active enzyme that initiates clotting. The contact-sensitive thrombocytes of other vertebrates are analogous to small disks of cytoplasm (platelets) in mammals. Platelets are derived from large bone-marrow cells (megakaryocytes). Although platelets aggregate in plasma under a variety of conditions, which also cause the aggregation of thrombocytes, and their clumping, or sticking, is accompanied by the liberation of several important substances, they contribute to the clotting of plasma only by making available a chemical component of their membranes (phospholipids). Platelets, however, are essential for sealing wounds in mammals.

Factor XII

Lymphocytes and lymph. Animals must recognize their own cells, so that they do not eat them. The system by which vertebrates protect themselves from foreign cells (*i.e.*, development of specific immunities), however, has not yet been found in the invertebrates. Hagfish appear to be the most primitive animals that have lymphocytes, form antibodies, and reject tissue grafts. From the higher fishes to man, lymphocytes and plasma cells become progressively more abundant, antibodies more specific, and tissue grafts less successful.

As blood flows through the capillaries, dissolved substances pass between the blood and the surrounding tissues. Most of these substances pass readily through the capillary walls, but a small amount of protein, once forced from the plasma, cannot return because the protein molecules are too large. This protein and waste fluids pass from the cells into the lymph vessels, which have much more permeable walls and within which the pressure is much lower than that in the capillaries. The fluids are pushed through the vessels by the motion of organs and muscles, their flow directed by valves along the way; in fishes, amphibians, reptiles, and some birds, a heartlike organ (the lymph heart) helps the circulation. As it flows, the lymph passes through many glandlike masses of tissue, called lymph nodes, and through the thymus, a glandular body present in all vertebrates. Birds have an extra lymphatic organ, the bursa of Fabricius. In all vertebrates, the lymph vessels combine, finally reaching a duct (*e.g.*, the thoracic duct in mammals) from which the lymph enters the venous bloodstream.

In very young animals, lymphocytes are formed in the thymus; later they form from cells in the bone marrow and are transported to, and deposited at, certain nodes or organs. The fate of each lymphocyte depends on the information or stimulation it receives at its point of deposition. The lymphocytes in gut-associated lymph tissues or those in the bursa of birds, for example, are apparently prepared to form antibodies if they are needed. In mammals, a lymphocyte at a lymph gland may be stimulated by a molecule (antigen) to form a specific antibody. Certain lymphocytes first form a globulin known as immunoglobulin M (IgM); then the lymphocytes divide, and each daughter cell receives some IgM. If stimulated again by more antigen molecules, the lymphocytes again divide, liberating their IgM and transforming into plasma cells that form a smaller globulin (IgG). Some antigen molecules probably remain with certain cells in the lymph node and eventually stimulate new lymphocytes passing the lymph node. Speed, intensity, and complexity of these reactions apparently increase from cyclostomes through elasmobranchs to bony fishes. Most of the globulins of fishes probably resemble human IgM. Amphibians, however, may be more advanced; bullfrogs form IgM, then IgG, or IgG first, depending on the type of antigen molecule injected. The antibodies formed by a bullfrog injected with serum of one mammalian species react with the serums of other mammals; the antibodies of mammals, however, are more specific. The serum of a rabbit immunized to serum of one fish species, for example, reacts less with serums of other fishes; in fact, the extent of interaction of the serums serves as a measure of evolutionary relationships among species.

Fate of lymphocytes

In vertebrates the thymus plays a role in determining which lymphocytes survive, apparently stimulating their division and then destroying undesired ones. Lymphocytes may spend only a few hours at a time in the blood and many months elsewhere. The variety of lymphatic systems among vertebrate species probably has some relationship to the immunological functions required for each. The ability of man's immunological system to distinguish differences in blood-group substances means that there are many blood incompatibilities; *i.e.*, few humans, unless they are twins, have completely identical sets of blood groups. Perhaps the thymus destroys cells that

know too much; *i.e.*, cells that would form antibodies against substances or tissues that are useful (see IMMUNITY).

HOMEOSTASIS

A large number of lymphocytes constantly are mobilized to fight random invasions in animals; the relatively low number of them that briefly reside in the blood at any time, however, remains remarkably constant. The complicated feedback systems that maintain a constant internal environment are called homeostasis. Homeostatic mechanisms mute the changes between rest and action or starving and eating, so that they provoke only small changes in the amounts of salts in cells and in the blood. The things that remain constant only with great effort are most precious to survival. These efforts result in variations in blood among different species; homeostasis, however, creates the uniformity within a species that allows distinctions to be made.

(L.V.)

Blood Circulation, Human

The circulatory system, in which the blood is propelled throughout the body, consists of four types of hollow containers: (1) the heart, or the central pump; (2) the arteries, or efferent vessels, delivering the blood to the tissues; (3) the capillaries, representing a fine network of very small vessels contained within the body tissues; and (4) the veins, larger vessels, returning the blood back to the heart. The quantity of blood within this closed system—the circulating blood volume—is, in the average adult, 5–6 litres, of which 60 percent is the liquid medium, plasma, and 40 percent the solid part, the blood cells. The entire amount of the circulating blood passes through each ventricle (lower chamber) of the heart every minute. The circulation consists of two complete cycles: the greater circulation, termed the systemic circulation, with vessels serving almost all the tissues of the body; and the lesser circulation, the pulmonary circulation, which distributes blood to the respiratory membranes of the lungs. The heart is thus a double pump, consisting of its right side, ejecting blood into the pulmonary artery and supporting the pulmonary circulation, and its left side, ejecting the blood into the aorta, the main artery that supplies the systemic circulation. The blood returning from the systemic circulation is drained into the right side of the heart and then pumped into the lungs; that returning from the pulmonary circulation enters the left side of the heart from which it is ejected into the systemic circulation. Thus the two cycles are hooked together in series. The large vessels emerging from the two cardiac ventricles are called the great vessels or the arterial trunks. Each one divides into smaller and smaller branches, eventually ending in the microscopic capillaries. The pulmonary artery divides directly and immediately into its branches, but the aorta takes a long course, with many side branches, before its final division into two arteries, one for each leg. Many of the side branches lead to semi-autonomous subdivisions of the systemic circulation.

Transport functions

There are many transport functions of the circulatory system; its design, however, as well as the composition of the blood contained in it, facilitates the most important function of the system—that of mediating the process of respiration. Every living cell of the body "breathes"; that is, consumes oxygen and emits carbon dioxide. Oxygen is carried by the blood from the heart to all tissues of the body, where, in the capillaries, an exchange takes place: oxygen is taken up according to tissue needs and, in return, carbon dioxide enters the blood. The blood then, poorer in oxygen but with a higher content of carbon dioxide, is carried to the right side of the heart and thence to the lungs, where another exchange takes place: oxygen is replenished and carbon dioxide given up, to be exhaled by the process of breathing. The relative amounts of oxygen and carbon dioxide carried in the blood form the basis for the division of blood into fully oxygenated, bright red, arterial blood contained in the arteries, and deoxygenated, dark red, venous blood, with a higher carbon dioxide content, contained in the veins. It should be understood that this description of arterial and venous blood applies only to the systemic circulation, because within the smaller pulmonary circuit the situation is reversed: the pulmonary artery contains the deoxygenated blood and the pulmonary veins contain the fully oxygenated blood.

The role of circulation in acting as a vehicle for the exchange of the two respiratory gases is the *sine qua non* of life. Body tissues cannot survive long without oxygen, and sensitive tissues, such as the brain cells, die when deprived of oxygen for more than four minutes. The circulation, however, plays a part in many other vital processes. As the principal vehicle of communication between parts of the body, blood transports chemical substances from one place to another; for example, nutrient substances (the breakdown products of carbohydrates, fats, and proteins) from their points of absorption to metabolic pools or storage depots, and from there to the users of this fuel. Hormones secreted into the blood by glands are distributed where needed. Waste products (other than carbon dioxide) are transported to the sites of their excretion or destruction, such as the kidneys, liver, and lungs. Blood also is a principal factor in the maintenance of body temperature. Finally, there is one other important function of the circulation; namely, to maintain the proper environment for metabolic processes by guarding the composition of the tissue fluid, which is separated from the blood plasma by an extremely thin membrane that permits a free-flowing exchange of water and soluble substances.

The circulation works with a remarkable economy: a system of priorities is established by the body, delivering blood to places where it is most needed at any given moment. The many built-in safety mechanisms and reserve capacities of the circulation provide for its proper function, even under adverse conditions, with a minimum expenditure of energy.

THE CENTRAL PUMP

The work of the heart

The workload of moving the blood within the circulatory system rests largely with the two central pumps—the right and the left sides of the heart, working synchronously but independently of one another. The work of the heart is considerable: in an average adult male each ventricle ejects six litres of blood per minute (about five in the female), or 720 litres per hour, 8,640 litres in 24 hours. Since the work performed by a pressure pump is roughly the product of its output and the pressure it builds up, the left side of the heart, supporting the high-pressure systemic circulation, performs a workload about five times greater than the right side, which empties into a low-pressure system. Consequently, the number of muscle cells within the left ventricle is proportionately larger than that in the right ventricle, and the muscle itself is thicker. The pumping action of the heart depends upon the rhythmic contraction of the two ventricles, followed by their relaxation. Contraction, or systole, of the muscles of the ventricles reduces the size of their cavities, ejecting the blood in them into two arterial trunks (into the aorta from the left ventricle and into the pulmonary artery from the right ventricle); relaxation, or diastole, of these muscles enlarges the cavities, drawing blood into the ventricles from the atria (upper heart chambers). The two atria also contract rhythmically, but their pumping action is only an auxiliary factor in the filling process of the ventricles.

Rhythmicity of the heart. The heart is composed largely of muscle cells that have contractile properties; *i.e.*, have the capability, by response to a stimulus, of

shortening their length, thus exerting considerable force. In addition to the large number of these cardiac muscle cells, the heart also contains a special type of muscle cell

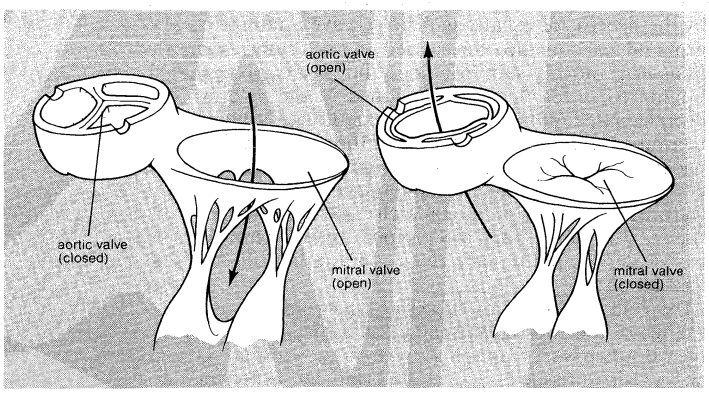

Figure 1: Cardiac valves: the mitral and aortic valves are shown in the closed and open positions.

that self-generates rhythmic impulses. These cells are concentrated in groups, forming identifiable structures within the inner surface of the heart. The sum total of all these structures is termed the conducting system, and it consists of: (1) the sinoatrial node (also known as the sinus node), (2) discrete pathways carrying the impulses along the atrial wall, (3) the atrioventricular node (A–V node), (4) the bundle of His, (5) the bundle branches and their secondary distributions, and (6) the Purkinje network. The sinoatrial node is a small structure, 10 × 3 mm, located in the right atrium near the mouth of the superior vena cava. The conducting pathways within the atrium are microscopic structures and have only recently been identified. The atrioventricular node is a flask-shaped structure, 8 × 6 × 4 mm, located at the junction of the interatrial septum (the partition between the two atria) and the back wall of the right atrium, near the orifice of the coronary sinus. From this node emanates the bundle of His, 2–4 mm in diameter and about 2 cm long, which runs along the interatrial septum and eventually enters the ventricular septum, where it divides equally into two bundle branches. The left bundle branch runs along the septal wall to the left ventricle for a short distance and then divides into two branches, each of which in turn subdivides into smaller branches. The right bundle branch runs along the septal wall of the right ventricle without subdividing until it reaches the apex of the heart, where many secondary branches occur. The terminal subdivisions of the two bundle branches connect with a fine network of fibres termed the Purkinje network, which covers the inner lining of both ventricles. This network transmits the conducted stimulus to the muscle, producing its contraction.

The conducting system

The specialized muscle cells of the conducting system differ in physiological properties from the remainder of the heart muscle cells by two features: (1) they are capable of self-excitation—*i.e.*, they generate rhythmic impulses; and (2) they are capable of conducting these impulses at rapid speeds. The sinoatrial node has the fastest rate of impulse formation. It is the primary pacemaker, where, under normal conditions, the heart beat originates. This node is richly supplied by terminals of the autonomic nervous system, which can transmit signals accelerating or slowing the basic rate—about 70 beats per minute—generated by the nodal cells. Under the inhibiting influences of the parasympathetic branch of the autonomic system, the rate may slow to about 40 per minute; sympathetic influences can accelerate the pacemaker to a rate of 200 per minute. The dominant influence is that of the sympathetic nervous system (accelerator nerves), which speed up the heart during exercise, excitement, fever, and in response to many other stimuli.

The atrioventricular node also has its inherent rhythm. Its impulse formation occurs at the rate of 50 beats per minute, but this impulse-generating function is not utilized under normal conditions. It is a standby, reserve pacemaker, ready to take over the rhythmicity of the heart only if the sinoatrial node fails to fire or slows down excessively. Its principal role lies in conducting the impulses coming from above and in delaying these impulses to permit good coordination between the contractions of the atria and ventricles. It also filters out (in a process sometimes called the triage effect) some undesirable or excessive impulses that might otherwise reach the ventricles.

The role of the atrioventricular node

The bundle of His, its bundle branches, and the Purkinje network have their own automaticity, which, however, is very slow, about 30–40 beats per minute. They represent the last line of defense, initiating slow contractions of the ventricles when both the upper nodes fail to fire or when the ventricular network becomes disconnected from the atria (heart block).

The normal impulse, originating in the sinoatrial node, activates the atria, producing their contraction about 0.02 second later. It reaches the atrioventricular node about 0.04 second after its origin, and then is conducted slowly through this node, emerging 0.1 second later. From this point on, the impulse is conducted rapidly throughout the bundles and the Purkinje network, producing contraction of the ventricles about 0.16 second after the contraction of the atria. The activation of the ventricle proceeds in a specific order producing ventricular contraction and facilitating a most efficient ejection of the blood into the arterial trunks.

The cardiac cycle. The cardiac cycle represents the complete sequence of contraction and relaxation of the heart. It is customary to divide the cycle according to the state of the ventricles: ventricular contraction, or systole, and ventricular relaxation, or diastole. At ordinary rates (70 per minute), systole occupies 40 percent, diastole 60 percent of the cycle. At faster or slower rates this ratio changes: above 100 beats per minute, systole lengthens to up to 50 percent of the cycle, and at slower rates, such as under 50 beats per minute, it shortens to 25 percent of the cycle.

The valves of the heart

The movement of blood during contraction and relaxation of the ventricles is made possible by the action of two sets of cardiac valves. The atrioventricular valves separate the ventricles from their respective atria. The left atrioventricular valve is called the mitral valve, and the right, the tricuspid valve. These valves are fairly thick structures attached to the orifice separating the left ventricle from the left atrium (mitral orifice) and to that separating the right ventricle from the right atrium (tricuspid orifice). The free edges of the three leaflets of the tricuspid valve and of the two leaflets of the mitral valve have attached to them a large number of thin chords (chordae tendineae) that extend down to muscular pyramids (papillary muscles) on the inside of each ventricle. During ventricular contraction higher pressures close the atrioventricular valves, but, in addition, contraction of the papillary muscles, participating in the general contraction of the ventricles, pulls the chordae tendineae taut, causing even firmer closure of the atrioventricular valves, thus enabling them to withstand the high pressure inside the ventricle during systole.

Two semilunar valves separate the ventricles from their arterial trunks: the aortic valve separates the left ventricle from the aorta and the pulmonary valve separates the right ventricle from the pulmonary artery. These valves are much thinner than the atrioventricular valves. Each consists of three flaps, or leaflets: thin, pocket-like structures attached to the orifices which separate each ventricle from its arterial trunk. When the valves are open, the valve leaflets float free in the stream of blood near the wall of the beginning parts of the aorta and pulmonary artery. Closure of the valve is produced at the start of ventricular relaxation when the column of blood in the aorta flows backward toward the ventricle and fills the pockets of the leaflets, pressing them tightly closed.

The two sets of valves generate acoustic vibrations (heart sounds) that can be heard by means of the stethoscope. The first heart sound occurs at the onset of systole, coinciding with closure of the atrioventricular valves. Although there is some controversy concerning the exact

mechanism of the first heart sound, it is generally accepted that its major component is produced by the sudden tensing of the atrioventricular valve leaflets, the chordae tendineae, the papillary muscles, and by the valve closure. The second sound is produced by closure of the semilunar valves, thus signifying the onset of diastole.

The onset of systole occurs when the atrioventricular valves are wide open and the atria and ventricles functionally act as a single chamber on each side of the heart. The pressure in this large chamber is 3 mm in the right side and 6 mm in the left side. The onset of systole raises the pressure in the ventricles, promptly shutting the atrioventricular valves and thus separating the atria from the ventricles. During the initial part of systole, tension in the ventricle rises and elevates the pressure, but the muscular fibres do not yet begin to shorten because both sets of valves are closed and no movement of blood can take place. When the pressure inside the left and right ventricles, measured in millimetres of mercury (Hg), exceeds that in the aorta (80 mm) and in the pulmonary artery (10 mm Hg) respectively, the semilunar valves are forced open, and the blood can be ejected. The initial period of systole, or rising tension without flow of blood, is referred to as the isometric (isovolumetric) contraction period and lasts about 0.03 second. The next period, the ejection of blood into the arterial trunks, takes place with the semilunar valves wide open. Now the ventricles and their arterial trunks have identical pressures, acting functionally as a single chamber. The ejection of blood, however, does not take place at an even rate. The initial ejection period transfers about half of the blood in the first quarter of the total ejection period and is termed the rapid ejection phase, lasting about 0.07 second. The remainder of systole involves a slower rate of ejection, with the other half of the blood entering the arterial trunks in the following 0.22 second. This is known as the slow ejection phase.

Ventricular relaxation (diastole) begins with the closure of the semilunar valves. The relaxing ventricular muscles decrease their tension, reducing intraventricular pressure, and thus cause the semilunar valves to close. No movement of blood is possible until the atrioventricular valves open. The period of fall in pressure without movement of blood is called the isometric (isovolumetric) relaxation phase and is analogous to the isometric phase of systole. This period lasts about 0.04 second. When the pressure falls below that in the atria, it forces the two atrioventricular valves open, and the blood is drawn into the ventricles from the atria. As in systole, the flow of blood into the ventricles does not occur at an even rate. The first part of the ventricular filling period (the rapid filling period) draws some 60 percent of the blood in about 0.10 second. The next period of the diastolic phase is the rest period, or diastasis, in which the rate of flow is diminished—only 10–15 percent of the blood enters the ventricle within about 0.18 second. The final period of diastole is the atrial contraction phase: the atria, having just received their excitation signals from the sinoatrial node, contract and eject the final portion of blood, 25–30 percent of the total, into the ventricles.

None of the cardiac chambers empties completely during the cardiac cycle. The ventricles eject one-half to two-thirds of their contents during systole; the atria are connected with the large venous reservoir from which they continuously receive blood, so that their blood content shows relatively little variation.

Cardiac output. The cardiac output is defined as that quantity of blood ejected by a cardiac ventricle into its arterial trunk in one minute. The quantity of blood expelled with each ventricular contraction is termed stroke volume or stroke output. The normal, average stroke output is 75 millilitres of blood; therefore, with a heart rate of 70 to 80 beats per minute, the cardiac output is between five and six litres per minute. The output into the two arterial trunks by the ventricles is identical under normal conditions; thus each ventricle ejects five to six litres of blood per minute. These figures apply to the basal state of the body; that is, to cover the minimal metabolic needs of an individual resting comfortably and motionlessly in bed. Since the principal role of the circulatory system is the transport function of the blood, regulation of cardiac output represents one of the most intricate processes in the body.

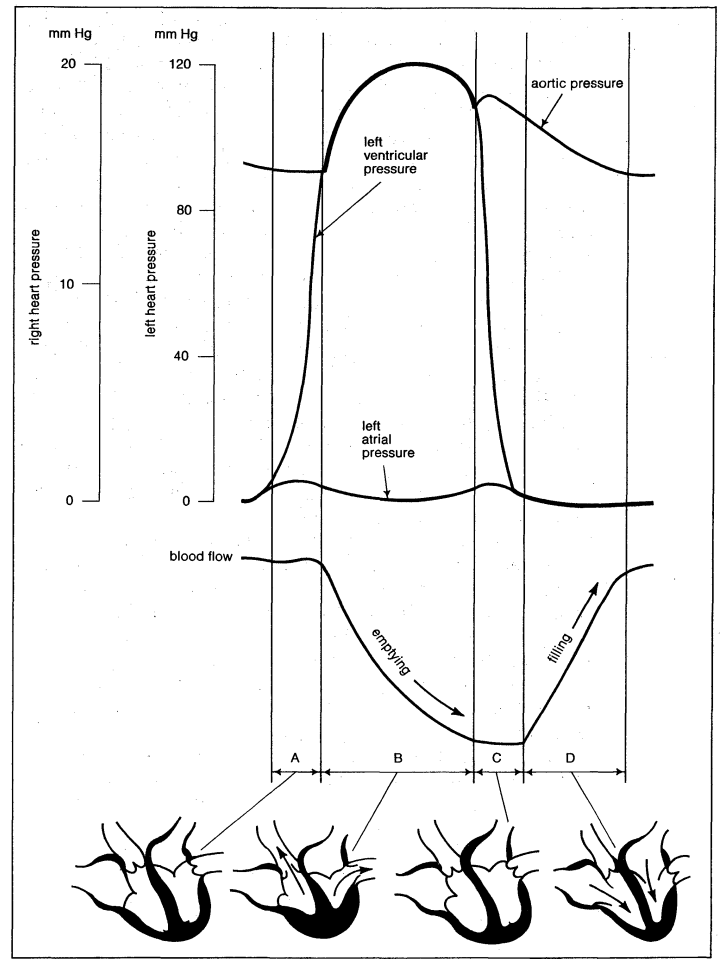

Figure 2: *Idealized curves of pressure and blood flow during the cardiac cycle, shown along with a presentation of the position of the cardiac valves.*
(A) Isometric contraction phase with all valves closed. (B) Ejection period of systole with semilunar valves open, atrioventricular valves closed. (C) Isometric relaxation phase, all valves closed. (D) Diastolic filling phase with semilunar valves closed, atrioventricular valves open. Two pressure scales are presented, to account for the systemic and pulmonary circulations.

Oxygen requirements of the body

The primary function of the circulation is the delivery of oxygen. It is customary to express the metabolic demands of the body in terms of oxygen requirement. The basal resting state, as described above for an average adult, requires the delivery of 250 millilitres of oxygen per minute. The quantity of blood delivered to the systemic circulation is six litres per minute; thus each litre of blood gives up about 40 ml of oxygen to the tissues. This figure represents the arteriovenous oxygen difference, or the difference in oxygen content between the blood entering the tissues and the blood leaving the tissues. The arteriovenous difference represents the index of oxygen utilization by the tissues and may be applied to the body as a whole or to any portion of the circulatory system. The normal arteriovenous oxygen difference of 40 ml per litre of blood represents only a small fraction of the available oxygen in the blood, which is about 180 ml per litre. At rest, therefore, tissues use less than 25 percent of the available oxygen in the blood perfusing them. This relationship can be expressed in another way: the arterial blood ejected into the systemic circulation is about 95 percent saturated with oxygen, and the mixed venous blood, returning to the right side of the heart after having perfused all tissues, still is 75 percent saturated with oxygen.

The importance of the regulation of cardiac output in response to changing metabolic demands of the body can best be appreciated when the high oxygen demands of the

body are recognized. If an individual, resting under basal conditions, begins to move about in bed or gets excited, oxygen demands may double—from 250 ml to 500 ml per minute. Mild exercise, such as walking at a slow pace across the room, may triple the oxygen demands. Strenuous exercise may increase the oxygen needs to two or three litres per minute—8–12 times the basal level. Some athletic feats demand four to six litres of oxygen per minute. How can the circulatory system solve the problem of delivering 20 times more oxygen than the basal value? First of all, exercise constitutes an emergency, during which oxygen reserves in the blood are more fully utilized. By extracting not just 25 percent but all the available oxygen from the blood, one litre of oxygen per minute, instead of 250 ml, becomes available. More oxygen than that may be needed and can only be delivered by increasing cardiac output. The heart is capable of increasing its output up to about five times its resting level, and is thus able to satisfy the demands imposed by strenuous exercise. These two factors, better utilization of available oxygen and increased cardiac output, work together for lesser degrees of metabolic needs. For example, if the oxygen demands double, utilization is likely to increase by 50 percent and cardiac output by 50 percent. Proportional contribution of the two factors satisfies the body demands in all situations. One of the principal reasons for the low level of maximum possible effort in a sedentary individual, and the very high level in the athlete, is the difference in efficiency with which the two circulatory systems can adapt themselves to the delivery of the increased amounts of oxygen required by the tissues.

It is obvious that large increases in cardiac output can take place only if more blood returns to the heart, inasmuch as the reservoir capacity of the heart itself is very limited. The quantity of blood returning to the right side of the heart from the systemic circulation is termed venous return and is the principal determinant of cardiac output. The venous return, in general, must equal the cardiac output, otherwise the circular movement of the blood could not take place. Momentary inequalities, however, frequently occur between venous return and cardiac output. The ability of the heart to handle the excess of blood returning to it rests with the adaptive mechanisms expressed by the "law of the heart" of Ernest Starling. This law postulates that when cardiac muscle is stretched, the resulting contraction becomes stronger in proportion to the degree of stretching. Thus the stretching, or increase in muscle fibre length, resulting from more blood entering the ventricle leads to a more forceful ventricular contraction, which, in turn, will expel a larger amount of blood. Conversely, a smaller venous return, by reducing the diastolic fibre length, will lower the stroke output. This mechanism can be compared to a bow and arrow: the more tension exerted upon the bow, the stronger the force generated, sending the arrow farther. A measurable expression of the degree of filling and of the fibre length during diastole is the end-diastolic filling pressure, or the pressure in a ventricle at the beginning of systole. A higher filling pressure will increase stroke output; lower pressure will decrease it. A recognized way of testing the function of the heart is to obtain the curve showing the relationship between the filling pressure and the cardiac output (*e.g.*, during distension of the heart by a blood transfusion). Such a cardiac function curve can characterize the performance of any heart, permitting the distinction between normal and abnormal performance, and also allows a study of the effect of drugs and other agents upon cardiac function.

Starling's "law of the heart"

An auxiliary mechanism aiding the regulation of cardiac output is the capability of the heart to empty itself more completely. Under basal conditions the volume in each ventricle is about 150 ml of blood, and at times only half of it is ejected with each beat. Under conditions of increased demand, the heart can reduce the residual volume (that remaining in a ventricle at the end of systole) to 10–20 ml. This stronger contraction—beyond that required to fulfill Starling's law of the heart—has been termed homeometric autoregulation of the heart, and is brought about mainly by the action of regulatory cardiac hormones (catecholamines).

Starling's law of the heart holds whenever there is an increase in both the heart rate and the stroke output. Produced by autonomic nervous reflexes, an increase in heart rate from the resting level of 70 beats per minute to the maximum rate during exercise of about 200 can increase cardiac output threefold. Further increase must involve augmentation of the stroke output. It is noteworthy that the resting heart rate is one of the determining factors of physical fitness: trained athletes often have resting rates as low as 40 to 50 beats per minute and can increase their cardiac output five times merely by accelerating the rate to 200. This is in addition to any further increase brought on by augmentation of the stroke output.

The process of adaptation of cardiac output to metabolic needs of the body has been discussed in terms of strenuous exercise, which imposes the heaviest demands upon the circulation. Obviously, between maximal demands and the basal state, there is a wide spectrum, and lesser degrees of exercise will invoke correspondingly smaller changes in cardiac output. Other factors influencing cardiac output include many situations: standing, which reduces venous return by the pooling of blood in the lower part of the body, lowers cardiac output by about 20 percent; fever increases metabolic demands and, consequently, cardiac output; high environmental temperatures may step up cardiac output. Excitement, postprandial digestive processes, high altitudes (lowered oxygen content in the air)—all increase cardiac output by invoking some of the previously described adaptive mechanisms.

THE SYSTEMIC CIRCULATION

The systemic circulation is initiated by the ejection of blood by the left ventricle into the aorta. The blood flows from there to every organ and tissue of the body (including even the lungs, which derive their nutritional blood supply from the systemic circulation; the working blood of the lungs, that to be supplied with oxygen, represents the pulmonary circulation). The systemic circulation at any given time contains about three-quarters of the total blood volume; the remaining quarter is contained in the heart and the pulmonary circulation. The systemic circulation consists of three divisions: the arterial system, the capillary system, and the venous system. The volume of blood contained in the systemic circulation is divided as follows: 20 percent is in the arterial system, 5 percent in the capillary system, and 75 percent in the venous system, which represents the great reservoir of blood.

Some hemodynamics

The arterial system. The arterial system delivers blood to all parts of the body under high pressure. Such pressure is essential for the proper perfusion of all organs and tissues. High pressure permits the proper distribution of the blood to the various tissues according to their needs. The arteries represent a system of elastic tubes (capable of increasing or decreasing their calibre), which become more numerous but of smaller calibre as they subdivide along their course. The flow of liquid through tubes is characterized by Poiseuille's law: (1) $V = \frac{dP \cdot r^2}{8\mu l}$ in which dP is the difference in pressure between two points of the circulation (pressure gradient), V is velocity of blood flow, r is the radius of the tube, μ is the viscosity of the fluid, and l is the length of the tube. In adapting the equation to conditions prevailing in the circulation of blood, the following further equations can be derived: (2) $R = \frac{8\mu l}{\pi r^4}$ (R = resistance). This indicates that resistance to flow in a vessel is directly proportional to the length of the vessel and the viscosity of blood and inversely proportional to the fourth power of the radius of the vessel. The final derived equation depicts the relationship between the flow (*e.g.*, cardiac output), pressure, and resistance: (3) $Q = \frac{dP}{R}$, or simply (4) $P = QR$, in which P is pressure, Q is output or volume of flow in a region, and R is resistance. This equation is analogous to Ohm's law, which states the relationship between electri-

cal currents, electromotive force, and the resistance of a conductor.

Resistance to blood flow represents the loss of energy through friction resulting from blood "squeezing" through a small vessel. Equation 4 indicates that pressure is proportional to resistance; *i.e.*, high pressure in the systemic circulation correlates with high resistance within the system. The resistance to flow by the aorta and the larger, and even the smaller, arteries is negligible. These vessels represent a high pressure system—a compression chamber (the German term *Windkessel* is often used in this connotation), an elastic bag, as it were, in which the high pressure is maintained by the resistance offered by the small vessels guarding the exit from the system. These vessels, the arterioles, are the smallest arteries, with an abrupt reduction in diameter from the larger ones. Arterioles have thick, muscular walls capable of constricting and relaxing. The arterioles are ordinarily in an intermediate state of partial constriction (tone of the vessel), ready to constrict further to increase their resistance, or dilate to reduce their resistance, as the need arises. Thus the energy, built up by the contraction of the left ventricle and stored in the arterial compression chamber as high pressure, is dissipated in overcoming the friction of the high-resistance arterioles. The normal systolic pressure of 120 mm Hg in the left ventricle, identical with that in the aorta, remains almost unchanged throughout even the small arteries. In the arterioles, however, the pressure drops promptly; entering the arterioles it lowers slightly to about 100 mm Hg; emerging from them it drops to about 30 mm Hg.

Equation 4, indicating that pressure is the product of flow (output) and resistance, applies to the entire systemic circulation. By resistance, then, is meant the sum total of the resistance in all arterioles in the body. This is expressed by the equation: (5) $R = R_1 + R_2 + R_3 + \ldots R_n$. It follows that the flow through each region of the body is also determined by the local resistance, so that a relaxation of a group of arterioles in any organ would automatically increase the blood flow through that organ. This principle is of fundamental importance in the process of the regulation of blood pressure as a whole, as well as the distribution of blood to areas where it is most needed, as will be discussed later.

The arteries—the elastic compression chamber—play an important role in the efficiency of the circulatory system. If blood were ejected from the heart into a rigid system of tubes, the intermittent pumping effect of the heart would be retained in the circulation. The blood would move forward during systole, but the flow would stop during diastole. Furthermore, the pressure during diastole would fall to a very low static-pressure level, which would depend upon the relationship of the volume of the blood to the capacity of the arterial system. The elasticity of the aorta and the other large arteries, however, makes the walls of these vessels distend during systole. The energy stored in the distended arteries is returned to the circulation during diastole: the pumping action then temporarily ceases, the arterial walls return to their former size, and the energy is used to propel the blood forward, making the flow continuous.

The pulse

The ejection of blood into the elastic compression chamber thus influences the flow of blood; it also determines the pressure sequence in the system. A curve, recording pressure in the arterial system, is called the arterial pulse curve. The first portion of the pulse curve, its systolic part, is identical with the corresponding part of the left ventricular pressure curve. The end of systole, the closure of the aortic valve, is signalled in the pulse curve by a sharp notch—the dicrotic notch—after which a gentle further fall in pressure takes place, related to the blood leaving the arterial system through the arterioles, until the lowest level is reached, which marks the diastolic pressure. A pressure curve can be recorded by placing a needle or tube in the aorta or an artery and connecting it to a recording manometer (pressure-measuring device). This is a method of direct measurement of the systemic blood pressure. A somewhat less accurate, but acceptable, method of measuring arterial pressure is the indirect method, using a sphygmomanometer, which is a pneumatic cuff that can be inflated and tightened around the upper arm, and which is connected with a mercury manometer or a calibrated air manometer. The pressure in the cuff is raised to a level well above the expected systolic pressure and then the air in the cuff is gradually released. High pressure completely stops the flow of blood in the temporarily collapsed artery of the arm, and as the cuff deflates the external pressure falls, the point is reached at which the blood begins to flow through the artery again. This point represents the systolic pressure level and is signified by the appearance of a sound that can be heard by means of a stethoscope placed in the bend of the elbow. Further deflation of the cuff leads to a point at which the sound becomes muffled or disappears. This represents the diastolic pressure.

The sudden distention of the first portion of the aorta by the blood ejected into it sets up a wave of elasticity that is conducted along the arterial system as the pulse wave. Since the distention creating the wave is proportional to changes in pressure, the pulse wave is identical with the pressure pulse recorded from the inside of the artery. Thus the pulse can be palpated over any accessible artery or can be recorded by an apparatus called the sphygmograph. The shape of the pulse wave is related to the quantity of blood ejected into the aorta, the speed of ejection, the elasticity of the arterial system, and the peripheral resistance. It may reflect certain abnormalities produced by disease—palpation of the pulse is one of the oldest techniques of physical examination. The pulse wave travels at high speeds—much higher than the actual movement of the blood. Its transmission occurs fastest in the more rigid, smaller arteries (about 30 m per sec), and more slowly in the large, more elastic arteries (3 to 10 m per sec). The movement of blood occurs much more slowly. For example, it takes 0.05 sec or less for the pulse wave to reach the carotid artery in the neck, but it takes 1–2 sec for the ejected blood to reach that point.

Regulation of pressure and flow

It has already been stated that the autonomic nervous system exerts an important influence upon the various functions of the circulation. It plays a paramount role in two essential regulatory functions within the systemic circulation: (1) the maintenance of arterial blood pressure, and (2) the distribution of the blood according to functions and needs of the various organs and parts of the body.

It can be surmised from Equation 4 that the systemic arteriolar resistance cannot be of a stable magnitude, for if it were, each time the cardiac output increased the blood pressure would rise in proportion; *i.e.*, a fivefold rise in cardiac output during exercise would increase the systolic pressure from 120 to 600 mm Hg. To forestall such a disaster, the arterial system possesses a sensitive self-regulatory mechanism. The arterioles are richly supplied by terminals of the autonomic nervous system—the sympathetic and parasympathetic nerves. The sympathetic nervous system has dual control over the cross-sectional size of arterioles, having both vasoconstricting (decreasing) and vasodilating (expanding) effects. The parasympathetic system has only vasodilating effects. The regulation of the size of the arterioles is a reflex phenomenon, unrelated to the conscious will of the individual. Signals from the autonomic nervous system reach the nerve terminal, where a chemical substance (transmitter) is released, changing the tone of the arteriole. Acetylcholine, a vasodilator, decreases the tone, and norepinephrine, a vasoconstrictor, increases it. The great arteries have in their walls sensing terminals, the most important of which are located in the arch of the aorta and in the major artery in the neck, the carotid artery (carotid sinus). These sensors respond to stretch: when more blood is ejected into the aorta the sensors recognize the stretch of the wall of the vessel and send the appropriate signal to the proper autonomic centre in the brain. This vasomotor centre then stimulates the vasodilating fibres in the arterioles, causing them to relax just the right amount to let out the excess blood and thus maintain the pressure at

its original level. This mechanism permits the arteriolar resistance to fall each time the output rises, and vice versa, maintaining a stable blood pressure in the arterial system.

The pressure-regulating mechanism applies to the total systemic arteriolar resistance, which, as stated, is the sum total of many subdivisions of the systemic circulation. The distribution of blood into these subdivisions represents the second essential regulating mechanism. The systemic circulation is subdivided not only topographically but also in accordance with the functional unity of certain widely spread tissues of the body. These subdivisions are connected in parallel with the central arteries; thus, the blood has the option of entering any subdivision in larger or smaller amounts—or not at all—without disrupting the systemic flow. The regulation of regional flow is related to the respective role and function of each region, which differ widely even under basal conditions, and the need for oxygen varies greatly from region to region. The main subdivisions of the arterial system are as follows: (1) The splanchnic circulation (gastrointestinal tract and abdominal organs) constitutes 24 percent of the systemic circulation; its basal oxygen utilization is roughly equivalent to the body average (expressed as an arteriovenous oxygen difference of 40 ml per litre of blood). (2) The renal circulation (kidneys) makes up 19 percent of systemic blood flow. This circuit has a low oxygen-utilization rate—the blood returning from the kidneys is almost as fully saturated with oxygen as when entering them. This overabundancy of flow above the obvious needs is caused by the fact that the blood is filtered by the kidneys of its wastes—whence the urine is formed. The kidneys are supplied with working blood over and above their nutrient blood. (3) The cerebral circulation (brain) is 13 percent of systemic flow. The brain demands and extracts more oxygen than the body average. (4) The coronary circulation (heart) comprises 4 percent of systemic flow. This circuit is the highest user of oxygen in the body, with the blood returning from the heart tissues very low in oxygen, about 30 percent (equivalent to an arteriovenous oxygen difference of 110 ml per litre of blood). The coronary circulation thus has a low reserve and it is extremely vulnerable, so that its adjustment to augmented needs is of crucial importance. (5) Circulation to the skeletal muscles contains 21 percent of systemic flow. At rest the oxygen utilization is higher than average (a work-saving device for this largest part of the body). (6) Circulation to the skin includes 9 percent of systemic flow. The skin, as is the case with the kidneys, has more abundant blood flow than it needs. This excess is related to one of its functions: blood perfuses the skin not only to nourish it but to help in regulating the body temperature. (7) Circulation to other organs in the body is 10 percent of systemic flow, and it utilizes about the average amount of oxygen.

Tissue blood supply

The above figures show the wide difference between the various regions in their respective blood supplies: some have an overabundance, others a scanty supply. The flow of blood into each region is, of course, determined by the tone of the arterioles—those more widely open and offering less resistance have higher flows; those with a higher tone have lower flows. The tone of the arterioles is capable of change in each region, independently from other regions, causing moment-to-moment shifts in blood perfusion of regions and organs. While all arterioles are under the influence of the autonomic nervous system and respond to signals from the vasomotor centre in participating in the general pressure-regulating mechanism, the differential nature of the flow is aided by the differences in the number of vasoconstrictor and vasodilator nerve fibres. In addition there are other mechanisms that produce local arteriolar dilation without the participation of the centres in the brain. Among these are local nervous reflexes (axon reflexes) that may dilate arterioles in a region. Furthermore, chemical substances play an important part in altering local resistance: these include many hormones such as vasopressin (secreted by the posterior pituitary gland), angiotensin (produced by the kidneys), histamine or the related H-substance (found in the skin), bradykinin (found in the salivary gland). In addition, other hormones referred to as unidentified vasodilator substances play a part in the regional variation of blood flow. This process is referred to as the metabolic autoregulation of blood flow and includes the dilatation of blood vessels by metabolic products of tissues in their close vicinity. Finally the essential blood gases—oxygen and carbon dioxide—play some regulatory part in vascular resistance: lack of oxygen or overabundance of carbon dioxide may influence the size of the blood vessels, generally by altering the blood pressure, or locally by redirecting flows.

The most drastic temporary adjustment of the regional blood flow occurs during exercise. It has already been pointed out that during exercise the cardiac output and oxygen utilization are greatly increased. In order to meet the extremely high demands of the working muscles for oxygen, the body also shifts all the blood it can spare to the working muscle. Thus the vital organs—the heart and brain—remain well supplied, but the splanchnic organs, the nonworking muscles, the kidneys, and the skin receive only a fraction of their usual blood supply for the duration of the exercise "emergency." A combination of chemical stimuli and nervous reflexes accomplishes this remarkable feat of body economy.

The capillary system. The capillaries are microscopically thin tubes present in every tissue of the body, forming such a dense network that virtually every cell in the body comes in close contact with the blood. The diameter of most capillaries is between 0.007 and 0.015 mm, but the total network of the capillaries has been estimated to be some 60,000 miles in length. The capillaries are the working vessels around which all the metabolic processes take place. The capillary is a thin tube, in most instances a single layer of cells surrounding a space for blood. Outside the capillaries is tissue fluid—interstitial fluid—in which these blood vessels are bathed.

The blood enters the capillaries from the arterioles, usually through intermediate-sized vessels between the two, called meta-arterioles. Blood flow through the capillary system differs from that through the arterial system in that all arteries, even the smaller meta-arterioles, always contain blood, but capillaries most of the time are empty and closed. At the junction between a capillary and a meta-arteriole there is a ringlike band of smooth muscle, the precapillary sphincter, which regulates the flow, opening some capillaries and closing others. The capillary blood flow occurs in spurts, the blood taking alternate pathways through the various capillaries in a given part of the tissue. Blood flow through the meta-arterioles and the capillaries is almost entirely regulated locally, with the most powerful regulating factor being the concentration of oxygen in the given tissue. In addition to the "true" capillaries, which represent nutritional channels supplying the tissues with oxygen and other needed substances, some organs have nonfunctioning capillaries that are merely a thoroughfare between the arterial and venous systems. These are called arteriovenous capillaries. They are particularly numerous in the skin, where they play an important role in the body's heat regulation. Even though the flow through the capillaries is intermittent, the number of capillaries is so numerous that a free metabolic exchange takes place almost continuously.

In the capillaries the circulation of blood reaches its destination and is able to fulfill its principal function—to supply all the cells with the material they need and to remove the waste products from the cells. This function of the blood is possible because the capillaries are in close proximity with every cell in the body, separated from them only by the thin capillary wall and the fluid in which the body cells float. The exchange occurs on the basis of two processes: (1) a chemical reaction that facilitates the exchange of oxygen (and to some extent carbon dioxide) and that depends on the special properties of hemoglobin (in the red blood cells), and (2) the physical process of diffusion. Both the chemical and physical processes lead to equilibration. An exchange occurs be-

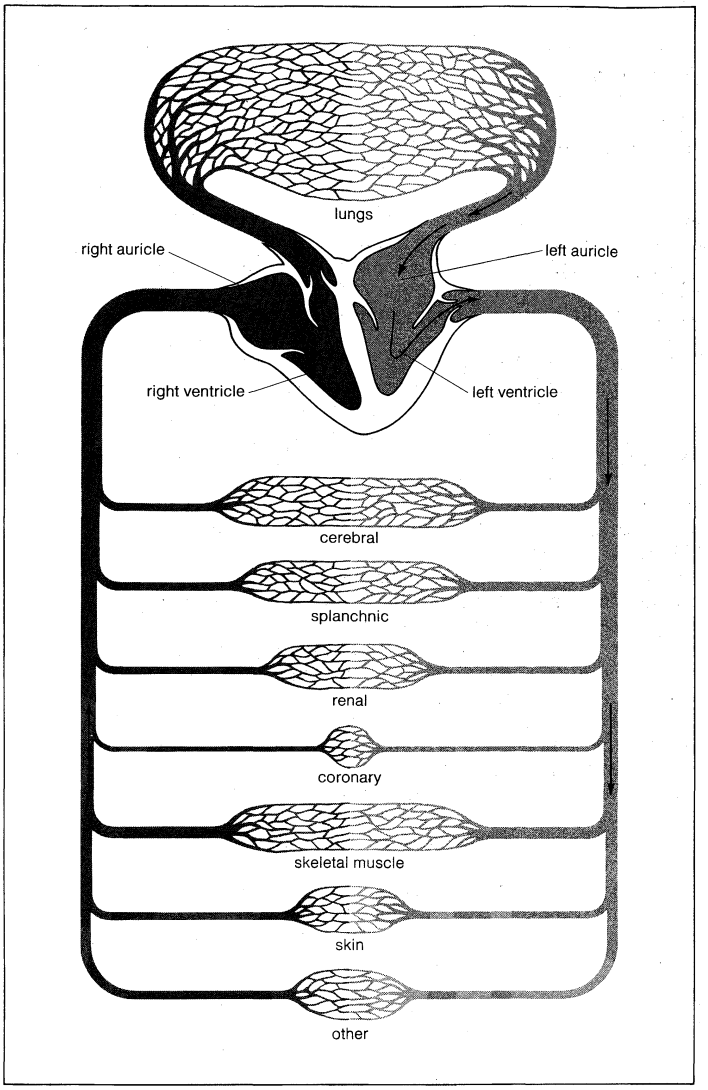

Figure 3: The systemic and pulmonary circulations, showing the principal subdivisions of the systemic circulation. Arterial blood is shown at the right, venous blood at the left.

tween the two media if the concentration of one substance is higher in one medium than in the other, and it continues until both concentrations are equal. The porous walls of the capillaries act as a permeable membrane, with selective permeability for different substances. The highest permeability (other than that for the respiratory gases) is that for water. Next come simple chemical substances of low molecular weight such as electrolytes (*e.g.*, sodium, potassium, and chloride ions) and urea. Carbohydrates and related substances of higher molecular weight have a lower index of permeability. Proteins and other giant molecular agents have a still lower index. Blood cells themselves are not exchanged in the ordinary capillaries, but there are special areas (manufacturing or hemopoietic units) that add new cells to the blood and "graveyards" that remove and destroy old cells. Thus, substances with high permeability have time to move between the two media until complete equilibrium is reached, while those of low permeability can accomplish partial exchange, so that the composition of the tissue fluid and the blood plasma never becomes identical.

Water exchange in the blood and tissues

Active exchange of water between plasma and tissue fluid occurs on a basis other than diffusion. It is driven into and out of the blood by pressure. There are four forces accountable for movement of water between the two media: (1) capillary pressure, which drives water out of the plasma toward the tissues; (2) tissue-fluid pressure, which drives water from tissue fluid to the inside of the capillary, thus opposing (1); (3) osmotic pressure of the plasma colloids, which tends to retain water in the plasma; and (4) osmotic pressure of the tissue fluid, a force similar to (3), which keeps water in the tissue spaces. Under normal conditions capillary pressure is higher in the arteriolar end of capillaries than in the venous end. As stated earlier, high pressure in the arterial system is dissipated by the resistance in arterioles, so that blood enters the capillaries under a driving pressure of about 30 mm Hg. Capillaries, as narrow vessels, offer resistance to flow and further reduce pressure to about 10 mm Hg at their venous ends. It is difficult to measure capillary pressure directly, but best estimates are that the mean, net capillary pressure is about 17 mm Hg. Capillary driving pressure (30–17 mm Hg) overcomes the opposing forces in the arterial half of the capillaries so that water is driven out of the plasma into the tissue fluid. In the venous half of the capillaries, lower pressure (17–10 mm Hg), combined with other forces, is relatively negative, and the water is returned to the plasma. Thus there is a constant exchange of water between blood plasma and extracellular fluid, with the water leaving the capillary at its arteriolar end and returning to the capillary at its venous end.

The magnitude of this capillary exchange of water can be appreciated by noting that 3 litres of blood plasma, coming in contact with 15 litres of extracellular fluid, exchange the blood volume some 45 times every minute. This large exchange makes it clear that the amount of water leaving the vascular system and that returning to it must be in nearly perfect balance—even the smallest imbalance would promptly drive plasma out of the blood or bring excess water into the circulation. This exchange of water is an important mechanism in the body's fluid retention. Should the plasma become too concentrated, as after excessive sweating, the capillary water balance is shifted to replace immediately the exact volume of water lost from the plasma, but no more. On the other hand, should excessive water imbibition dilute the plasma, the surplus of water will be removed by the capillary-exchange process until the kidneys are able to dispose of the excess.

The venous system. It has been stated earlier that the systemic venous system contains about 75 percent of the volume of blood within the systemic circulation. This inequality is related to the very slow speed of the circulation in this system, since the velocity of blood flow in any part of the circulatory system is directly proportional to the volume of blood in this part and inversely to cardiac output. The veins collect the blood from the capillary system. The smallest vessels continuous with the distal ends of the capillaries are the venules. Venules converge into small veins, which join into progressively larger ones until all the blood is draining into the caval system of two large veins returning to the heart. These two veins are the superior vena cava, which returns blood from the part of the body above the heart, and the inferior vena cava, which returns the blood from most parts of the body below the level of the heart. Both venae cavae enter the right atrium at its posterior upper and posterior lower areas, respectively.

The driving pressure returning the venous blood to the heart is very low because the arterial pressure, as it has been explained, is almost entirely dissipated by transport through the arterioles and capillaries. Thus blood enters the venous system with only a few millimetres of pressure above that in the right atrium. This low driving pressure may or may not suffice to move the blood upward toward the heart in an individual lying down, but is totally inadequate to do so in the erect human unless aided by other mechanisms, because then the blood must oppose the force of gravity. All veins located below the level of the right atrium thus have the weight of a column of blood added to their intrinsic intravascular pressure; those above the level of the heart have gravity aiding their drainage. Hydrostatic pressure in an average adult at the level of the toes is very high, about 90 mm Hg. The problem of moving the blood uphill to the heart is solved

by several pumping mechanisms. The flow toward the heart is facilitated, first of all, by venous valves. These are pocket-like structures attached to the inner walls of the veins at short distances from each other; they open to permit blood to flow toward the heart but, when the column of blood stops moving, close tightly, preventing backflow. Furthermore, the large veins in the legs are surrounded by muscle tissue. Each contraction of the muscles with the slightest motion, even the tone of the muscles when standing, exerts a milking action, moving the blood upward. This mechanism is called the muscle pump. When the veins reach the abdominal cavity and enter the inferior vena cava, valves are no longer present but another mechanism becomes operative. The abdominal cavity contains many organs whose specific gravity approximates that of blood. Pressure in the abdominal cavity is thus dissipated, as if the great veins were suspended in a liquid medium. The total pressure in the abdomen is influenced by the motion of the diaphragm, the principal respiratory muscle, which maintains the pressure at about zero, or slightly below the atmospheric pressure. To complete this mechanism, the negative pressure inside the chest (thoracic) cavity causes the blood to be sucked from the low-pressure abdominal cavity, up the vena cava, and into the right atrium. The intrathoracic negative pressure increases (*i.e.*, becomes more negative) during inspiration, accelerating the return of blood to the heart, and decreases during expiration, decreasing the return of blood. This combined action of the thorax and abdomen in enhancing the venous return of blood is called the abdominothoracic pump. The return of blood from the part of the body located above the level of the right atrium, as stated, is aided by forces of gravity. Most of the veins that are located above the level of the heart are partly closed. These veins open only enough to let the blood flow through. The principal reservoir function of the venous system is located at a level below the heart.

Venous return

The venous system, as the largest reservoir in the body, has an additional function that only recently has been appreciated. The veins have a tone—a state of partial constriction—that permits them to contract and dilate, thereby regulating the venous return to the heart, and, by the previously described mechanism, the cardiac output. This mechanism plays an important role in conditions in which cardiac output has to increase rapidly; for example, during the very initiation of exercise before the working muscles pump out the additional blood, resetting the circulation at a higher output level.

The venous system has been described as comparable to a river, collecting tributaries that arise from a merging of several smaller streams. There is, however, one exception to this system: the portal vein system, which involves all the veins draining the gastrointestinal tract and the spleen. The various veins from these sources drain, in the usual manner, into the single, large portal vein. This vein, however, takes a short course inside the abdominal cavity, enters the lower surface of the liver, divides again into smaller veins, which, inside the liver, divide into venules and capillaries—broader than average capillaries —termed sinusoids. All the blood from the gastrointestinal tract and the spleen is thus brought to the liver, where it gets detoxified and where certain fuel reserves are stored. After this process of filtration, the blood from the portal circulation mixes with the arterial blood entering the liver (through the hepatic artery) for the purpose of nutrition. The capillaries then converge into a system of venules, small and large veins, and eventually reach the large hepatic vein, draining into the inferior vena cava. This double circulation of the liver facilitates an important function of this organ—guarding the body against absorption of harmful substances from the gastrointestinal tract.

THE PULMONARY CIRCULATION

The pulmonary circulation involves the right side of the heart, the pulmonary artery and its branches, the pulmonary capillary system, and the pulmonary veins. Venous blood with reduced oxygen content, having returned to the right atrium from the systemic veins, is pumped into the pulmonary artery by the right ventricle. The volume of blood contained in the pulmonary blood vessels is about 12 percent of the total blood volume. The "lesser circulation," as applied to the pulmonary blood flow, refers not only to the smaller volume but also to the smaller circuit. Despite the differences in size and volume between the two circulations, the quantity of blood ejected into the pulmonary artery equals that ejected into the greater circulation; for the two circulations are in series with each other. An inequality in output of the two ventricles would promptly empty one circulation into the other.

There is still another important difference between the two circulations: the pulmonary arterial circuit is a low-pressure circulation. There are reasons why a high perfusion pressure is not needed in the lungs. First, the compact size of the pulmonary circulation is easily perfused under lower pressure; second, the fact that the circulation supplies only one paired organ obviates the complicated regulatory mechanisms of the systemic circulation.

It should be pointed out that the pulmonary circulation supplies the lungs only with working blood destined for the metabolic exchange of blood gases. The nutrient blood for the lungs comes from the systemic circulation as the bronchial circulation. Thus the lungs, as the liver, have a dual circulation. Unlike the liver, however, where the nutrient blood and the working blood jointly leave through the same system of veins, the lungs have two venous systems, the pulmonary and the bronchial, making two independent circulations except for minute communications between them.

The pulmonary arterial system. The right ventricle works under low pressure, and its filling pressure and ejection pressure are lower than in the left side of the heart. The filling pressure, however, is only slightly lower (3 mm Hg as opposed to 6–8 mm Hg on the left side), while the ejection pressure is one-sixth of the systemic pressure (20 mm Hg relative to 120 mm Hg on the left).

The main pulmonary artery (also called the pulmonary trunk) is a short vessel, about 4–5 cm long in the adult, which divides into two major branches, each supplying one lung. These are the right and the left branches, also called the right pulmonary artery and the left pulmonary artery. These branches, in turn, subdivide into principal branches for each of the five lobes of the lungs and then divide further and further until they reach the pulmonary arterioles, vessels comparable in size to the systemic arterioles. Being subjected to lower pressure, the pulmonary arteries and their branches are much thinner than correspondingly sized vessels in the systemic circulation. This difference is most marked in the arterioles, which have very little muscular tissue. The pulmonary arterioles are thus wide open, offering very little resistance to blood flow; hence the low pressure in this system. Unlike the systemic arterioles, the pulmonary small vessels have a very scanty supply of autonomic nerve endings. It was long believed that these vessels had no tone and were incapable of constricting or dilating under stimuli from the autonomic nervous system. It has now been demonstrated that such reactivity of the pulmonary arterioles does exist. Normally the important stimulus for this arteriolar constriction is a lowered content of oxygen in the inspired air, such as at high altitudes, where the constriction of the pulmonary arterioles can elevate pressure in the pulmonary arterial system to twice its normal value. In some diseases even more severe constriction may occur, leading to a condition that is known as pulmonary hypertension.

Although the neurogenic (*i.e.*, produced by the nervous system) responses of the pulmonary arterioles play a much lesser role than comparable responses on the systemic side, the pulmonary vessels are effectively regulated by the contents (*i.e.*, oxygen pressure) of the alveoli (thin, globular membranes enveloping the minute air bubbles).

Any reduction of oxygen in the alveolar air causes constriction of the pulmonary arterioles in adjacent areas and the blood is deflected to those parts of the lung where oxygen is more plentiful. This is called autoregulation of pulmonary blood flow. The importance of this adjustment of flow is that even in health certain portions of the lungs are better ventilated than others. As will be explained later, flow of blood through poorly ventilated alveoli could reduce oxygen saturation of the arterial blood and would be undesirable for body mechanics. The upper portions of the lungs are less well ventilated than the lower, hence more blood flow is directed toward the lower portions.

The pulmonary capillary circulation. The pulmonary arterioles lead to the pulmonary capillaries. Intermediate vessels and constricting sphincters, present in the systemic circulation, have not been identified in the pulmonary circulation. The number of capillaries located in the walls of the alveoli is greater than the basal needs—only one-fourth to one-fifth of them are utilized under conditions of rest. During exercise the blood flow through the lungs increases—as it must because the output of both circulations rises up to five times normal—and more capillaries open up to accommodate the increase. A wide-open capillary tree actually offers less resistance to flow than the more limited perfusion at rest, hence the pulmonary arterial pressure does not rise. Thus, although regulation of pressure in the systemic circulation requires a complicated mechanism for reflex dilatation of arterioles, this problem is solved in the pulmonary circulation by the expedient mechanism of opening a greater number of capillary channels.

The gas exchange in the lungs occurs efficiently despite the speed with which the blood flows through the pulmonary capillary. The process here is the reverse of that in the systemic capillaries; *i.e.*, oxygen enters the blood and carbon dioxide leaves it. Again, this is a chemical process and not one of physical diffusion. The blood in the pulmonary capillaries is separated from the air in the alveoli by a single layer of cells and a thin membrane through which these gases are easily transported.

The mechanism of exchange between water and extracellular fluid in the capillaries was explained earlier. In the lungs, the same forces are at work. Pressure in the capillaries, however, ranges from 10 to 5 mm Hg instead of from 30 to 10 mm Hg as in the systemic capillaries. Thus the same colloid pressure with a lower capillary pressure would tend to absorb water from tissue fluid in the lungs. Absorption is prevented by negative pressure in the air system, which counteracts the intravascular forces and maintains a water balance similar to that occurring in other organs.

The pulmonary venous system. From the pulmonary capillaries, blood, now fully saturated with oxygen, enters the pulmonary venules, which converge into small veins, then into successively larger veins in the manner of the venous system in general. The largest vessels, the pulmonary veins, enter the posterior portion of the left atrium of the heart. In contrast to the systemic circulation, which enters the heart via two great veins, there are four pulmonary veins, two from each lung. The blood enters the heart under a pressure of 5–6 mm Hg. Gravity, so important in the systemic circulation, plays no part in the pulmonary venous drainage. Blood is moved by various means: by pressure transmitted from the pulmonary artery, by the negative pressure in the thorax, and by diastolic suction exerted by the left ventricle drawing blood from its atrium.

The pulmonary circulation as a whole is influenced by the pressure in the thorax. The entire circuit is contained in a medium where there is negative pressure, periodically increasing and decreasing. During inspiration, when the negative pressure is accentuated, blood flow in the pulmonary circulation increases and accelerates, while at the same time the pulmonary pressure rises slightly. During expiration the negative pressure in the thorax decreases and the blood flow in the pulmonary circulation lessens and slows down.

THE LYMPHATIC SYSTEM

The transport function of blood, other than that for gas exchange, is aided by an auxiliary system of vessels—the lymphatic system (*q.v.*). This system is somewhat similar to the venous system. It starts with lymphatic capillaries, vessels as ubiquitous as blood capillaries, which converge into larger vessels, draining finally into the lymphatic duct, its largest vessel. The lymphatic duct runs upward along the inner surface of the spine and eventually empties into the venous blood system, entering a large tributary vein of the superior vena cava in the uppermost part of the thorax. Blood flow in the larger lymphatic vessels is aided by the same factors facilitating venous return of blood.

The principal role of the lymphatic system is the transport of substances consisting of large molecules, particularly proteins and fatty compounds. Lymphatic capillaries have large pores, and giant-molecular substances migrate easily into and out of such capillaries. The lymph—fluid in the lymphatic system—replenishes the blood plasma with proteins. Fatty substances are absorbed by the lymphatics from the gastrointestinal tract and then carried to the blood for distribution to the appropriate organs.

The lymphatic system contains a set of filters—the lymph nodes—where noxious substances are removed from the circulation.

Blood Diseases

The blood diseases are abnormal conditions that involve the corpuscular elements of the blood—the red blood corpuscles, the leukocytes, or white blood cells, and the platelets—and the tissues in which they are formed—the bone marrow, the lymph nodes, the spleen; *i.e.*, the "hematopoietic system." This definition, however, needs expansion and modification: In certain types of illness (*e.g.*, pneumonia, appendicitis) the number of leukocytes is increased, and qualitative changes in the leukocytes take place as well; these increases in the leukocytes, called leukocytosis, do not represent "blood disease." In other diseases, as will be mentioned below, a reduction in the number of red corpuscles in the blood (anemia) occurs; such anemia is not usually thought of as representing a "blood disease," but it does represent the response of the hematopoietic system to the underlying disease. Strictly speaking, the term blood disease refers only to those types of anemia and those disorders of leukocytes, of platelets, of coagulation, and of the bone marrow and lymph nodes and spleen in which the blood-forming organs are the primary tissues that are involved.

In the following discussion, all varieties of alterations in the three corpuscular elements of the blood will be discussed. For convenience, disorders chiefly affecting the red corpuscles, the leukocytes, the platelets, and the process of blood coagulation will be considered in turn, but, as will become apparent, alterations in disease do not necessarily occur in only one of these groups of corpus-

cles; in its reactions in disease the hematopoietic system often reacts as a unit.

Since the blood circulates throughout the body and carries nutritive substances as well as waste products, it is not surprising that by its examination the presence of disease can be detected. Examination of the blood may be considered in two categories; namely, the analysis of the fluid portion, the plasma, and the study of the corpuscles. Examination of the plasma includes measurement of plasma proteins, blood sugar, salts (which, being in solution and in the ionic state, are referred to as electrolytes), and various hormones. Such measurements are useful in the identification of diseases that are not classified as blood diseases; *e.g.*, diabetes, kidney disease, and thyroid disease.

Development of understanding of the blood and blood diseases. The blood has fascinated mankind as long as human thought has been recorded and human memory recalls. Long before the nature and composition of blood were known, a variety of complaints was attributed to disordered blood. The red blood corpuscles were not recognized until the 17th century, and it was another 100 years before one of the forms of the white corpuscles, the lymphocyte, and the clotting of blood were described. In the 19th century other forms of leukocytes were discovered and a number of diseases of the blood and blood-forming organs were distinguished.

In the 19th century and also in the first quarter of the 20th century much attention was given to descriptions of the morphologic changes—the changes in form and structure—that take place in the blood in disease and to the clinical manifestations of the various blood diseases. In the years that followed, a more physiologic approach began to develop, concerned with the mechanisms underlying the development of disease and with the ways in which abnormalities might be corrected. Following World War II, progress was greatly accelerated by the strong financial support that medical science received, and, in what will perhaps be looked upon as the "golden age of medical research," knowledge was gained at an ever-accelerating pace. Changing priorities in the 1970s may result in a serious slackening of this pace.

Methods of study. The study of a particular instance of disease involves inquiry into the circumstances of its development, the symptoms, and the course of the illness (the history). A thorough physical examination of the affected person and specific laboratory tests are essential for an intelligent approach to treatment.

Features of laboratory and physical examinations

In the case of the blood, certain features of the physical examination are especially important in diagnosis. These include noting the presence or absence of pallor or, the opposite, an excess of colour; jaundice, red tongue, enlargement of the heart and liver; the presence or absence of small purple spots or larger bruises in the skin; enlargement of lymph glands (nodes); enlargement of the spleen; and tenderness of the bones.

Laboratory studies particularly valuable in diagnosis include (1) determination of the existence of anemia or polycythemia (see below); (2) study of the white corpuscles, their number, and their proportions as to type; (3) enumeration of the blood platelets and a study of the blood-clotting process; and (4), in many instances, a study of the bone marrow. Further, it is sometimes necessary to remove a lymph node for microscopic examination, and X-ray examinations may be necessary for the detection of organ or lymph node enlargement or bone abnormalities. The more unusual cases may require further examinations; *e.g.*, special biochemical procedures. Measurement of total blood volume is rarely useful, partly because readjustments in plasma volume take place rapidly, thereby restoring total blood volume toward normal levels, and partly because methods of red cell and plasma volume measurement are not exact.

Disorders affecting red cells

The quantity of red blood cells (RBC) in normal human beings varies with age and sex as well as with external conditions, primarily atmospheric pressure. At sea level an average normal man has 5,400,000 red blood cells per cubic millimetre of blood. These carry an average of 16 grams of hemoglobin per 100 millilitres of blood. If such blood is centrifuged so that the red blood cells are packed in a special tube known as the hematocrit, they are found, on the average, to occupy 47 percent of the volume of the blood. In the average woman, the normal figures are lower than this (red cell count 4,800,000; hemoglobin 14 grams, volume of packed red cells 42 percent). In the newborn infant they are higher but decrease in the course of several weeks to levels below those of the normal woman; thereafter, they rise gradually. The differences in male and female blood begin to appear at about the time of puberty. It should be emphasized that these figures represent average values; those found in normal persons range approximately 15 percent on either side of this mean.

Normal values for red blood cells

From the physiologic standpoint, it is the quantity of hemoglobin in the blood that is important, because this iron-containing protein is required for the transport of oxygen from the lungs to the tissues. In disease, as well as in certain situations in which physiologic adjustments take place, the quantity of hemoglobin may be reduced below normal levels, anemia, or may be increased above normal, polycythemia.

THE ANEMIAS

Anemia varies in severity. The reduced amount of oxygen in the blood of anemic persons may be a cause of their symptoms and of the consequent poor functioning of organs such as the heart, the skeletal muscle, and the brain, but the tolerance of different persons for anemia varies greatly and depends in part upon the rate at which anemia has developed. When anemia has developed gradually, affected persons may endure severe grades of anemia with few or no complaints, whereas rapidly developing anemia will cause severe symptoms; if sufficiently severe and rapid in development, anemia can be fatal.

Anemia is always a sign, either predominant or incidental, of some underlying congenital condition or acquired disease. There are many varieties of anemia. Their clinical manifestations are, in the main, similar, and yet they must be differentiated because their causes differ and consequently their treatment is not the same. Differentiation is based on the history and physical examination, which may reveal an underlying cause, and on examination of the blood. The latter includes measurement of the degree of anemia and microscopic study of the blood corpuscles. If the number of red corpuscles, the hemoglobin concentration of the blood, and the volume of packed red cells are known, one can calculate the mean volume and hemoglobin content. The mean corpuscular volume (MCV) normally is 82 to 92 cubic microns, and about a third of this is hemoglobin (mean corpuscular hemoglobin concentration, MCHC, normally is 32 to 36 percent). These, if determined accurately, are useful indices of the nature of an anemia.

Under the microscope the red cells of man appear as round biconcave discs of uniform size with an average diameter of about 7.5 microns, or 0.0075 millimetre (a common pin is about one millimetre thick). Microscopic inspection of films of blood dried on glass slides and stained with aniline dyes allows observation of variations in the size and colour and other abnormalities of individual red cells and also permits examination of the white blood corpuscles and platelets.

Derangement of function in anemia. Red cells are formed within the marrow cavities of the central bones of the adult human skeleton (skull, spine, ribs, breastbone, pelvic bones). Under the microscope the marrow is seen to contain hosts of nucleated red cells (erythroblasts), as well as white blood cells of all stages of development and megakaryocytes, the source of blood platelets. The erythroblasts are present in various stages of development toward the mature, adult, nonnucleated, hemoglobin-containing red corpuscles that will be released into the circulating blood.

Normal production of red blood cells

The newly arrived red corpuscles in the circulation remain as reticulocytes, young red cells with a characteristic threadlike network, for two or three days. Each day's output of new red corpuscles survives an average of 120 days before succumbing to old age. The red corpuscles are able to withstand the vicissitudes of the circulation, thanks to energy supplied by glucose absorbed from the plasma; the glucose is metabolized by a variety of enzymes. Ultimately the red cells are broken down by specialized reticuloendothelial cells that are found throughout the body, and especially in the spleen and liver. The hemoglobin is digested into its components: iron, a red pigment with a ring-shaped structural formula (porphyrin), and a protein (globin). The iron and the protein remain within the body to be used over and over again in the formation of new hemoglobin, but the porphyrin ring opens and is changed chemically to become the yellow pigment of the blood plasma, bilirubin. This is then excreted by the liver and gives the bile its characteristic colour.

In a healthy person, red cell production (erythropoiesis) is so well adjusted to red cell destruction that the levels of red cells and hemoglobin remain constant. The circulation is a closed system from which there normally is no loss of blood, except that which occurs physiologically in menstruation. Anemia results when (1) the production of red cells and hemoglobin lags behind the normal rate of their destruction; (2) excessive destruction exceeds production; or (3) blood loss occurs. The bone marrow normally is capable of increasing production as much as sixfold to eightfold through an increased rate of development from the primitive cells. Anemia ensues when the normal fine balance between production, destruction, and physiologic loss is upset and erythropoiesis has not been accelerated to a degree sufficient to reestablish normal blood values.

The rate of production of red cells by the bone marrow normally is controlled by a physiologic feedback mechanism analogous to the thermostatic control of temperature in a room. The mechanism is triggered by a reduction of oxygen in the tissues (hypoxia) and operates through the action of a hormone, erythropoietin, in the formation of which the kidney plays an important role.

Failure of production may be caused by deficiency of certain essential materials, such as iron or folic acid or vitamin B_{12}, or may be due to other causes, such as the presence of certain types of disease—*e.g.*, infection; damage of the bone marrow by ionizing radiation or by drugs or other chemical agents; or anatomical alterations in the bone marrow, as by leukemia or tumour metastases (migration of tumour cells to the marrow from distant sites of origin). Accelerated destruction may occur for any one of a large variety of causes that will be discussed below (see *Hemolytic anemias*). Finally, blood loss may result from trauma or may be associated with a variety of diseases.

Classification of anemias by size of red cells

Persons whose anemia is due to increased destruction of red cells have excessive amounts of bilirubin in the plasma and appear to be slightly jaundiced, and the excess pigments darken the excreta. Certain laboratory tests serve to measure the degree of excessive pigment production. When the bone marrow is producing more red cells, the number of reticulocytes in the blood increases. These cells, in addition to their unique staining characteristics, are larger than fully mature red corpuscles. If their number is increased sufficiently, the MCV of the cells in the circulation is increased. The anemia is then characterized as macrocytic.

Macrocytic anemia also is produced when anemia results from impaired production of red cells; *e.g.*, when vitamin B_{12} is lacking. In other circumstances, as for example when there is a deficiency of iron, the circulating red corpuscles are smaller than normal and poorly filled with hemoglobin—this is termed hypochromic microcytic anemia. In still other forms of anemia there is no significant alteration in the size, shape, or coloration of the red cells—normocytic anemias.

Anemias may be classified according to the underlying abnormality in the basic physiologic mechanism (decreased production, increased destruction, blood loss) or on morphologic grounds (macrocytic, normocytic, or microcytic hypochromic) or according to their cause (*e.g.*, vitamin B_{12} deficiency). In practice it is by a combination of clinical, morphologic, and physiologic studies that the cause is determined. Accurate diagnosis is essential before treatment is attempted because, just as their causes differ widely, so the treatment of anemia differs from one patient to another. Indiscriminate treatment by the use of hematinics (drugs that stimulate production of red cells or hemoglobin) is wasteful and can be dangerous.

Other classifications of anemias

Megaloblastic anemias. Lack of vitamin B_{12} or folic acid leads to the production in the bone marrow of abnormal nucleated red cells known as megaloblasts. Such cells can be identified by their characteristic appearance. When such a vitamin deficiency occurs, bone marrow activity is seriously impaired and erythropoiesis becomes largely ineffective. Anemia develops, the number of reticulocytes is reduced, and even the numbers of granulocytes (leukocytes that contain granules in the cell substance outside the nucleus) and platelets are decreased. The adult red cells that are formed from megaloblasts are larger than normal, resulting in a macrocytic anemia. The impaired and ineffective erythropoiesis is associated with accelerated destruction of the red corpuscles, thereby providing the features of a hemolytic anemia.

Deficiency of vitamin B_{12} is manifested in other tissues as well as in the hematopoietic system. The tongue becomes sore and appears abnormally smooth. There is defective function of the intestine, resulting in "indigestion" and sometimes diarrhea. Most serious is degeneration of certain motor and sensory tracts of the spinal cord, because if vitamin B_{12} deficiency has been present for some time, treatment with vitamin B_{12} may not correct it. Initial complaints of numbness and tingling of fingers and toes may, without treatment, eventually progress to great instability of gait or virtual paralysis.

Sources of vitamin B_{12}; pernicious anemia

Vitamin B_{12} is a red, cobalt-containing vitamin that is found in animal but not in vegetable foods. Unlike other vitamins, it is not formed by higher plants but only by certain bacteria and molds and in the rumina of sheep and cattle, provided that traces of cobalt are present in their fodder. In other species, including man, vitamin B_{12} must be obtained passively, by eating food of animal source. Furthermore, this vitamin is not absorbed efficiently from the human intestinal tract unless a certain secretion of the stomach, the so-called intrinsic factor, is available to concentrate the vitamin on the intestinal wall.

The most common form of vitamin B_{12} deficiency is pernicious anemia, a condition first described by the English physician Thomas Addison in 1855 and usually affecting patients past middle life. In this disorder all stomach secretion fails, perhaps as the result of an allergic process consisting of the production of antibodies directed against the stomach lining. The tendency to form such antibodies may be hereditary.

The discovery of vitamin B_{12} came about because of the investigations of the American physician George H. Whipple, which were concerned with the study of the value of various foods in promoting the formation of hemoglobin in dogs made anemic by bleeding, and of American physicians George R. Minot and William P. Murphy, who tested the value of liver, the food found by Whipple to be most effective in the treatment of pernicious anemia. It is an interesting commentary on the ways of the growth of knowledge that the activity of the foods tested by Whipple was due mainly to their iron content rather than to the presence of vitamin B_{12}. Fortunately, from the standpoint of the victim of pernicious anemia, the once certain death was transformed to life and good health, at first if he consumed a half pound of liver per day, then if he received regular amounts of liver extract orally or by injection, and now if he is given, by injection, the equivalent of a millionth of a gram of vitamin B_{12} per day. In practice, the necessary amount of this vitamin can be given once a month or even once in three months. Oral treatment with vitamin B_{12} is possible but inefficient.

Investigations by William B. Castle, American physician and medical scientist, of the nature of the abnormality of the stomach in pernicious anemia, following the dramatic although rather fortuitous discovery of the value of liver therapy in pernicious anemia, and studies by other scientists profoundly influenced the study of hematology and converted it from a largely descriptive to a dynamic field based on a physiologic approach.

Other forms of vitamin B_{12} deficiency are rare. They are seen in complete vegetarians; in persons whose stomachs have been completely removed; in individuals who are heavily infested with the fish tapeworm *Diphyllobothrium latum* or have intestinal cul-de-sacs or partial obstructions, when competition by the tapeworms or by bacteria for vitamin B_{12} deprives the host; and in persons with primary intestinal diseases that affect the absorptive capacity of the small intestine (ileum). In these conditions, additional nutritional deficiencies, as of folic acid and iron, are likely to develop.

Effects of folic-acid deficiency

Blood changes similar to those occurring in vitamin B_{12} deficiency result from deficiency of folic acid. Folic acid is a vitamin found in leafy vegetables, but it is also synthesized by certain intestinal bacteria. In man, deficiency usually is the result of a highly defective diet, of chronic intestinal malabsorption as mentioned above, or of cirrhosis of the liver. In rare instances, additional dietary deficiency of vitamin C may produce clinical signs of scurvy and interfere with the conversion of dietary folic acid in the liver to its internally active form. Pregnancy greatly increases the need for this vitamin, and megaloblastic anemia may result. In some cases of long-continued accelerated production of red blood cells, as in some persons with thalassemia (see below), folic-acid deficiency may develop. This type of deficiency also has been observed in some patients receiving certain drugs, especially anticonvulsants.

Unless folic-acid deficiency is complicated by the presence of intestinal or liver disease, its treatment rarely requires more than the institution of a normal diet. In any event, the oral administration of folic acid, or its synthetic equivalent, pteroylglutamic acid, relieves the megaloblastic anemia. This effect can be demonstrated even in pernicious anemia, but in that condition the nervous system is not protected against the effects of vitamin B_{12} deficiency and serious damage to the nervous system may occur unless vitamin B_{12} is given.

In the above conditions, megaloblastic anemia develops as the result of dietary deficiency, faulty absorption of, or increased demands for, vitamin B_{12} or folic acid or both. In addition to these circumstances, selective vitamin B_{12} malabsorption may be the consequence of a hereditary defect. Deranged metabolism may play a role in some instances of megaloblastic anemia of pregnancy. Metabolic antagonism is thought to be the mechanism underlying the megaloblastic anemia associated with the therapeutic use of certain anticonvulsant drugs and some drugs employed in the treatment of leukemia and other forms of cancer.

Normocytic normochromic anemias. The term normocytic normochromic anemia is applied to those forms of anemia in which the mean size and hemoglobin content of the red corpuscles are within normal limits. Usually microscopic examination of the red cells shows them to be much like normal cells, but in many instances there is some variation from the normal. In other cases, there may be marked variations in size and shape, but these are such as to equalize one another, thus resulting in normal mean values. The normocytic anemias are a miscellaneous group, by no means as homogeneous as the megaloblastic anemias.

Anemias associated with loss of blood and chronic infections

Anemia caused by the sudden loss of blood is necessarily normocytic at first, since the cells that remain in the circulation are normal. The blood loss stimulates increased production, and the young cells that enter the blood in response are larger than their fellows. If they are present in sufficient number, the anemia temporarily becomes macrocytic (but not megaloblastic).

The causes of acute blood loss, too numerous to list, include trauma, peptic ulceration of the bowel, and ulcerative lesions of other types. Treatment includes replacement, by transfusion, of the blood lost and appropriate steps directed against the cause.

A common form of anemia is that occurring in association with various chronic infections and in a variety of chronic systemic diseases. As a rule the anemia is not severe, although the anemia associated with chronic renal insufficiency (defective functioning of the kidneys) may be extremely so. Most normocytic anemias appear to be the result of impaired production of red cells and somewhat shortened survival of red cells. The anemia of chronic disorders is characterized by abnormally low levels of iron in the plasma in the face of excessive quantities in the reticuloendothelial cells (cells whose function is ingestion and destruction of other cells and of foreign particles) of the bone marrow. Successful treatment depends on the possibility of eliminating or relieving the underlying disorder.

The mild anemias associated with deficiencies of the anterior pituitary, thyroid, adrenocortical, and testicular hormones usually are normocytic. As in the case of anemia associated with chronic infections or various systemic diseases, the symptoms usually are those of the underlying condition, although sometimes anemia may be the most prominent sign. Unless complicated by deficiencies of vitamin B_{12} or iron, these anemias are abolished by appropriate treatment with the lacking hormone.

Invasion of bone marrow by cancer cells carried by the blood stream, if sufficiently great, is accompanied by anemia, usually normocytic in type. It is thought that such anemia is due to impaired production of red cells through mechanical interference. Whether this be true or not, a characteristic sign in the peripheral blood is the appearance of many irregularities in the size and shape of the red cells and of nucleated red cells; the latter normally never leave the bone marrow.

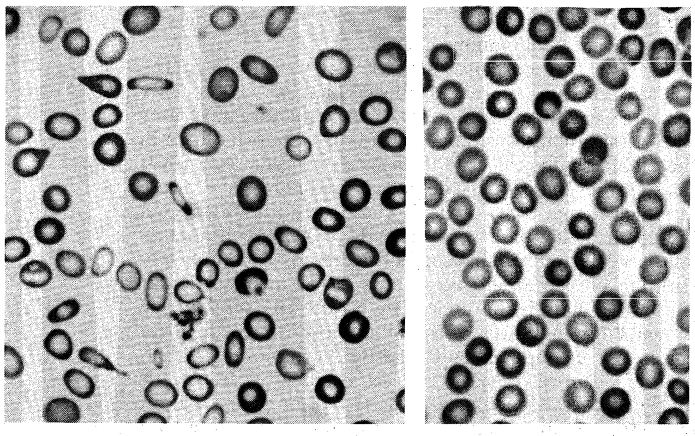
In aplastic anemia the normally red marrow becomes fatty and yellow and fails to form enough of its three cellular products—red cells, white cells, and platelets. Anemia with few or no reticulocytes, reduced levels of the types of leukocytes formed in the bone marrow (granulocytes), and reduced platelets in the blood are characteristic. The results are weakness, increased susceptibility to infections, especially of the mouth and gums, and bleeding manifestations. The last are harmless in the skin but quickly fatal in the brain. In a number of cases the onset of aplastic anemia has been found to have been preceded by exposure to such organic chemicals as benzol, insecticides, or a variety of drugs, including especially the antibiotic chloramphenicol. It is well established that sufficient exposure to ionizing radiation or to benzol or recognized myelosuppressive (bone-marrow–suppressive) agents, such as those used in the treatment of leukemia, will produce aplastic anemia, but other potential causes of such anemia seem to be harmless to hundreds or even thousands of persons. Their ill effects, therefore, would seem to depend on a peculiar sensitivity.

Aplastic anemia

Treatment consists of cessation of further exposure to any potential causative agent, administration of appropriate antibacterial drugs if infection occurs, and repeated blood transfusions in the hope of sustaining the afflicted person until spontaneous recovery of bone marrow function occurs. Sometimes the administration of the male sex hormone, with or without corticosteroid hormone, may be of some value.

Hypochromic microcytic anemias. Hypochromic microcytic anemias, characterized by the presence in the circulating blood of red cells that are smaller than normal and poorly filled with hemoglobin, fall into two main categories.

Deficiency of iron is probably the most common cause of anemia throughout the world. Iron is required for hemoglobin formation; if the supply is insufficient to produce normal quantities of hemoglobin, the bone marrow ultimately is forced to produce cells that are smaller than normal and poorly filled with hemoglobin. Iron is derived from the diet and absorbed in the intestinal tract.



Photomicrograph of a blood smear from a case of hypochromic microcytic anemia due to iron deficiency. Red corpuscles from normal blood are shown, for comparison, at right. (Wright's stain, magnified about 726 ×.)
Maxwell M. Wintrobe, *Clinical Hematology*, 6th ed.

Once in the body, it is retained and used over and over again, only minimal amounts being lost through shedding of cells from the skin and the exposed membranes and through normal menstruation. Deficiency results if the dietary supplies of iron are insufficient to meet the needs; if absorption is faulty, as in malabsorption disorders; or if blood loss is occurring. Excessive menstrual loss is a common cause of iron deficiency in women, bleeding peptic ulcer in men. Iron deficiency is common in infancy and childhood, because demands are great for the ever-expanding pool of circulating hemoglobin in the growing body, and in pregnancy when the fetus must be supplied with iron. Hookworm infestation is a common cause of iron deficiency where conditions for the worm are favourable, because the intestinal blood loss caused by the myriads of worms is great.

Sources of iron; prevalence of iron-deficiency anemia

The body of the human adult normally contains two to six grams (0.07 to 0.18 ounce) iron, of which about half is in hemoglobin. In the adult male, unless bleeding and consequent iron loss take place, there is virtually no more need for iron. Milk is a poor source of iron; meat and green leafy vegetables are good sources. Victims of iron-deficiency anemia are pale but not jaundiced. The deficiency of iron-containing enzymes in the tissues, if sufficiently great, results in a smooth tongue; brittle, flattened fingernails; and lustreless hair. Under the name of chlorosis, this type of anemia was mentioned in popular literature and depicted in paintings, especially those of the Dutch masters, until the present century. It is not necessarily less common now, but no doubt is less severe in Europe and in North America than it once was. The only treatment required is oral administration of iron salts in some palatable form, such as ferrous sulfate.

Small red cells poorly filled with hemoglobin are characteristic of a hereditary disorder of hemoglobin formation, thalassemia, that is common among people of Mediterranean stock and will be discussed below. With the exception of iron deficiency and thalassemia, hypochromic microcytic anemia is rare. It is seen in anemia responsive to the vitamin pyridoxine, where the anemia probably results from a metabolic fault in the synthesis of the heme portion of hemoglobin. Sideroblastic anemia, characterized by the presence in the bone marrow of nucleated red cells surrounded by a ring of iron granules ("ringed sideroblasts") and by a proportion of small, pale red cells in the blood, is of unknown cause and difficult to treat.

Diagnosis and causes of hemolytic anemia

Hemolytic anemias. Destruction of red corpuscles at a rate substantially greater than occurs normally, if not compensated for by accelerated production, causes a type of anemia called hemolytic. Increased red cell destruction is recognized by demonstrating increased quantities of the pigmentary products of their destruction, such as bilirubin and urobilinogen, in the blood plasma, urine, and stools, as mentioned earlier, and also by evidence of accelerated erythropoiesis, such as an increase in the number of young corpuscles (reticulocytes) in the blood. When blood destruction is extremely rapid or occurs in the blood vessels, free hemoglobin will be found in the urine (hemoglobinuria). Treatment varies with the cause of the hemolytic anemia.

There are two principal causes of hemolytic anemia: (1) inherently defective red cells and (2) an environment hostile to red cells.

Abnormalities within the red cell are usually congenital and hereditary. They include hereditary spherocytosis, sickle-cell anemia, and thalassemia, as well as a number of less common conditions. Sickle-cell anemia, thalassemia, and other diseases involving abnormality of the hemoglobin are forms of hemolytic anemia but will be discussed in a special section below.

Hereditary spherocytosis is characterized by the presence in the blood of red cells that appear small, stain densely for hemoglobin, and look nearly spherical. Such cells are mechanically fragile and readily swell up and burst in dilute salt solution. In the body they break up when deprived of free access to plasma glucose. The abnormality is aggravated by a tendency for the cells to remain longer than usual in the spleen, because of their spheroidal shape. The corpuscular defect may appear if it is inherited from either parent (*i.e.*, it is inherited as a dominant gene). The anemia varies in severity. It may be so mild as to pass for years unnoticed, but it may suddenly become severe; *e.g.*, when an incidental respiratory infection briefly suppresses the accelerated production of red cells necessary to meet the constantly increased rate of their destruction. Removal of the spleen, which always is enlarged, cures the anemia by eliminating the site of sequestration and destruction of the red cells but, of course, does not prevent future hereditary transmission of the disease.

Hereditary enzyme deficiencies of the red cell cause hemolytic anemia. The anaerobic (oxygenless) metabolism of the red cell depends on the normal function of a large number of enzymes. Hemolytic anemias resulting from "inborn errors" in the main process of glucose breakdown in the red cell usually must be inherited from both parents to become manifest. The degree of anemia varies among the different enzyme lesions and even among persons with the same enzyme deficiency. In some instances of severe hemolytic anemia, removal of the spleen has ameliorated the disease.

Abnormalities also have been discovered in the alternative process of glucose metabolism, known as the phosphogluconate oxidative or "shunt" glycolytic pathway. They include deficiencies in the enzymes glutathione reductase, glutathione, and erythrocytic glutathione peroxidase. The deficiencies of the first two enzymes are transmitted as an autosomal dominant trait (that is, it may become manifest if inherited from one parent) and an autosomal recessive trait (it needs inheritance from both parents to become manifest), respectively. Deficiency of another enzyme, glucose-6-phosphate dehydrogenase (G6PD), is rather common. The frequency of this disorder varies from 1 to 36 percent among different Caucasian population groups. It is especially frequent in Mediterranean peoples. Chronic hemolysis and anemia may be present, and in some individuals ingestion of fava beans may induce severe destruction of red cells. A different variety of G6PD deficiency has been demonstrated in 10 to 14 percent of American Negroes and is of special interest in that the defect is harmless unless the individual is exposed to certain drugs, such as certain antimalarial compounds (*e.g.*, primaquine) and sulfonamides. The full effect of the deficiency is rarely observed in females.

Still other forms of hemolytic anemias due to intrinsic red cell abnormalities are known, some of which are hereditary, and others acquired. An example of the latter is pernicious anemia (see above) resulting from vitamin B_{12} deficiency. In certain types of hemolytic anemia, the intrinsic red cell abnormality is harmful only in special circumstances; *e.g.*, the G6PD deficiency mentioned above.

Hemolytic anemia can also result as the consequence of

an environment hostile to the red cell. This type represents most of the acquired forms of hemolytic anemia as distinguished from the hereditary varieties already discussed. Certain chemical agents destroy red cells whenever sufficient amounts are given (*e.g.*, phenylhydrazine); others are harmful only to certain sensitive individuals. A number of the toxic drugs are oxidants or are transformed into oxidizing substances in the body. Injury may be accidental, as with moth ball (naphthalene) ingestion in children, or it may be the undesirable effect of a drug used therapeutically. Individual sensitivity is of several kinds. There is the susceptibility of certain Negro men to antimalarial compounds mentioned above. This is attributable to a sex-linked, inherited deficiency of the enzyme G6PD. In other instances, sensitivity is on an immunologic basis; *e.g.*, hemolytic anemia caused by penicillin, quinidine, or alpha-methyldopa (a drug used in the treatment of elevated blood pressure). The anemia develops rapidly over a few days and without transfusions may be fatal.

A long recognized type of hemolytic anemia is that associated with the transfusion of incompatible red cells. The substances alpha- and beta-isoagglutinin, which occur naturally in the blood, destroy the red cells when incompatible blood is given by transfusion. Besides the best known blood groups—A, B, and O—there are other groups, incompatibility with which may account for transfusion reactions. The Rhesus (Rh) groups and the Kell groups are examples. In hemolytic disease of the newborn (erythroblastosis fetalis) the destruction of the blood of the fetus by that of the mother may be due to Rh or to ABO incompatibility. The events that take place are, first, the passage of incompatible red cells from the fetus into the circulation of the mother through a break in the placental blood vessels; then development of antibodies in the mother; and, finally, passage of these antibodies into the fetus, with consequent anemia and jaundice.

A form of hemolytic anemia that is relatively common depends on the formation of antibodies within the patient's body against his own red cells (autoimmune hemolytic anemia). This may occur in association with the presence of certain diseases, or there may be no apparent cause. Such anemias may be severe but often can be controlled by the administration of adrenocorticosteroids and treatment of the underlying disease, if one is present. In a number of instances, splenectomy—removal of the spleen—is necessary and is usually partially or wholly effective in relieving the anemia. The effectiveness of splenectomy is attributed to the removal of the organ in which red cells, coated with antibody, are selectively trapped and destroyed.

The mechanism underlying the development of autoimmune hemolytic anemia is mystifying because the substance that causes development of the hypothetical autoantibodies—the antigen—is unknown. Trapping of the red cells by the spleen is thought to depend on the fact that red cells coated with incomplete (nonhemolytic) antibody, when brought into contact with reticuloendothelial cells, adhere, become spherical, and break down.

Other varieties of hemolytic anemia include that associated with mechanical trauma, such as that produced by the impact of red corpuscles on artificial heart valves, excessive heat, and infectious agents (*e.g.*, the organism causing malaria).

Types of normal and of abnormal hemoglobin

Thalassemia and the hemoglobinopathies. Hemoglobin is composed of a porphyrin compound heme and globin. Normal adult hemoglobin (Hb A) consists mainly (97 percent) of globin containing two pairs of chains of amino acids, of which the alpha chain consists of 141 amino acids, the beta chain 146. (A chain of amino acids is called a peptide or, alternatively, when many amino acids make up the chain, a polypeptide.) A minor fraction of normal adult hemoglobin (Hb A_2) possesses a different second set of polypeptide chains, delta chains in place of beta chains. In fetal life, a different hemoglobin is present (Hb F); this progressively decreases in amount during infancy. Like Hb A_2, fetal hemoglobin possesses a pair of the same alpha chains as in Hb A, but the second set is different (gamma chains).

In normal hemoglobin, the order in which the amino acids follow one another in the chain is always exactly the same. Studies by a number of investigators have now shown that qualitative and quantitative abnormalities in the globin chains can lead to disease. In thalassemia it is thought that the primary defect is a reduction in the rate at which alpha, beta, or delta chains are manufactured, the chains being otherwise normal. In sickle-cell anemia and in other abnormalities affecting hemoglobin, the substitution of one amino acid for another at a particular site in the chain is the underlying fault. The substitution of valyl for glutamyl in the sixth position of the beta chain, for example, results in the formation of Hb S (that of sickle-cell disease) instead of Hb A. The defect is inherited as a Mendelian recessive: If only one parent transmits the abnormality, the offspring inherits the trait but is harmed relatively little. If the trait is inherited from both parents, the serious and ultimately fatal disease sickle-cell anemia is the consequence. Since the first characterization of the nature of the abnormality in Hb S by Linus Pauling and his associates (1949) more than 100 abnormal hemoglobins have been identified, and other forms of "molecular disease" have been recognized as well. Fortunately, most abnormal hemoglobins are not sufficiently affected to alter their function, and therefore no observable illness occurs. Several of these are extremely rare.

Sickle-cell trait and sickle-cell anemia

Sickle-cell anemia occurs almost exclusively in Negroes, about 7 percent of whom, in the United States, carry the sickle-cell trait. The actual disease, sickle-cell anemia, is less common (0.3 to 2.5 percent). In this condition most of the red cells of a sample of fresh blood look normally disc-shaped—discoidal—until deprived of oxygen, when the characteristic sickle- or crescent-shaped forms with threadlike extremities appear. Re-exposure to oxygen causes immediate reversion to the discoidal form. Sickle-cell anemia is characterized by severe chronic anemia, punctuated by painful crises, the latter being due to blockage of the capillary beds in various organs by masses of sickled red cells. This gives rise to fever and episodic pains in the chest, abdomen, or joints that are difficult to distinguish from the effects of other diseases. Death from anemia, from infections, or, ultimately, from heart or kidney failure often occurs before the age of 35 to 40 years. No treatment other than transfusion has been found to be effective.

Thalassemia

Thalassemia (Greek: "sea blood") is so called because it was first discovered among peoples around the Mediterranean Sea, among whom its incidence is high. This condition, when inherited from one parent, is called thalassemia minor; it causes serious disease only when inherited from both parents (thalassemia major, Cooley's anemia). Thalassemia now is known also to be common in Thailand and elsewhere in the Far East. The red cells in this condition are unusually flat with central staining areas and for this reason have been called target cells. In the mild form of the disease, thalassemia minor, there usually is only slight or no anemia, and life expectancy is normal. Thalassemia major is characterized by severe anemia, great enlargement of the spleen, and body deformities associated with enlargement of the bone marrow. The latter presumably represents a response to the need for greatly accelerated red cell production. The skull may be so deformed as to produce a mongoloid appearance, and body growth is impaired. Many victims die in childhood. Transfusions are of only temporary value and lead to excessive iron in the tissues. Removal of the spleen is not usually beneficial; apparently the short-lived red cells are destroyed elsewhere.

The defect in thalassemia may involve the beta chains of globin (beta-thalassemia), the alpha chains (alpha-thalassemia), the delta chains (delta-thalassemia), or both delta- and beta-chain synthesis. In the last (delta–beta-thalassemia), Hb F concentrations usually are considerably elevated. Beta-thalassemia comprises over 90 percent of all thalassemias. Alpha-thalassemia inherited from both par-

ents results in intra-uterine fetal death or severe disease of the newborn child (hydrops fetalis).

In most forms of hemoglobin abnormality only a single amino acid substitution occurs, but there may be combinations of hemoglobin abnormalities, or a hemoglobin abnormality may be inherited from one parent and thalassemia from the other. Thus, sickle-thalassemia, Hb C-S disease, and Hb E-thalassemia are relatively common.

Not only may anemia result from the inheritance of a hemoglobin abnormality but in certain forms of hemoglobinopathy there may be polycythemia—overproduction of red cells—resulting from the increased oxygen affinity of the abnormal hemoglobin (*e.g.*, Hb Chesapeake); impaired reversible association of the hemoglobin with oxygen, thereby interfering with oxygen transport and resulting in cyanosis (a bluish coloration of the skin because the blood lacks sufficient oxygen) and methemoglobinemia (abnormal amounts of methemoglobin in the blood; methemoglobin is a form of hemoglobin that combines lastingly rather than temporarily with oxygen); diminished oxygen binding (Hb Kansas); and normal heme–oxygen interaction, but with formation of a hemoglobin that precipitates readily, resulting in hemolytic anemia, abnormal structures (Heinz bodies) in the red cells, and abnormal pigment in the urine.

THE POLYCYTHEMIAS

The term polycythemia signifies an increase above the normal in the number of red corpuscles in the circulating blood. This increase is usually accompanied by a corresponding increase in the quantity of hemoglobin and in the volume of packed red corpuscles. The increase may be associated with an increase in the total quantity of red blood cells in the body (absolute polycythemia) or may be only relative. The latter situation occurs when, through loss of blood plasma, the concentration of red cells becomes greater than normal in the circulating blood. Relative polycythemia may be the consequence of abnormally lowered fluid intake or of marked loss of body fluid, such as occurs in persistent vomiting, severe diarrhea, or copious sweating or when water is caused to shift from the circulation into the tissue cells.

Absolute polycythemia occurring in response to some known stimulus is usually termed erythrocytosis, in contrast to erythremia, or polycythemia vera, which is a disease of unknown cause.

Erythrocytosis develops in the presence of defective saturation of the arterial blood with oxygen. This may result from decreased atmospheric pressure, as at high altitudes or from impaired pulmonary ventilation. The sustained increase in red cells in persons who reside permanently at high altitudes is a direct result of the diminished oxygen pressure in the environment. Chronic pulmonary disease may produce chronic hypoxemia (reduced oxygen tension in the blood) and lead to erythrocytosis; *e.g.*, emphysema—abnormal distension of the lungs with air. Extreme obesity also may severely impair pulmonary ventilation and thereby cause erythrocytosis (Pickwick syndrome).

Congenital heart disorders that permit shunting of blood from its normal path through the pulmonary circuit, thereby preventing adequate aeration of the blood, can cause erythrocytosis, as can a defect in the circulating hemoglobin. The latter defect may be congenital because of an enzymatic or a hemoglobin abnormality, as mentioned above; or it may be acquired as the result of the excessive use of coal-tar derivatives, such as phenacetin, which convert hemoglobin to pigments incapable of carrying oxygen (methemoglobin, sulfhemoglobin). Lastly, erythrocytosis can develop in the presence of certain types of tumours and as the result of the action of adrenocortical secretions. Treatment of polycythemia due to any of these causes involves the correction or alleviation of the primary abnormality.

Erythremia, or polycythemia vera, is a condition of unknown causation in which the numbers of red cells, and often also the numbers of white corpuscles and platelets, are increased and the spleen usually is enlarged. Persons affected with this disease have an exceptionally ruddy complexion and may complain of headaches, dizziness, a feeling of fullness, and other symptoms. Because of the excessive quantities of red cells, the blood is usually thick, and its flow is retarded; it sometimes clots in the vessels (thrombosis) of the heart, the brain, or the extremities with extremely serious consequences. The simplest method of treatment is to remove the blood, one pint at a time, from a vein until the cellular level approaches normal and the symptoms disappear. Another useful method involves the injection of radioactive phosphorus; this material is carried to the bones, where the radioactivity acts directly upon the blood-producing elements in the bone marrow and impairs their productive capacity. The administration of the phosphorus is repeated, when necessary, at intervals of three months or longer. The possibly untoward effects of ionizing radiation must always be kept in mind when this material is used. Small doses of such drugs as busulfan have been used in place of radioactive phosphorus.

Diseases related to leukocytes (white cells)

White cells include granulocytes, lymphocytes, and monocytes. Normally, the white cell count in an adult, in round numbers, ranges from 5,000 to 10,000 cells per cubic millimetre of blood.

The granulocytes as a group make up between 50 percent and 65 percent of the white cell total. There are three subgroupings of granulocytes based on the type of dye absorbed by the granules in the cytoplasm when the cells are stained in preparation for microscopic examination. Neutrophils, which absorb neutral dyes, are the largest group, numbering 3,000 to 5,500 per cubic millimetre of blood in an adult, or about two-thirds of all the white cells. Eosinophils, which take up acidic dyes such as eosin, number from 50 to 400 in an adult, or 1–4 percent of the total. Basophils, which take up basic stains, number from 0 to 40 in an adult, or up to 1 percent.

Lymphocytes, of which there are generally from 2,000 to 3,000 in an adult (28 percent to 42 percent of all white cells), possess a round nucleus that occupies most of the cell. Monocytes, which number from 300 to 700 (4 percent to 8 percent), have a lobulated nucleus with rounding projections and are the largest of all the white cells.

CHANGES IN NUMBER OF WHITE CELLS

Variations in the number of white cells in humans occur normally from hour to hour, the highest counts being recorded in the afternoon and the lowest in the early morning. Temporary increases also normally occur during muscular exercise, menstruation, pregnancy, and childbirth, as well as in emotional states.

Abnormal changes in the count, appearance, or proportion of the various white cells are indicative of pathological conditions in the body.

Leukocytosis. The condition in which white cells are present in greater numbers than normal is termed leukocytosis. It is usually caused by an increase in the number of granulocytes (especially neutrophils), some of which may be immature (myelocytes). Most often leukocytosis is the result of the presence of an infection, usually caused by pyogenic (pus-producing) organisms such as streptococcus, staphylococcus, gonococcus, pneumococcus, or meningococcus. Leukocyte counts of 12,000 to 20,000 per cubic millimetre during infections are not unusual. As the number of cells increases, the proportion of immature cells usually rises, perhaps because the demands on the leukocyte-producing tissues in the bone marrow have increased to the point at which there is an insufficient number of mature cells for delivery into the circulation. This picture of immaturity is referred to as a "shift to the left." As the infection subsides, the number of younger forms and the total white cell count decrease and ultimately return to normal. During the period of repair following an inflammatory reaction, the monocytes may increase in number, and subsequently the lymphocytes will become more numerous.

Certain types of infection are characterized from the

Lymphocytosis; infectious mononucleosis

beginning by an increase in the number of small lymphocytes unaccompanied by increases in monocytes or granulocytes. Such lymphocytosis is seen in whooping cough and in infectious lymphocytosis, a rare disorder probably of viral origin. Moderate degrees of lymphocytosis are encountered in certain chronic infections such as tuberculosis and brucellosis.

Infectious mononucleosis is a unique form of lymphocytosis in that the lymphocytes are larger than normal and often contain vacuoles—empty spaces—in their cytoplasm. Leukocyte counts of 15,000 to 30,000 per cubic millimetre are common, but a deficiency in the number of leukocytes can occur. As a rule there is no accompanying anemia or alteration in platelets; rarely the latter may be decreased in number, and extremely rarely hemolytic anemia develops. Infectious mononucleosis occurs predominantly in persons from 10 to 30 years of age and probably is due to a virus. It is thought to be transmitted by oral contact with exchange of saliva. Discomfort, fever, sore throat, and grippelike symptoms, together with enlargement of lymph nodes and spleen, characterize the condition. The blood serum contains an antibody (sheep cell or heterophil agglutinin) that is characteristic of the disease. The symptoms of this disease vary in severity in different persons, but often they are mild. Recovery takes place, as a rule, within several weeks.

Monocytosis, an increase in the number of monocytes in the blood, occurs in association with certain infectious processes, especially subacute bacterial endocarditis—inflammation of the lining of the heart—and malaria.

Eosinophilia, an increase in the number of eosinophilic leukocytes, is encountered in many allergic reactions and parasitic infections. It is especially characteristic of infestation by trichina larvae, which are ingested when infected, poorly cooked pork or pork products are eaten.

Leukopenia. The term leukopenia refers to leukocyte counts that are abnormally low (below 5,000 per cubic millimetre). Like leukocytosis, which is usually due to an increase of neutrophils (neutrophilia), leukopenia usually is due to a reduction in the number of neutrophils (neutropenia). Of itself, neutropenia causes no symptoms, but persons with neutropenia of any cause may suffer from frequent and severe bacterial infections. The term agranulocytosis refers to an acute disorder characterized by severe sore throat, fever, and marked prostration associated with extreme reduction in the number of neutrophilic granulocytes or even their complete disappearance from the blood.

Formerly, agranulocytosis often ended in death. It was later recognized that the disorder was due to sensitivity to a coal-tar product, aminopyrine (Pyramidon). It is now known that a number of drugs used therapeutically may cause neutropenia in sensitive persons, and, if this is not discovered and exposure to the offending agent is not stopped, sore throat, fever, and other signs of infection may develop and death can ensue. The severity of the infection is due to the lowered resistance that results from absence of granulocytes. Drugs that cause neutropenia include pain relievers, antihistamines, tranquillizers, anticonvulsants, antimicrobial agents, sulfonamide derivatives, and antithyroid drugs. In persons with unusual sensitivity, agranulocytosis may result from a single dose of a drug.

Neutropenia also is associated with certain types of infections (*e.g.*, typhoid, brucellosis, measles) and with certain diseases involving the bone marrow (*e.g.*, aplastic anemia) or the spleen. In addition, sufficiently high doses of radiation will cause neutropenia, as will certain antitumour agents.

Treatment includes removal of the cause of the neutropenia and the use of antibiotics appropriate for the existing infection.

LEUKEMIAS

Nature, types, and cause of leukemia. The term leukemia means "white blood" and arose from the discovery of extremely large numbers of white blood cells in the blood of certain persons; counts as high as 500,000 per cubic millimetre and even 1,000,000 per cubic millimetre may be found in some instances.

Leukemia is a fatal disease of the blood-forming organs that is encountered at all ages and in both sexes. The frequency of occurrence of this disease throughout the world has increased substantially during the 20th century. There are two main varieties of leukemia, myelogenous, or granulocytic, and lymphatic. These terms refer to the types of cells that are involved. Each of these types is further subdivided into acute and chronic categories, and additional, less common varieties are recognized, as will be mentioned below. The excessive cellular accumulation observed in all forms of leukemia is, in the acute leukemias and in chronic myelogenous leukemia, no doubt due to an overall increase in the rate of cell proliferation. This may not be true of chronic lymphatic leukemia. In that condition the primary defect may be a decreased rate of destruction of small lymphocytes.

The development of spontaneous or induced leukemia in mice as well as in certain other animals has been associated with a filterable virus. That such a virus is related to the disease in man has not been definitely proved. In mice, a variety of factors other than the virus determine whether the animal will or will not develop leukemia; certain strains of mice harbour a leukemia-causing agent and yet rarely develop leukemia. Thus genetic factors, as well as external factors such as ionizing irradiation, contribute to the development of leukemia. In man, ionizing irradiation is the one unequivocally proved leukemia-inducing agent. Survivors of the atomic bomb in Hiroshima and Nagasaki, the pioneering radiologists who used inadequately shielded apparatus, and certain patients receiving irradiation are known to have developed leukemia with a frequency far exceeding that of the general population. Noteworthy is the fact that almost all radiation-induced leukemia has been of the granulocytic variety.

There is suggestive evidence that certain chemicals and drugs, notably benzol and phenylbutazone, may cause leukemia. That genetic factors lead to an increased frequency of leukemia in certain selected instances is suggested by the higher concordance rate for acute leukemia observed in identical as compared with fraternal twins and the frequency of development of acute myeloblastic leukemia in children with Down's syndrome (mongolism), where there is a recognized chromosome defect. Evidence for the role of trauma, hormones (especially estrogens), infections, and psychological and other influences as factors leading to the development of leukemia is unconvincing.

Clinical manifestations. The terms acute and chronic refer to the duration of the untreated disease. Before the advent of modern chemotherapy, patients with acute leukemia would usually die within weeks or months of the first manifestations of the disease. The life-span of patients with chronic leukemia is measured in years.

Early signs of leukemia

Leukemia primarily involves the bone marrow, lymph nodes, and spleen. The lymph nodes and spleen usually are enlarged. Changes also take place in the leukocytes, red cells, and platelets, with consequent anemia and bleeding manifestations. The first symptoms may be weakness and an increased tendency to become fatigued because of anemia; or hemorrhages into the skin and nosebleed or gum bleeding due to a decrease in the number of platelets. In the acute leukemias these symptoms may be severe, the anemia may progress rapidly, and there may be fever. Chronic leukemia is more insidious in development, and the early manifestations may be overlooked until enlargement of the spleen or lymph nodes is discovered. Leukemia is recognized by examination of the blood, supplemented in many instances by examination of the bone marrow.

Acute leukemia is marked by the presence in the blood of immature cells normally not found there. In the lymphoblastic variety, most frequently seen in children, the cells are immature forms of the lymphatic series of cells. In myeloblastic leukemia, the predominant cells are the youngest recognizable precursors (myeloblasts) of the

neutrophils of the blood. In a third and the least common variety, acute monocytic leukemia, the immature cells appear to be precursors of the monocytes of the blood. Myeloblastic and monocytic leukemia occur more commonly in adults and adolescents than in young children. In general, acute leukemia occurs in young persons, but no age group is exempt.

The total white cell count usually is increased but not uncommonly is normal or lower than normal (leukopenic). In such cases, abnormal immature cells may nevertheless be seen in the blood. In all forms of acute leukemia, the typical cells are found in abundance in the bone marrow. "Aleukemic" leukemia refers to those instances of leukemia in which no abnormal cells are found in the blood; in these instances the leukemia is identified by examinations of the bone marrow.

Chronic granulocytic (myelogenous) leukemia is characterized by the appearance in the blood of large numbers of immature white cells of the granulocytic series in the stage following the myeloblast, namely, myelocytes. The spleen becomes enlarged, anemia develops, and the affected person may lose weight. The platelets may be normal or increased in number, abnormally low values being found only in the late stages of the disease or as an unintended result of therapy. The disease is most commonly encountered in persons between the ages of 20 and 45 years. With treatment, the leukocyte count falls to normal, anemia is relieved, the size of the spleen is greatly reduced, and a sense of well-being returns. When the leukocyte count rises again, treatment is re-instituted. Such cycles of treatment, remission, and beginning relapse with rise of leukocyte count can be repeated many times. Unfortunately, a stage ultimately is reached when treatment no longer is effective. The disease then often terminates in a form resembling acute leukemia ("blastic crisis"). There is considerable variation in the duration of the disease. Although in various series mean life-span has been about 3¼ years, many affected persons live in good general condition for five to ten years and sometimes longer.

Chronic lymphocytic leukemia differs in many ways from other forms of leukemia. It occurs most often in people over 50 years of age, and its course usually is rather benign. It is mainly characterized by an increase in the number of lymphocytes in the blood, often accompanied by more or less generalized enlargement of lymph nodes and the spleen. Affected persons may carry on for many years, without treatment and without any other manifestations. There may be no anemia and no loss of weight. Life-span in this disease is measured in terms of 5, 10, and even 15 years, occasionally even longer. Two events mark a change in the state of relative good health. One is the development of anemia, sometimes hemolytic in type, often accompanied by some decrease in the number of platelets. The other is impairment of immune mechanisms, resulting in great susceptibility to bacterial infections.

Treatment and chances of survival

Treatment differs according to the type of leukemia. Consequently, proper classification of the leukemia is the first step, once the diagnosis of leukemia has been made. Treatment of all types of leukemia reduces illness and, in acute leukemia, prolongs life. Cure of leukemia is not yet a realistic eventuality, but there are a few persons with acute leukemia who may have been cured; more than 100 affected persons, a small fraction of the total number affected, have shown no evidence of the disease for 5 to more than 15 years. Cure of chronic leukemia is as yet unknown, but spontaneous improvement may occur in any of the forms of leukemia.

A number of drugs are used for the treatment of leukemia and, now less frequently than before chemotherapy was available, various forms of irradiation. The therapeutic agents are all myelotoxic; *i.e.*, they injure all the cells of the bone marrow, normal cells as well as leukemic cells. Their mode of action is through direct damage to the dividing stem cell (unspecialized cell from which specialized cells develop) or by slowing or cessation of cell division. These effects may be accomplished by antimetabolites, substances that interfere with the synthesis of deoxyribonucelic acid (DNA, a constituent of the chromosomes in the cell nucleus), by blocking DNA strand duplication through the binding of drugs such as the nitrogen mustards with the base groups of DNA, by disruption of the mitotic spindle during cell division, or by interfering with the formation or functioning of ribonucleic acid (RNA, a substance that is manufactured in the cell nucleus and that plays an essential role in the production of protein and in other cell functions).

Much skill and experience are needed in steering the narrow path between maximum possible kill of the leukemic cells and tolerable injury to the normal cells of the host. In the process of treatment anemia may increase; the body defenses, through the decrease in the number of neutrophils, may be impaired, and the platelets may be greatly reduced in number. Anemia can be treated with blood transfusions, and serious reductions in platelets can be met for a time with platelet transfusions. Attempts have been made to prevent infection by isolation of patients and by sterilizing the gastrointestinal tract with appropriate antibiotics. When serious infections develop, as they often do, they are treated with antibiotics and by the introduction of leukocytes; the effectiveness of these measures is limited.

Acute lymphoblastic leukemia is more successfully treated than are other forms of acute leukemia. At least one complete remission can be brought about in almost all patients, and the average survival exceeds two years. Certain drugs are used to bring about remission; if the remission is complete, the patient becomes well, and no signs of the disease are demonstrable in the blood or bone marrow; drugs other than those used to induce remission often are more useful in maintaining the remission than the remission-inducing drugs.

Acute myeloblastic leukemia and acute monocytic leukemia are less effectively treated by available drugs than is acute lymphoblastic leukemia. Transplantation of normal bone marrow, following total irradiation of the patient to destroy all his normal bone marrow cells as well as the leukemic cells, has shown promise only when an identical twin was available as the source of marrow for transplantation.

Chronic myelocytic leukemia is treated with a drug, busulfan, in daily doses until the leukocyte count has returned to normal; by this time the patient usually feels well. Treatment then is interrupted until the leukocyte count has risen to about 50,000 cells per cubic millimetre, when treatment is resumed. This can be repeated many times, and thus the affected person is maintained in good health for years. Not infrequently the intervals between treatments are six months in duration or longer. Busulfan, however, like other antileukemic agents, can injure the bone marrow, and other adverse effects may occur. Other drugs and X-ray therapy also have been used but are somewhat less valuable than busulfan.

Chronic lymphocytic leukemia seems best untreated, as long as anemia is not present or glandular enlargement is not too troublesome. Many of the chemotherapeutic agents increase the rate of infection, a risk this disease carries already. The high leukocyte counts in themselves are not harmful. When there is severe anemia, however, or when the platelet count is very low and bleeding manifestations are severe, adrenocorticosteroid hormones are given, preferably for only short periods.

The lymphomas, malignant tumours of the blood-forming tissues, include lymphosarcoma, reticulum-cell sarcoma, and Hodgkin's disease. In these disorders there may be no striking abnormalities in the blood, even though large tumours develop in the lymph nodes, spleen, bone, and other tissues and in organs such as the stomach and liver. In general, the course of reticulum-cell sarcoma is brief, the affected person succumbing in months or a year or two. The course of lymphosarcoma may sometimes be slower than this, while the course of Hodgkin's disease varies greatly, ranging from six months in the rare case to several years in the majority of cases and many years in a few. Like chronic leukemia, these

conditions are treated by irradiation as well as by certain chemical agents.

Hodgkin's disease; multiple myeloma

Hodgkin's disease, the most common of these conditions, differs from the others in that its course sometimes resembles that of an infectious disease rather than a tumour. There may be fever as well as lymph-node enlargement; leukocytosis often occurs. The disease generally starts as a painless lump, often in the neck. Lymph nodes in many locations in the body, such as the chest cavity and the abdominal cavity, ultimately enlarge, however, as does the spleen. Anemia and weight loss ensue, and death ultimately occurs.

Another malignant disease, probably related to the above conditions, is multiple myeloma, which is characterized by a malignant overgrowth of plasma or plasma-like cells within the bone marrow. This severely painful disorder causes defects in the bone of the skull, the ribs, the spine, and the pelvis that ultimately result in fractures. As the bone marrow becomes more and more involved, anemia develops and hemorrhages occur: the number of leukocytes may be low, and abnormal myeloma or plasma cells are found in the bone marrow. This disorder is associated with a peculiar disturbance in protein metabolism. Certain blood proteins—globulins—may be found greatly increased, and the urine often contains a unique protein called the Bence-Jones protein. A type of chronic kidney disease often develops, probably as a result of the high concentration of Bence-Jones protein in the kidney tubules; this frequently is the ultimate cause of death. In some cases the condition remains quiescent for a time, but death is inevitable. Adrenocorticosteroid hormones and chemotherapeutic agents have been used in the treatment of multiple myeloma.

Diseases related to platelets

BLEEDING DISORDERS

Several different agents keep blood from flowing out of the blood vessels and into the tissues: the lining of the blood vessels, the blood platelets (thrombocytes), and certain compounds and enzymes in the blood that tend to promote the formation of a clot.

The capillaries (minute blood vessels in intimate contact with the tissues) are elastic and have smooth linings; when the capillaries are cut, the linings normally retract about the injured area, serving to prevent further blood loss. The blood platelets are very small cellular particles (not actually cells) derived from the largest cells of the bone marrow—the megakaryocytes. The platelets number normally 200,000 to 400,000 per cubic millimetre of blood. They plug small leaks in blood vessels and participate in the clotting process. Disintegrating platelets release substances that take part in a series of complex chemical reactions in the blood that result in the production of a firm blood clot.

Causes of bleeding disorders. *Vascular weakness.* In cases of vitamin C (ascorbic acid) deficiency, capillary integrity is lost, and blood oozes into the tissues; under these conditions—*i.e.*, widespread capillary injury—the normal number of platelets (which tend to plug small breaks in blood vessels) is not sufficient.

Thrombocytopenia. Reduction in the number of blood platelets, termed thrombocytopenia, may come about as the result of impaired production of platelets or of increased destruction. Thrombocytopenia associated with such blood diseases as aplastic anemia and leukemia is attributed to impaired production, as is that associated with excessive irradiation and that which follows exposure to certain chemical agents such as benzol or the chemicals used in the treatment of leukemia. In sensitive persons, drugs such as quinidine, chlorothiazides, and some sulfonamides provoke platelet antibodies and platelet destruction, with resulting thrombocytopenia. In the case of still other drugs such a mechanism has not been as clearly demonstrated. Thrombocytopenia may also temporarily accompany certain infections, such as measles, and various systemic disorders, such as systemic lupus erythematosus. The list of circumstances in which thrombocytopenia may occur is long, and the mechanism is not always understood. There is a form of thrombocytopenia that has not been associated with any underlying cause—idiopathic thrombocytopenic purpura.

Thrombocytopenia, if sufficiently severe, is accompanied by spontaneous bleeding from the capillaries; this causes either tiny purplish spots (petechiae) or larger black and blue areas (ecchymoses) to appear in the skin; bleeding occurs commonly from the nose and gums and occasionally from other sites such as the urinary tract and the intestines. When hemorrhage occurs in the brain it is usually fatal.

Faulty coagulation. Deficiencies in any of the chemical and enzymatic factors involved in coagulation result in hemorrhages following minor injuries. In some of these disorders a specific deficiency is due to a heritable defect (*e.g.*, hemophilia); in others, an acquired pathological condition may be responsible for the deficiency (*e.g.*, conditions interfering with absorption of vitamin K). Bleeding also may be the result of faulty platelet function (thrombasthenia and thrombocytopathies).

Thrombocytosis. Substantial increases in numbers of platelets, presumably due to increased production, are seen (1) in diseases in which cells normally formed in the bone marrow are produced in excess (chronic myelocytic leukemia, polycythemia vera), (2) after removal of the spleen, and, (3) rarely, in the absence of associated diseases. Of itself, thrombocytosis rarely causes any ill effects.

Varieties of purpura

Purpura. The term purpura refers to the presence of tiny, purple spots in the skin (petechiae) resulting from the escape of some red cells out of the smallest blood vessels, the capillaries, or larger hemorrhagic areas (ecchymoses). Purpura may or may not be associated with thrombocytopenia. Some of the causes of thrombocytopenia were mentioned above. A form that is relatively common and of unknown cause is called idiopathic thrombocytopenic purpura (ITP). It usually occurs in children, adolescents, and young adults. It may follow an infection and often disappears without treatment. This condition probably represents an autoimmune process. If it does not resolve spontaneously or after treatment with adrenocorticosteroid hormones, removal of the spleen will cure more than two-thirds of cases.

There are many varieties of nonthrombocytopenic purpura. These usually are the result of some vascular weakness (vascular purpura) and may be mild and of no consequence, as in the minor bruises occurring in women and those seen in the elderly. Other instances may be troublesome and even painful. They may be associated with exposure to various infectious or chemical agents and occur with various diseases. A form that may be serious is Henoch–Schönlein purpura, which has been attributed to sensitivity to certain foods, drugs, or infectious agents, but is poorly understood. In this condition, there may be serious bleeding from the bowel, abdominal pain or joint pain and swelling.

COAGULATION DISORDERS

Hemophilia

Among coagulation disorders are included a number of bleeding disorders that are related to defects in the clotting of blood. The best known of these is hemophilia, which is due to an inherited defect transmitted by the female but manifested only in the male. The abnormal bleeding, sometimes spontaneous but often the result of slight injuries, occurs as a consequence of a lack of antihemophilic globulin (factor VIII; there are thirteen numbered "factors," or substances in the blood, that participate in the complex process of blood clotting) and may threaten the life of the victim or cripple him as a result of hemorrhages into joints.

The term bleeder once was considered to be more or less synonymous with hemophilia. Now that many other causes of abnormal bleeding besides deficiency of antihemophilic globulin have been discovered, the term bleeder has no specific meaning.

A closely related disorder is PTC (plasma thromboplastin component; coagulation factor IX) deficiency, or "Christmas disease." The inheritance of this bleeding dis-

order is like that of hemophilia, but a different substance is lacking. As more knowledge has been gained of the intricate process of blood coagulation, more and more bleeding disorders have been discovered. These include PTA (plasma thromboplastin antecedent, factor XI), factor V, factor VII, factor X, and prothrombin deficiency. Many of these conditions are due to inherited defects, but some occur as the result of action by toxic agents.

Hypoprothrombinemia, a deficiency in prothrombin, coagulation factor II, occurs most commonly in cases of obstructive jaundice, in which the flow of bile into the bowel is interrupted. Bile is necessary for the absorption of vitamin K, which is needed in prothrombin formation. When biliary obstruction is prolonged, vitamin K deficiency occurs, and hypoprothrombinemia develops. Similar changes may take place when absorption of vitamin K is impaired by conditions such as chronic diarrhea. Hypoprothrombinemia also occurs in the newborn infant as hemorrhagic disease of the newborn. This form of prothrombin deficiency can be prevented by administration of vitamin K to the mother during labour. Hypoprothrombinemia also can be produced deliberately by the use of substances such as bishydroxycoumarin when it is necessary to prolong clotting time.

Fibrinogenopenia refers to a reduction in the amount of the clotting factor fibrinogen (a plasma protein) in the blood. Fibrinogenopenia is seen in rare instances as a heritable disorder, but more commonly it is found as a complication of labour following pregnancy (defibrination syndrome).

Von Willebrand's disease (pseudohemophilia, vascular hemophilia) in some areas is second in frequency only to classical hemophilia. Transmitted as an autosomal dominant trait, this disorder appears to be due to deficiency of a plasma factor that is essential for normal platelet or vascular function and is also required for normal synthesis of the antihemophilia factor, VIII. The symptoms consist mainly of bleeding through the skin and mucous membranes, as in the purpuras, but symptoms similar to those of hemophilia may also occur.

In coagulation disorders, bleeding can be stopped if adequate amounts of the deficient factor can be given. Normal blood plasma supplies these, but the various types of factor concentrates that are being made available are preferable because they permit the administration of much larger quantities of the missing substances than can be supplied by blood or plasma transfusions (see BLEEDING AND BLOOD CLOTTING).

Blood Groups

Blood groups are classifications of blood, based on the properties of red cells as determined by antigens. Knowledge of these groups developed during the course of centuries of experience with the introduction of blood from one person or other animal into another.

GENERAL SURVEY OF BLOOD GROUPING

Historical background. William Harvey announced his observations on the circulation of the blood in 1616, and his famous monograph entitled *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* (*On the Motion of the Heart and Blood in Animals*, 1653) was published in 1628. This discovery that blood circulates around the body in a closed system was an essential prerequisite of the concept of transfusing blood from one animal to another of the same or different species. In England experiments on the transfusion of blood were pioneered in dogs in 1665 by Richard Lower. A later experiment, in which dogs were also used, is described in the diary of Samuel Pepys in the entry for November 14, 1666. In November 1667, Lower transfused the blood of a lamb into a man; this event also is recorded in Pepys' diary. Meanwhile, in France, Jean-Baptiste Denis had also been transfusing lambs' blood into human subjects. After a fatality, Denis was arrested, and the procedure of transfusing the blood of other animals into man was prohibited by an act of the Chamber of Deputies in 1668. Little advance was made in the next 150 years. In 19th-century England, interest was reawakened by the activities of James Blundell, whose humanitarian instincts had been aroused by the frequently fatal outcome of hemorrhage occurring after childbirth. He insisted that it was better to use human blood for transfusion in such cases. By 1875, 347 examples of transfusions had been recorded. During the years 1875–1900, another hiatus occurred as the result of the introduction of the treatment of shock by injecting physiologic saline solution (salt solution of the same osmotic pressure as the blood).

Early transfusions

The German physiologist Leonard Landois had recorded, in 1875, that if the red blood cells of an animal belonging to one species were mixed with serum taken from an animal of another species, clumping of the red cells usually occurred and that sometimes the red cells burst—*i.e.*, hemolyzed. (Blood plasma is the whole blood except for its formed elements—the red and white cells and the platelets; blood serum is the liquid after the formed elements and the clotting factors have been removed.) He attributed the appearance of black urine after transfusion of heterologous blood (blood from a different species) to the hemolysis of the incompatible red cells. Thus, the dangers of transfusing blood of another species to man were established scientifically. Safe transfusion as it is known today rests primarily on two more advances, the first of which was the discovery of the human ABO blood groups by the biologist Karl Landsteiner in 1900. Landsteiner labelled with the letter O blood the red cells of which he found not to be clumped by serum from other persons; cells from a second lot of blood samples were clumped by serum from other persons and were labelled A. The red cells from blood the serum of which clumped A red cells were themselves clumped by A serum and were labelled B. Thus, the red cells of group A blood, for example, have a particular substance, called an antigen, on their surfaces that reacts with the serum from people of groups B and O. The ABO blood groups and other groups discovered later, such as Kell, Diego, Lutheran, Duffy, and Kidd, are determined in this manner, and it is in this way that blood groups are defined. The second advance involved the use of substances such as sodium citrate to prevent clotting of the blood being used in transfusion. These substances are innocuous when given by infusion to man. World War I occasioned many practical advances in the techniques of blood transfusion.

Antigens and antibodies. As has been stated, blood groups are determined by the presence of antigenic substances on the surfaces of the red cells. An antigen has been defined as a substance that can, in certain circumstances, excite the production of the corresponding antibody. (An antigenic substance that can excite antibody production is also correctly termed an immunogen.) An antibody is a substance capable of reacting specifically with particular antigens. The human red cells carry many such antigens. Because the reaction between red cells and corresponding antibody usually results in clumping—agglutination—of the red cells, the antigens are often referred to as agglutinogens. Antibodies are part of the

Definitions of antigen and antibody

circulating plasma proteins known as immunoglobulins, distinguished into several classes by molecular size and weight and other biochemical properties. Most blood group antibodies are located either in the class of immunoglobulin known as IgG or that known as IgM.

It has been customary to distinguish between naturally occurring antibodies and immune antibodies. So-called naturally occurring antibodies are invariably present in individuals lacking the corresponding antigen—for example, anti-A in the plasma of people of blood group B and anti-B in the plasma of people of blood group A. The view is gaining ground, however, that these antibodies are induced by environmental exposure, because substances with A and B activity are widely distributed throughout the plant and animal kingdoms. Immune antibodies—for example, rhesus antibodies (see below)—occur only if they are invoked by exposure to the corresponding antigen. Immunization against (*i.e.*, the production of antibodies against) blood group antigens in human subjects can occur as a result of pregnancy (see below *Blood groups and disease*), therapeutic transfusion, or deliberate immunization. The combination of pregnancy and transfusion is a particularly potent stimulus. Individual blood group antigens vary in their antigenic potential; for example, some of the antigens belonging to the rhesus system are strongly immunogenic, whereas the antigens of the Kidd and Duffy blood group systems are much weaker immunogens.

The individual blood groups. In Table 1 the well-established human blood group systems are listed in chronological order. The discovery of the ABO blood group system in 1900 was the result of a deliberate search for intra-species differences in man. The application of knowledge of the ABO system in blood transfusion practice is vital, since mistakes can have fatal consequences. Twenty-seven years after the discovery, Landsteiner, with his colleague Philip Levine, discovered the MN and P blood group systems because they had the idea of immunizing another species with human blood. The discovery of the rhesus system by Landsteiner and Alexander S. Wiener, in 1940, was made because they tested with human red cells antisera developed in rabbits and guinea pigs by immunization of the animals with the red cells of the rhesus monkey, *Macaca mulatta*. A few months elapsed before it was realized that antibodies indicating antigens of the rhesus system could be found in human beings as a result of pregnancies or blood transfusions. All the other blood group systems were first described by use of antibodies found in patients. Frequently, such discoveries resulted from the search for the explanation of unexpected unfavourable reaction in a patient after a transfusion with formerly compatible blood. In such cases the antibodies in the recipient were produced against hitherto unidentified antigens in the donor's blood. In the case of the rhesus system the presence of antibody in the maternal serum directed against antigens present on the child's red cells can have most serious consequences because of antigen–antibody reactions that produce the disease entity known as hemolytic disease of the newborn, or erythroblastosis fetalis. Some of the other blood group systems —for example, the Kell and Kidd systems—were discovered because an infant was found to be suffering from hemolytic disease of the newborn when mother and child were compatible as far as the rhesus system was concerned.

Table 1: Major Human Blood Group Systems

system	date of discovery	main antigens
ABO	1900	A_1, A_2, B, H
MNSs	1927	M, N, S, s
P	1927	P_1, P_2
Rh	1940	D, C, c, E, e
Lutheran	1945	Lu^a, Lu^b
Kell	1946	K, k
Lewis	1946	Le^a, Le^b
Duffy	1950	Fy^a, Fy^b
Kidd	1951	Jk^a, Jk^b
Diego	1955	Di^a, Di^b
Yt	1956	Yt^a, Yt^b
I	1956	I, i
Xg	1962	Xg^a
Dombrock	1965	Do^a

Blood group antigens in tissues. The blood group antigens are inherited characteristics; they are present primarily on the red cells as a property of the cell membrane. The antigens of almost all the systems have been detected in fetal red cells and remain present constantly throughout life. The I system is an exception in that the I antigen is much weaker and the i antigen much stronger in the cells of infants than in those of adults.

Presence of ABO antigens in tissues

There is no doubt that the antigens of the ABO system are widely distributed throughout the tissues. These antigens have been unequivocally identified on the other formed elements circulating in the blood besides the red cells; *i.e.*, on the platelets and the white cells (both lymphocytes and polymorphonuclear leukocytes). They are present in skin, the epithelial (lining) cells of the gastrointestinal tract, the kidney, the urinary tract, and in the lining of the blood vessels. Evidence for the presence of the antigens of other blood group systems on cells other than red cells is less well substantiated, and sometimes the opinions of different workers are at variance. Among the red cells antigens, only those of the ABO system are regarded clinically as tissue antigens and therefore need to be considered in transplantation.

As they occur on the red cells the blood group substances are in an alcohol-soluble form. In the ABO and Lewis systems, the blood group specific substances also occur in tissue fluids and secretions in a water-soluble form. In the case of the Lewis system the antigens are primarily in the secretions, and their presence on the red cells is dependent on passive absorption onto the cells from the plasma.

Chemistry of the blood group substances. Knowledge of the chemistry of the ABH and Lewis blood group substances has accrued not from extraction of red cells but by analyses of the water-soluble products. (The specificity of the only ABO blood group substance secreted by persons of group O is called H.) The substances are glycoproteins (that is, substances the molecules of which have sugar and protein fractions) containing a high percentage of carbohydrate. The specificity is associated with the carbohydrate part of the molecule.

Much less is known about the chemical composition of the other blood group systems. Some success has been obtained in extracting MN substances from red cells; P_1 substance has been identified in the fluid inside hydatid cysts in sheep, and a diversity of compounds have been found that inhibit the reactions between the Rh antigens of red cells and the corresponding antibodies. (Hydatid cysts are the sacs containing tapeworm larvae in the embryonic stage.) Some substances with blood group specificity are listed in Table 2.

Table 2: Substances with Blood Group Activity

antigenic determinant	specific carbohydrate
A	*N*-acetyl-D-galactosamine
B	D-galactose
H	L-fucose
	N-acetyl-D-glucosamine
Le^a Le^b	L-fucose
M	*N*-acetylneuraminic acid
N	*N*-acetylneuraminic acid

METHODS OF BLOOD GROUPING

Identification of blood groups. *The agglutination test.* The basic technique in identification of blood groups is the agglutination test. In its simplest form, a volume of serum containing antibody is added to a thin suspension (2–5 percent) of the red cells suspended in physiological saline solution in a small tube with a narrow diameter. After incubation for an adequate time, at the appropriate temperature, the red cells will have settled to the bottom

of the tube. These sedimented red cells are examined macroscopically (with the naked eye) for agglutination, or they may be spread on a slide and looked at through a low-power microscope. An antibody that agglutinates red cells when they are suspended in saline solution is called a complete antibody. With powerful complete antibodies, such as anti-A and anti-B, agglutination reactions visible to the naked eye take place when a drop of antibody is placed on a tile together with a drop containing red cells in suspension. After stirring, the tile is rocked, and agglutination is visible in a few moments. It is always necessary in blood grouping to include a positive and negative control for each test that is done.

Incomplete antibody

An antibody that does not clump red cells when they are suspended in saline solution is called incomplete. Such antibodies block the antigenic sites of the red cells so that subsequent addition of complete antibody of the same specificity does not result in agglutination. Incomplete antibodies will agglutinate red cells carrying the appropriate antigen when the cells are suspended in media containing protein. Albumin from the blood of cattle is a substance that is frequently used for this purpose. Red cells may also be rendered specifically agglutinable by incomplete antibodies after treatment with such enzymes as trypsin, papain, ficin, or bromelin.

The Coombs test. When an incomplete antibody reacts with the red cells in saline solution, the antigenic sites become coated with antibody globulin (gamma globulin). This means that, although no visible reaction has taken place, gamma globulin is bound to the cell membrane. The presence of this antibody globulin on cells that have been thoroughly washed in saline solution can be detected by a test that is called the indirect Coombs test after its inventor, the English immunologist Robert Royston Amos Coombs. The Coombs reagent is made by immunizing rabbits with human gamma globulin. The rabbits respond by making anti-human globulin that must be purified by removal of unwanted components before use. The Coombs reagent is then added to the washed cells on a tile, and if they are coated by antibody globulin, after gentle rocking, agglutinates will form.

In certain diseases, anemia may be caused by the coating of red cells with antibody globulins. This can happen when a mother has made antibodies against the red cells of her newborn child, or if a person makes an auto-antibody against his own red cells. The presence of this antibody can be detected by the direct Coombs test, in which the patient's red cells are washed thoroughly and tested on a tile with the Coombs reagent.

Absorption, elution, and titration. If a serum contains a mixture of two antibodies, it is possible to prepare pure samples of each by a technique that is called absorption. By this technique an unwanted antibody is removed by mixing the antiserum with red cells carrying the appropriate antigen, which interacts with the antibody and binds it to the cell surface. These red cells are washed thoroughly and spun down tightly by centrifugation, all the fluid above the cells is removed, and the cells are then said to be packed. The cells are packed to avoid dilution of the antibody being prepared. The purification of the Coombs reagent, mentioned earlier, is done in the same way.

If red cells have absorbed antibody globulin onto their surfaces, the antibody can sometimes be recovered by a process known as elution. One simple way of eluting from washed red cells is to heat them at 56° C (133° F) in a small volume of saline solution. This technique is sometimes useful in the identification of antibodies.

The technique used to determine the strength of an antibody is called titration. Doubling dilutions of the antisera are made in a suitable medium, in a series of tubes. Cells carrying the appropriate antigen are added, and the agglutination reactions are read and scored for the degree of positivity. The actual titre (concentration) of the antibody is given by the dilution at which some degree of agglutination, however weak, can still be seen. This would not be a safe dilution to use for blood grouping purposes. If an antiserum can be diluted, the dilution chosen must be such that strong positive reactions occur with selected positive control cells.

Uses of inhibition tests

Inhibition tests. Inhibition tests are used to detect the presence of substances with blood group specificity in solutions. If an active substance is added to antibody, neutralization of the antibody's activity prevents agglutination when, subsequently, red cells carrying the antigen in question are added to the mixture. This technique was of prime importance in the elucidation of the chemistry of the ABO and Lewis blood group substances. Inhibition tests are also used to find the substances normally secreted by an individual, as in the saliva. Finally, the inhibition test has applications in forensic medicine as a means of identifying antigens in bloodstains.

Hemolysis. Laboratory tests in which hemolysis (destruction) of the red cells is the end point are not used frequently in blood grouping. For hemolysis to take place, a particular component of fresh serum called complement must be present. Complement must be added to the mixture of antibody and red cells. It may sometimes be desirable to look for hemolysins that destroy group A red cells in mothers whose group A children are incompatible, or in individuals, not belonging to groups A or AB, who have been immunized with tetanus toxoid that contains substances with group A specificity.

Hemolytic reactions may occur in patients given transfusions of blood that is incompatible or has already hemolyzed. The sera of such patients require special investigations for the presence of hemoglobin that has escaped from red cells destroyed within the body and for the breakdown products of other red cell constituents.

Sources of antibodies and antigens. Normal donors are used as the source of supply of the so-called naturally occurring antibodies, such as those of the ABO, P, and Lewis systems. These antibodies work best at temperatures below that of the body (37° C, or 98.6° F); in the case of cold agglutinins, such as anti-P_1, the antibody is most active at 4° C. Most antibodies used in blood grouping must be searched for in immunized donors.

Antibodies for MN typing are usually raised in rabbits —similarly for the Coombs reagent. Antibodies prepared in this way have to be absorbed free of unwanted components and carefully standardized before use.

An unlikely source of substances with specific blood group activity has been found in certain plants. Plant agglutinins are called lectins. Some useful reagents extracted from seeds are anti-H from *Ulex europaeus* (common gorse); anti-A_1, from another member of the pulse family Fabaceae (Leguminosae), *Dolichos biflorus;* and anti-N from a South American plant, *Vicia graminea.* Agglutinins have also been found in animals; for example, the fluid pressed from the land snail *Octala lactea.*

Difficulties in blood grouping. Suspensions of cells suitable for blood grouping can be prepared from blood taken with or without an anticoagulant. Serologists have individual preferences. After such infections as pneumonia, red cells may become agglutinable by almost all normal sera because of exposure of a hitherto hidden antigenic site (T), as a result of the action of bacterial enzymes. When the patient recovers, the blood also returns to normal with respect to agglutination. It is unusual for the red cells to reflect antigenicity other than that determined by the individual's genetic makeup. The presence of an acquired B antigen on the red cells has been described occasionally in diseases of the colon.

Blood group antibodies are usually stored frozen solid, and in this condition they will keep for years. Contaminated sera or any that have lost activity can give false positive or negative results. The serologist is unlikely to be misled by this because all the tests are controlled. Particularly potent antibodies are sometimes formed by the deliberate immunization of men or of women past the childbearing stage. Before they are issued for routine use, the antibodies must be standardized with a selection of red cells from different donors who have been tested for all the known antigens. The cells can be taken fresh from volunteers or from a bank of stored frozen cells. Blood samples with rare antigens may be exchanged on an international basis.

Identification of antibodies. When an antibody is found that apparently does not correspond to any that are already known, it must first be tested with a large panel of typed red cells, which should include representation from different races. (An antigen common in one population may be rare in a different racial group.) Statistical evaluation can then be made to see whether the reactions of the new antibody are independent of all the systems known at the time of testing. Finally, the pattern of inheritance of a new blood group antigen can be established by testing families whose members have been typed for all the known systems. This is the way in which the inheritance patterns of a new system are demonstrated.

USES OF BLOOD GROUPING

Tests of blood donors

Medical uses. *Transfusion.* Blood donors must be healthy. A sample of their blood is tested to ensure that the level of hemoglobin is satisfactory and that there has been no previous venereal disease or liver infection. Correct matching for the ABO system is vital. Compatible donors on the basis of their possessing A, B, or O blood are shown in Table 3.

Table 3: The ABO Groups in Transfusion

group	antigen on red cells	antibody in serum	possible donors	forbidden donors
A	A	anti-B	group A, O	group B, AB
B	B	anti-A	group B, O	group A, AB
O	neither	anti-A and anti-B	group O	group A, B, AB
AB	A and B	neither	all groups	none

Potential donors are also tested for some of the antigens of the Rh system, since it is essential to know whether they are Rh-positive or Rh-negative. This involves testing for the D (Rh_o) antigen. Rh-positive blood must never be given to Rh-negative females before or during the childbearing age. If such a woman subsequently became pregnant with an Rh-positive fetus, she might form anti-Rh antibody, even though the pregnancy was the first, and the child might suffer from hemolytic disease of the newborn.

Direct match test

Care is taken not to give a transfusion unless the cells of the donor have been tested against the recipient's serum. If this compatibility test indicates the presence of antibody in the recipient's serum for the antigens carried by the donor's cells, the blood is not suitable for transfusion because an unfavourable reaction might occur. The test for compatibility is called the direct match test. It involves testing the recipient's serum with the donor's cells, suspended in saline solution at 20° C and 37° C, in albumin at 37° C, and by the indirect Coombs test at 37° C. These are adequate screening tests for most naturally occurring and immune antibodies.

If, in spite of all the compatibility tests, a reaction does occur after the transfusion is given (the unfavourable reaction often takes the form of a fever), an even more careful search must be made for any red cell antibody that might be the cause. A reaction after transfusion is not necessarily due to red cell antigen–antibody reactions. It could be caused by the presence of antibodies to the donor's platelets or white blood cells. Transfusion reactions are a particular hazard for persons requiring multiple transfusions.

Organ transplants. The ABO antigens are widely distributed throughout the tissues of the body. Therefore, when organs, such as kidneys, are transplanted, most surgeons prefer to use organs that are matched to the recipient's with respect to the ABO antigen system, although the occasional survival of a grafted ABO-incompatible kidney has occurred. The remaining red cell antigen systems are not relevant in organ transplantation.

Blood groups and disease. The question whether the blood groups merely have nuisance value in clinical practice has led to a search for evidence of associations with disease. The possibility that people with particular antigens are more or less likely to get certain diseases has inspired a great deal of work, but convincing positive correlations are few in number. Cancer of the stomach is more common in people of group A than in those of groups O and B. Duodenal ulceration is more common in nonsecretors of ABH substances than in secretors.

Hemolytic disease of the newborn

On the other hand, hemolytic disease of the newborn is undoubtedly due to blood group incompatibility between mother and child. Only certain of the blood group systems—Rh, Kell, Kidd, Diego, and, rarely, ABO, Duffy, and MNS—have been implicated in this disease. The most common cause of hemolytic disease of the newborn is incompatibility for the Rh antigen D (Rh_o) between mother and child. If the mother is Rh-negative (does not have the Rh antigens) and the child is Rh-positive, then the mother may form anti-D, which can react with the child's cells. The antibody molecules are small enough to pass through the placental barrier and enter the fetal circulation. The antibody can then coat the fetal red cells and ultimately destroy them. Thus, the baby may be anemic at birth. This anemia can be treated by giving the baby transfusions of Rh-negative blood. Often the blood is exchanged, and the child's own Rh-positive red cells coated with antibody are removed. The supply of maternal antibody lasts for only a few weeks. The transfusion tides the child over the time while the antibody persists; once the antibody has disappeared, the child's own genetically constituted Rh-positive cells will survive normally.

It is most unusual for Rh antibody to be formed in a first pregnancy with an Rh-positive fetus unless the mother has at some time received a transfusion of Rh-positive blood. This is because the mother does not become immunized until fetal red cells carrying the D (Rh_o) antigen have entered her circulation. This does not happen to any great extent during pregnancy, but while the baby is being born significant numbers of fetal cells can enter the maternal circulation. These fetal cells are the stimulus for immunization. The effect of this does not become apparent until the mother becomes pregnant with her second Rh-positive fetus.

Hemolytic disease of the newborn is now a preventable disease. The observation that pointed the way to this medical advance was that Rh-negative mothers who gave birth to ABO-incompatible Rh-positive babies had a smaller risk of having diseased children than similar mothers with ABO-compatible ones. This protection afforded by ABO incompatibility results from the elimination of ABO-incompatible fetal cells from the maternal circulation by the corresponding anti-A or anti-B antibody. Thus, the cells do not survive long enough to immunize the mother against the Rh antigen. The prophylactic treatment for hemolytic disease consists of giving an Rh-negative mother an injection of powerful anti-D antibody soon after she has given birth. This antibody mops up the offending red cells, and the mother is prevented from becoming immunized.

Evidence against paternity

Evidence with respect to paternity. Although blood group studies cannot be used to prove paternity, they can provide unequivocal evidence that a man is not the father of a particular child. Since the blood groups are inherited, a child cannot have a blood group antigen that is not present in one or both parents. For example, if the child in question belongs to group A and both the mother and the putative father are group O, the man is excluded from paternity. Table 4 shows the phenotypes (observed characters) of the offspring that can and cannot be produced in the matings on the ABO system, considering only the three alleles (alternative genes) *A*, *B*, and *O*. Furthermore, if one parent is genetically homozygous for a particular antigen—that is, has inherited the gene for it from both the grandfather and grandmother of the child—then that antigen must appear in the blood of the child. For example, on the MN system, a father whose phenotype is M and whose genotype is *MM* (in other words, a father who is of blood type M and has inherited the characteristic from both parents) must transmit an *M* allele to all his progeny. The genotypes of possible children in the various matings of the MN system are shown in Table 5.

Table 4: Exclusions of Paternity on the ABO System

matings	possible children	impossible children
O × O	O	A, B, AB
O × A	O, A	B, AB
O × B	O, B	A, AB
O × AB	A, B	O, AB
A × A	O, A	B, AB
A × B	O, A, B, AB	
A × AB	A, B, AB	O
B × B	O, B	A, AB
B × AB	A, B, AB	O
AB × AB	A, B, AB	O

In medicolegal work it is important that the blood samples are properly identified. If the ABO (including the subdivision of A into A_1 and A_2), MNS, Rh, and at least three of the following antigens, Fy^a, K, Lu^a, and Jk^a, are tested for, the chance of proving nonpaternity is about 62 percent.

Blood groups as genetic markers

Blood groups and genetic linkage. The blood group genes act as markers of the chromosomes that carry them. The site of a particular genetic system on a chromosome is called a locus. Each locus may be the site of several alleles (alternative genes). In an ordinary cell of the body the human chromosome set consists of 46 pairs, 22 pairs of autosomes (chromosomes other than sex chromosomes), and two sex chromosomes, designated XX in females and XY in males. The loci of the blood group systems are on the autosomes, except for Xg, which is unique among the blood groups in being located on the X-chromosome. Genes carried by the X-chromosome are said to be sex-linked. Since the blood groups are inherited in a regular fashion, they can be used as genetic markers in family studies to investigate whether any two particular loci are sited on the same chromosome; *i.e.*, are linked. The genes sited at loci on the same chromosome travel together from parent to child, and, if the loci are close together, the genes will rarely be separated.

Loci that are further apart can be separated by recombination. This happens when material is exchanged between homologous chromosomes (pair of chromosomes) by crossing over during the process of formation of the sex cells. The reproductive cells contain half the number of chromosomes of the rest of the body; ova carry an X-chromosome and spermatozoa an X or a Y. The characteristic number of 46 chromosomes is restored at fertilization. In a classical pedigree linkage study, all the members of a family are examined for a test character and typed for all available genetic markers that are not confined to the antigens of the red cells. The pedigree is then inspected for evidence of the nonindependent segregation of pairs of characters. The results must be assessed statistically, and computer programs are also available for this type of analysis.

Advances in seeing and identifying chromosomes

Since 1956 it has been feasible to culture human cells and to make microscopic preparations in which the chromosomes can be seen. Furthermore, since 1970 it has been possible to identify each human chromosome individually. This means that it is possible not only to find linkage groups in man but also to assign genetic markers to the chromosome that carries them.

Genetic linkages and a location concerning blood group systems are shown in Table 6. The locus of the Lutheran blood group system is on the same chromosome as the locus that controls the secretion of ABH substances. These two loci are on the same chromosome as that for an inherited wasting disease of the muscles, myotonic dystrophy.

This knowledge can be applied to the problem of antenatal diagnosis—that is, the determination of whether or not the disease is present in the fetus. The amniotic fluid contains secretions of the fetus, and this fluid can be sampled during pregnancy, a procedure known as amniocentesis. If the family of the unborn child is available for testing, then by determining the antigens present in the amniotic fluid, there is sometimes enough evidence to predict the chances that the child will be affected with the disease.

The linkage group comprising the locus for the nail–patella syndrome, an inherited abnormality of certain bones and the nails, for the enzyme system adenylate kinase, and for the ABO blood group system, is more of academic interest, as is the linkage quartet that includes the Rh blood group system.

Table 6: Genetic Linkages and Location Involving Blood Groups

linkages			location
myotonic dystrophy disease	nail–patella syndrome disease	phosphoglucomutase, enzyme	
secretion of ABH	adenylate kinase enzyme	elliptocytosis (oval red cells) anomaly	congenital cataract disease
Lutheran blood group	ABO blood group	Rh blood group	Duffy blood group
		6-phosphogluconate dehydrogenase	

chromosome number 1

The first blood group system to be sited was the Duffy locus on chromosome 1. Since one type of congenital cataract is genetically linked to Duffy, the locus for the cataract must also be on chromosome 1.

The Xg blood group system has been used in attempts to map the genes on the sex chromosome. Two clusters of genes have been identified: one around a locus for colour blindness and the other around Xg. These two loci are not within a measurable distance of each other by the technique of pedigree analysis. Unfortunately, it appears that the Xg locus is sited at the far end of the short arm of the X-chromosome. It would be a more useful marker if it were sited in the middle of the chromosome.

Genetic pathways. In some of the blood group systems the amount of antigen produced depends on the genetic constitution. For example, the red cells of a person whose genotype is MM show more M antigen than do MN red cells. The amount of antigen produced can also be influenced by the position of the genes. Such effects within a genetic complex can be due to determinants on the same chromosome—they are then said to be in cis—or to determinants on the opposite chromosome of a chromosome pair—in trans.

Antigen production and the position of the genes

In the Rh combination cdE/cde, more E antigen is produced than in the combination cDE/cde. This can be interpreted as a suppressing effect, on the E antigen, of the presence of D in cis. An example of suppression in the trans situation is that more C antigen is detectable on the red cells from CDe/cde donors than on those of CDe/cDE people.

The cis/trans test can also be used to see whether genetic determinants are in the same or different cistrons. A cistron is a smaller unit of genetic material than the gene as defined by classical recombination in multicel-

Table 5: The MN System, Genotypes of Possible Children

genotypes of matings	genotypes of possible children
MM × *MM*	*MM*
MM × *MN*	*MM*, *MN*
MM × *NN*	*MN*
MN × *MN*	*MM*, *MN*, *NN*
MN × *NN*	*MN*, *NN*
NN × *NN*	*NN*

lular organisms. It can be defined in bacteria and fungi, in which it has been shown that genetic sites within the same cistron can complement each other. This type of analysis can be applied to the study of a complex genetic locus such as Rh. Various compound antigens are produced when the determinants are aligned in cis but not when they are in trans. Examples of such compound antigens are ce, Ce, and CE. Observations on the Rh system lead to the conclusion that the Ce and Ee sites may be in the same cistron but that the D genetic site probably is not.

During the 1940s there evolved two different schools of thought about the genetics of the Rh system. Alexander Wiener maintained that the inheritance is controlled by a single complex locus, and this view was reflected in his nomenclature. The view of Sir Ronald Aylmer Fisher and Robert Russell Race was that the system is controlled by three pairs of closely linked genes, *C-c*, *D-d*, and *E-e*. The changed conception of the gene has tended to reconcile the two viewpoints.

As knowledge of the blood groups progressed, it became apparent that the pathway leading from the gene to the production of antigen on the red cells involved a series of biochemical changes. It is known that in some systems—for example, ABO and Rh—several gene loci become involved. One of the loci controls the production of a precursor substance, and the products of the other loci modify this substance sequentially. It is interesting in this context to consider that an antigenic idiosyncrasy within a family is reproduced so precisely in all of its members.

The detection of recombination (exchange of material between chromosomes) or mutation in human families is complicated by the difficulty of excluding illegitimacy. In spite of the large number of families that have been studied, there is only one example of recombination, within the Rh system, that stands up to criticism. As far as germ cell mutations are concerned, only one possible case has been described. This paucity of examples may indicate that the mutation rate for blood group genes is lower than that estimated for other human genes (of the order of one in 50,000).

Twins and chimeras. Blood groups can be used to find out whether twins, triplets, or quadruplets differ from each other. It is not possible to prove that a twin pair is identical—only to estimate the chance that this is so. The blood groups were used to show that quadruplets born in Australia in 1950 were all different and, furthermore, that four eggs were involved.

Differences between some identical twins

It is possible for twins arising from a single egg and sperm not to have the same complement of chromosomes. This can happen if an error occurs during cell division after the formation of the zygote (fertilized ovum) and a chromosome is lost from one twin but not from the other. Some recorded examples involve the loss of a sex chromosome, X or Y, from one twin, producing an XY, XO pair or an XX, XO pair. The XO sex chromosome complement is associated with a characteristic syndrome (complex of symptoms) of an incomplete female phenotype. Such twin pairs are identical for all the characters carried by the autosomes.

An individual may be constituted of a mixture of cells of different zygotic lineage. This can occur if there is an exchange of cells between a pair of nonidentical twins during embryonic life through a communal vascular channel. This phenomenon was first described in cattle, and such twins are called chimeras. Several examples are known in man. They come to light when blood group studies reveal a mixture of two populations of cells in a donor who has not received transfusions. Another way in which a dual population of cells may arise is when two sperm and one egg are involved in the formation of a single zygote. The paternal contributions to the offspring can be sorted out by studying the genetic markers, including blood groups.

Blood groups and anthropology. The different races of man have different frequencies of the various blood group antigens. There are a few phenotypes that are so peculiar to a certain population that they can be used to diagnose racial origin. These are listed in Table 7. The presence of the Di^a antigen indicates a Mongolian origin; the frequency of the antigen is about 10 percent among the Japanese and Chinese, but it has not been found in Eskimos. The Fy (a− b−) phenotype is characteristic of Negroes; Negro origin can also be recognized by the presence of the Js^a antigen, which forms part of the Kell system. The V antigen, listed in Table 7, is a compound antigen.

Table 7: Blood Group Antigens Peculiar to Different Races
(in percentage)

system	population		
	Caucasian	Mongolian	Negro
Diego			
Di^a antigen	0	36	0
Duffy			
Fy (a− b−)	0	—	68–90
Kell			
Js^a antigen	0	—	20
Rh system			
V antigen	0.5	—	27–40

When a population is being investigated, an adequate sample of the people is classified according to the phenotypes. The gene and genotype frequencies can be computed from the phenotype percentages. Among the blood group systems, most is known about the distribution of the ABO groups. This is true not only because the system has been under investigation longest (since World War I), but also because the typing reagents are easy to obtain.

Distribution of ABO groups

The frequency of the *A* gene is high in western Europe, western Asia, and among Australian Aborigines and certain American Indian tribes in North America. The *O* gene frequency is high in north and western Europe and south West Africa. Isolated populations such as the Indians of South and Central America may be entirely of group O. The maximum frequency of the *B* gene occurs in Central Asia and northern India. The *B* gene was probably absent from American Indians and Australian Aborigines before racial admixture occurred with the coming of the white man.

On the Rh system most northern and central European populations differ from each other only slightly and are characterized by a *cde* (*r*) frequency of about 40 percent. The frequencies of the most common Rh combinations of the English are given in Table 8; they are representative of all Caucasian populations. The peoples of Africa show a preponderance of the complex *cDe* (R^o), and the frequency of *cde* (*r*) is about 20 percent. In eastern Asia, *cde* (*r*) is almost absent, and, since everyone has the D (Rh_o) antigen, hemolytic disease of the newborn, due to the presence of maternal anti-D, is unknown in these populations.

Table 8: Frequency of the Most Common Rh Gene Complexes in the English Population
(in percentage)

gene complex	frequency
*CDe** (R^1)†	41
cde (*r*)	39
cDE (R^2)	14
cDe (R^o)	3
C^wDe (R^{1w})	1
cdE (*r''*)	1
Cde (*r'*)	1
CDE (R^z)	<1

*Fisher–Race notation. †Wiener notation.

The frequencies of M and N vary less on the whole throughout the world than the antigens of the ABO and Rh systems. There are some rare antigens belonging to

this system that are found only in Negroes. Another distinct feature is that about 1 percent of Negroes have neither S nor s on their red cells. Everyone else has one or both of these antigens, which belong to the MN system.

The uniqueness of the genetic characters of Africans probably results from their long isolation from the rest of mankind. The blood group frequencies in small inbred populations reflect the influences of genetic drift. In a small community an allele can be lost from the genetic pool if individuals carrying it happen to be infertile, while people with unusual fertility can promote an increase in frequency of a particular allele. It has been suggested, for example, that *B* alleles were lost by chance from American Indians and Australian Aborigines when these communities were small. There are pronounced discrepancies in blood group frequencies between the people of eastern Asia and the aboriginal people of America. On the other hand, Polynesians resemble American Indians and Eskimos more closely than any other people of a different continent. This does not prove that the ancestors of the Polynesians came from America, but it shows that aboriginal Americans have more recent ancestors in common with Polynesians than with Eastern Asiatics.

Blood groups in nonhuman primates. Nonhuman primates carry blood group antigens that can be detected with reagents used for typing human beings. The closer their evolutionary relationship to man, the greater is their similarity with respect to antigens. The red cells of the apes, with the exception of the gorilla, give reactions on the ABO system that are indistinguishable from those of human cells. Chimpanzees are most frequently group A, but group O is represented. Orangutans are usually A, with the occasional group B or AB. Gibbons can be of any group except O, and gorillas have a B-like antigen that is not identical with the human one in activity. In both Old and New World monkeys the red cells do not react with anti-A or with anti-B, but, when the secretions are examined, A and B substances can be detected. Furthermore, agglutinins, bearing a reciprocal relationship to the substance secreted, are present in the serum. The red cells of the apes have been shown to carry M-like and N-like antigens.

The ABO system and primates

As far as the Rh system is concerned, chimpanzees carry two Rh antigens D (Rh_o) and c (hr′) but not the others, whereas gibbons have only c (hr′). The red cells of monkeys do not give clear-cut reactions with human anti-Rh sera. The original Rh antibody (anti-Rh_o) was formed when rabbits and guinea pigs were immunized with the cells of rhesus monkeys, and the specificity appeared to be the same as the antibody formed in patients, which was also called anti-D (Rh_o). Later, it became apparent that the antibodies from the two different sources were not developing in response to (defining) the same antigen.

By the time this happened it was too late to change the name Rh, important in clinical medicine. It was therefore decided that the antigen defined by the nonhuman antibody should be called LW, thus honouring Landsteiner and Wiener. The gene locus for LW is separate from that for Rh, but the two systems are in competition for a precursor substance. Most people have the LW antigen, but a very few do not.

Blood groups and biology. In some situations blood group substances remain stable over hundreds of years. It has been shown that ABH substances are still present in bones and mummified tissue from ancient Egyptian tombs. The stability of the frequencies of the blood group genes is an example of balanced polymorphism (the existence of a variety of forms within a species). The selective forces favouring or disfavouring a particular allele are counterbalanced. Direct evidence of a selective value for any given allele is lacking. The genetic effect of fatal hemolytic disease due to anti-D (Rh_o) has been the elimination of heterozygotes (individuals inheriting a characteristic from one parent only), so this cannot have had a profound effect on the relative frequencies of gene complexes with and without D. Reports on the effects of the ABO group incompatibility on fertility have been conflicting. Nevertheless, the blood group genes may have effects that are not yet recognized.

The blood groups are an important means of identifying an individual. Their relevance in medicine lies in the practice of blood transfusion and the effects of incompatibility between mother and child. To date, studies of the inheritance of the blood groups have increased knowledge of genetic mechanisms in man; in the future they will probably play an important role in the mapping of the human chromosomes.

Board and Tile Games

Board and tile games are games played with a number of pieces on a specially constructed or marked board or with marked pieces (tiles) on a tabletop or other flat surface. Primitive man appears to have invented games for divinitary purposes—through them the gods could reveal the future to those able to understand their signs. Individuals faced with alternatives would toss a marked stick into the air, allowing the throw to determine their course of action.

The historical boundary between divination and pastime is ill defined. Board games doubtless were part of the mystical equipment of sages and soothsayers, later adapted for relaxation and pleasure. As late as 1895, when the French were attacking the capital of Madagascar, the native queen and her advisors relied more on the supposed prophetic result of a game of Fanorona (see below) than on the actual performance of their army. Dice, cards, teetotums (spinning dice), and wheels have all been used in fortune telling.

A few cultures, including the Eskimo and the Australian aborigine, had no board games. The Maori of New Zealand had one board game, Mu Torere (see below), although this may have been an adaption of a game introduced by Europeans. The peoples of South America do not seem to have any indigenous board games; those played are variants of games introduced from Africa and Europe.

This article is intended for the general reader, who may have no knowledge of the games described. It discusses the history and main types of board and tile games and their principles of play. More detailed information on rules and how to play the various games can be found in the books listed in the bibliography.

BOARD GAMES

History—development of Backgammon. The oldest gaming boards known (Figure 1A) were found by the British archaeologist Sir Leonard Woolley in the royal tombs of Ur and date from about 3000 BC. Each player had seven marked pieces, and moves were controlled by the use of six pyramidal dice, two of the four corners

being tipped with inlay. Three white and three lapis lazuli dice made a set. No account of how to play the game has survived.

From R.C. Bell, *Board and Table Games from Many Civilizations* (two volumes), Oxford University Press

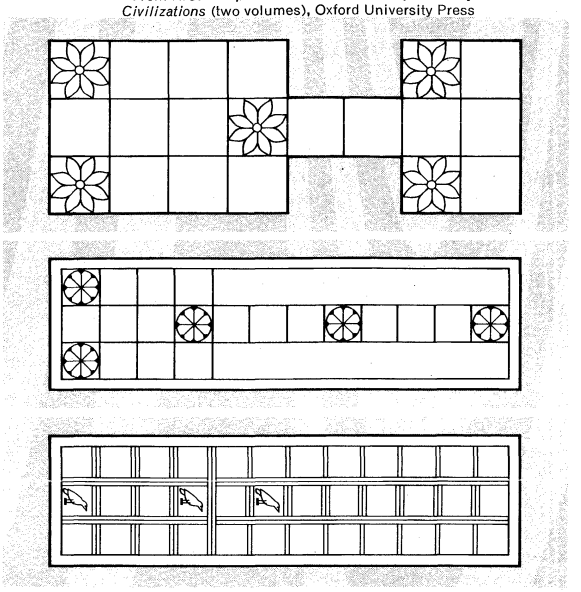

Figure 1: (Top) Game board found in the royal tombs of Ur. (Centre) Board for Egyptian game Senat. (Bottom) Game board found at Ak-hor, Egypt, for Game of Thirty Squares.

Later, the Egyptians used boards that appear to have been derived from those of Ur. Several have been found in tombs of the Empire age, about 1580 BC (Figure 1). Many of these boards were built as a box, containing dice and pieces within, and on the underside another game, known to archaeologists as the Game of Thirty Squares (Figure 1). The moves were controlled by four throwing sticks, two white and two black. Some sets contained two knuckle bones (ankle bones of sheep, marked on four sides), and a board from Ak-hor held a long die. (Long dice, with four marked faces, appear to be a natural progression from a split stick with two faces, one curved and the other flat. Cubic dice appear to be a relatively late development.)

The Game of Thirty Squares was adapted by the Romans for their Ludus Duodecim Scriptorum, with cubic dice replacing the earlier long die (Figure 2A). In the 1st century AD Ludus Duodecim Scriptorum was replaced by Tabula, a variant with only two rows of marked spaces (Figure 2B).

During the Middle Ages Tabula developed into Tables, from which Backgammon (Tric-trac) is derived (see DICE AND DICE GAMES). The development of Backgammon demonstrates how games passed from one civilization to another, undergoing modifications with the modern form bearing little resemblance to its ancient prototype.

Race games. Race games use boards with tracks marked off into spaces, some of which may be reward or penalty areas. Players race one or more pieces along the track according to throws of sticks or dice. The player whose pieces complete the course first is the winner.

From R.C. Bell, *Board and Table Games from Many Civilizations* (two volumes), Oxford University Press

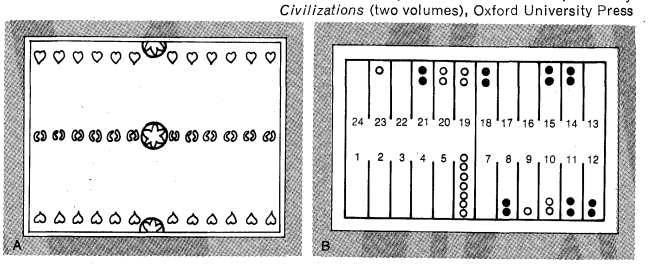

Figure 2: (A) Ludus Duodecim Scriptorum board. (B) Tabula board with game in progress.

Nyout. An early and widely disseminated group is based on a circle and cross, wholly surviving in the Korean game of Nyout (Figure 3A). Pieces, called "horses," move around the circle as directed by the throws of four sticks, which are flat on one surface and rounded on the other. If a horse lands on a cardinal point the player has the option of short circuiting home along the limbs of the cross, or continuing around the circle. If a horse lands on a square occupied by a rival's horse, the latter is sent back to start again. The game is won by the player whose horses first return to the starting point.

Circle and cross games

Pachisi. This game spread westward to India, where the shape of the board was modified by the circle being pressed inward along the sides of the cross. As Pachisi, (Figure 3B), the game became a race around the outside of the cross and up the centre of the limb nearest the player to the central square. The moves of the pieces were controlled by the throws of a long die, or by five cowrie shells, in which case the number of spaces moved depended upon the number of mouths facing upward. The Mughal emperors (16th–17th centuries) laid out courtyards in their palaces as Pachisi boards, and girls from the harem, dressed in different colours, moved about the board in response to the throws of the players gathered on a raised central dais. One of these courtyards survives at the palace in Āgra. About 1880 the game was taken to England, where it was modified and patented as Ludo. It is still a favourite with children at Christmas.

From R.C. Bell, *Board and Table Games from Many Civilizations* (two volumes), Oxford University Press

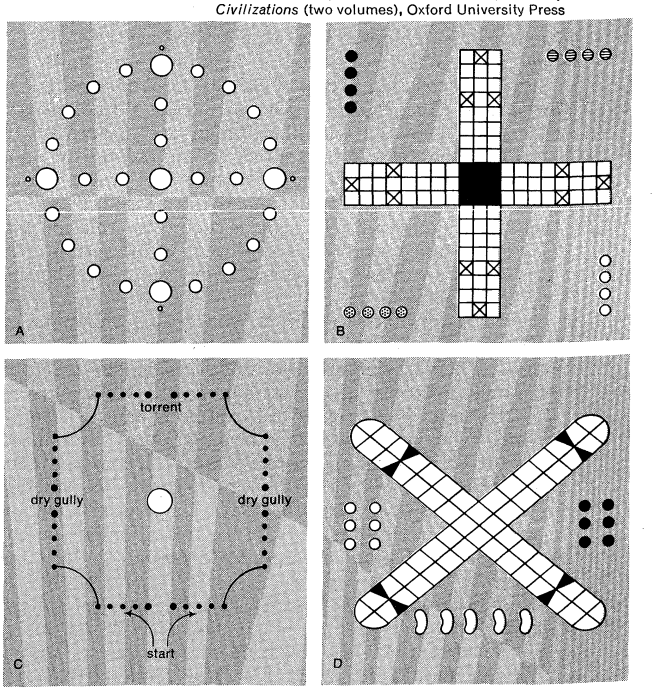

Figure 3: (A) Game board for Nyout. (B) Game board for Pachisi. (C) Zohn Ahl track. (D) Patolli cross with counters and beans.

Zohn Ahl. Circle and cross games also spread eastward into North America, and many forms survived among the Amerindians. One, Zohn Ahl, was played by the women of the Kiowa Indians in Oklahoma. The board was marked out on the ground with 40 small stones, the points being the intervals between the stones. In the centre was a flat stone, onto which dicing sticks similar to those used in Nyout were thrown. The wide gap at the north represented a river in flood, while those at the east and west were dry streams (Figure 3C). Each team had one runner and the moves of the runners were controlled by the throws of four sticks; the runners moving in opposite directions around the track. Each team started with four pebbles, which were used as counters.

A circuit of the track counted as a lap, and the winner

of a lap took a counter from the opposing team. If a runner fell into the torrent at the north or was hit by the opposing runner landing on the same space, the runner had to return to the beginning and the team forfeited a counter. A runner landing in a dry gully forfeited a turn of play. The game ended when one side held all the counters. In Zohn Ahl the circle was preserved, but the cross had disappeared except for the cardinal points, which had changed from points of advantage to penalty points.

Patolli. In the Aztec game of Patolli the circle disappeared, and the cross became a double track; the pieces were semiprecious stones, and the moves were controlled by the throws of five beans, with one side plain and the other hollowed out (Figure 3D). The Spanish Conquistadors found the nobles of Montezuma's court playing Patolli for high stakes.

Totolospi. The Hopi Indians of Arizona played Totolospi, in which the cross was degenerate, though still recognizable (Figure 4A). In another of their games only one limb of the cross had survived (Figure 4B). The moves of the stone markers were controlled by the throws of three staves, each with a flat and a curved face. The boards were scratched on slabs of sandstone.

From R.C. Bell, *Board and Table Games from Many Civilizations* (two volumes), Oxford University Press

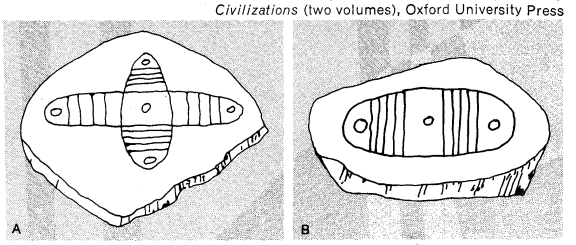

Figure 4: (A) Cruciform board for game Totolospi. (B) Alternate Totolospi board in which cross has become a single track.

Spiral track games

Game of Goose. Many race games use a spiral track. The Game of Goose was invented in Florence under the reign of Francesco de' Medici, 1574 to 1587, who sent one to Philip II of Spain. It spread rapidly to other parts of Europe, reaching England in 1597. Sixty-three points, consecutively numbered, are arranged as a spiral. Any number of players can take part, each having his own marker, which is entered on the first point and borne off from the last. Moves are determined by throws of two dice. If a higher number is thrown than that required to reach 63, the surplus is played backward from 63. Some points are marked with a goose; if a player's marker lands on such a point, that player may make another throw with the dice. Other points bear penalties, requiring the marker to go back, lose a turn, or pay counters as a penalty.

The Game of Goose was followed by many games of similar type, some designed to teach children history, geography, architecture, zoology, and moral improvement. Hundreds of race games of varying ingenuity and interest have been invented, only to be replaced by others.

War games. The games of this group simulate battles between opposing forces.

Shaturanga. Boards invented for one game have been used for others; the 64-square board for an ancient Indian race game, Ashtapada, was taken over about the 5th century AD for the four-handed war game Shaturanga, a forerunner of chess. Each player had eight pieces; a rajah, horse, elephant, boat, and four pawns, or foot soldiers representing the four corps of an army—cavalry, elephants, boatmen, and infantry (Figure 5A). The red and black pieces were loosely allied against the green and yellow. Each piece had a different power of movement and a long die determined the type of piece moved at each turn of play. On throwing a "two" the boat moved, a "three" the horseman; a "four" the elephant; and a "five" the rajah or one of the soldiers.

If a piece moved onto a square occupied by an enemy piece, the latter was removed from the board. Boatmen and soldiers were not permitted to capture major pieces; they could, however, capture each other. The object of the game was for a rajah to seize an enemy throne—the initial square of a rajah. On moving onto this square he won a stake from the defeated player. If a rajah mounted his ally's throne he assumed command of the allied forces as well as his own.

Chess-related games

From R.C. Bell, *Board and Table Games from Many Civilizations* (two volumes), Oxford University Press

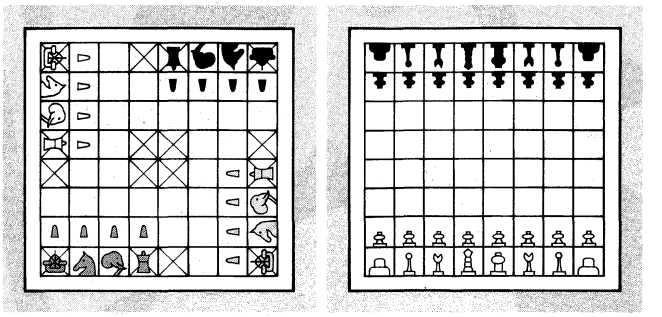

Figure 5: (A) Shaturanga pieces arranged for a game on an Ashtapada board. (B) Arrangement of pieces for Shatranj.

Shatranj. Gambling was forbidden in the ninth book of the Laws of Manu (about the first century BC), and Shaturanga players evaded trouble by discarding the die and turning the game into one of skill. Other changes followed, including the reduction of the four armies to two and making the second rajahs into prime ministers with only half their former power of movement. The new game, Shatranj (Figure 5B), traditionally was introduced into Persia about AD 550; it was played by the Arabs and later appeared at the Byzantine court. It was played in Europe by AD 700, but by then the weak prime minister had become the most powerful piece on the board, the queen. Shatranj also spread eastward from India, entering Burma, Thailand, China, and Japan, with modifications in each.

Chinese chess. In Chinese chess (Hsiang-ch'i) elephants, horsemen, infantry, cannon, and war chariots fight to capture the enemy general, who is confined within a fortress. The two armies are separated by a river, which is impassable to the elephants. The chessmen are cylindrical with the rank written on the upper face; one player's pieces in red and the other's in green. They are placed on the intersections instead of the squares, the board becoming a grid of 9 × 10 points. The moves differ from those in Shatranj—for instance, cannon can only capture by jumping over an intervening piece onto their target. They cannot jump over more than one piece in a move and do not jump unless making a capture. The earliest reference to Hsiang-ch'i was about AD 840.

Japanese chess. Japanese chess, or the General's Game (Sho-gi), is played on a board of 9 × 9 rectangles. The pieces are shaped like little coffins, with the rank written on the upper surface and a promoted rank on the underside. The pieces are all the same colour, and possession is indicated by the direction of the pointed end, a player's pieces being directed toward the enemy. When a piece enters enemy territory it is promoted and turned over, but promotion may be delayed at the player's option—for example, an Honourable Horse with its power of leaping over intervening pieces may be preferred to the more powerful Gold General, since check by an Honourable Horse cannot be covered.

A unique feature of Japanese chess is reintroduction of captured pieces into a player's own formation—instead of moving a piece, a player may enter a prisoner onto any unoccupied space, pointing it toward the enemy. The game ends when one of the Jewelled Generals is checkmate, or unable to move without being captured.

The Alquerque group

Alquerque. Boards similar to those for Alquerque have been discovered in Egypt dating back to about 1400 BC. Figure 6 shows an Alquerque board ready for play. The pieces move from any point to an adjacent point along a marked line. If the adjacent point is occupied by

an enemy piece and the next point beyond it on the line is empty, the player's piece may make a short jump over the hostile piece and remove it from the board. If another piece is then similarly exposed, it is taken in the same move by a second short jump, a change of direction being allowed. In this way, several pieces may be captured in one turn of play. If a piece can make a capture, it must do so, even to the player's disadvantage.

From R.C. Bell, *Board and Table Games from Many Civilizations* (two volumes), Oxford University Press

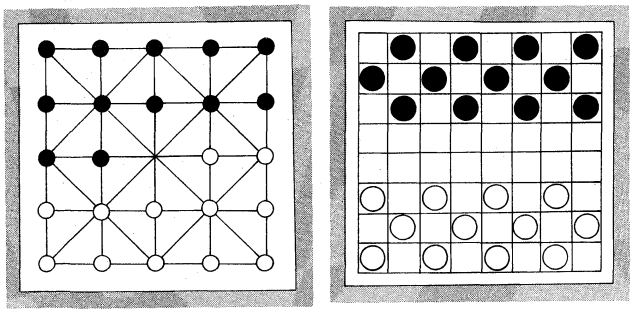

Figure 6: *The Alquerque Group.*
(Left) Starting position of pieces on an Alquerque board.
(Right) English Draughts board with pieces in place.

Draughts, or Checkers. About AD 1100 Alquerque was modified to Les Dames by being played on the black squares of a chessboard (Figure 6, right). Each player had 12 pieces, movement being one square diagonally forward, and capture by a short jump over an enemy piece onto an empty square beyond. Multiple captures were allowed in a turn of play. When a piece reached the opposite side of the board it was promoted to a king and permitted to move diagonally backward as well as forward. The 16th-century addition of compulsory capture under penalty of huffing, or loss of the offending piece, resulted in the modern game of Draughts, or Checkers.

Fanorona. Alquerque likewise sired Fanorona, when, about 1680, the board was doubled, the number of pieces increased to 44, and the method of capture changed. White starts and moves along any line to an adjacent point. If a move ends on a point nearest a point or points in the line of movement occupied by enemy pieces in unbroken sequence, these are captured by approach and removed. Capture may also be by withdrawal—a piece moving away from a point contiguous with a point or points occupied by enemy pieces in the line of movement captures those pieces. Captures are compulsory, but on the first move by each player only one sequence can be taken. On later turns a player may make several captures, either by approach or withdrawal, changing direction each time a capture is made.

The Tafl group

Hala-tafl (Fox and Geese). The war games already described have been between equal forces, but in northern Europe the Tafl group simulated miniature battles between unequal forces. The larger force tried to hem the smaller in, and the latter, equipped with a piece of special power tried to break out or destroy the aggressor.

In Icelandic Hala-tafl 13 geese are arranged as in Figure 7A, and a fox is placed on any vacant point. The fox and geese can move in any direction along a line to the next point. If a fox jumps over a goose and lands on an empty point beyond, the goose is killed and removed from the board. Two or more geese can be killed by a series of short jumps by the fox. The geese cannot jump but try to crowd the fox into immobility to win. If the fox kills enough geese, they become too weak to immobilize the fox and lose the game.

Officers and Sepoys. In later variants the geese were increased to 17 but deprived of the power of moving backward. During the Indian mutiny (1857–1858) the variant Asalto was renamed Officers and Sepoys (Figure 7B). The square represented a fort, and one player placed two officers on any two points within its walls. All pieces moved one point at a time along any marked line, but the sepoys moved only toward the fort. The officers captured by a short jump but were subject to huffing. The sepoys won if they occupied every point in the fort or if they immobilized the officers.

Tablut. In the game Tablut (Figure 7C), described by the Swedish botanist Linnaeus in 1732, eight Swedish soldiers and a Swedish king tried to break through a cordon of 16 Muscovites. The board was marked into 9 × 9 squares, the central one being a throne that only the king could occupy. All pieces could move any number of unoccupied squares orthogonally—straight along a row or column, not diagonally. A piece was captured and removed from the board when an opponent occupied both adjacent squares in a row or column. This was custodian capture. A piece could, however, move safely onto an empty square between two enemy pieces. The king was captured if surrounded on all four sides by enemy pieces, or on three sides and the throne. If the king was captured, the Muscovites were victorious; but, if he reached any square at the periphery of the board, he escaped from their trap and won the game.

Hnefatafl. Tablut seems to be a simplification of Hnefatafl, played by the Saxons in northern England in the 10th century AD. In this game, a black fleet of 24 ships and a kingship was attacked by a white fleet of 48 ships (Figure 7D). The rules were the same as in Tablut, the kingship being sunk when surrounded on four sides by enemy vessels or victorious when making its escape to the edge of the board.

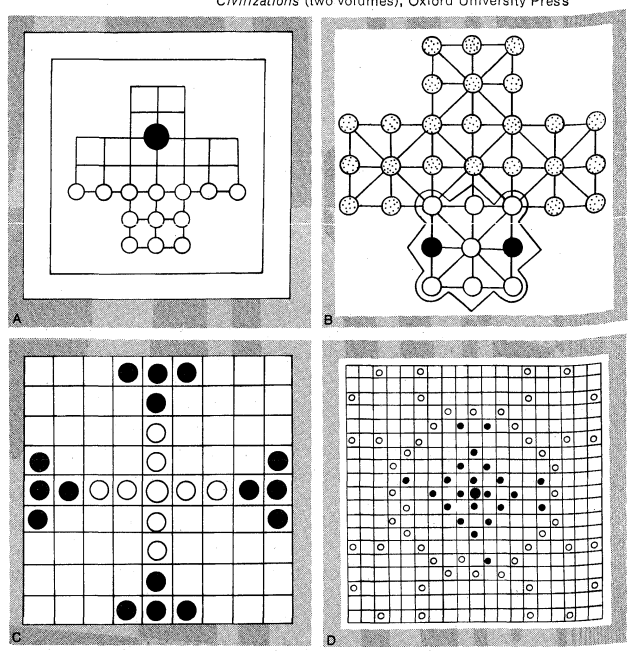

Figure 7: *Game boards.*
(A) Fox and Geese. (B) Officers and Sepoys. (C) Tablut.
(D) Hnefatafl.

Games of position. In these games the players try to place their pieces in winning formations.

Dara. The Dakarkari people in North Africa play Dara with a "board" of 30 small holes dug in the ground (Figure 8A). Each player has 12 distinctive pieces, which are placed one at a time in alternate turns of play into the holes. When all have been placed, or sown, the second phase begins. Each player alternately moves one of his pieces orthogonally (not diagonally) to the next hole, trying to form a line of three pieces in consecutive holes orthogonally. When such a three is formed, the player removes any one of his opponent's pieces from the board. Lines of four pieces do not count. The game ends when one player is unable to make lines of three.

Games of threes

Nine Men's Morris. Nine Men's Morris (Mill or Merelles) is more complex and widespread—board designs have been found cut into the roofing slabs of a temple at

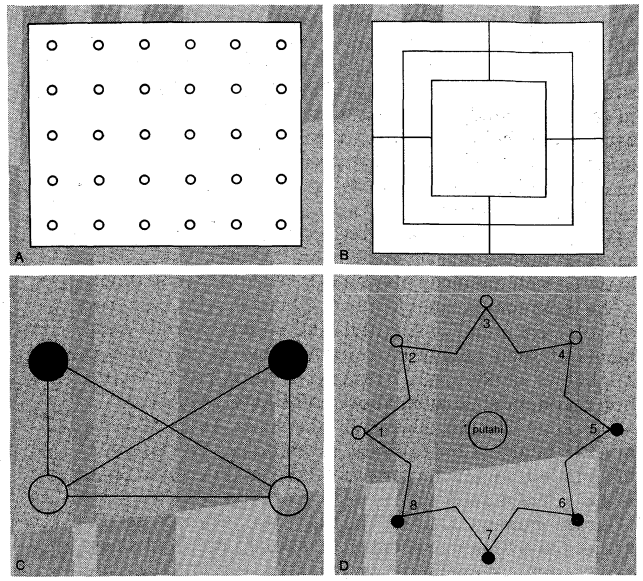

Figure 8: *Game boards.*

(D) Mu Torere.
From R.C. Bell, *Board and Table Games from Many Civilizations* (two volumes), Oxford University Press

Kurna in Egypt (*c.* 1400 BC), into the steps at Mihintale in Ceylon (AD 21), in prehistoric lake dwellings in Europe, and on the Gokstad Viking ship (*c.* AD 900). Each player has nine pieces and introduces them onto the points of the board (Figure 8B) in alternate moves of play. On forming a line of three pieces, called a mill, he removes one of his opponent's pieces from the board, but not one which is in a mill. When all the pieces have been entered, play continues by alternate moves of pieces to an adjacent vacant point along a line. Pieces cannot pass an opposing mill. A player wins the game by blocking his opponent's pieces or by reducing his opponent's pieces to two.

P'ang ho ch'i. In P'ang ho ch'i (Canton, China), or Onmoul-ko-no (Korea), the players each have two stones of distinctive colour, and they move one stone by alternate turns of play along any line to the next empty point, trying to block the opponent's stones (Figure 8C). The game can be started with the board empty, the stones being introduced in alternate turns of play.

Blocking games

Mu Torere. The Maori in New Zealand play Mu Torere on an eight-pointed star (Figure 8D). Each player has four pieces, which are placed on four adjacent points, the centre or *putahi* being empty. The players then move a piece alternately. Only one piece is allowed on each point, and jumping over pieces is illegal. There are three possible types of move: from one point to an adjacent empty point; from a point to the empty *putahi*, provided that one adjacent point is occupied by an enemy piece; and from the *putahi* to an empty point. The player blocking his opponent wins.

Go. The game known as Go or I-go in Japan, Wei-ch'i in China, and Pa-tok in Korea is ranked by many as the greatest intellectual game. The leading exponents are Japanese, and Go has an enormous following. The board is marked into a grid of 19 × 19 lines forming 361 points. Nine of these are marked to help in orientation and handicapping. Each player has a bowl containing disk-shaped stones. Black has 181 stones, and White 180. At the beginning the board is empty. The weaker player takes the black stones and plays first, which gives him a slight advantage. He places a stone on any point, and play continues alternately, one stone being placed at each turn. Once played, stones remain until the end of the game unless they are captured and removed from the board.

Games of territorial possession

The players try to control vacant points in such a way that they cannot be occupied by an opponent's stones, and the player who possesses the most vacant points at the end of the game wins. Stones completely surrounded by those of the opposite colour without empty points orthogonally adjacent to them are captured and removed from the board (Figures 9a and 9b), but this is not the primary object of the game. It is possible to win without making a single capture. A stone cannot be placed on a point completely surrounded by enemy stones unless it makes a capture by so doing (Figures 9c and 9d). A stone cannot occupy the last free point of one of its own groups unless enemy stones are captured by this action (Figure 9e).

Vacant points controlled by stones of one colour are called eyes, and a group with two eyes is impregnable (Figure 9f). A group of stones in diagonal contact may contain empty points, but the disconnected stones can be attacked and the formation killed. Such empty points are "false eyes" and may be mistakenly constructed by the novice instead of real eyes (Figure 9f).

When a player has just captured a stone in a repetitive position known as a *ko* (Figure 9g), his opponent must make one play elsewhere on the board. This rule prevents the likelihood of perpetual positions and a drawn game. If there are three *ko* on the board at once, however, the game is drawn.

If opposing formations are interlocked in an impasse, or *seki* (Figure 9h), they are left alone until the end of the game and then discarded.

At the end of the game any vacant points between opposing formations that are not controlled by either side

From R.C. Bell, *Board and Table Games from Many Civilizations* (two volumes), Oxford University Press

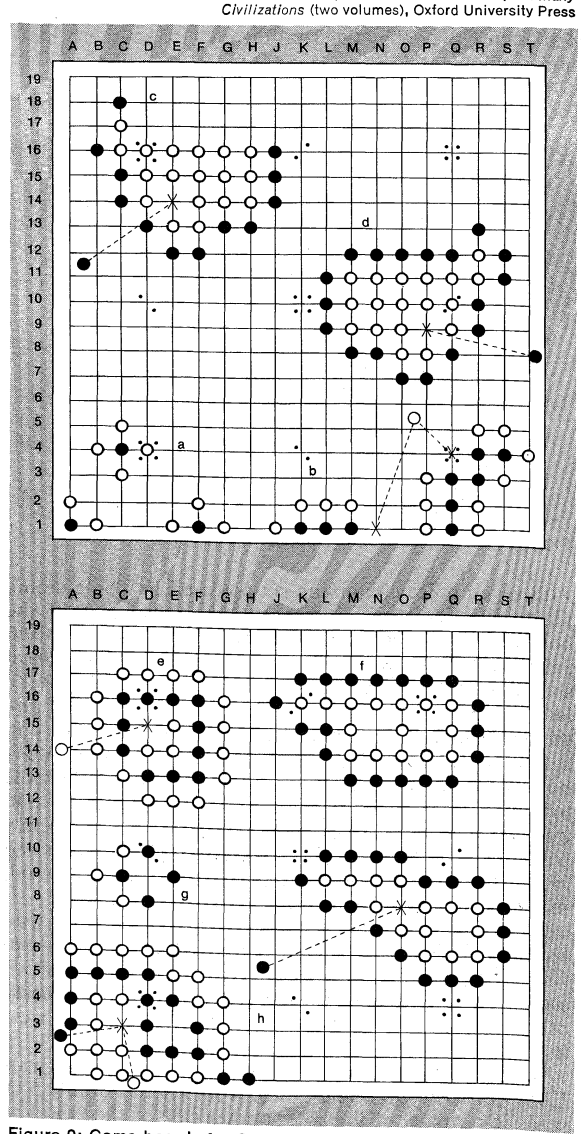

Figure 9: Game boards for Go, showing playing situations.

are filled in to help in adding up the final score. Stones that are not surrounded, but can inevitably be so, are "dead" and are removed at the end of the game without further play. When profitless points have been filled, and dead stones removed from each player's territories, each player places his opponent's captured stones on vacant enemy points, thus reducing the opposing score by the number of pieces held.

Players of equal skill play Black alternately, but if one wins three times consecutively he gives his opponent a handicap of two stones and increases this gradually until they meet on equal terms. Casual games may last about two hours, and professional matches up to three days.

Mancala games. These are games in which players distribute pieces into rows of holes under varying rules that allow accumulation of pieces by capture. They are widely played in Africa and Asia and areas influenced by those cultures. The games appear to have originated in ancient Egypt. Sets of deeply cut holes have been found in the roofing slabs of the Kurna temple in Egypt (*c.* 1400 BC), and other sets are cut into the summit of the damaged portion of the great pylon built in Ptolemaic times (305–30 BC) at the entrance to the temple of Karnak. These boards consist of two rows of six, seven, and eight saucer-shaped hollows. Boards have also been found in Arabia antedating Muhammad, whose followers carried variations of the game throughout Islām. Negro slaves took Mancala games to the West Indies, where forms are still played identical with those in remote villages in west Africa.

Pallanguli. One of the simplest forms of Mancala is Pallanguli, played by the Tamil women of southern India and Ceylon (now Sri Lanka) (Figure 10). Players start

From R.C. Bell, *Board and Table Games from Many Civilizations* (two volumes), Oxford University Press

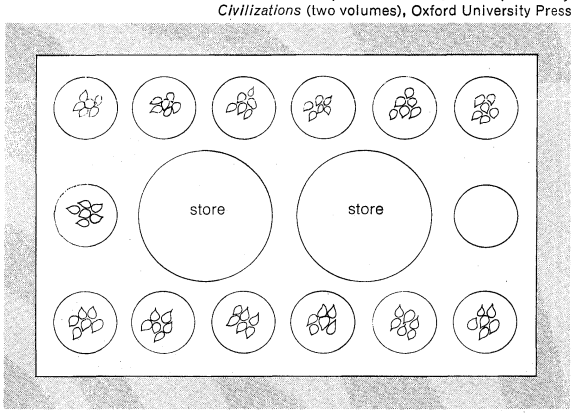

Figure 10: Game board for Pallanguli.

with seven holes containing six seeds each. The opening player lifts the seeds from any hole on her side of the board and moving counterclockwise sows one seed into each hole. If she reaches the end of her side of the board, she continues sowing in her opponent's holes. When the last seed of a lift falls into a hole she picks up all the seeds in the next hole and continues sowing as before in the same direction. If the last seed of a lift falls into a hole with an empty hole beyond, any seeds in the hole immediately beyond the empty hole are captured and put into the player's store hole; she then continues play from the next loaded hole beyond; but, if the last seed of a lift falls into a hole with two empty holes beyond, she wins nothing and her turn ceases.

Her opponent then plays by lifting the seeds or seed from any hole on her side of the board and plays as before. The game continues by alternate turns of play. Four seeds in a hole is called a cow; they become the property of the owner of the hole and are lifted at once and placed in the player's store while play continues.

At the end of the first round each player lifts the seeds from her store hole and restores to six the number of seeds in as many of the holes on her side of the board as possible, any remainder being returned to her store. The loser of the first round will not be able to fill all her holes, and these "rubbish holes" are marked with a little stick. The winner of the round fills all her seven holes, and the surplus is placed in her store. The player with first move in the first round has second move in the second round, each round being played in this way, and the rubbish holes are left empty. The game ends when one player is reduced to less than six seeds and is unable to fill even one hole at the beginning of a round.

During any round the losing player may win enough seeds to reopen one or more rubbish holes, and a game between well-balanced players can last a very long time.

The most complicated forms of Mancala with four rows of holes are found in southern and eastern Africa. Fragments of such boards have been found in the ruins of Zimbabwe in Rhodesia, remains of an African civilization that flourished from about AD 1400 to 1800.

Chisolo. Chisolo, played by the Baila of Zambia, requires a board of four rows of seven holes scooped out of the ground with a larger store hole at one end. Small stones serve as counters.

Career games. During the last half century several games have been marketed that simulate life in business, exploration, scholarship, journalism, diplomacy, and crime detection. Most games in this group suffer from a "point of no return"—initially there is an interesting struggle for power, but at a critical point one player outstrips the others to such an extent that they cannot defeat him, though victory may be long delayed.

Monopoly

One of the best known career games is Monopoly (copyright 1935). The players buy, rent, and sell properties, striving to become business tycoons. Each player starts with an equal amount of play money and a marker, which moves around the board according to the throws of two dice. Each player throws the dice to begin and the highest scorer leads by placing his marker on the corner marked "GO," throws the dice and moves his marker as directed. Play continues with the player on his left. More than one marker can rest on the same space at the same time.

When a marker lands on a space not already owned, the player may buy it from the bank. The board is marked out with spaces indicating building sites, railway stations, utilities, rewards, and penalties. The banker holds 32 green houses and 12 red hotels and two sets of cards for "chance" and "community chest" spaces. There are title cards for every property. The banker pays salaries and bonuses, sells properties to the players, and loans money when required on mortgages.

Word games. The popularity of crosswords has led to the invention of several word games played on boards.

Scrabble

One of the best is Scrabble, for two, three, or four players, first marketed in 1948. A set consists of a board marked with 15 × 15 squares, and 100 wood or plastic tiles, each bearing a letter and a number. The tiles are shuffled face downward and each player takes one. The holder of the tile nearest the beginning of the alphabet draws first and begins the game. The tiles are put back face downward and shuffled. Each player chooses seven tiles and places them on a rack. Play is clockwise.

The opening player combines two or more of his letters to form a word and places them on the board, with one letter on the centre square, to read either across or down. Diagonal words are not allowed. The player completes his turn by counting and announcing his score, and then draws as many new letters as he has played, thus retaining seven letters in his rack.

The next players add one or more letters to those on the board to form new words. Each player's score is recorded after each turn of play. When two or more words are formed in a single turn, each is scored, and the common letter is counted in the score for each word. Any letter of a word placed on an ordinary gray square earns the numerical value marked on the tile. Tiles placed on certain coloured squares earn bonus scores. At the end of the game each player's score is reduced by the sum of his unplayed letters, and if one player has used all his letters, his score is increased by the sum of all unplayed letters in his opponent's hands.

TILE GAMES

Dominoes. Dominoes appear to have originated in China, and the Chinese set represents the possible throws of two Chinese dice, the latter having six faces marked with a large red pip, two black pips, three black pips, four red pips, five black pips, and six black pips. The colour of the pips is important in some domino games. The sixes are half red pips and half black (Figure 11). A Chinese

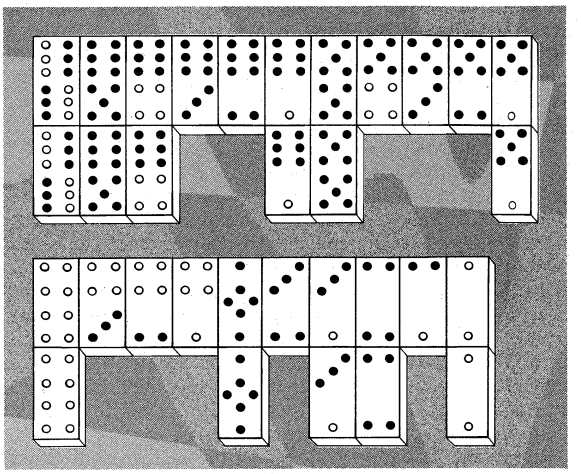

Figure 11: Set of Chinese Dominoes.

domino set consists of 32 tiles, some being duplicated and belonging to the civil series, the others for the military series. Identical tiles of the civil series pair together, while tiles of the military series pair by total count.

Dominoes appeared in Europe at the end of the 18th century, possibly imported from China, but with three important differences: there were no red pips, no duplicate tiles, and a blank sequence had been added. A set consisted of 28 tiles. Double-nine and double-twelve sets are obtainable but are less popular than the double-six. The best dominoes are made of ivory or bone backed with ebony.

Probably the simplest and most representative of the many games played with dominoes is the Block Game. Tiles are shuffled face downward and each player draws one; the player with the highest double, or if no double is drawn, the tile with most pips, becomes the leader. The dominoes are returned to the pool, reshuffled, and the players draw five dominoes each; if there are only two players, they draw seven each. The leader plays a domino, and the player on the left matches one end if possible. If he cannot he loses the turn and the next player tries. When no one can play, the game is blocked, and each player counts the pips on the tiles remaining in his hand. The player with the lowest number scores the total number of pips in his opponents' hands plus those in his own. The first player to reach 121 wins the game.

Other domino games include All Fives (Muggins), All Threes, Threes and Fives, Sniff, Domino Whist, and Matador.

Ma-jong (Mah-Jongg). Ma-jong became popular in China about 1900. It is played with a set of 136 tiles, 128 counters, two dice, a *tong* box, markers, and four stands for the tiles. There are four of each kind of tile, classed as honour and minor tiles. Honour tiles, which count double, are the red, white, and green Dragons; the East, South, West, and North Winds; and the ones and nines of the suits. Minor tiles are the twos through eights of the three suits—bamboos, circles, and characters. Many sets have eight additional tiles—four Flowers and four Seasons—but these are rarely used.

Play begins by building four walls seventeen tiles long and two high, all face down. The players then throw a pair of dice, the highest scorer becoming East Wind. East throws again, and starting with his own wall, counts counterclockwise around the walls, until he reaches the wall indicated by the throw of the dice. He then breaks this wall at the same number from the right end of the wall and places these two tiles on the first and third pair of tiles. These two "loose" tiles form, with the six pairs of tiles beneath them, the dead wall.

East takes the first four tiles to the left of the breach, South the next four, followed by West and North, continuing in this order until all players have drawn 12 tiles. Each then draws one more, except East, who draws two.

East starts by discarding an unwanted tile onto the centre of the table; and South follows by picking it up if he needs it to make a pung (three of a kind), or taking a tile from the wall, and then discarding a tile into the centre. This continues around the table, each player trying to collect four pungs and a pair; the first to do so calling "ma-jong." If a player holds a pair in his hand and a third of the same kind is discarded, he may call "pung" and take it out of the discard pile even if it is not his turn to play. Adding it to his pair, he places the three tiles face upward by his rack. This is an exposed pung and worth two points. Honour tiles count double.

If a player has a concealed pung in his hand, and the fourth tile is discarded, the player may call "quong," add it to his pung and expose them on the table, scoring eight points. A concealed quong is 16 points and is placed face downward on the table. On forming a quong the player takes one of the loose tiles off the wall into his hand. If the second loose tile is used, two more tiles are lifted from the dead wall to form new loose tiles.

To go ma-jong quickly, a player may include one non-scoring sequence of three suit tiles, called a chow. A tile for a chow may come from the wall or from a discard but may only be drawn in turn. If two players want a discarded tile, a player going ma-jong takes first priority, next one who needs it for a pung or quong, and lastly one who needs it for a chow.

The last 14 tiles in the wall, excluding the loose tiles are not used. If no one has completed his hand when this section of the wall is reached, the game is drawn.

There are several special hands not described here, and scoring is complicated. In Western Ma-jong hands must be cleared and contain tiles of only one suit or honours to go ma-jong.

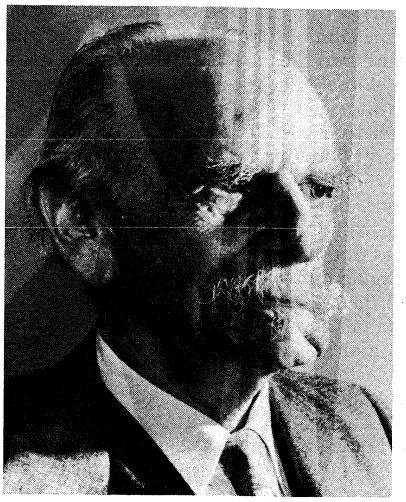
Boas, Franz

Franz Boas was the founder of the kind of general anthropology—relativistic, culture-centred, nonracist—that became dominant in the 20th century. He was a specialist in the cultures and languages of American Indians. But he was also the purposeful organizer of a profession and the great teacher of most of two generations of scientists who developed anthropology in the United States.

Born in Minden, a small town in Westphalia, now in



Boas, 1941.
Wide World Photos

West Germany, on July 9, 1858, the son of a merchant, he was of delicate health as a child and spent much of his time with books. His parents were free-thinking liberals

Early years

who held to the ideals of the revolution of 1848. Although Jewish, he grew up feeling completely German. From the age of five he took an interest in the natural sciences—botany, geography, zoology, geology, and astronomy. While studying at the *Gymnasium* in Minden he became deeply interested in the history of culture, although this was not taught in the school. He followed his various intellectual bents at the universities of Heidelberg, Bonn, and Kiel, taking his Ph.D. in physics and geography at Kiel in 1881.

After a year's military service Boas continued his studies in Berlin, then undertook a year-long scientific expedition to Baffin Island in 1883–84. Firmly interested now in human cultures, he took posts in an ethnological museum in Berlin and on the faculty of geography at the University of Berlin.

On his way back from a study of the Indians of Vancouver Island in 1886, he stopped in New York and decided to stay. He found a position as an editor of the magazine *Science*, married Marie A.E. Krackowizer, and began his long academic career.

Boas' first teaching position was at the newly founded Clark University in 1889. Next, he spent a period in Chicago, where he assisted in the preparation of the anthropological exhibitions at the 1893 Columbian Exposition and held a post at the Field Museum of Natural History. In 1896 he became lecturer in physical anthropology and in 1899 professor of anthropology at Columbia University. From 1896 to 1905 he was also curator of anthropology at the American Museum of Natural History in New York; in that capacity he directed and edited the reports submitted by the Jesup North Pacific Expedition, an investigation of the relationships between the aboriginal peoples of Siberia and of North America.

Career in America

From his earliest years in America, Boas was an innovative and prodigiously productive scholar, contributing equally to statistical physical anthropology, descriptive and theoretical linguistics, and American Indian ethnology, including important studies of folklore and art. His personal research contributions alone would have given him an important place in the history of science, but he also exerted enormous influence as a teacher. By the turn of the century, national leadership in anthropology was firmly in Boas' hands. In 1906, at the age of 48, he was presented with the *Festschrift* usually awarded by his colleagues to a scholar nearing retirement. The 36 years that followed were no less productive, influential, or honoured. Boas established the *International Journal of American Linguistics*, was one of the founders of the American Anthropological Association, president (1931) of the American Association for the Advancement of Science, and a member of many other scientific societies.

In 1911 Boas published *The Mind of Primitive Man*, a series of lectures on culture and race. It was often referred to in the 1920s by those who were opposed to new U.S. immigration restrictions based on presumed racial differences. In the 1930s the Nazis in Germany burned the book and rescinded his Ph.D. degree, which Kiel University had in 1931 ceremonially reconfirmed. Boas updated and enlarged the book in 1937; the revision had an influence in the civil rights struggle that took place in the U.S. during the 1950s.

Boas and his wife had six children, only three of whom survived them. Although Boas suffered a heart attack in 1931, he remained professionally active until December 22, 1942, when he died at the age of 84.

Significance

The revolutionary significance of Boas' work can only be understood in terms of the differing beliefs of anthropologists about man. Almost all anthropologists have almost always believed that the human species is one; but not as many of them believed in Boas' day that the races of mankind show equally the human capacity to develop cultural forms. It is partly because of Boas' influence that the proposition is now almost universally accepted that every surviving population large enough to have a distribution of individual differences shows equally the human capacity to develop cultural forms; and that differences in outcome are attributed by anthropologists to historic "cultural" rather than genetic factors.

Within this common framework there have sometimes been differences in view as to the actual attainments of particular peoples. Some anthropologists, often calling themselves "evolutionary," argue that some peoples have achieved "higher" states of culture, leaving behind—at least temporarily—other peoples. They believe that the differences between "civilized" and "primitive" peoples are the result of environmental, cultural, and historical circumstances. Other anthropologists, frequently called cultural relativists, argue that the evolutionary view is ethnocentric, deriving from a human disposition to characterize groups other than one's own as inferior, and that all surviving human groups have evolved equally but in different ways.

Franz Boas was of the second persuasion. Since British and U. S. anthropologists in the last third of the 19th century were not particularly disposed to this view, Boas' success in making it overwhelmingly dominant was all the more remarkable. While he had originally assumed as a natural scientist that universal laws must exist that would explain how different peoples have wound up with their characteristic ways of life, he concluded that the problem was too complex for any general solution. Laws of cultural causation, he argued, had to be discovered rather than assumed.

Boas' view requires the anthropologist to be capable of understanding all factors that might influence the histories of peoples. Thus, to assert that cultural differences are not the result of biological differences, one must know something of biology; and to see the interrelations of man and his environment, the anthropologist must understand such things as migration, nutrition, child-raising customs, and disease, as well as the movements and interrelations of peoples and their cultures. Anthropology then becomes holistic and eclectic, involved in any field of science or scholarship that appears relevant to a particular problem.

BIBLIOGRAPHY. There is no definitive biography of Boas. Useful discussions of the man and his work may be found in the following: GEORGE W. STOCKING, *Race, Culture and Evolution* (1968); WALTER R. GOLDSCHMIDT (ed.), *The Anthropology of Franz Boas: Essays on the Centennial of His Birth* (1959); JUNE HELM (ed.), *Pioneers of American Anthropology: The Uses of Biography*, pp. 83–222 (1966); MELVILLE J. HERSKOVITS, *Franz Boas: The Science of Man in the Making* (1953); ABRAM KARDINER and EDWARD PREBLE, *They Studied Man*, pp. 134–159 (1961); ALEXANDER LESSER in the *International Encyclopedia of the Social Sciences*, vol. 2, pp. 99–110 (1968); and *Dictionary of Scientific Biography*, vol. 2, pp. 207–213 (1970).

Boating and Yachting

Boating and yachting for pleasure have been enjoyed for several centuries but have increased tremendously in popularity in the 20th century, particularly in North America, western Europe, and Australasia. Though boating is most often engaged in as a pleasure for its own sake, it is also enjoyed as a competitive sport.

The sports aspects of boating are dealt with in this article under the following headings:

I. Rowing

Rowing, technically, is the manual propulsion of a boat using a single oar as a lever in a succession of strokes. The performer is called an oarsman; rowing is an activity for pairs of oarsmen. The use by one person of two oars, one in each hand, is termed sculling. An oar consists of a shaft of wood with a rounded handle at one end and a shaped blade at the other. The shaft may either be solid or consist of two halves partially hollowed out and glued together. The latter construction is used for racing oars in order to save weight and increase flexibility. The blade—a thin, broadened surface—is either flat overall or slightly curved at the sides and tip to produce a firmer grip of the water. The loom, or middle portion of the oar, rests in a notch or oarlock (rowlock) or between tholepins on the gunwale of the boat or on swivels on outriggers (called riggers), which serve as a fulcrum for the oar. The loom is protected against wear in this area of contact with a short sleeve of leather or plastic. Rowing boats used by fishermen often are equipped with modifications of these devices designed to keep the oar from slipping overboard if released; these may include, for example, a steel pin fitted to the gunwale or small outrigger, over which an eye, drilled through the loom of the oar and protected with a steel collar, is slipped. Racing oars have fixed leather or adjustable metal or plastic collars—called buttons—to prevent slippage outboard.

Description of rowing

The oarsman, seated with his feet resting on a brace, or stretcher, covers (dips) his blade square in the water (the entry). Then he uses his legs, shoulders, and body weight to exert pressure against the oar, which functions as a lever turning around its fulcrum to drive the craft past the point of entry. He completes the stroke by lifting the blade out of the water (the finish) and swings forward to begin the cycle again. No stroke is completely efficient, as some degree of blade slip occurs in the water. Fundamental factors in the mechanics of rowing are the position of the oar button, the height of the rigging, the setting of the thole or swivel pin, and outboard length of the oar, which together determine the amount of leverage available.

The characteristics of rowing apply equally to the use of an oar in each hand, or sculling, but a scull is much shorter than an oar. In both methods, the oarsman or sculler is seated on a thwart or sliding seat facing the stern of his craft. Among commercial watermen, sculling is the propulsion of a boat using a single, long oar with a flat blade worked to and fro from a notch in the stern transom. The blade is made to describe a figure eight beneath the surface, acting like the tail of a fish to give both propulsion and direction.

HISTORY

Rowing in ancient times was the principal method of propelling vessels of war and ships of state. As the size of such vessels increased, sails gradually displaced oars, although large galleys continued to be rowed in the Mediterranean until the 18th century. The oarsmen, generally prisoners of war or criminals, were chained to their benches, whence the term galley slaves. As the oars were extremely long overall (in order to reach the water below), it was not unusual for several men to handle each oar. Their combined weight was required to raise the oar out of the water and their combined strength to pull it. Galleys were rated according to the number of tiers of oars. The first recorded Roman fleet consisted of triremes (three-tier galleys). The complement of a galley was considerable; *e.g.*, Amenhotep II of ancient Egypt is recorded as the tireless stroke of a crew of 200 men. The first recorded amateur oarsmen were the islanders who entertained Odysseus on his return to Ithaca.

The earliest invasions of England were effected with the help of oars. In 54 BC Julius Caesar depended largely on oars when crossing the English Channel. Like the Romans, the Anglo-Saxons and later the Danes rowed and sailed across the North Sea to enter the estuaries along the east coast of England.

Early boat racing. Boat racing is first recorded at a Venetian regatta (Italian *regata*) that featured a gondola race in 1300. In 1529 the first recorded boat race for women took place, also in Venice.

The watermen of London

In England, racing in rowing boats dates from the time when the only bridges across the lower reaches of the Thames were London and Chelsea. Anyone wishing to cross the river elsewhere had to hail a ferry, typically a light sculling boat, or skiff, operated by a waterman. The occupation of waterman was defined by statute as "the trade of rowing," and in Queen Anne's time (reigned 1702–14) about 10,000 watermen were licensed to earn their living on the Thames above London Bridge. They all wore special livery, some being particularly magnificent. Wagering developed between the gentry as to the relative merits (speed and skill) of the watermen manning the ferries, and stakes sometimes ran high. The ferry craft became known as wager boats, and it was for these watermen that the race for "Doggett's Coat and Badge" was instituted in 1716. Thomas Doggett, its founder, was an actor who blandly decreed in his bequest that the race should be rowed "for ever," and so far it has been, annually each summer between those earliest bridges—London and Chelsea. The inaugural race commemorated the succession of the House of Hanover to the throne of England. The winner received an orange-coloured uniform; in the years since, the livery has changed and is now red, and the status of the competitor has altered from professional waterman to amateur rower.

The Henley Royal Regatta. The reaches of the Thames at Henley are the most beautiful along the river and, because of a straight stretch of more than a mile immediately below the town, offer an ideal course for rowing races. Thus, in 1839 the townsfolk included boat racing as a special attraction to bring visitors to their market town for the annual fete. In 1851 Prince Albert became patron and gave the regatta its royal prefix.

The regatta has attracted competitors from all parts of the world, and the Grand Challenge Cup for eight oars (established 1839) and the Diamond Challenge Sculls for single scullers (1844) have long been the most coveted trophies in rowing. Other events open to all amateurs are the Stewards' Challenge Cup for fours, the Silver Goblets for pair oars, and the Double Sculls (added 1939). The first trophy to be won by a crew from outside England was the Stewards' Cup (1847, for colleges and schools), won by Columbia University in 1878. The Princess Elizabeth Cup for schoolboys was established in 1947.

Other early races. The first recorded boat race in the United States was in 1811, when the ferrymen of Whitehall in New York City defeated their Long Island and Staten Island rivals on the Hudson. In 1824, in the first Anglo-American contest, they outrowed a crew of Thames watermen from the visiting British frigate "Hussar," in a four-mile race. Rowing as a sport is first recorded in Tasmania at a regatta in 1830, and in Australia in 1832; and the first rowing club in New Zealand was formed at Canterbury in 1861.

The sport was introduced in Russia in 1842 by the British colony in St. Petersburg, the rowers racing annually on the Neva River for a pair of silver sculls. In Austria, Belgium, Denmark, France, Finland, Germany, The Netherlands, Italy, Norway, Poland, Switzerland, and Yugoslavia the sport of rowing has also been engaged in for many years (see below *Major events*).

Development as an organized sport. The first form of rowing by amateurs in England was a simple imitation of the races between ferrymen. Sculling was coupled with boxing in the early days of rowing as a sport. The great oarsmen included some of the best boxing champions of their day, and some rowing clubs had boxing sections. Rowing began as a sport at Oxford in about the 1790s, when "the caps and tassels of the students formed a curious contrast with their employment at the oars." By 1805 the students were using six-oared boats borrowed from local people, and in the following year Eton College introduced the sport. Westminster School followed suit in 1813, when it started its *Water Ledger* (minutes book). Racing in eight-man boats is first recorded at Oxford in 1815, when Brasenose College led all others.

Rowing at English schools

Many clubs sprang to life but disappeared almost as quickly. There were no amateur regattas, so racing took the form of private challenges, often for a side stake. There were, however, annual regattas for professionals, the earliest being at Chester before 1814. Leander Club was founded in about 1815 and rapidly acquired the prestige it still enjoys. For nearly 150 years its crews were composed mostly of Oxford and Cambridge varsity oarsmen, but in the late 1960s its Henley-winning eights were pre-university students. Cambridge took up rowing later than Oxford, because its river, the Cam, was less suited to the sport than the Thames. Most of the oldest English clubs were founded between 1840 and 1870, and the Amateur Rowing Association was formed in 1882.

In Australia, rowing is organized in each of the six states. Most of the clubs are located in Melbourne and Sydney, and there has been competitive interstate rowing since 1863. In Canada, the 1870s were the heyday of the professional scullers. As the distinction between professional and amateur rowing became more sharply drawn, Canada, like England, developed numerous amateur rowing clubs. Among the rowing centres are Brockville, Toronto, Hamilton, St. Catherines, Vancouver, and Winnipeg.

In the United States the first organization of amateur clubs was the Castle Garden Boat Club Association of New York (1834). Light, keelless racing shells appeared in the U.S. soon after their introduction in England (1847), and in 1857 it was an American, J.C. Babcock of Nassau Boat Club, New York, who conceived the idea of the sliding seat, which did not replace the fixed seat in England until 1871. The boat clubs along the Schuylkill River at Philadelphia were organized as the Schuylkill Navy in 1858. The National Association of Amateur Oarsmen (NAAO) was founded in 1872.

Intercollegiate races

The oldest intercollegiate contest in the U.S. is the Yale–Harvard boat race (it antedates football by 17 years), first rowed in 1852 on Lake Winnipesaukee. In the 1870s rowing became popular at a number of Eastern colleges. In 1895 the Poughkeepsie Regatta was established. It attracted all the foremost collegiate and university crews to the Hudson. Rowing was established on the Pacific coast in 1899, and the Washington–California race soon became the rowing feature of the Far West. In 1902 the American Rowing Association was formed to increase intercollegiate competition with early-season short-distance sprints, concluding with an annual regatta over the Henley distance of 1 mi 500 yd (approximately). Thus, this regatta became popularly known as the American Henley.

The international authority and governing body for international competition is the Fédération Internationale des Sociétés d'Aviron (FISA). There are 40 member countries, including all those mentioned above, together with Argentina, Brazil, Bulgaria, Ceylon, Chile, Cuba, Czechoslovakia, Greece, Hungary, Republic of Ireland, Israel, Korea, Morocco, Peru, Poland, Romania, South Africa, Spain, Sweden, Turkey, United Arab Republic, and Uruguay.

COMPETITIVE ROWING

The governing bodies for rowing in each nation are responsible for establishing the qualifications necessary for anyone to engage in amateur rowing competition. It is the responsibility of each national governing body to hold a championship regatta each year and to select those who are to compete in international events organized by FISA.

FISA is responsible for organizing and conducting the rowing events in the Olympic Games. In addition, it conducts a European championship regatta in most years and a world-championship regatta every four years between the Olympics. A junior championship was introduced in 1970. Competition in all FISA regattas is open only to member nations. For the Olympic regatta, entries from any nation are acceptable, provided that the amateur status of competitors is in accordance with the Olympic rules.

In most rowing countries there are several regattas of national importance. In addition to open competition, rowing clubs throughout the world still hold private, annual matches with traditional rivals.

Crews race side-by-side at regattas, sometimes six or more abreast on inland courses and twice as many on the sea. Processional racing (racing in which competing crews or scullers start in procession and are timed individually at start and finish) has also become well established in a number of countries since 1926, when the Head of the River Race on the Thames was founded. It is rowed over 4¼ mi (7,200 m) between Mortlake and Putney. Over 3,000 competitors take part annually in more than 300 shells.

Major events. The oldest event of world renown in rowing is the Oxford versus Cambridge boat race (the University Boat Race), which was first rowed at Henley in 1829. Seven years later the second race took place from Westminster to Putney. There were four more races over this course before the present 4¼-mi Putney to Mortlake course was first used, in 1845. In 1856 it became an annual event that was interrupted only by World Wars I and II. Henley Royal Regatta (see above *The Henley Royal Regatta*) is the oldest major event in the rowing calendar, but it does not have international recognition because the course is not still water and is also too narrow to meet FISA requirements (see below *Course and equipment*).

The European Championships. The European Championships were founded in 1892 and included eights, coxed fours and sculls (see below *World Championships*). France was outstanding in the early days of the championships, doing equally well in eights, four-man boats with coxswain (fours with coxswain, or coxed fours), and single sculls. Belgium also held a dominant position in European rowing throughout the 20 years preceding World War I. The country's record of winning the European eights title seven years in succession (1897–1903) has never been equalled, and Belgian fours with coxswain were European champions 11 times (1897–1907). Swiss oarsmen were the first European fours with coxswain champions in 1893, and they have won titles in all seven classes. Germany, The Netherlands, and Italy have also been in the forefront of rowing in Europe since before 1930, and since then Austria, Denmark, Hungary, and Yugoslavia have also made their presence felt.

Leading European and Olympic champions

Olympic championships. The first modern Olympiad, held in Athens in 1896, did not include rowing, but the sport did find a place in the 1900 games held in Paris. In 1904 the games took place in St. Louis, Missouri, where the United States made a clean sweep in all four rowing events. Great Britain did likewise in the 1908 Olympic regatta at Henley. The United States, Germany, and Great Britain have been the most successful medal winners in the 16 Olympic Regattas held through 1972.

World Championships. The World Championships were founded in 1962, and they include the same events as the Olympics: eights, fours with and without coxswain, pairs with and without coxswain, and double and single sculls. Over two dozen countries compete, and the prestige of winning is prized among oarsmen as highly as an Olympic rowing title. The only other event of international importance beyond the confines of a single continent is the North American Championships, which were first held in Canada in 1967.

Course and equipment. All races under FISA rules must take place over a 2,000-m (6,600 ft) straight course on still water. Each crew or sculler races in a separate lane marked with buoys. There are six lanes, and it is customary for crews who fail to reach the finals to row for seventh to 12th place in a separate final.

Racing shells

Racing shells are used in all major events. They range in length overall from 58 ft (18 m) for an eight, down to 42 ft (13 m) for a four, 32 ft (10 m) for a pair, and 25 ft (8 m) for a single sculling boat. The weight varies according to the materials used for the skin, riggers, and framework; *e.g.*, a sculling boat without riggers can weigh as little as 20 lb (9 kg), but if it is to last several seasons it is more likely to be 5 lb (2 kg) heavier.

The weight of oars also depends on the method of construction, while the overall dimensions can vary appreciably depending upon the specification required by individual coaches or crews. Oars—with a wide variety of blade shapes and sizes—are mostly variations on an overall length of 12 ft (4 m) to 12 ft 6 in with a 24-in- (61-cm-) long blade that is seldom more than 6¼ in (15.9 cm) wide at the tip and 7½ in (19 cm) at its widest point of curvature. Two other key factors in racing shells are the type and setting of the outrigger and the length of the slide along which the seated oarsman travels each stroke. Here again, the choice is individual to coaches or crews. Light riggers save weight but are not so durable. Friction also has to be considered in deciding which kind of slide and seat runners to select. The length of a slide is usually between 26 and 29 in (66 and 74 cm).

Ewing Galloway

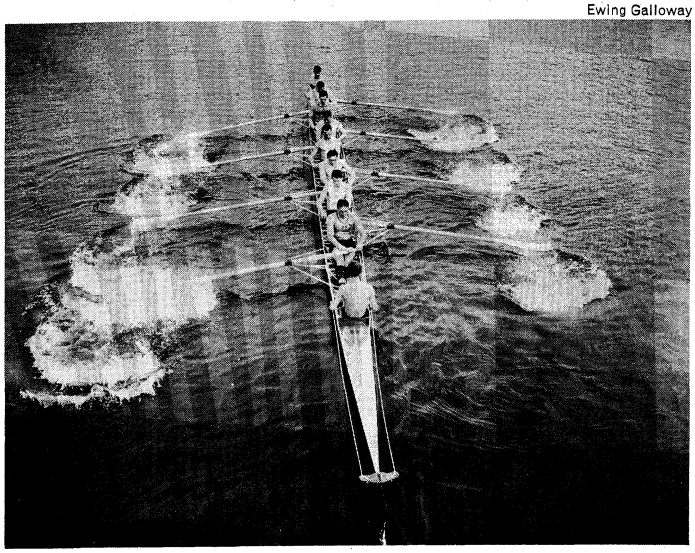

Figure 1: Crew stroking an eight-oared shell.

The race. The following synopsis of the rules governing competition is intended to aid the spectator in understanding the start, conduct, and finish of a race, including why a boat may be disqualified or a race re-rowed. In boat racing a competitor not at the start at the specified time may be disqualified. The race is started when the starter is satisfied that the competitors are ready. He holds up a flag, says "Are you ready?" and if there is no reply says "Go." There is a distinct pause between the two calls. If there is a false start (*i.e.*, a crew starts before "Go") the competitors are recalled. A competitor refusing to start again or persistently starting early may be disqualified. A competitor leaving his proper course does so at his peril and may be disqualified if he thereby interferes with an opponent or if there is a foul. A foul occurs if, after a race has been started, a competitor comes into contact by his oar, scull, boat, or person with the oar, scull, boat, or person of an opponent. It is considered interference if a competitor by his conduct impedes the progress of an opponent who is on his proper course. In the event of a foul or interference, the umpire has power to allow the race to continue, to restart the competitors not disqualified or to order competitors not disqualified to re-row the race.

Occasions for a disqualification or foul

A competitor must abide by his own accidents, but if he is interfered with by some outside agency the umpire can re-start the race according to his discretion or order a re-row. A competitor receiving advice, assistance, or steering aid during a race may be disqualified. The whole distance must be completed by the full crew before a competitor can be held to have won a race. The umpire's jurisdiction extends over the whole race, from the time it is specified to start until it ends. The judge decides the order in which boats pass the winning post. The decisions of both these officials are final, and a competitor failing to abide by the decisions of the umpire or failing to follow his directions may be disqualified.

Technique. Special terminology is used to describe the racing stroke. The entry of the blade into the water is known as the catch. A stroke consists of all of the motions of an oarsman until his oar is again in the position from which he started. The recovery is the part of the stroke when the blade travels forward out of the water as the oarsman swings toward the stern. Feathering is turning the blade horizontally by a motion of the wrist as the oar handle is depressed to raise the blade clear of the water at the beginning of the recovery. The finish is the extraction of the blade after driving the boat through the water. Squaring is the turning of the blade from horizontal to vertical toward the end of the recovery in preparation for the catch. Balance is the skill of applying gentle pressure with legs and hands against the stretcher (footrest) and swivel pin to keep the boat running level throughout the recovery. If an oarsman feathers too soon, too much, or too little or if the boat lurches (loses balance), and his blade is caught in the water (dives), he catches a crab. Rate of striking (rating) is the number of complete strokes rowed per minute. Swift calculations are usually based on three strokes on a special timer that shows the equivalent rate per minute; *e.g.*, three strokes in five seconds is a rate of 36 strokes per minute.

Racing-stroke terminology

Strokes and styles. The orthodox "English Stroke" was based on early fixed-seat rowing at Eton, Oxford, and Cambridge. Body swing was the main source of power, and the arms were used chiefly as connecting rods to transfer the weight of the body to the oar. After the

introduction of the sliding seat (in the United States 1857, in England 1871), leg drive was added. The emphasis, however, was still on body swing, with the body swinging well past the vertical position at the finish. This required strong stomach and back muscles, which took time to develop.

Challenge to the orthodox stroke

The first challenge to this orthodox stroke came from an Australian, Steve Fairbairn, who entered Jesus College, Cambridge, in 1881. A member and coach of his crew, he upset tradition by winning races with a stroke that emphasized leg drive and arm pull. He considered smooth blade work more important than exaggerated body work, and his stroke sacrificed form for speed.

His method was adapted by foreign crews and led to innovations that are now commonplace. Slides were lengthened, swivel rowlocks replaced fixed pins, and crews were seated in a straight line instead of the staggered seating used originally in eights and fours.

English methods did not take root in the United States, where the first college coaches were professional scullers who adapted the sculling stroke to sweep rowing. In 1873 Yale introduced a stroke based on English principles that brought them considerable success for the next 20 years. Hiram Conibear at the University of Washington developed the "American stroke" in 1907. His system dominated United States college rowing for the next 30 years. It was not until 1953 that another coach made a significant impact on world rowing. He was Karl Adam, of Ratzeburg, West Germany. Like Conibear, he had never rowed or sculled before he started coaching. He was a boxer who cut across previous training methods by transposing methods based on *Fahrtspiel* ("speed play") and interval training (short sprints alternating with long paddles) from athletics to rowing.

Women's rowing. There are some records of women's rowing before 1914, but they did not take up the sport seriously until after World War I. In the early 1920s several clubs were established in England, and they sent crews to Australia, Belgium, France, and Poland to race. Women in more than a dozen other countries also took to the sport, and by the mid-1950s there was sufficient strength in Europe to justify the introduction of a championship. The Women's European Championships have been held annually since the inaugural event in Amsterdam in 1954. Racing takes place over 1,000 m (3,300 ft) in eights, coxed fours, quadruple sculls, double sculls, and single sculls. The U.S.S.R. has an outstanding championship record with numerous wins in all classes. Next best have been Germany and Hungary. Other nations that have competed regularly but with only occasional success are Austria, Bulgaria, Czechoslovakia, Denmark, France, Great Britain, The Netherlands, Poland, and Romania. (K.L.O.)

II. Canoeing

Canoeing is the manual propulsion of a lightweight boat, usually pointed at both ends, by a crew of one or more, facing forward and using paddles (not oars) that are not attached to the boat; canoe sailing is sailing such a craft under dismountable sails and spars. Several types of boats are covered by this definition, but only three are employed in international sports competition: the open canoe evolved from the birchbark of the North American Indian, with which single-bladed paddles are used; the decked canoe derived from the kayak of the Eskimo, with double-bladed paddles; and the sailing canoe, which may be an open canoe fitted with sailing rig and leeboards or a very specialized racing craft derived from the decked canoe. In the United States the term canoe is usually reserved for the open canoe, and the term kayak is used for decked, paddling canoes. In Great Britain, until recently, the term canoe was used for both open and decked craft, the name Canadian canoe being used to distinguish the open from the decked form. The term kayak for all decked, paddling craft is gaining currency.

Origins of the canoe and the kayak

HISTORY

Early canoes and kayaks. The canoe was the first true boat (excepting rafts and floats) to be built by primitive man. It exists in every part of the world, and excavations have unearthed specimens from the Stone Age. The canoes built by primitive peoples belong to one of three basic types—bark canoes, skin boats, and dugouts. Bark canoes are associated with the North American Indians who inhabited the forests where the white birch tree grew; but bark canoes are also found in eastern Siberia, South America, Africa, and Australia. An example of a skin boat is the kayak of the Eskimo, used from the Bering Sea to Greenland, but this class also includes hide boats of the Plains Indians and the coracles of Britain and India. Dugouts are made by hollowing out and shaping a tree trunk, and they have a worldwide distribution. Dugout canoes range in size from small, personal canoes to the huge war canoes of the coastal Indians of British Columbia and the Maori of New Zealand.

Development of modern canoes and of the sport. Native canoes were used for transport and hunting, and it is likely that the young men raced against each other, but it is accepted that the modern sport of canoeing was introduced to the world by a Scottish sportsman, traveller, and philanthropist, John MacGregor, in the years following 1865. In that year he designed a decked travelling canoe, which he named "Rob Roy," and in it he made a journey on the waterways of Europe. On his return he wrote a book, *A Thousand Miles in the Rob Roy Canoe on Rivers and Lakes of Europe* (1866), which became a best-seller, and he also lectured on his experiences. Between 1866 and 1869 he made further journeys by canoe in Scandinavia, Egypt, and Palestine and published accounts of them. His books and lectures aroused great interest among sportsmen and many took up this new sport.

"Rob Roy" decked canoes

The first Rob Roy had a length of 15 ft (4½ m) and a beam of 30 in (76 cm), and, with paddles, mast, and sail, it weighed 90 lb (41 kg). MacGregor's second and subsequent canoes were 14 ft (4 m) long, 26 in (66 cm) in beam, and weighed 72 lb (33 kg). The hull was of oak and the deck of cedar, and the paddler sat in a well or cockpit, his back supported by a backrest and his feet braced against a footrest. He used a double-bladed paddle based on the kind MacGregor had seen used with the bark canoes of Kamchatka, in Siberia. In order to be able to make use of favourable winds, a small mast and sail were carried, which could be stowed inside the canoe.

Rob Roy canoes achieved great popularity, and soon racing models were developed called Single Streaks, from their construction from two thin strakes or planks. Although made to suit the user, these racing Rob Roys averaged about 20 ft (6 m) in length and 22 in (56 cm) in beam. Within a few years a Rob Roy model for four paddlers, the ancestor of modern kayak fours, had appeared. In North America the development of racing craft led to wider, deeper, and shorter craft than in England, the paddlers sitting higher and using longer paddles.

Explorers, trappers, and timbermen had adopted the Indian open birchbark for travel through the northern wilderness of forest and lake, but in the course of time the superior tools and skills of the white men were used to improve on the bark canoe, while retaining its best design features. About 1870 the all-wood canoe was perfected and came to be known as the Canadian canoe, and a few years later, in the United States, the canvas-covered canoe was developed. Together these modern versions of the indigenous canoe spread through North America and to several countries of western Europe. In America they supplanted the Rob Roy both for cruising and competition, and in Britain they won favour for pleasure boating and cruising on inland waters.

Canadian open canoes

During the latter part of the 19th and early part of the 20th centuries steady improvement took place in the design of racing craft, but between 1920 and 1930 came rapid developments. From Scandinavia came new designs for racing and touring kayaks, and in Germany the invention of the *Faltboot*, or folding boat, made boat ownership practicable for young people who did not live near water and who lacked facilities for housing and transporting rigid craft. By 1930 the folding canoe had reached Britain and had brought about a revival of in-

terest in canoe touring, and this led to a renewal of activity in every branch of the sport. In North America, where the open canoe had retained a strong following, the advantages offered by the folding canoe were slower in being appreciated, but finally it was accepted. Following 1945, new materials became available, and with the materials new methods of construction and new design possibilities. Waterproof glues made possible cold and hot molding processes leading to strong, light, and resilient hulls. Aluminum canoes were built combining lightness and strength with durability; and many designs appeared for home construction of kayaks by assembling a wooden framework and covering it with a skin of waterproofed canvas. The material being used increasingly for all types of canoe, by both amateurs and professionals, is glass reinforced plastic (GRP), commonly known as glass fibre. This material is cheap, strong and resilient, weatherproof, easily repaired, and requires a minimum of maintenance.

Prototype sailing canoes

In 1869 a pioneer British canoeist, W. Baden Powell, carried out a journey in Sweden and the Baltic, using a Rob Roy canoe, "Nautilus I," and on his return designed a new canoe, "Nautilus II," to make a more effective use of sail. In 1870 he went on to design "Nautilus III," in which he gave complete priority to sailing qualities. "Nautilus III" was the prototype of a long line of sailing canoes in Britain and America, all classed as "Nautilus Type." From this time the development of canoes for paddling and for sailing followed divergent paths. As the years passed, improved models and rigs were produced, and about 1886, a leading American canoe sailor, Paul Butler, added the sliding outrigger seat, which allowed a helmsman to slide out to windward as shifting ballast.

Following many years of separate development of sailing canoes in Britain and America, in 1933 a "Restricted Class" rule was drawn up and agreed between the Royal Canoe Club and the New York Canoe Club, and the "International Canoe" was born. This class of sailing canoe, with a maximum sail area of ten square metres (108 square feet), was in 1946 adopted by the International Canoe Federation as the official ICF International Class, and in 1970 it became a one-design class (see *One-Design* under *Yachting*, below).

Development of organized canoeing. Soon after the return of MacGregor from his European journey the young men who had taken up the sport suggested that he form a club to foster it, and in 1866 the Canoe Club was formed "To improve canoes, promote canoeing and unite canoeists." The first members included distinguished sportsmen, travellers, mountaineers, and athletes, and the heir to the British throne, H.R.H. Edward, Prince of Wales, who became the first commodore. In an appendix to the first edition of his book *The Rob Roy on the Jordan* (1869), MacGregor referred to the club as having "200 members and not one drowned." In 1873 Queen Victoria granted the Canoe Club a charter as the Royal Canoe Club (RCC) and it grew rapidly and extended its influence widely.

In 1887 the British Canoe Association (BCA) was formed, as a cruising organization. Though it was never formally dissolved, it became moribund early in the 20th century. In 1933 a new British Canoe Association came into being and fused with the Camping Club, and in 1936 the British Canoe Union became the governing body for the sport in all its aspects.

In 1871 the New York Canoe Club was founded, being the first canoe club in North America, and in 1880 came the American Canoe Association (ACA) as the governing body of the sport in the United States. By 1886, MacGregor was able to record that the clubs of the ACA had a total membership of at least 2,000 members. An international authority to legislate for the sport was founded in 1924 under the name Internationale Repräsentationsschaft des Kanusport (IRK), and in 1946 a new organization was set up with the name International Canoe Federation, taking over all the functions and responsibilities of the IRK.

Canoeing as a recreation. Canoeing began as a non-competitive recreation, and even now, in most countries, the majority of canoeists use their canoes for recreation rather than competition. Recreational canoeing covers a wide and varied field. It includes paddling on local streams and lakes for enjoyment and relaxation; touring on canals, rivers, lakes, and sea, with the canoe used primarily as a form of transport; the use of the canoe in fishing, hunting, camping, and other recreations; and wilderness expeditions, an extension of touring into more adventurous fields demanding greater resourcefulness. Other recreational uses include wild-water, or white-water, sport, running the rapids of mountain torrents, an activity demanding a high degree of skill and with a considerable element of danger; and surf canoeing, another form of wild-water sport in the ocean surf.

White-water and surf canoeing

Many of these activities are included in the programs of youth organizations because they encourage the development of observation, initiative, judgment, self-reliance, and endurance, as well as great technical skill. In organizations that stress the value of service to the community by young people, such as Britain's Corps of Canoe Lifeguards, the members are trained to apply their skills as canoeists to beach patrol and rescue service, flood reconnaissance, expedition leadership, and voluntary coaching of canoeing.

COMPETITIVE CANOEING

Canoe classes and events. Competitions are organized at world, continental, national, divisional, state, and club levels. World and continental championships (the latter at junior and senior levels) are organized by national federations under the authority and supervision of the ICF. In competitive canoeing, the one-man Canadian canoe is designated C-1 and the two-man canoe as C-2; the one-man kayak is designated K-1, the two-man kayak as K-2, and the four-man kayak as K-4. Championships are conducted in three classes: flat-water racing, wild-water racing and slalom, and canoe sailing. All international competition is at metric distances.

Flat-water racing. World flat-water racing championships are held annually and may be combined with continental championships. Events for men include 500-metre, 1,000-metre, and 10,000-metre races for K-1, K-2, and K-4, C-1 and C-2, and the 4x500-metre relay in which each member of each four-man team paddles 500 metres for a total of 2,000 metres. The events for women are the 500-metre for K-1 and K-2.

Wild-water racing and slalom. World wild-water racing and slalom championships are held biennially. Men's events are for K-1, C-1, and C-2; women's for K-1; and mixed pairs' for C-2. There are individual and team events in each class, each team consisting of three boats.

Canoe sailing. Canoe sailing world championships are held triennially. The championship is for men sailing the International Class 10-square-metre decked sailing canoe.

Olympic Games. Every fourth year the canoe regatta of the Olympic Games replaces the World Championships for that year. Canoe events for men have been included in the Olympic Games since 1936, and for women since 1948. The Olympic events are racing, for men, 1,000 metres for K-1, K-2, and K-4, and C-1 and C-2; and for women, 500 metres for K-1 and K-2; and slalom, for men, K-1, C-1, and C-2; and for women, K-1.

International challenge trophies. The Paddling Challenge Cup of the Royal Canoe Club (Great Britain) was instituted in 1874 and is for annual competition over 10,000 metres in single kayaks (K-1). The International Challenge Cup of the New York Canoe Club was instituted in 1885 as a perpetual prize for the decked, sailing canoe.

National competitions. In the United States, Canada, Australia, and Great Britain, annual competitions are organized at all levels for the recognized ICF classes and courses, and, in addition, each country includes a certain number of national classes and courses in flat-water regattas, long-distance, and marathon races. In the United States the national classes include four-man single blade, a cruising class of sailing canoes, and classes for open canoes with racing rigs. In Great Britain

there is an emphasis on long-distance events, of which a classic is the race from Devizes to Westminster, 125 miles (200 kilometres) with 77 portages and raced nonstop.

Courses, equipment, and specifications. Regulations controlling the equipment, courses, and rules for the several branches of competitive canoeing are laid down by the ICF.

Flat-water racing. Courses for 500 metre and 1,000 metre are straight with provision for nine lanes, each nine metres wide, and water of uniform depth, if possible, of 3 metres. If 10,000-metre races are held on looped courses the radius of the turns is not less than 50 metres and the last 1,000 metres must be straight. In 500 metre and 1,000 metre no "hanging" (riding the wash of another craft and gaining an advantage therefrom) is permitted, though it is allowed in the first 9,000 metres of the 10,000-metre events. When hanging is not allowed, a five-metre rule forbids any competitor to come within five metres (16 feet) of another competitor in any direction. In the approach to a turn, a competitor being overlapped by another on the inside must leave room for the overlapping boat if the bow of that boat has reached a point even with the body of the competitor being overtaken, or with the forward edge of the cockpit, in the case of a kayak.

Long-distance racing. Long-distance racing is not controlled by ICF rules. Regulations vary from country to country. The course may be on river, estuary, or sea, with natural hazards found in such waters. Weirs and falls may be run, or "shot," or portaged. Mass starts are the custom, the canoes being lined up either on the water or on the bank. Classic events are the Sella Race in Spain and the Liffey Descent in Ireland.

Canoe slalom. The slalom event consists of the negotiation of a course of up to 800 metres (2,600 feet) on fast, turbulent water with natural and artificial hazards. The competitor must pass through 25 to 30 gates (pairs of poles hung from overhead wires); to touch the poles, or miss a gate, is to incur the award of penalty seconds, which are added to the recorded time, to arrive at the final result. To increase the difficulty of the course, some gates must be taken stern first, some against adverse currents, and a "team gate" must be negotiated by all three members of a team within 15 seconds. Judges at each gate signal a clean passage or the award of penalties. The craft used in slalom must be highly manoeuvrable, and the competitor needs to be able to carry out recovery from a capsize by means of his paddle.

Racing on fast and turbulent waters

Figure 2: Two-man wild-water canoe in competition (U.S. team at the 1971 World Championships at Merano, Italy).

Wild-water (or white-water) racing. Wild-water is graded in six categories according to difficulty, and wild-water racing at international or championship level is held on a course of from three to eight kilometres (two to five miles) of the highest (*i.e.*, most difficult) grade, with every form of natural obstacle. This form of racing demands the utmost physical effort, mental alertness, skill in canoe handling, and high personal courage. The Canadian canoe used in slalom and wild-water racing is now decked in for additional strength, round holes being left in the deck in which the paddlers kneel on both knees, wearing spray covers to prevent water entering the canoe. Being partially held in by straps they are able to right the capsized canoe by a paddle stroke, similar to the Eskimo roll stroke. Competitors must wear crash helmets and life jackets or other personal buoyancy.

Canoe sailing. International races are held in the 10-square-metre (having a sail area of 10 square metres) decked, sailing canoe IC, a one-design craft controlled by the ICF. The rules for canoe sailing are as for all other forms of competitive sailing, and similar courses are used. In the United States there are also events for the cruising canoe with a 40-square-foot lateen rig, leeboards, and steered by the paddle. Sweden and Germany also have competitions for their own national classes of decked canoes. (J.W.D.)

III. Yachting

Yachting is considered here as the sport of racing and cruising in sailing craft. All boats designed primarily for pleasure, no matter what their size, can be called yachts. The yacht is traced to Holland in the 16th and 17th centuries. The *jacht*, short for *jachtschiff*, a fast, light, sloop-rigged sailing vessel (also fast pirate ship, from hunting ship: *jacht, jagen*, hunt or chase), was developed there on the many canals, lakes, and estuaries. "Mary," a boat of the type, was presented by the Dutch to Charles II of England in 1660. Yachting as a sport, however, dates from the early 19th century. Its beginnings are traced below.

HISTORY

From their royal introduction into Great Britain at the Restoration until the coronation of Victoria, racing and pleasure sailing were esoteric pastimes rather than national sports; and though there was a Cork Water Club (now the Royal Cork Yacht Club) in 1720 and a Cumberland Fleet (of which the Royal Thames Yacht Club is the descendant) in 1775, yachting and boating as they are now known did not appear until the three decades following the establishment of the Yacht Club (now the Royal Yacht Squadron) at Cowes, Isle of Wight, in 1812. The sport was encouraged by the royal and official patronage naturally extended to it in a seafaring nation. During these decades there was energetic founding of yacht clubs at points on the coast where the local conditions suggested the pleasures of sailing; and a national institution was born.

Early English and American yachts. Among the earliest English yachts of which there is any record were the "Pearl," 95 tons, built in 1820 at Wivenhoe, Essex, and the "Arrow," 84 tons, built in 1822, and for 58 years one of the most successful cutters afloat; one of the largest, the "Alarm," was built in 1830 at Lymington, Hampshire, from the lines of a famous smuggler captured off the Isle of Wight. Some yachtsmen at this time preferred still bigger vessels and owned square-topsail schooners and craft resembling the contemporary naval brigs. Of such vessels were the "Waterwitch," built at Cowes in 1832, while Lord Yarborough's second "Falcon" was a full-rig ship of 351 tons, pierced for ten guns a side and with a crew under naval discipline. It was a quaint, buccaneering phase of yachting.

Although sailing for pleasure was a popular diversion in the American Colonies at an early time, the first boat known to be built exclusively for that purpose was the "Fancy" of New York (1717). The second was the 22-ton sloop "Jefferson," built in 1801 for a wealthy shipmaster, of Salem, Mass., who, in 1815, also commissioned the schooner "Cleopatra's Barge" and sailed her to the Mediterranean. The first large U.S. yacht, "Cleopatra's Barge" was 83 feet (25 metres) long on the waterline, had a 23-foot (7-metre) beam, and was furnished with great luxury.

Living in Hoboken, N.J., on the banks of the Hudson

The Stevens Brothers

River across from New York City, was the Stevens family, after whom Stevens Institute of Technology was named. John C. Stevens and his brother Edwin A. were the first prominent yachtsmen in the New York area. In 1809 they built the 20-foot (6-metre) sailboat "Diver," in 1816 the 56-foot (17-metre) "Trouble," and in 1820, "Double Trouble," believed to have been the first sailboat with twin, side-by-side hulls, or catamaran (see below *Multihulled boats*), built in the U.S. Their other boats included, in 1832 the 65-foot schooner "Wave," in 1839 the 91-foot (28-metre) waterline schooner "Onkahye," and in 1844 the 49-foot (15-metre) waterline schooner "Gimcrack." The latter was the yacht aboard which the New York Yacht Club (NYYC) was organized on June 30, 1844. Another brother, Robert L. Stevens, in 1846 designed the 88-foot (27-metre) waterline sloop "Maria," which incorporated certain features to be found in modern yachts, such as a hollow boom and crosscut sails. By this time there were a number of yachts racing on New York Harbor, and the archives of the NYYC show eight yachts enrolled in the fleet in 1844.

The yachts of that date tended to follow the models that had been developed for commercial purposes, and most of them were schooner-rigged, following the lead of the fast New York pilot schooners, although the "Maria" resembled more closely the Hudson River sloops that carried cargo on the Hudson River between New York City and Albany.

As in the United States, the English yachts that evolved from the working craft in the last days of sail embodied in their shape the fish form—wide, bluff bows, their greatest beam at about one-third of their length from forward, and long, streamlined afterbodies. A trend toward finer lines forward was reinforced by the success of the "America" in 1851, and thereafter the form of yachts changed. Bluff bows with an angle of entrance of about 30° were replaced by bows with an angle of less than 20°.

Beginnings of organized yachting. Although the Knickerbocker Boat Club of New York was founded in 1811, it was disbanded the following year, and organized yachting can be regarded as dating from the founding of the NYYC in 1844. Some of America's more important early yacht clubs and their dates of organization follow: Southern Yacht Club, New Orleans, (1849); Detroit Yacht Club (1865); Boston Yacht Club (1866); San Francisco Yacht Club (1869); Eastern Yacht Club, Marblehead, Mass. (1870); Seawanhaka-Corinthian Yacht Club, Oyster Bay, N.Y. (1871); Chicago Yacht Club (1875); and Larchmont Yacht Club (1880). There were about 1,500 active yacht clubs in the United States in the 1970s. Many of them were located on freshwater.

The Yacht Racing Association (YRA) was founded in England in 1875 with the object of providing a set of rules governing regatta sailing, and by 1881 most of the important clubs were members of the association. The Prince of Wales (afterward Edward VII) was its president. He was also commodore of the Royal Thames Yacht Club and of the Royal Yacht Squadron, and during these years the influence of the YRA was established. The Royal Ocean Racing Club (RORC) was founded as the Ocean Racing Club in 1925 with the principal objects of encouraging long-distance yacht racing and the building and navigation of sailing vessels in which speed and seaworthiness were combined.

Much of Australia's yachting history is spanned by the life of the Royal Sydney Yacht Squadron, which held its centenary in 1962, and in that year also first challenged for the America's Cup. The Australian yachting scene falls naturally into the groups of the six principal coastal states. As increasingly is the case in other parts of the world, the sport consists largely of small-boat racing, and also as in other countries, Australians follow the pattern of going to the sea for their leisure, fishing, and cruising, as well as racing.

Development of design and rigging. Before 1870 yachts were usually turned out by rule of thumb by local builders, each builder having his favourite type. Usually the hulls were "modelled": *i.e.*, a half model was whittled out before the frames were set up for the full-sized boat.

Hull design. The type of hull most in favour along the U.S. Atlantic seaboard was a broad-of-beam, shallow-draft, centreboard craft with great initial stability, carrying a large spread of canvas, and with a relatively small amount of ballast. Boats of this type were usually fast in smooth water but were not particularly good sea boats. The centreboard was housed in a "trunk" located on the centreline of the yacht and was lowered through a slot in the keel in order to give the boat sufficient lateral plane to work into the wind. Even quite large yachts were built on this model. One, 94 feet (29 metres) overall, 26½-foot (8-metre) beam, had a draft of only five feet two inches (157 centimetres) with her centreboard up.

Design of the "America"

At this time the so-called fish, or cod's head and mackerel tail, form was in favour. It is generally believed that George Steers of New York, designer of the yacht "America," introduced the narrow, pointed bow in designing the pilot schooners for which he was famous. The victory of 100-foot (30-metre), 170-ton "America" in a 53-mile (85-kilometre) race around the Isle of Wight against a large fleet of British yachts in 1851 was probably the greatest single stimulant to the early development of American yachting. Steers' boats caused a revolution in yacht design, but it was not until 1870 that the lines of the cutter "Vindex" were drawn on paper. It was the first American yacht to be built from a drawing rather than a model.

English yacht designers of high technical ability and rare artistic gifts designed yachts as a distinct branch of naval architecture. The evidence of contemporary scientific researches in ship design was applied to the shaping of yachts and, after 1874, led to a second fundamental change in design—the reduction of wetted surface. Incidental to this evolution was a return toward the fuller bows of the pre-"America" period.

In 1876 the yacht "Mohawk," a 140-foot (43-metre) schooner, capsized at anchor in a squall, drowning her owner and several guests. The disaster caused the advocates of beamy, shallow-draft centreboarders to take stock of type, and led to the design of the so-called compromise sloop "Mischief," a 67-foot (20-metre) iron centreboarder, with a slightly deeper hull than the old skimming dishes. She relied not only on beam but also on the placement of her ballast lower in the hull for stability. "Mischief" successfully defended the America's Cup in 1881 against the Canadian challenger "Atalanta," also a centreboarder.

Decline of the shallow-draft skimming-dish design

In that year a 46-foot (14-metre) cutter "Madge" arrived in the U.S. from Scotland. During her first summer she won most of her races boat-for-boat against the best centreboarders. Her phenomenal success greatly influenced the design of the compromise cutter "Puritan," which defended the America's Cup against the "Genesta" in 1885.

Influence of the America's Cup. The America's Cup contests exerted great influence in the matter of design. Initially, they brought together two opposed ideas: the beamy, shallow-draft, centreboard American type and the deep-keeled vessel of the British tradition. In 1885 the opposing types were well exemplified in the "Puritan" and the "Genesta"; but the four matches of the next decade witnessed a gradual merging of the two conceptions, until in 1895 the British challenger was actually the beamier of the two boats. Subsequently, the enormous sums spent on Cup yachts raised the science and art of design to a level of exceptional refinement.

The success of "Puritan" made her designer Edward Burgess the most popular U.S. designer, and the Burgess hull soon became the accepted U.S. standard. He subsequently designed two more successful America's Cup defenders, "Mayflower" and "Volunteer."

In 1891 Nathanael G. Herreshoff, of Bristol, R.I., turned out a yacht that was destined to revolutionize yacht design once more. This yacht was "Gloriana," with the yacht's forefoot boldy cut away so that her profile showed an easy sweep from the stemhead to the bottom of the keel.

When the next challenge for the America's Cup (1893) was received from the Royal Yacht Squadron, Herreshoff

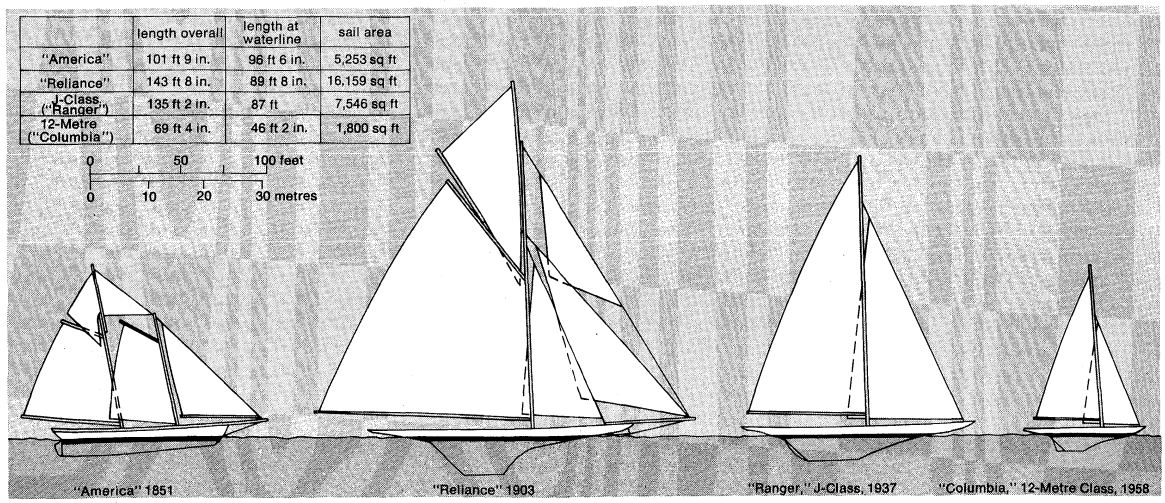

Figure 3: Evolution of America's Cup racing yacht design (from left): "America," original winner of the cup; "Reliance," largest defender; "Ranger," typical J-Class defender; "Columbia," typical 12-Metre Class yacht, the first 12-Metre defender.

The Herreshoff designs

designed the successful defender, the sloop "Vigilant." While a keelboat, she also carried a centreboard that worked through a slot in the lead keel. After the "Vigilant," Herreshoff designed the successive defenders up to and including the 1920 contest, when "Resolute" successfully defended, and Herreshoff was recognized as the foremost yacht designer in America.

By 1930 when Sir Thomas Lipton made his last challenge with "Shamrock V," Herreshoff had retired and "Enterprise," the defender of that year, was designed by Burgess' son W. Starling Burgess.

The "Rainbow," defender in the 1934 race, was also from Burgess' drafting board. In 1937, he collaborated with a young designer, Olin Stephens, in the design of "Ranger." Stephens himself was to produce three more Cup defenders: "Columbia" (1958), "Constellation" (1964), and "Intrepid" (1967).

"Intrepid" brought to Cup racing the cutaway, underwater profile that had come to general popularity among ocean racers in the latter part of the 1960s, following the tremendous success enjoyed over an extended period of time by a number of stock fibreglass so-called Cal-40 class yachts built in California. The modern underbody configurations saved wetted surface and increased downwind steering ability by separating the rudder from the keel and placing it away aft, either as a free-standing balanced spade or with a skeg (a projection aft of the keel to support the rudder) at its leading edge. Small auxiliary rudders, popularly known as trim tabs, were sometimes retained on the trailing edge of fin keels in order to impart greater lift. "Intrepid" was fitted with a double-rudder configuration of this nature.

Rig design. Probably no one factor contributed more to the speed of yachts than the development of modern rigs. After 1920 the science of aerodynamics was applied by naval architects to the design of sail plans, resulting in a revolutionary change in yacht rigs. Tall, narrow sail plans, with a long, efficient leading edge, replaced the older gaff rig of roughly trapezoid-shaped mainsails with the base longer than the perpendicular.

The new mainsails were triangular (called Marconi, Bermudian, or jib-headed) and were set on tall masts with a ratio of hoist to foot (aspect ratio) of 2:1 up to 3½:1. In the case of the J-Class yachts (America's Cup class, 1930–37), masts were as high as 165 feet (50 metres) on a waterline length of 80 feet (24 metres). Large masthead fore-triangles and overlapping headsails followed as a natural consequence and tremendous jibsails, overlapping the mainsail by as much as two-thirds the length of the main boom and with a luff (forward edge) as tall as the mast, came into use. These were called Genoa jibs because the first one was used on a yacht racing off Genoa, Italy. So efficient were the new rigs that yachts carrying from 25 to 40 percent less sail area than formerly had as much as or more speed than the old, larger sail spread. The new rigs were also easier to handle and a smaller crew sufficed, while the elimination of the gaff and the topmast, to say nothing of the use of aluminum that became the dominant spar material in the 1960s, saved weight aloft.

Large, full spinnakers, cut much like a parachute, also replaced the old, smaller, flatter spinnakers and had greater pulling power.

Rating rules. Prior to the emergence of the one-design classes (see below), nearly all sailboats were individually designed and custom-built. To enable such boats to race each other, either on equal terms or on a handicap basis, rating classes were established. These were based on measurement formulas applied to length, sail area, and other factors affecting design and speed, the theory being that all boats with the same rating could compete fairly against each other. Each owner and designer, of course, attempted to create the fastest boat possible within limits set by the rules. Before 1905, for example, American boats were rated by adding the square root of the sail area to the waterline length and dividing by two. Under this rule, the same tendency became apparent as in England— to develop flat-bodied hulls with long overhangs and light displacement, producing an extreme skimming-dish type. This reached its limit in the America's Cup defender "Reliance" (1903), which had overhangs totalling more than 50 feet (15 metres) on a waterline length of 89 feet 8 inches (27 metres). Following this match a conference of yachting organizations in 1905 adopted the Universal Rule that, while retaining length and sail area as the chief factors, also used displacement in the formula and controlled overhangs, draft, freeboard, and other elements, by imposing penalties. It produced a more seaworthy vessel and, while amended several times, the America's Cup matches were sailed under it through 1937. The formula was 18 percent of the product of length times the square root of the sail area, divided by the cube root of displacement, equals the rating. The International Rule (adopted 1906) was considerably more complex but retained many of the same factors as the Universal Rule.

The Universal Rule

Ocean racing was conducted primarily under the Cruising Club of America (CCA) and Royal Ocean Racing Club measurement rules after the decade of the 1930s. This type of racing is on a handicap basis with time allowance derived from rating. The offshore racing yacht evolved during 1929–39 was the derivative of the International Rule craft, whose fundamental seaworthiness was proved in offshore racing. Encouraging the development were such American yachts as "Dorade," winner of the Fastnet Race (see below) in 1931 and 1933, and "Stormy

Weather," winner in 1935. The British yachts "Maid of Malham" and "Ortac" of 1936 epitomized the new type of seagoing racing yacht in which the speed of the International Rule boats was blended with the robustness of the earlier cruisers to produce a new and exceptionally versatile type of yacht.

In 1933 a formula was adopted by the RORC to approximate the immersed bulk of the boat by means of simple internal measurements capable of being made with the yacht afloat. It was considered essential that it should be possible to measure the boat without access to scale drawings or the necessity of hauling it out of the water. Apart from the basic formula, the rule comprised clauses by which bonuses or penalties in rating were derived in accordance with the yacht's characteristics.

As a result of the interest in the Bermuda Race, U.S. naval architects commenced to design to the measurement rule then in use, which was a simple one. But it soon became apparent that a more restrictive measurement rule was required to equalize the changes of divergent types and promote sound design. Accordingly, a scientific rule called the Cruising Club of America Rule, drawn up in 1940, became the basis for measurement for nearly all important long-distance races in the United States.

In the late 1960s, with ever-growing interest in international ocean racing, a demand arose for the RORC and CCA to merge their rules so that a yacht could be measured in home waters and race anywhere in the world under this rating. The most enduring features of the RORC and CCA rules were thus retained in the International Offshore Rating (IOR), which quickly became a world standard. (B.D.B.)

Types of boats. *Small boats and one-design classes.* One of the fastest growing areas in the field of sailing is that of one-design class boats. All boats in a one-design class are built to the same specifications in length, beam, sail area, and other elements. Racing between such boats can be held on an even basis with no handicapping necessary.

True one-design and development classes

In practice there are variations within the class-boat concept. These range from the true one-design to boats that are called development classes. Development classes race on a boat-for-boat basis but the class rules controlling them encourage individuals to experiment in specified fields within established parameters.

An example of the true one-design class would be the 13-foot 10-inch (4-metre) Sunfish, popular throughout the world and strictly controlled in all areas. Hulls, sails, and rig specifications are set, and even minor changes are not permitted without an official ruling by the governing body of the class. The International 14, on the other hand, is a development class that by its very nature allows continuous experimentation in hull design, construction techniques, sails, and rigging within the class rules. The 11-foot (3-metre) Moth and 32-foot 5.5-Metre are other examples of open or development classes.

In the middle area of these two extremes lies the majority of the one-design classes—boats that may vary to some extent in such areas as construction materials and cockpit layout (for example, many classes permit hull construction in both fibreglass and wood, and spars in aluminum or wood). The Snipe, Lightning, and Star are examples of this middle area.

The one-design concept is an old one, one that appears to have started in Ireland with a proposal for a 13-foot (4-metre) centreboard boat. The designer, in a circular issued in 1886, stated that such a boat would result in

> a race where every boat will have the same chance, and will call for throughout continued attention in order to gain every little advantage to be got in order to win, and not a mere procession of boats, and a race that will be a contest of the crew and not one of designers and sailmakers.

The boats were known as Water Wags. At just about the same time (1887), records indicate that one-design racing started in the United States in North Haven, Maine, when a class called North Haven dinghies became active.

Shortly after World War I, there was a boom in yacht building—particularly in the smaller classes. During that period numerous one-design classes, all small by comparison with prewar yachts, came to the fore. This was partly attributable to the great increase in postwar costs but also because interest in yachting was spreading and many owners preferred sailing their own boats to employing professionals. The first popular one-design class, the Star, was developed from the 17-foot (5-metre) Bug Class. In 1910 the design was modified, increasing the overall length to 22 feet 8½ inches (7 metres) with a sail area of 285 square feet (26 square metres), and the larger boat was christened "Star." The Star Class Association of America was formed in 1915, being replaced in 1923 by the International Star Class Yacht Racing Association. By the second half of the 20th century, the class was worldwide in scope and numbered more than 5,000 boats. Competition in the class is keen; it is one of the Olympic class boats, and international as well as national and regional contests are held annually. In the late 1920s, several International Rule classes also became popular, including the 6-, 8-, and 12-metre, the "sixes" being most numerous. A number of international races were held in this class in which British, Scottish, Swedish, Italian, and other yachtsmen participated. Formerly an Olympic class yacht, its expense resulted in its decline after the 1952 Games.

The popular Star and other one-design classes

Some Popular One-Design Classes

	length (feet and inches)
Aqua-Cat catamaran	12 2
Bluejay	13 6
Cal 20	20
El Toro	7 11
Ensign	22 6
Enterprise	13 3
Fireball	16 2
5-0-5	16 6
Flying Junior	13 3
420	13 9
Hobie Cat	13 11
Lightning	19
Mirror	10 10
OK Dinghy	13 1½
Optimist pram	8
Penguin	11 5
Snipe	15 6
Sunfish	13 10
Thistle	17
Tornado catamaran	20

One-design classes range from those geared to the junior sailor (such as the 8-foot [2-metre] Optimist pram) to such high-performance boats as the two-man, trapeze-rigged 19-foot 10-inch (6-metre) Flying Dutchman, designed by Uffa van Essen (see below *Olympic boats*). Class organizations plan and schedule championships, maintain the class rules, and through a technical committee, maintain a close watch on new developments.

Scows. On certain waters of Canada, Barnegat Bay, N.J., and other sheltered coastal waters, and especially in Wisconsin, Illinois, Iowa, Missouri, Minnesota, and Indiana in the United States, the scow type, also known as the Inland Lake scow, has been highly developed. These boats are extremely flat, draw only a few inches, have two leeboards (bilge boards), instead of one centreboard, double rudders, and are sailed without fixed ballast. On a reach (at a right angle to the wind) they are exceedingly fast, having been clocked at speeds of more than 25 miles per hour (40 kilometres per hour). Contests for the Seawanhaka Cup, first offered in 1895 by the Seawanhaka-Corinthian Yacht Club of Oyster Bay, N.Y., for international competition among small yachts, did much toward the development of the scow. The Inland Lake Yachting Association (1897) governs an extensive scow racing and regatta schedule. There are recognized classes, ranging in size from the M, 16 feet (5 metres) overall, to the A, 38 feet (12 metres) overall. Class X, a conventional one-design, the only nonscow sponsored by the Inland Lake Yachting Association, is used as a junior trainer.

Multihulled boats. In the field of multihulled sailboats, the catamaran (two hulls) has made the greatest

Catamarans

inroads into the one-design and class fields. The concept of the multihull design is, of course, an old one, dating back about 2,500 years. Its acceptance for sports sailing on a large scale is of fairly recent origin, however. Numerous classes exist, with great appeal to those in search of high speed and shallow draft. The 12-foot 2-inch (4-metre) Aqua-Cat, 18-foot 9-inch (6-metre) Cougar, 14-foot and 16-foot (4- and 5-metre) Hobie Cat, 18-foot 9-inch (6-metre) Pacific Cat, 18-foot (5-metre) Phoenix, and 20-foot (6-metre) Shark are all popular classes, and the International Yacht Racing Union has discussed the 20-foot (6-metre) Tornado catamaran for potential Olympic status in 1976. Larger catamarans have engaged in ocean sailing. A similar type of boat employing three hulls is known as a trimaran.

Day sailers and cruisers. Day sailing and cruising purely for pleasure and recreation attract a far greater following than any other aspect of the sport. Day sailers take many forms. They are roomy, steady, practical, and enjoyable boats on which to spend a day or part of a day or evening sailing. Generally the term applies to any sailboat, not primarily a racing boat, that lacks accommodations for overnight living aboard.

The cruising sailboat, although small enough to be handled by a crew of one or two, or perhaps half a dozen, is equipped for living aboard, at least overnight. Many are capable of making long ocean voyages and even of circling the globe. Instead of the tall masts of the racer, the masts of the cruising sailboat are lower and stronger and sail area is less, to put less strain on hull and rigging. Hard-to-handle spinnakers are almost nonexistent. Rigging and construction are heavier. The boat is built to weather storms and withstand the weight of crushing waves. Rigs are "balanced" so that with the wheel lashed the boat can sail herself hour after hour while the crew sleeps, eats, or mends.

Yacht clubs and organizations. The controlling body of the sport of yachting is the International Yacht Racing Union (IYRU), founded in 1907. The organization is made up of national authorities from the various member nations, such as the Australian Yachting Federation, Fédération Royale Belge de Yachting, Federación Mexicana de Vela, the North American Yacht Racing Union, and others. The object of IYRU is to promote the sport of amateur yachting. Committees are the permanent committee, keelboat technical committee, centreboard boat technical committee, constitution committee, class policy and organization committee, and youth committee. The latter has established guidelines for an annual IYRU Youth Championship with entries from 15 to 19 years of age, held on different waters throughout the world. The permanent committee nominates the classes of boats that are sailed in Olympic Games competition.

The International Yacht Racing Union

Sailing and yacht clubs. With few exceptions, sailboat racing and all organized boating activity are conducted under the auspices of a vast network of chartered yacht clubs found clustered around boating centres all over the world. The oldest is the Royal Cork Yacht Club established in Ireland in 1720 as the Cork Water Club. Most of these clubs are affiliated with their own national or regional authority; *e.g.*, the Royal Yachting Association, for Great Britain, the North American Yacht Racing Union, for North America. While the primary purpose of most clubs is social, they also make an important contribution to boating as a whole by establishing competitive standards, promoting competitive events, and attending to the endless details of executing these.

Some clubs may have specialized objects, such as the Cruising Club of America or its British counterpart, the Royal Ocean Racing Club, both organizing offshore racing events and regulating the handicapping of ocean racers. There are also many clubs that cater exclusively to powerboats.

In addition to races for sailboats and predicted log races for powerboats, most yacht clubs hold regattas in which events are not limited to boats built for racing, and many conduct overnight, or longer, cruises.

The North American Yacht Racing Union. Regulations affecting yacht racing and measurement rules, up to about 1900, had been in the hands of individual yacht clubs or local yacht-racing associations composed of clubs in the same locality. There was thus lack of uniformity in different sections of the country. At the time of the agitation for a new measurement rule to supersede the length-and-sail-area rule, the New York Yacht Club called a conference of yachting organizations of the Atlantic coast and the Great Lakes to bring about uniformity by persuading the other sections to adopt the Universal Rule then being formulated. This was a step forward, but after the conference there still was no real governing body for yachting affairs in the United States until local yacht-racing associations and yacht clubs formed the North American Yacht Racing Union (NAYRU) in 1925. This was the first permanent legislative and governing body for sailing of national scope in the United States, and through it both the racing and measurement rules were standardized and an appeals board for racing members was formed.

In 1927 delegates from this union met with delegates of the International Yacht Racing Union in London to bring about closer international cooperation. Realizing the value to the sport of international racing, the union recognized (in addition to the Universal Rule) the International Rule used in European countries, with the result that several international classes were built and became popular in the United States. Meetings of the International Union's permanent committee are held annually, with NAYRU representatives participating.

NAYRU championship events

The NAYRU annually administers five North American sailing championships that bring top U.S. and Canadian sailors together after regional qualifying events are held. The five are the Mallory Cup (men), Adams Cup (women), Sears Cup (junior), O'Day Trophy (single-handed), and Prince of Wales Trophy (match racing).

Beginning in 1967, NAYRU became active in administering ocean racing. This rapidly growing part of the sport required national organization for numbering, equipment requirements, and the choosing of international teams.

The Royal Yachting Association. Immediately after World War II, the need for a national representative body for yachting in Great Britain, competent to deal with port, harbour, and other authorities, and with the government, became evident. The Yacht Racing Association, which was financially supported by the yacht clubs, was a basis for such an organization, and steps were taken to broaden its activities. A general purposes committee was founded to deal with yachting matters as a whole. These included such diverse questions as that of a projected purchase tax on yachts, the municipal rating of yachts' moorings, the siting of oil refineries and bombing ranges in unspoiled coastal areas, and the pollution of coastal and estuary water. To express the enlarged functions of the association its name was changed early in 1952 to that of the Yachting Association. Later in the same year the prefix Royal was granted. (E.M.Ho.)

THE SPORT OF SAILING

Courses. Sailboat races are held over two general types of courses: point-to-point and closed courses. Most ocean racing is point-to-point, as, for example, across the Atlantic, the Bermuda Race from Newport to Bermuda, and the Transpacific from California to Hawaii. Some ocean races are sailed to or around some objective (an island, a buoy, or other marker) and back; and some competitions combine both types of races.

Small-boat races usually are sailed on closed courses, most commonly triangular.

How a boat sails. The sails of a boat are airfoils that by their angle of incidence to the airstream (the wind) generate the drive that propels the boat. The trim of the sails is governed mainly by the angle of the desired course to the wind. When sailing to windward (Figures 4F and 4G), the boat's course is at the smallest practicable angle to the wind. The sails are then trimmed to an angle with the wind that produces their greatest driving force—an angle that is usually about 10° and varies with the efficiency of the sails. The resultant force produced by the sails may be further resolved into a component in the di-

rection of the desired course (drive) and another normal to it (leeway force). Under the conditions of Figures 4F and 4G, the drive force will be about one-third of that producing leeway. The latter has to be resisted by the boat, whose ability in this respect is one determinant of the smallest practicable angle of the course to the wind.

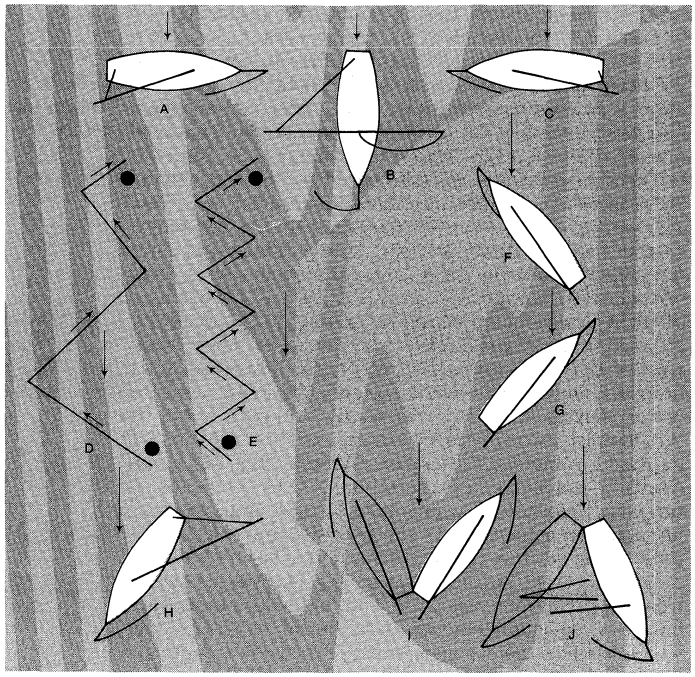

Figure 4: *Points of sail.*
(A) Reaching on port tack. (B) Running. (C) Reaching on starboard tack. (D, E) Course tacking to windward. (F) Close-hauled on starboard tack. (G) Close-hauled on port tack. (H) Sailing on a broad reach with a quartering wind. (I) Tacking. (J) Jibing. Arrows indicate direction of the wind.

Sailing into the wind

Very efficient racing craft may sail at about 35° to the wind; undistinguished performers may not be able to sail closer than 55° without suffering from excessive drift to leeward.

When the boat's course lies at right angles to the wind (Figures 4A and 4C) the sails are still trimmed at approximately the same angle of incidence to the airstream, but their angle to the course is bigger and accordingly the driving force is increased and that to leeward reduced. On this point of sailing the drive and leeway forces are approximately equal, and a boat is faster under the condition in Figures 4A and 4C, than those of Figures 4F and 4G. When the course is such as to bring the wind still further aft, the sails reach the aerodynamic condition known as stalled, and also the direction of the drive force swings with the sails closer to the direction of motion (Figures 4H and 4J) until the two coincide when the wind is astern as in Figure 4B. When the direction of the wind is abaft the beam and it is no longer possible to trim the sails to a uniform angle of incidence of about 10°, the most efficient sails are those with a full curvature—such as the spinnaker (Figure 4B)—which deflects the maximum volume of wind through the biggest possible angle. It will be evident that under the conditions of Figures 4F and 4G, when a boat is said to be close-hauled or on a tack, it is necessary to follow a zigzag course (Figures 4D and 4E) in order to reach a point dead to windward. When the bow of a boat is steered through the eye of the wind she is said to be tacking (Figure 4I); when the same evolution, of bringing the wind from one side to the other, is performed by steering so that the wind passes round the stern, she is said to be jibing or gybing (Figure 4J; see also SAILS AND SAILING VESSELS).

The America's Cup. This 100-guinea cup was offered in 1851 by the Royal Yacht Squadron for a race around the Isle of Wight, and was won by the "America." In 1857 the syndicate that had built "America" gave the cup (thereafter known as the America's Cup) to the New York Yacht Club as a perpetual challenge trophy to be raced for by yachts of foreign countries. The first challenge for the Cup was made in 1870 with "Magic" (U.S.) successfully defending against "Cambria" (U.K.) and starting an unparalleled winning streak.

The original deed of gift imposed disadvantages on challenging yachts, but a mutual consent clause ironed out several difficulties, and subsequent modifications of the original deed during the lifetime of the donors further improved the challengers' chances. Finally, in 1956, at the request of the New York Yacht Club, the New York State Supreme Court eliminated a clause requiring the challenger to sail on her own bottom to the scene of the contest. At the same time the permissible waterline length for single-masted vessels was reduced from 65 to 44 feet (20 to 13 metres), in order to include 12-Metre class boats, which are approximately ⅔ the length and ⅙ the displacement of J-class yachts previously used. These changes permitted a challenger to tune up in her home waters and be shipped for final prerace trials.

Changes in America's Cup rules

The record of America's Cup races is given in SPORTING RECORD in the *Ready Reference and Index*.

The America's Cup races enjoy the greatest public fame of all international yachting contests. They have on occasion, however, become battles of wits and complicated legislation as much as sailing, and a source of discords that at times were inflated into minor international incidents. Among such incidents were the defending club's early refusal to permit the challenging yacht to race against only one defender; and Lord Dunraven's allegations in 1895 that his "Valkyrie III" had been fouled by the U.S. yacht "Defender" and that the spectator fleet's crowding had endangered him. In the late 1890s, ruffled feelings were smothered by the genial tea magnate Sir Thomas Lipton, who was thereafter so much in the public eye with his "Shamrocks" and five challenges between 1899 and 1930 that the famous Cup was often thought of erroneously as the Lipton Cup. Subsequent contretemps have arisen from the New York Yacht Club's decision in 1934 that a protest could not be entertained because T.O.M. Sopwith's "Endeavour" had not promptly shown a protest flag; and "Gretel II's" disqualification in 1970 (second race of series) for a starting-line infraction after she had crossed the finish line first.

Many causes can be found for the unvarying failure of the challengers. So long as defenders were lightly built, the challengers were handicapped by the requirement of having to sail the ocean and the rugged construction the voyage necessitated. But after 1920 rules governing the construction of the yachts ensured that challenger and defender alike should be of comparable strength, and the most persistent cause of the challenger's failure was probably inferior organization and handling. The defenders were tuned to a high pitch racing against one or several defense candidates while challengers often never had a serious race until the Cup match started. For the first time in 1970, challenger eliminations (won 4–0 by Australia's "Gretel II" over "France") were permitted—further enhancing the possibility the sporting world's most remarkable winning streak might someday be broken.

Offshore sailing. *Transatlantic racing.* The first transatlantic yacht race (Sandy Hook, N.J., to England) took place among three American schooners in December 1866. Contestants were the "Henrietta," "Fleetwing," and "Vesta." The "Henrietta" won; her time, 13 days 21 hours 45 minutes. Transatlantic match races were held between "Cambria" and "Dauntless" from Daunt Rock, Ire., to Sandy Hook in 1870, and between "Coronet" and "Dauntless" from Sandy Hook to the Lizard, a prominent headland in the English Channel, in 1887. In 1905, 11 yachts raced from Sandy Hook to the Lizard. The winner, "Atlantic," a three-masted schooner, covered the 3,031 miles (4,877 kilometres) in 12 days 4 hours 1 minute. Her best day's run of 341 miles (549 kilometres) remained a record for yachts into the second half of the 20th century.

Again in 1928, under new ownership, "Atlantic" made a try for transatlantic honours, but was defeated by the

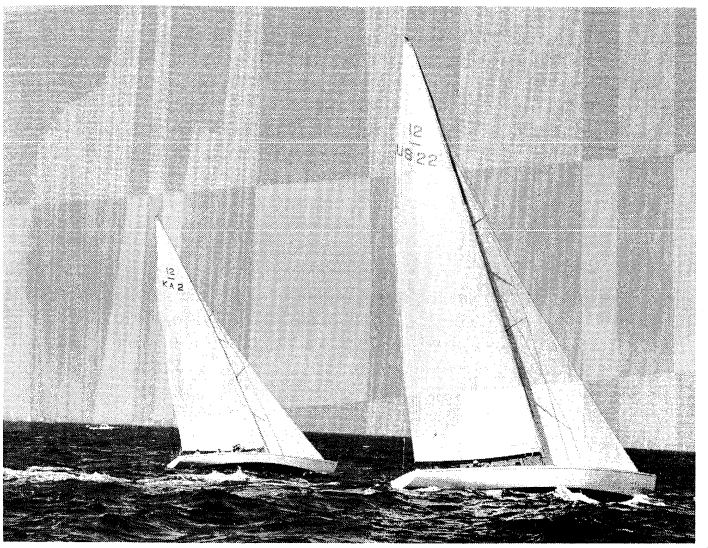

Figure 5: America's Cup competitors (left) "Dame Pattie" (Australia) and "Intrepid" (U.S.) close-hauled on starboard tack in the first race of the 1967 challenge series. "Intrepid" was the winner.
B. Devereux Barker III

Small craft in trans-atlantic racing

schooner "Elena," in a race to Santander, Spain, for the King of Spain's Cup. In a concurrent race for the Queen's Cup, which marked the debut of small craft in transatlantic racing, the 59-foot (18-metre) schooner "Niña" won from three competitors—one of which, the schooner "Rofa," sank without loss of life. "Niña" cruised from Spain to England where she became the first U.S. yacht to win the Fastnet Race. Other transatlantic races for small craft were held at irregular intervals after that time.

In 1931, "Dorade," a 52-foot (16-metre) yawl, built the previous year for her designer, was a winner by a remarkable 66 hours in a 10-boat fleet that raced from Newport, R.I., to Plymouth, Eng. Her elapsed time of 17 days 1 hour (32 years later the 57-foot "Ondine" sailed an identical course in 18 days 8 hours) proved for good that small yachts could be raced in safety across the Atlantic and started a trend away from the schooner rig, which had been most popular among ocean racers. In 1936, a 3,400-mile (5,500 kilometre) race from Bermuda to Cuxhaven, W. Ger., attracted one Dutch and seven German entries, but no American or British boats. The 59-foot (18-metre) "Roland von Bremen" was overall winner.

Rafael Posso, life commodore of the Havana Yacht Club, in 1951 promoted a 4,200-mile (6,800 kilometre) transatlantic race from Havana to San Sebastián, Spain. Sailed in June and July, the American ketch "Malabar XIII" won from three competitors. In 1955 the race from Havana to San Sebastián was again held and was won by the Spanish yawl "Mare Nostrum," from American, Cuban, and Argentine entries.

In 1960 the 47½-foot (14.5-metre) yawl "Figaro" won a 3,370-mile (5,240-kilometre) race from Bermuda to the Skaw light vessel in the Skagerrak, from an entry list of 17 yachts. The U.S., England, Sweden, and Germany were represented. Three years later the 57-foot (17-metre) aluminum yawl "Ondine" won from 13 other U.S. yachts a race from Newport to Plymouth. In 1966 a record transatlantic entry list of 42 yachts raced from Bermuda to the Skaw. "Ondine" won the top prize again.

In 1968 there was a race for 33 yachts from Bermuda to Travemünde, W. Germany, that was plagued by light air on the last leg across the North Sea to the finish. The winner was the 47-foot (14-metre) yawl "Indigo." In 1969 a race from Newport to Cork, Ire., in celebration (a year early) of the Royal Cork Yacht Club's 250th anniversary, attracted 23 entries over which the 73-foot (22-metre) yawl "Kialoa II" prevailed. Transatlantic races were scheduled to be sailed from Bermuda to Bayona, Spain, in 1972, from Newport to Plymouth in 1975.

The Bermuda and other ocean races. In 1906 Thomas Fleming Day, to demonstrate that small yachts, if properly designed, built, and handled, could go to sea with safety, promoted a race from New York to Bermuda in which there were three starters. The winner was "Tamerlane," a 38-foot (12-metre) yawl. After five years, interest in the Bermuda Race died out.

The Bermuda Race

In 1922 a group of cruising yachtsmen organized the Cruising Club of America. Among this group were several who felt that ocean racing would be beneficial to the development of both yachts and yachtsmen. Accordingly, a committee was formed (not under CCA auspices, however) to revive the race to Bermuda (660 nautical miles). There were 22 entries; the winner was "Malabar IV," designed, owned, and skippered by John G. Alden. Subsequent races were run thereafter in even years, except during World War II. The start of the 1932 race was shifted to Montauk Point, Long Island (distance 628 miles), and the 1936 and subsequent races were started from Newport (635 miles). In 1970 the length of the race was increased to 685 miles (1,100 kilometres) by making the Argus Bank Texas Tower, 25 miles southwest of Bermuda, a mark of the course. A record of 71 hours 35 minutes 43 seconds, established in 1932 by the cutter "Highland Light," was finally broken in 1956 by the Swedish-owned yawl "Bolero," with a time of 70 hours 11 minutes 37 seconds. Winner that year was Carleton Mitchell's keel-centreboard 38½-foot (12-metre) yawl "Finisterre," winner also in 1958 and 1960—an unparalleled achievement. The 1966 Bermuda Race was remarkable for the number of participants—167 yachts, of which 11 did not finish, primarily because of severe weather conditions near the end. All Bermuda Race finishes were handled by the Royal Bermuda Yacht Club, which has been a cosponsor since 1923. (For a complete list of winners see SPORTING RECORD in the *Ready Reference and Index.*)

Immediately prior to the forming of the RORC in 1925 a race had been sailed from Ryde, Isle of Wight, around the Fastnet rock (off the southwest coast of Ireland), and back to Plymouth, Devon, a distance of about 605 miles (975 kilometres). A race around the Fastnet was held annually between 1925 and 1931 and thenceforward every other year in alternation with the Bermuda Race.

Beken of Cowes

The Transpacific Race

The 2,225-mile (3,580-kilometre) Transpacific Race from San Pedro, Calif., to Diamond Head, Oahu, Hawaii (formerly sailed also from the California harbours of Santa Barbara, Balboa, Santa Monica, and San Francisco), ranks with the Bermuda Race in age, importance, and total number of races sailed. First held in 1906 and

repeated at irregular intervals, it was in 1928 embraced by the newly organized Transpacific Yacht Club and in 1939 was made a biennial to alternate with the Bermuda Race. There being no limitation on overall length (the largest yacht to sail the course was the 161-foot [49-metre] schooner "Goodwill") and the course being predominantly downwind, the race is notable for the good speeds sustained. Thus in 1949 the 98-foot (30-metre) schooner "Morning Star" covered the distance in 10 days 10 hours 13 minutes, and in 1955, when she had been rerigged as a ketch, reduced her previous time to 9 days 15 hours 5 minutes. In 1965 the 72-foot (22-metre) ketch "Ticonderoga" bettered the record by 1 hour 14 minutes. This record was bettered by the 73-foot ketch "Blackfin" in 1969. "Blackfin's" record is 9 days 10 hours 21 minutes. (For a complete list of Fastnet and Honolulu winners, see SPORTING RECORD in the *Ready Reference and Index*.)

Of major importance in the Southern Hemisphere is the 635-mile race (rated distance, 680 miles) from Sydney to Hobart, Tasmania, annually scheduled for December 26. Inaugurated in 1945 by the Cruising Yacht Club of Australia and the Royal Yacht Club of Tasmania, it was first won by John H. Illingworth in his cutter "Rani." By 1967 participation had increased to 67 entries. A three-time winner (1963–64–65) was "Freya."

Solo races across the Atlantic

A phase of ocean racing that grew at a remarkable pace in the 1960s was that of single-handing across the Atlantic Ocean. Three such races, which were to be called the world's loneliest and toughest sporting contests, were sailed westward the distance of nearly 3,000 miles (5,000 kilometres) between Plymouth, England and the United States. In 1960 there were five entrants, and Francis Chichester, who was later to be knighted for his single-handed passage around the world, won with "Gipsy Moth III" in 40 days. In 1964 Eric Tabarly of France sailed the course in 27 days 2 hours in "Pen Duick II," and in doing so beat 14 other entries, including Chichester, who shaved 10 days off his 1960 winning time in finishing second in the race. In 1968, 35 boats started the race and Geoffrey William of England won in the 57-foot (17-metre) ketch "Sir Thomas Lipton" in 25 days 18 hours 33 minutes.

The Admiral's Cup. In 1957 the Royal Ocean Racing Club established the Admiral's Cup as a perpetual award for biennial international team racing in yachts of 30–60-foot waterline length, later modified to 29–60-foot International Offshore Rating. Two short races and two ocean races, culminating in the Fastnet and totalling about 900 miles (1,450 kilometres), constitute a series. Great Britain retained the trophy in its first year, but lost to The Netherlands in 1959 and in 1961 to the United States. In 1963 the British team regained the increasingly important Cup from the United States and again won in 1965. Australia claimed the Cup in 1967; the United States in 1969.

The One Ton Cup. From 1907 to 1955 a premier international trophy, the One Ton Cup was put up in 1965 for challenge by the Cercle de la Voile de Paris for boats of up to 22-foot Royal Ocean Racing Club rating. Competing nations are allowed to enter up to three yachts each. The first three challenges in the 1960s consisted of three races, the first and third of 30 miles "round the buoys" and the second, counting double, of up to 300 miles (500 kilometres). Beginning in 1965 the format was changed so that one long race was sandwiched between four day races, a total of five. The first contest was won by "Diana III," of Denmark, from over 13 starters. In 1966 in Denmark, the 37-foot (11-metre) "Tina" won over 24 boats from nine countries. In 1967 another and quite similar design, "Optimist," from Germany, won at Le Havre, France, where the 1965 series also had been staged. "Optimist" repeated her victory in 1968 off Helgoland Island, West Germany. A New Zealand crew sailing "Rainbow II" won at Helgoland in 1969, and in early 1971 Australia's "Stormy Petrel" took top honours off Auckland. The concept of ocean racing without handicap appeared to have caught on permanently with deep-water sailors the world over. The most competitive of the One Ton Cup boats are designed especially for the series, but they also compete in other offshore racing events. Maximum rating in 1971 was 27.5 under the International Offshore Rating rule. (B.D.B.)

Small-boat racing. *Olympic Games.* The first yachting events in the history of the Olympic Games were scheduled for 1896 in Greece but were cancelled because of bad weather. It was 1900, therefore, at the next Games in Paris, when competitive sailing became an actual part of the Olympic program.

Olympic classes of boats

The classes of boats used in the Olympics have ranged from fleets of 8-, 6-, and 10-Metres and an over-10-metre category in the first games to the 5.5-Metre/Dragon/Star/Flying Dutchman/Finn slate prevalent from 1960 through 1968, the longest period without a change. The all-time high in the number of classes competing was at Antwerp, Belgium, in 1920 when there were 14. As of 1972, there were officially six classes competing.

Ellen Horan

Figure 7: Small, one-design boats, International Finn Class, just before the start of a race. Finns are an Olympic class.

Reasons behind the selection and/or dropping of a specific class have varied. At the 1912 Games in Stockholm, for example, the committee suggested that the 15-metre boats that raced in the 1908 Games be dropped because of the difficulty of having such a large vessel manned exclusively by amateurs. Today, classes for the Olympics are officially named by the International Olympic Committee (IOC) based on the recommendations and advice of the International Yacht Racing Union. The IYRU makes its selection of Olympic classes from what it has designated as Group A classes, a categorization that was established in 1965 and is defined as "modern, high-performance classes incorporating the latest design features and techniques." Included in Group A are the Dragon, Soling, Star, Tempest, 470, Flying Dutchman, 5-0-5, Finn, Fireball, Contender, Tornado catamaran, Australis catamaran, 5.5-Meter, and C-Class catamaran.

This list is added to from time to time. The Group B designation is given to "classes which are not considered suitable for Group A and classes which have been granted international status because of popular support, or because they provide a good training for yacht racing." These include the 12-Metre, 6-Metre, 8-Metre cruiser/racer, International 14, 12-square metre Sharpie, Lightning, Snipe, Vaurien, Enterprise, and Cadet. At the IYRU meeting in 1967, it was decided that at least one class in each Olympiad should be replaced. The committee stated, however, that this would not necessarily be the class that had been in the Games the longest, nor would it mean that the dropped class could not be reinstated later to Olympic status.

At the Olympic Games in 1972, when the sailing events were held at Kiel, Germany, the classes were the 29-foot 2 inch (9-metre) Dragon (an Olympic class since 1948), the 26-foot 9 inch (8-metre) Soling (a new Olympic class replacing the 5.5-Metre, which had been in the Games since 1960), the 22-foot 7½ inch (7-metre) Star (an Olympic class since 1932), the 19-foot 10 inch (6-metre)

Flying Dutchman (an Olympic class since 1960), the 14-foot 9 inch (4.5-metre) Finn (an Olympic class since 1952), and the 21-foot 11¾ inch (6.7-metre) Tempest (in the Olympics for the first time in 1972 as a result of the IYRU's request to the IOC for a sixth class, granted in 1969). For the Games in 1976, the IYRU issued a "Declaration of Intent" stating that the Olympic classes should be modern, high-performance boats and should consist of two keelboats, three centreboard boats, and the Tornado catamaran.

To qualify for an Olympic berth, the sailor must expose himself continuously to competition on an international level. Generally speaking, to select the sailing team for the Olympics every four years, the larger countries hold trials in each of the Olympic classes (some countries send partial teams if they are not particularly strong in a specific class). Actual selection practices vary. The German Yachting Association in determining its team for the 1968 Games at Acapulco, Mexico, for example, specified that those wishing to participate in the final trials would have to have placed in the top 25 percent of at least three of some six major European regattas during the previous year. In other countries, where fleets in the final trials might prove unwieldy in size, an area or district qualifying regatta is held to establish who may participate in the final trials. Most countries try to hold their final trials in an area that resembles the actual Olympic site in wind strength and sailing conditions. At the Olympics themselves, the IYRU is responsible for all the technical details of organizing the regatta.

Olympic scoring

Under the rules for an Olympic regatta, there are seven races held for each class and scoring is based on the best six of these. The Olympic scoring system is 0 points for first place, 3 for second, 5.7 for third, 8 for fourth, 10 for fifth, 11.7 for sixth, and the finishing place plus 6 points for seventh place and thereafter. The lowest total score wins. (The complete rules on the Olympic Scoring System are printed in the *International Yacht Racing Union 1971 Year Book.*)

The influence of the Olympics is widespread. With its emphasis on high performance, it has spawned a type of regatta in many parts of the world that adheres closely to the Olympic format. One such regatta is the Canadian Olympic Training Regatta at Kingston, Ontario, which was first held in 1969. Open to the Olympic classes as well as a number of Olympic-type classes, it was started with the intention of exposing Canadian sailors to the best competition possible with the result of fielding a strong Olympic team. (For Olympic Games winners, see ATHLETIC GAMES AND CONTESTS: *Olympic record.*)

Yachting events are included in the quadrenniel Pan-American Games, which started in 1951. Classes involved are the Olympic classes and the Snipe and Lightning, though not all of these classes have participated each time. The class organizations within each country are responsible for holding elimination trials to determine the individual representatives.

One-design class championships

Other small-boat championships. Depending on their size and popularity, one-design classes set up annual international and world championships in addition to national and district events. Fleets are the backbone of every class organization and, where the class involved is a large one, certain qualifying requirements at either the fleet or district level are necessary to establish which skippers may sail in the major championships. The Snipe class, for example, works on both the fleet and district level for entry to the U.S. National Championship, going on the basis of one boat eligible for every five in the fleet. The top three boats from the district championships may also attend the nationals, as well as the previous year's champion. Entries must have participated in at least five season races at the fleet level. The Snipe class holds its World Championship every two years, open to one sailor from each member country (usually the national champion) and to the previous world titleholder.

Smaller classes may not have any prerequisites for a class member to participate in national title events but often, if the fleet at a championship is too large, it will be divided up into sections or flights that then proceed to race against one another to determine the champion. A number of classes also hold junior championships in conjunction with their national events. Classes vary the locale of their championship events in a number of ways, usually alternating among the various districts it has set up within a country. Other classes permit the national champion to set the site for the following year's national championship. All of these decisions are regulated by the individual class bylaws.

In the United States, a number of the scow classes hold what they refer to as Blue Chip regattas in addition to their major national title events. Participation is limited to approximately 25 top boats, selected by a committee on the basis of their standings throughout the year.

In areas where a particular one-design class may not be well enough established to race as a fleet, or in specific regattas that pit one class against another in order to measure relative performance, methods of handicapping are set up. One method that is used throughout the world is the Portsmouth Yardstick System, devised in 1949 in England. The purpose of it is to rate boats so that they may race on an even basis, and it revolves around establishing a Portsmouth Number for each class. This number represents the time it takes for specific classes to sail over a common distance, and the numbers, administered by the Royal Yachting Association, are studied each year and revised as necessary. Handicapping is also done by using such systems as the *Yachting* One-of-a-Kind formula, a measurement system of rating one-design classes based on length and sail area.

In addition to championships held within the format of the class organizations, yacht clubs also hold regattas that may be open to numerous classes. The "race week" format is an established one with such large events as the Marblehead (Mass.) Race Week, annually attracting local sailors for the competition. Fixtures such as the Bermuda Invitational International Race Week and Germany's Kiel Week appeal not only to the local sailors but continue to attract more and more participants from other countries as they become synonymous with top competition.

Multihull boat races

One of the most interesting areas of competition in multihulls is the match-race series for the International Catamaran Challenge Trophy, known unofficially as the Little America's Cup. The event was started in 1961, and the trophy was donated by Sea Cliff (N.Y.) Yacht Club. Boats used are the C-Class catamaran, a highly refined racing machine that, because of the simplicity of the class rules, offers an exceptional scientific and technological challenge to the designer, as well as to the crew of two that races the boats. The maximum length of the C-Class catamaran is 25 feet (8 metres), maximum extreme beam is 14 feet (4 metres), and maximum sail area including the spar is 300 square feet (28 square metres).

The competition is truly international in flavour, with the governing rules stating that the event should move around the world irrespective of winner. The title is awarded after a best-of-seven series, with the first boat to win four races declared the winner. Though there are relatively few C-Class catamarans, the class commands a considerable amount of interest and also holds a World Championship. C-Class catamarans have been clocked at 30 miles (48 kilometres) per hour. (E.M.Ho.)

IV. Motorboating

Motorboating is the operation of a relatively small vessel driven by an internal-combustion engine or engines. As a sport it is generally practiced in competition in the form of racing or piloting and navigation contests; for travel by water (cruising) or the pleasure and freedom derived from being afloat; or for the enjoyment of related sports such as fishing, hunting, swimming, skin diving, and water skiing.

SPEEDBOATS

History. The internal-combustion engine was applied to boat propulsion in the late 1880s and the 1890s, but it was the internal-combustion engine as developed for the automobile that started motorboating as a sport

Beginning of organized races

when, about 1900, some French automobile enthusiasts adapted the engines to small boats and the autoboat was created. The idea quickly spread to England and the United States and organized races began to be held. In 1903, Sir Alfred Harmsworth (later Viscount Northcliffe) established the British International Trophy for motorboat competition (later known as the Harmsworth Trophy) and the first international, perpetual trophy in the sport was won that year by S.F. Edge's "Napier I," with a speed of 19.53 miles per hour (31.42 kilometres per hour) on a course at Queenstown (Cobh), Ireland. The same year, the American Power Boat Association was formed and in 1904 the Columbia Yacht Club of New York presented the challenge cup (Gold Cup) to the association "for the purpose of promoting speed contests and improving . . . engines for, and the lines of, power boats." The cup was won that year by C.C. Riotte's "Standard" at 23.6 miles per hour (38.0 kilometres per hour). Also in 1904, the magazine *Motor Boat* was introduced by the Temple Press, London, and a magazine of the same name became the first United States periodical to be devoted to the new sport. In 1905, the first U.S. annual National Motor Boat Show was held in New York City and became an international marketplace for motorboats that still flourished in the 1970s.

Speedboat design. The hulls of boats are classed as planing types, which skim across the surface, and displacement types, which push through the water. All speedboats of the early 1900s were displacement types and attempts to improve performance involved making the shape better suited to move through the water or installing more horsepower. Because the displacement hull, with its V-shaped or rounded bottom, relatively deep draft and narrow width for its length, sharp bow, and narrow stern, can never plane on the surface no matter how much power is applied, the efforts of designers were directed toward the development of hulls with flat surfaces that at speed would rise to the surface and skim across the water, thus reducing the wetted surface and thereby the friction and resistance between hull and water. William Froude of England originally advanced the idea of the three-point hydroplane in the 1870s and a plan for a planing-type hull was submitted to the British Admiralty in the same decade, but no engine with low enough weight per horsepower was available, so that the idea of the hydroplane languished until the autoboat had been developed. Just who applied the idea first is unknown, but simple, rectangular flat-bottomed skimmers were being raced in Europe in 1907. Early hydroplanes were stepped to reduce wetted surface, some with a single step and some with multiple steps, but they were merely a series of single, flat planes. In 1908, William H. Fauber of Chicago and Nanterre, France, saw the possibility of improving the box-section, stepped skimmers by combining the step principle with the V-section bottom and he patented an idea for an eight-step, V-bottom hull in England. About the same time, single-screw, round-bottom displacement hulls were giving way to twin-screw, V-bottom types. In the 1910 Harmsworth Trophy race, a multiple-step Fauber-Saunders British hydroplane named "Pioneer" sped past the speedy "Dixie III," an American V-bottom displacement boat. The fact that "Pioneer" broke down and "Dixie III" won the race at 36.04 miles per hour (57.99 kilometres per hour) did not change the picture for observers. In 1911, an Italian named Enrico Forlanini built the first hydrofoil boat, and in 1912, at least five builders were offering stock boats of the planing type.

Speeds. From the early competitive speeds of 20 miles per hour (32 kilometres per hour) in 1904, race boats developed to the point where unlimited propeller-driven hydroplanes were running heats at well over 100 miles per hour (160 kilometres per hour) in 1955. The huge craft would do over 150 miles per hour (240 kilometres per hour) on the straightaways, but had to slow down for the turns at each end of the course. Sir Malcolm Campbell held the one-mile water speed record of 141.74 miles per hour (228.6 kilometres per hour) from 1939 to 1950, when the revolutionary three-point hydroplane "Slo-Mo-Shun IV" took the record with an average of 160.323 miles per hour (257.960 kilometres per hour) on Lake Washington at Seattle, Washington, in June 1950. Two years later, the same boat increased its speed to 178.497 miles per hour (287.202 kilometres per hour). Donald Malcolm Campbell, son of Sir Malcolm, on July 23, 1955, became the first man successfully to pilot a jet-propelled boat over an official time course. His mark was 202.32 miles per hour (325.53 kilometres per hour). At least two men, John Cobb of England and Mario Verga of Italy, were killed in the 1950s trying to reach 200 miles per hour (320 kilometres per hour). The younger Campbell later boosted his record to 239.07 miles per hour (384.66 kilometres per hour) on Coniston Water in England on November 7, 1957, and on the same water on May 14, 1959, he was officially timed at 260.35 miles per hour (418.90 kilometres per hour). On June 30, 1967, "Hustler," with a Westinghouse jet engine, raised the speed to 285.213 miles per hour (458.901 kilometres per hour) at Guntersville, Alabama.

Water speed records

While inboard speeds were approaching 200 miles per hour (320 kilometres per hour) the world's outboard pilots were making a concerted effort to pass 100 miles per hour (160 kilometres per hour) on a mile straightaway run. Finally, Massimo Leto di Priolo of Italy hit 100.36 statute miles per hour (161.48 kilometres per hour) in a Molinari Class X hydroplane with a special Lesco engine in December 1954. Bert Ross, Jr., owner and driver of a Class X Mercury-powered Jones hull, raised that to 115.547 miles per hour (185.915 kilometres per hour) at Seattle, Washington, on May 4, 1960. In inboards, "Miss U.S. I" was clocked at 200.419 miles per hour (322.53 kilometres per hour), at Guntersville, Alabama, on April 17, 1962. It was the first non-jet-propelled craft to surpass 200 miles per hour.

Racing. The major divisions in motorboat competition are stock inboard, stock outboard, inboard hydroplane, and outboard hydroplane. Each division has a number of classes, depending mostly on engine displacement. Some of the smaller craft are barely big enough to hold the driver; the largest, the unlimited hydroplanes, weigh close to four tons. Many hundreds of races and regattas are held each year in the United States under the sanction of the American Power Boat Association, governing body for the sport in that country. Most races are held over closed courses. Some, like the Mississippi Marathon or the Six Heures de Paris, are endurance events. In a separate division, pleasure boats compete in marathons of 50 to more than 250 miles. In 1922, the Union of International Motorboating (UIM) was organized, largely through the work of John Ward of Ireland, who was its first secretary. The idea was to provide a clearinghouse for world records for the various classes racing in Europe, but it spread to encompass the whole world. The voting members grew to more than 40 nations, each represented by a national authority, usually the largest federation of power-boating clubs in the nation. Expansion of UIM activities has produced a commission for technical matters, one for sports matters, one for offshore racing, and a tourist commission that governs pleasure boating in Europe and has greatly simplified passage between countries. The UIM awards a world championship by allowing points for the first six finishers in selected offshore powerboat races in different countries. The 1970 winner was Vincenzo Balestrieri of Rome, who won for the second time in three years by taking four world events: the Wills International in England, the Miami-Nassau Race from the U.S. to the Bahamas, and two Italian events, the Naples Trophy and the Viareggio. Previous winners were James R. Wynne (1964 and 1966), Richard Bertram (1965), and Donald Aronow (1967 and 1969).

The Union of International Motorboating

CABIN CRUISERS

The earliest cruisers developed from long, narrow rowing or sailing vessels of 16 to 20 feet (5 to 6 metres) that had been popular in the 1890s. These were adapted to take engines and became launches, and the first step toward the cruiser was the addition of a removable awning.

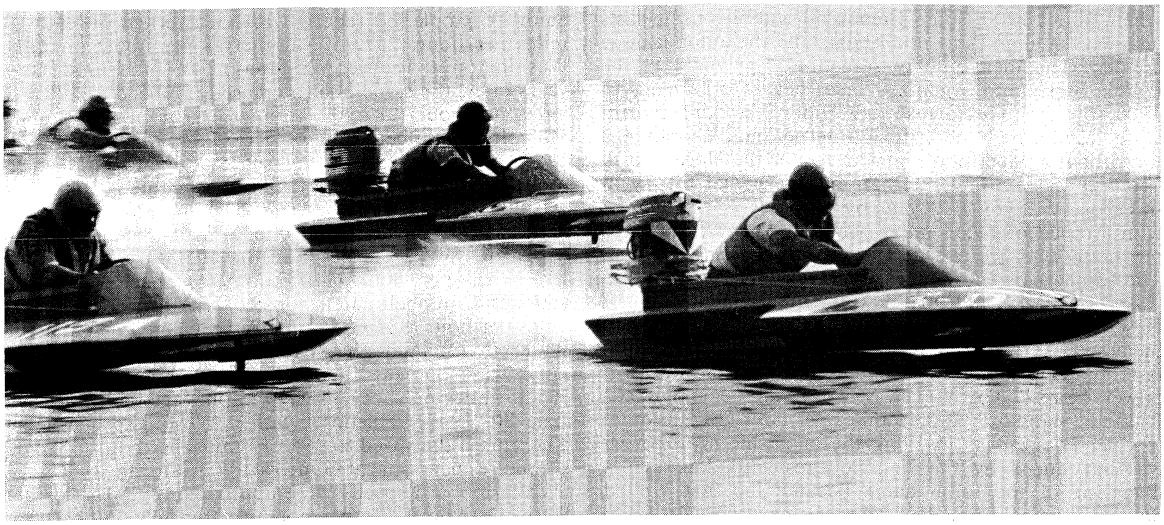

Figure 8: Outboard hydroplanes skimming over the water during a race at Southbury, Connecticut, 1970.
H.W. Magnuson

Next came a light, wooden roof supported by stanchions screwed to the coaming. Side curtains followed, then glass windows. Eventually, cabin launches from 30 to 80 feet (9 to 24 metres) were being built. The hulls were graceful but the windowed, trolly-like superstructures were ungainly. The first departure from this type came with the substitution of a low, forward cabin similar to those common on sailboats. Fitted with small windows or deadlights, it was called a hunting cabin to appeal to duck hunters. The low cabin, with narrow beam and sitting or minimum standing headroom, persisted right up to World War II, and the hulls remained displacement types. After the war, small outboard cruisers began to appear, with planing hulls basically the same as the outboard runabouts that had become popular. Small inboard cruisers followed, also with planing hulls, and a boating boom in small craft that peaked at the end of the 1950s lent further impetus to cabin-cruiser design, for many people became ready to move up from the runabout hulls they had purchased. Beam, depth, and headroom increased in small cruisers and maximum accommodation in minimum length became the byword of builders. There has been an upward trend in the length of cruisers, for family boating has become a common source of recreation and more room afloat is required. Keeping pace, boatyards have become marinas that provide dockage, fuel, water, electricity, and such shoreside facilities as lounges, restaurants, entertainment, laundry service, and even swimming pools.

Changes in cruiser design

The U.S. Power Squadrons, for owners and others interested in cabin cruisers and powerboats, was organized in 1914 as something of a small-boat naval reserve. With about 80,000 members in about 400 units in 30 districts in the United States as well as Yokohama, Japan; Okinawa; the Panama Canal Zone; and Puerto Rico, it is the most highly organized boating force in the world. A notable feature of its activities is the provision of instructional classes covering all aspects of boating, including pilotage and navigation. There are many clubs in Great Britain that offer instruction, notably the Little Ship Club and the Cruising Association of London, and the Clyde Cruising Club with headquarters in Glasgow, although none of these confines its membership to either powerboat or sailing men.

Many yacht clubs organize competitive powerboat events. Called predicted log races, navigational skill rather than speed is the basis for scoring. In these, the skipper of a boat predicts the exact time he will pass specified points around a predetermined course. Not allowed a watch, he must adjust the speed of his boat to such variables as wind and tide and current so that the time requirement is met. The skipper coming closest to his prediction wins.

OTHER MOTORBOATS

Motor sailers. The motor sailer is what the name implies—a boat that can be driven under power or sail or both. The engine is larger than that found in an auxiliary sailboat (where the power is used primarily for getting in and out of harbour) and the sails are less efficient than they are in a cruising or racing sailboat. However, the lesser sail efficiency is a result of bluff ends and heavier construction with roomier accommodations below. The motor sailer still has a smooth design that enables it to make a steady eight to ten knots under power, with the sails providing a steadying effect, and, if necessary it can always make port under sail alone.

Houseboats. The houseboat in its simplest form is a floating home, permanently moored in a sheltered location, with moving possible only by towing. Such a craft has a barge-type hull, broad-beamed and flat-bottomed, with maximum living area and minimum seaworthiness. In the 1950s, small houseboats with barge-type hulls and outboard motor brackets began to achieve some popularity. Other houseboats with pontoon-type hulls bridged by a flat deck were less satisfactory from the standpoint of load-carrying capacity and stability. As motor horsepower increased and controls improved, hull refinements to improve performance included curving the bow up and shaping it more to a point and changing the flat bottom to a shallow V. The advent of the stern drive, inboard-outboard motor in 1959, followed by models of ever-increasing horsepower in the 1960s, lent the final impetus. Within the decade, 40-foot (12-metre) houseboats were travelling 30 miles per hour (50 kilometres per hour) in coastal waters. High-speed houseboats, which have achieved the most popularity, range from 22-foot (7-metre) camper types to complete luxury homes of 60 feet (18 metres) or more. All have the ability to operate in relatively shallow water and most can travel at speed in three-foot (one-metre) seas. However, they are not considered to be offshore cruisers, for their shallow draft, high sides, and large window expanse make them highly vulnerable in heavy-weather conditions.

Utility boats. The utility boat is most often thought of as an unpretentious motorboat from 15 to 23 feet (5 to 7 metres) with a forward deck, a windshield, forward helmsman and companion seats, and a large, open cockpit that can serve a multitude of purposes. Power may be outboard, stern drive, or inboard, and the design is such that care and maintenance are simplified. These craft appeal to fishermen and to families, different members of which may enjoy fishing, water skiing, day cruising, picnicking afloat, swimming, or skin diving, either separately or in groups. The utility may have a removable shelter top or a hardtop over the forward area of the cockpit. In either case, side and after curtains may fully

enclose the boat and air mattresses may be used in the cockpit for roughing it on overnight or weekend trips.

Other variations. Other variations of the motorboat include sport fishermen, which are utilities or offshore cruisers with special emphasis on cockpits rigged for fishing; pontoon deckboats, which have hulls consisting of pontoons or cylinders bridged by a flat deck surrounded by a railing and topped by a pipe-supported canopy and are used for swimming, picnicking or day cruising; inflatable craft, which serve as outboard-powered dinghies with the addition of a bracket or as high-speed sport boats with the addition of rigid flooring and a strong transom to take an outboard of higher horsepower. (J.Sm.)

BIBLIOGRAPHY

Rowing: G.C. BOURNE, *A Text-Book of Oarsmanship* (1925), describes the theory and art of rowing, oar and boat design, coaching, and muscular action. DESMOND HILL, *Instructions in Rowing* (1963), is a comprehensive guide for coaching beginners upward. J.A.N. RAILTON, *International Rowing* (1969), analyzes the factors behind the international success of several countries. HYLTON R. CLEAVER, *A History of Rowing* (1957), is an historical review of rowing in England from the earliest days of the professional watermen on the Thames. R.F. KELLEY, *American Rowing* (1932), traces the development of rowing in the United States. R.D. BURNELL, *Sculling for Rowing* (1968), examines the use of sculling to train for rowing; his *Oxford and Cambridge Boat Race 1829–1953* (1954), tells the story of the first 99 races, and the *Henley Regatta* (1957), is a comprehensive record of the development of the event since its inception in 1839.

Canoeing: PETER DWIGHT WHITNEY, *White-Water Sport* (1960), on the art and science of canoeing on white water (well illustrated with diagrams and photographs), the book gives valuable guidance to all taking up this sport both as a recreation and in the field of slalom and white-water racing. ALAN BYDE, *Living Canoeing* (1969), is a book on the sport of canoeing with special emphasis on advanced techniques for white-water sport on river and surf; includes clear instructions well supported by diagrams. AMERICAN NATIONAL RED CROSS, *Canoeing* (1956), is an interesting, well-presented textbook for all involved in canoeing instruction (exceptionally sound on the handling of the Canadian canoe). CHARLES SUTHERLAND, *Modern Canoeing* (1964), describes in detail the many types of canoes and how to handle them; it examines canoeing possibilities in Britain, including general touring, white-water sport, and sea canoeing, and gives guidance on all aspects of competitive canoeing. PIERRE PULLING, *Principles of Canoeing* (1954), written by a professional woodsman and guide, provides sensible advice for both students and teachers. ISTVAN GRANEK, *Paddling Kayaks and Canoes*, trans. from the Hungarian (n.d.), is the authoritative coaching textbook on the subject of canoe racing, by the leading European coach. JAMES HORNELL, *Water Transport* (1946), is an erudite and comprehensive account of the origins and early development of the craft used by men on river, lake, and sea. BRITISH CANOE UNION, *Guide to the Waterways of the British Isles*, rev. ed. (1970), is the only complete guide to the inland and coastal canoeing waters of the British Isles.

Yachting: There are a number of books geared to the interests of both the beginning and advanced small-boat sailor. The following represent some of those currently available: BILL ROBINSON, *Better Sailing for Boys and Girls* (1968), is aimed at the youngest would-be sailors and explains the basics of sailing technique. PHILIPPE HARLE, *The Glenans Sailing Manual*, rev. ed. (1967), is directed more toward the adult who is starting off in the sport and includes details about boat handling, sails, the characteristics of different types of boats, and related subjects. FESSENDEN BLANCHARD and THEODORE JONES, *Sailboat Classes of North America*, rev. ed. (1968), includes pictures and basic details about popular sailboat types. Books on tactics are numerous; among those of continuing interest are: R.N. BAVIER, *Sailing To Win* (1969), based on the author's experience in dinghies and class boats up to ocean racers and Twelve Metres; PAUL ELVSTROM, *Elvström Speaks on Yacht Racing* (1969), probably the finest small-boat sailor in the world and winner of four Olympic Gold Medals; JOHN D.A. OAKELEY, *Winning* (1970), one of England's top Flying Dutchman sailors, who delves into valuable detail on all parts of the small one-design boat and discusses racing techniques, and STUART WALKER (ed.), *Performance Advances in Small Boats* (1969), in which 22 of America's top small-boat sailors discuss the latest developments in design and racing techniques in their classes. (*History and other specific topics*): H.L. STONE, W.H. TAYLOR, and W.R. ROBINSON, *The America's Cup Races*, rev. ed. (1970), is the best and most accurate of many histories of the event. F.S. KINNEY (ed.), *Skene's Elements of Yacht Design*, rev. ed. (1962), is the classic work on the subject. R.N. BAVIER, *A View from the Cockpit* (1966), is the skipper's own story of the successful 1964 America's Cup defense. G.W. MIXTER, *Primer of Navigation*, 5th ed. (1967), is a classic reference work. Included among the better general and special histories are: H.I. CHAPELLE, *American Small Sailing Craft* (1951); BILL ROBINSON, *The World of Yachting* (1966); ALFRED F. LOOMIS, *Ocean Racing: 1866–1935* (1936, reprinted 1967); and C. SHERMAN HOYT, *Memoirs* (1950). GERSHOM BRADFORD, *Glossary of Sea Terms* (1954), is a dictionary of nautical language. W.H. DE FONTAINE and B.D. BARKER III, *1001 Questions Answered About Boats and Boating* (1966), is a general reference work that covers a wide variety of topics. J.H. ILLINGWORTH, *Further Offshore*, 6th ed. rev. (1969), is the best known guide among beginning offshore sailors.

Motorboating: JOHN TEALE, *High Speed Motor Boats* (1969) contains information on hull forms employed, model testing, speed predicting, spray rails and hull trimming devices, with an analysis of stern gear, engine bearers, and fuel systems; UFFA FOX, *Seamanlike Sense in Powercraft* (1968), on propulsion systems from the oar to the turbine, hulls from rowboats to cruiser-type warships, air cushion craft, the screw propeller, underwater gear, hull efficiency, and modern ocean power-boat racing; JACK WEST, *Modern Powerboats* (1970), on hull types, propulsion, control, instrument, fuel, wiring, water, refrigeration, and sanitation systems, deck and safety equipment, navigation and communication, and competitive powerboating; PETER DU CANE, *High-Speed Small Craft*, 2nd rev. ed. (1957) on the naval architecture of powerboats up to 130 feet in length; C.F. CHAPMAN, *Piloting, Seamanship and Small Boat Handling* (1971), the overall operation of small craft, including terminology, regulations, equipment requirements, rules of the road, navigation, weather, electronics, signaling, and marlinspike seamanship; D. PHILLIPS-BIRT, *Motor Yacht and Boat Design* (1953), an introduction to the naval architecture of displacement and planning powerboats, with sections on aesthetics, behaviour at sea, and examples in design.

Boccaccio, Giovanni

Giovanni Boccaccio, generally thought of only as the author of the earthy tales in the *Decameron*, was in fact one of the greatest figures in the history of European literature. The early scholarship and writing on the texts of ancient Greece and Rome that became the driving force behind the Humanism of the Renaissance can be traced to Boccaccio and his older contemporary Petrarch and their friends. With Petrarch, he not only marked out the paths along which this Humanism was to develop but also participated in the raising of literature in modern languages to the level and status of the classics of antiquity. It was Boccaccio, too, who raised to literary dignity ottava rima, the verse metre of the popular minstrels, which was eventually to become the characteristic vehicle for Italian verse.

Boccaccio was born in Paris in 1313. His father, Boccaccio di Chellino, called Boccaccino, was a merchant whose family lived originally in Certaldo in Tuscany. Boccaccino's brother Giovanni, however, had moved to Florence not later than 1297, and Boccaccino had followed him. Boccaccio could thus describe himself as a citizen of Certaldo or of Florence, despite the accident of his Parisian birth. His mother was probably French, but his contradictory statements about her in his *Filocolo* and in his *Ninfale d'Ameto*—that she was a young girl of royal birth and that she was a widowed gentlewoman—may both be discounted as examples of a sort of autobiographical embellishment to which he was much inclined, particularly when writing of his early years, in conformity with recognized literary patterns of the time. The year of his birth is given by Petrarch, and Boccaccio's own statement that he was born in Paris of a French mother is supported by documents showing that his father was in Paris in 1310, 1313, and 1314 for business transactions in which the great banking house of the Bardi was engaged.

Family

Youth. Boccaccio passed his early childhood rather unhappily in Florence. His father had no sympathy for Boccaccio's literary inclinations and sent him, not later than 1328, to Naples to learn business, probably in an of-

Boccaccio, detail of a fresco by Andrea del Castagno (*c.* 1421–57). In the Cenacolo di Sant' Apollonia, Florence.
Alinari—Mansell

fice of the Bardi. Boccaccio claims to have spent six years in this situation and seems also to have spent an equal period studying canon law—likewise on his father's insistence because of the prospect of emoluments but against his own inclination. His claim to have been determined on a literary career from birth is probably to be regarded partly as another autobiographical embellishment of his past.

The Bardi, of whose business his father had become an associate, dominated the court of Naples by means of their loans. Moreover, the king, Robert of Anjou, took pleasure in surrounding himself with men of letters. All doors, then, were open to Boccaccio in Naples, and the years that he spent there were decisive for his education and his tastes. His commercial activity brought him into contact with everyday life in its varied aspects, and his experience of the aristocracy of the business world was to give his writing the special quality that recommended it to that milieu, above all. Contact with the court, on the other hand, showed him all that survived of the splendours of chivalry and feudalism and aroused in him a taste for high and decorous endeavour and for the old nobility's courage, self-control, and courtesy, which he was to pass on to his own world, that of the rising bourgeoisie. He mixed with the learned men of the court and the friends and admirers of Petrarch, through whom he came to know the work of Petrarch himself.

These years in Naples, moreover, were the years of Boccaccio's love for Fiammetta, whose person dominates all his literary activity up to the *Decameron*, in which there also appears a Fiammetta whose character somewhat resembles that of the Fiammetta of his earlier works. Boccaccio's accounts of the love affair are certainly romanticized and contradict one another occasionally: in the earliest works Fiammetta is unfaithful, whereas in the *Elegia di Madonna Fiammetta* it is she who is betrayed; and in *Il filocolo* she is a king's daughter, whereas in *Ameto* and in *Fiammetta* she is only the daughter of a noblewoman married to a rich bourgeois and courted by the king. Attempts to use passages from Boccaccio's writings to identify Fiammetta with a supposedly historical Maria, natural daughter of King Robert and wife of a count of Aquino, are therefore untrustworthy—the more so since there is no documentary proof that this Maria ever existed.

It was probably in 1340 that Boccaccio was recalled to Florence by his father, involved in the bankruptcy of the Bardi. The sheltered period of his life thus came to an end, and thenceforward there were to be only difficulties and occasional periods of poverty. From Naples, however, the young Boccaccio brought with him a store of literary work already completed. *La caccia di Diana* ("Diana's Hunt"), his earliest work, is a short poem, in terza rima (an iambic verse consisting of stanzas of three lines), of no great merit, in which a number of beautiful women of Naples are reviewed within the loose framework of a fable. Much more important are two works with themes derived from medieval romances: *Il filocolo* (*c.* 1336), a prose work in five books on the loves and adventures of Florio and Biancofiore (Floire and Blanchefleur), and *Il filostrato* (*c.* 1338), a short poem in ottava rima, telling the story of Troilus and the faithless Criseida. The *Teseida* (probably begun in Naples and finished in Florence, 1340–41) is an ambitious epic of 12 cantos in ottava rima in which the wars of Theseus serve as a background for the love of two friends, Arcita and Palemone, for the same woman, Emilia: Arcita finally wins her in a tournament but dies immediately.

Early works

While all these themes of chivalry and love had long been familiar in courtly circles and were already in favour also with the bourgeoisie and even with the lower classes, Boccaccio not only enriched them with the fruits of his own acute observation of real life and insight into the human heart but also sought to present them nobly and illustriously by a display of learning and rhetorical ornament, so as to make his Italian worthy of comparison with the monuments of Latin literature. These early works had immediate effect outside Italy: Chaucer drew inspiration from *Il filostrato* for his own *Troilus and Criseyde* (as Shakespeare was later to do for *Troilus and Cressida*) and from *Teseida* for his "Knight's Tale" in *The Canterbury Tales*.

Florentine years. The 10 or 12 years following Boccaccio's return to Florence, about 1340, are the period of his full maturity, culminating in the *Decameron*. From 1341 to 1342 he was working on *Il ninfale d'Ameto* ("Ameto's Story of the Nymphs"), in prose and terza rima, which describes how a rude shepherd is raised to spiritual refinement and worldly honour through love. Next came *L'amorosa visione* ("The Amorous Vision"; 1342–43), a mediocre allegorical poem of 50 short cantos in terza rima, in obvious imitation of Dante but revealing also some affinity with Petrarch's *Trionfi* ("Triumphs"), so that some critics have argued that Petrarch's poem was in fact inspired by Boccaccio's. The prose *Elegia di Madonna Fiammetta* (1343–44) shows remarkable psychological penetration, though the style and narrative method are heavy.

The slightly later *Ninfale fiesolano* (perhaps 1344–45), in ottava rima, on the love of the shepherd Africo for the nymph Mensola, is written with a graceful and studied simplicity foreshadowing 15th-century poetry. To complete the survey of Boccaccio's Italian writings before the *Decameron*, mention must be made of the *Rime* ("Poems"), begun in his youth but continued throughout his life, for the most part in the style established for the love lyric by the Sicilian school, by the exponents of the *dolce stil nuovo* ("sweet new style") school, which emphasized delicacy of expression, or by Petrarch.

Boccaccio, meanwhile, was trying continually to put his financial affairs in order, though he never succeeded in doing so. Little is known, however, of the detail of his life in the period following his return to Florence. He was at Ravenna between 1345 and 1346, at Forlì in 1347, in Florence during the ravages of the Black Death in 1348, and in Florence again in 1349.

The "Decameron." It was probably in the years 1348–53 that Boccaccio composed the *Decameron* in the form in which it is read today. In the broad sweep of its range and its alternately tragic and comic views of life, it is rightly regarded as his masterpiece. Stylistically, it is the most perfect example of Italian classical prose, and its influence on Renaissance literature throughout Europe was enormous.

The *Decameron* begins with the flight of ten young people (seven women and three men) from plague-stricken Florence in 1348. They retire to a rich, well-watered countryside, where, in the course of a fortnight, each member of the party has a turn as king or queen over the others, deciding in detail how their day shall be spent and directing their leisurely walks, their outdoor conversations, their dances and songs, and, above all, their alternate storytelling. This storytelling occupies ten days of the fortnight (the rest being set aside for personal adornment or for religious devotions); hence the title of the book itself, *Decameron*, or "Ten Days' Work." The stories thus amount to 100 in all. Each of the days, moreover, ends with a canzone (song) for dancing sung by one of the storytellers, and these canzoni include some of Boccaccio's finest lyric poetry.

Structure of the *Decameron*

In choosing a framework of this sort for his stories, Boccaccio was following a tradition familiar in Oriental and medieval literature. To this tradition, however, he brought a new element. In addition to the 100 stories, he has a master theme, namely, the way of life of the refined bourgeoisie, who combined respect for conventions with an open-minded attitude to personal behaviour.

The sombre tones of the opening passages of the book, in which the plague and the moral and social chaos that accompanies it are described in the grand manner, are in sharp contrast to the scintillating liveliness of Day I, which is spent almost entirely in witty disputation, and to the playful atmosphere of intrigue that characterizes the tales of adventure or deception related on Days II and III. With Day IV and its stories of unhappy love, the gloomy note returns; but Day V brings some relief, though it does not entirely dissipate the echo of solemnity, by giving happy endings to stories of love that does not at first run smoothly. Day VI reintroduces the gaiety of Day I and constitutes the overture to the great comic score, Days VII, VIII, and IX, which are given over to laughter, trickery, and license. Finally, in Day X, all the themes of the preceding days are brought to their most exalted pitch, the impure made pure and the common made heroic. Even if it is not always artistically convincing, this conclusion forms a noble testament, ending with the glorification of fidelity, constancy, and womanly obedience in the story of Griselda.

The prefaces to the days and to the individual stories and certain passages of especial magnificence based on classical models (on Livy at his most florid or on Apuleius at his richest, rather than on Cicero), with their select vocabulary and their elaborate periods, have long held the attention of critics. But there is also another Boccaccio: the master of the spoken word and of the swift, vivid, tense narrative free from the proliferation of ornament. These two aspects of the *Decameron* make it the fountainhead of Italian literary prose for the next centuries.

The romantic view of the *Decameron*, propounded by Francesco De Sanctis, who regarded it as a "Human Comedy" in succession to Dante's *Divine Comedy* and Boccaccio as the pioneer of a new moral order superseding that of the Middle Ages, is no longer tenable, since the Middle Ages can no longer be presented as having been wholly ascetic or wholly turned toward God in contrast with a Renaissance concerned only with the human. Medieval literature in general does not ignore man and the flesh and even has passages that exalt the individual; and the men of the Renaissance, far from ignoring God, strove in many ways to reconcile religious truth and Christian doctrine with both ancient philosophy and the new science.

Also, in particular, the whole corpus of Boccaccio's work is basically medieval in subject matter, form, and taste, at least in its point of departure. It is the spirit in which Boccaccio treats his subjects and his forms that is new. Boccaccio in the *Decameron* for the first time deliberately shows man striving with fortune and learning to overcome it and even, when possible, to exploit it. This marked dualism of virtue and fortune lies at the root of the feeling and thought of the Renaissance. The *Decameron* exalts essentially what Machiavelli was to call the virtue of man: his intelligence, his eagerness, his sense of proportion, his tireless self-control, and his power to bend events to his own designs. To be truly noble, according to the *Decameron*, man must accept life as it is, without bitterness, must accept, above all, the consequences of his own action, however contrary to his expectation or even tragic they may be. To realize his own earthly happiness, he must confine his desire to what is humanly possible and renounce the absolute without regret. Thus Boccaccio insists both on man's powers and on their inescapable limitations. A sense of spiritual realities and an affirmation of moral values underlying the frivolity even in the most licentious passages of the *Decameron* are features of Boccaccio's work that modern criticism has brought to light and that make it no longer possible to regard him only as an obscene mocker or sensual cynic.

Attitudes toward man

During the years in which Boccaccio is believed to have written the *Decameron*, the Florentines appointed him ambassador to the lords of Romagna in 1350; municipal councillor and also ambassador to Louis, duke of Bavaria, in the Tirol in 1351; and ambassador to Pope Innocent VI in 1354.

But of far more lasting importance than official honours was Boccaccio's first meeting with Petrarch, in Florence in 1350, which began a friendship doing honour to both. Boccaccio, who had already written a life of Petrarch in Latin (*De vita et moribus Francisci Petrarchae*), revered the older man as his master, though respect did not preclude frank criticism. Petrarch proved himself a serene and ready counsellor and a reliable helper. Together, through the exchange of books, news, and ideas and through the stimulus that they afforded one another, they laid the foundations of the humanist reconquest of classical antiquity.

Friendship with Petrarch

His meeting with Petrarch, which occurred when he was already working on the *Decameron*, helped to bring about decisive change in Boccaccio's literary activity. After the *Decameron*, of which Petrarch remained in ignorance until the very last years of his life, Boccaccio wrote nothing in Italian except *Corbaccio* (a satire on a widow who had jilted him), his late writings on Dante, and perhaps an occasional lyric. Turning instead to Latin, he devoted himself to humanist scholarship rather than to imaginative or poetic creation. His encyclopaedic *De genealogia deorum gentilium* ("On the Genealogy of the Gods of the Gentiles"), medieval in structure but Humanist in spirit, was probably begun in the very year of his meeting with Petrarch but was continuously corrected and revised until his death. His *Bucolicum carmen* (1351–66), a series of allegorical eclogues (short pastoral poems) on contemporary events, follows Classical models on lines already indicated by Dante and Petrarch. His *De claris mulieribus* (1360–74), a collection of biographies of famous women, is the complement of Petrarch's *De viris illustribus* ("On Famous Men"), just as his *De casibus virorum illustrium* ("On the Fates of Famous Men"; 1355–74), on the inevitable catastrophe awaiting all who are too fortunate, reflects Petrarch's *De remediis utriusque fortunae* ("On the Relief of Each Man's Lot"). Finally, there is his compilation of classical geographic names, *De montibus, silvis, fontibus, lacubus, fluminibus, stagnis seu paludibus, et de nominibus maris* ("On Mountains, Forests, Springs, Lakes, Rivers, Swamps or Marshes, and on the Names of the Sea"; 1355–74).

The meeting with Petrarch, however, was not the only cause of the change in Boccaccio's writing. A premature weakening of his physical powers and disappointments in love may also have contributed to it. Some such occurrence would explain how Boccaccio, having previously written always in praise of women and love, came suddenly to write the bitterly misogynistic *Corbaccio* and then turn his genius elsewhere. Furthermore, there are signs that he may have begun to feel religious scruples. Petrarch describes how the Carthusian monk Pietro Petrone, on his deathbed in 1362, sent another Carthusian, Gioacchino Ciani, to exhort Boccaccio to renounce his worldly studies; and it was Petrarch who then dissuaded Boccaccio from burning his own works and selling his library. As early as 1360, moreover, Boccaccio's way of life was regarded as austere enough to justify his being

entrusted with a pastoral cure of souls in a cathedral. He had taken minor orders many years earlier, perhaps at first only in the hope of being given benefices.

Boccaccio's circle in Florence was of vital importance as a nucleus of early Humanism. Leonzio Pilato, whom Boccaccio housed from 1360 to 1362 and whose nomination as reader in Greek at the Studio (the old University of Florence) he procured, made the rough Latin translation through which Petrarch and Boccaccio became acquainted with Homer's poems—the starting point of Greek studies by the Humanists. The recovery of Latin Classical texts—Varro, Martial, Apuleius, Seneca, Ovid, and, above all, Tacitus—likewise occupied Boccaccio's admiring attention. Even so, he did not neglect Italian poetry, his enthusiasm for his immediate predecessors, especially Dante, being one of the characteristics that distinguish him from Petrarch. His *Vita di Dante Alighieri* or *Trattatello in laude di Dante* ("Little Tractate in Praise of Dante") and the two abridged editions of it that he made show his devotion to Dante's memory.

Last years. All these studies were pursued in poverty, sometimes almost in destitution, and Boccaccio had to earn most of his income by transcribing his own works or those of others. In 1362, on the invitation of Niccolò Acciaiuoli, a Florentine banker and statesman who served as chief adviser to Joanna, queen of Naples, Boccaccio went to Naples in some hope but was disappointed and returned at once to Florence. Then, in 1363, he retired to Certaldo. He was twice sent as ambassador to Pope Urban V, at Avignon in 1365 and in Rome in 1367. In 1370–71 he paid another visit to Naples with no better success than in 1362. In October 1373 he began public readings of Dante's *Divina commedia* in the church of S. Stefano di Badia in Florence. A revised text of the commentary that he gave with these readings is still extant but breaks off in the 17th canto of the *Inferno*, at the point that he had reached when, early in 1374, ill health and the criticisms of those who disapproved of his explaining Dante to the multitude made him lose heart. Petrarch's death in July 1374 was another grief to him, and he retired again to Certaldo.

Commentaries on Dante

There Boccaccio died, on Dec. 21, 1375, and was buried in the church of SS. Michele e Jacopo. Franco Sacchetti expressed the general dismay of men of letters at the death within 18 months of the two great writers when he said that all poetry was now extinct.

Boccaccio and the Renaissance. Boccaccio was a man of the Renaissance in almost every sense. His Humanism comprised not only Classical studies and the attempt to rediscover and reinterpret ancient texts but also the "humanism of the vernacular," which he and Petrarch consciously initiated. This Humanism implied the raising of literature in the modern languages to the level of the classical by setting standards for it and then conforming to those standards. Such an undertaking, however, requires the writer to master his own caprices and impulses, to submit to the restraints of an illustrious and unalterable tradition, to tame his passions by the exercise of his intellect in the interests of formal perfection: poetic originality is to be sought only within the confines of tradition. In the second half of the 15th century and in the 16th century, Humanism did produce a vernacular literature in conformity with these requirements: indeed, the Humanist principle that the Classical ideal should permeate the whole of contemporary life had as its natural consequence that the language and literature in which modern life was expressed should receive the stamp of classicism. Boccaccio advanced farther than Petrarch in this direction not only because he sought to dignify prose as well as poetry but also because, in his *Ninfale fiesolano*, in his *Elegia di Madonna Fiammetta*, and in the *Decameron*, he ennobled everyday experience, tragic and comic alike. Although his *Teseida* and his *Ninfale d' Ameto* invite comparison with classical genres (as do Petrarch's *Trionfi*), his *Filocolo* and his *Filostrato* raise to the level of learned art the literature of chivalry and love that had fallen to the level of the populace. The same attention to popular and medieval themes characterized Italian culture in the second half of the 15th century. Without Boccaccio, the culmination of the Renaissance would be historically incomprehensible.

MAJOR WORKS

IN ITALIAN: *La caccia di Diana* (earliest known work), short poem in terza rima; *Il filocolo*, 5 bks. (*c.* 1336; *A Pleasaunt Disport of Diuers Noble Personages* by Henry Grantham, 1567; with introduction by Edward Hutton, 1927; modernized with introduction by Thomas Bell, 1931), prose; *Il filostrato* (*c.* 1338; Eng. trans. by W.M. Rossetti, 1873; by N.E. Griffin and A.B. Myrick, 1929; by R.K. Gordon, 1934), short poem in ottava rima; *Teseida* (*c.* 1340–41), epic of 12 cantos in ottava rima; *Il ninfale d'Ameto*, or *Commedia delle Ninfe fiorentine* (1341–42), prose and terza rima; *L'amorosa visione* (1342–43), allegorical poem of 50 short cantos in terza rima; *Elegia di Madonna Fiammetta*, or *Fiammetta amorosa* (1343–44; *Amorous Fiammetta* by Bartholomew Young, 1587; rev. by Edward Hutton, 1926; new ed. by K.H. Josling, 1929), prose; *Il ninfale fiesolano* (perhaps 1344–45; in *Two Tracts*, Cyril H. Wilkinson's edition of John Goubourne's Elizabethan version in prose of A. Guercin du Donno, 1946), poem in ottava rima; *Decameron* (probably 1348–53; Eng. trans. 1620; by J.M. Rigg, 1903 and 1960; by Richard Aldington, 1930 and 1958), poem and 100 prose stories, each ending with a canzone of poetry; *Il Corbaccio*, or *Laberinto d'amore* (1354–55), prose; *Vita di Dante Alighieri*, or *Trattatello in laude di Dante*, 1354–55; *Life of Dante* by P.H. Wicksteed, 1898), prose; *Esposizioni sopra la Commedia di Dante* (1373, incomplete at death), prose; *Rime* (composed throughout life, critical and purified text pub. 1914), poems.

IN LATIN: *De vita et moribus Francisci Petrarchae* (1343–45), prose; *De genealogia deorum gentilium* (probably begun 1350, but continuously corrected and rev. until death; *Boccaccio on Poetry: Being the Preface and the Fourteenth and Fifteenth Books of Boccaccio's "Genealogia . . ."* by Charles G. Osgood, 1930), prose, general proem, and 15 books; *Bucolicum carmen* (1351–66; *Boccaccio's Olympia* by Israel Gollancz, 1913), allegorical ecologues; *De casibus virorum illustrium*, 9 bks. (1355–74; *Fall of Princes* by John Lydgate from a French version, 1431–38; ed. by Henry Bergen, 1923–27), prose; *De claris mulieribus* (*c.* 1360–74; *Forty-six Lives Translated from Boccaccio's De claris mulieribus*, by Henry Parker, Lord Morley, and ed. by Herbert G. Wright, 1943; *Concerning Famous Women* by Guido A. Guarino, 1964), prose; *De montibus, silvis, fontibus, lacubus, fluminibus, stagnis seu paludibus, et de nominibus maris* (1355–74), prose.

LETTERS: *Epistola consolatoria a messer Pino de' Rossi; Eristulae rerum familiarum; Le Lettere edite e inedite di Messer Giovanni Boccaccio* (1877).

BIBLIOGRAPHY

Editions: Modern editions of Boccaccio's minor works in Italian are as follows: *Il filocolo*, ed. by S. BATTAGLIA (1938); *Il filostrato* and *Il ninfale fiesolano*, ed. by V. PERNICONE (1937); *Teseida*, ed. by S. BATTAGLIA (1938) and by A. RONCAGLIA (1941); *L'Ameto, Lettere, il Corbaccio*, ed. by N. BRUSCOLI (1940); *Il Corbaccio*, ed. by TAUNO NURMEELA (1968); *L'amorosa visione*, ed. by V. BRANCA (1944); *Elegia di Madonna Fiammetta, con le chiose inedite*, ed. by V. PERNICONE (1939) and by F. AGENO (1954); *Le rime, l'amorosa visione, la caccia di Diana*, ed. by V. BRANCA (1939; new ed. of *Le rime* and *La caccia di Diana*, 1958); *Il commento alla Divina Commedia e altri scritti intorno a Dante*, ed. by D. GUERRI, 4 vol. (1918–26). Complete works, ed. by V. BRANCA: II. *Filostrato*, ed. by V. BRANCA, *Teseida delle nozze di Emilia*, ed. by A. LIMENTANI, *Commedia delle Ninfe fiorentine*, ed. by A.E. QUAGLIO (1964); VI. *Esposizione sopra la Commedia di Dante*, ed. by G. PADOAN (1965); I. *La caccia di Diana*, ed. by V. BRANCA, *Il Filocolo*, ed. by A.E. QUAGLIO. Selections from *Il filocolo*, the *Ameto* and the *Elegia di Madonna Fiammetta* are included in the selections from the *Decameron* by E. BIANCHI, C. SALINARI, and N. SAPEGNO, 6th ed. (1952). Of Boccaccio's Latin works *Bucolicum carmen* and some poems and letters, as well as some shorter poems, are printed in *Opere latine minori*, ed. by A.F. MASSERA (1928); there is an edition of the *Genealogia deorum gentilium libri* by V. ROMANO, 2 vol. (1951). There are editions of the *Decameron* by U. BOSCO (1946–51); by G. PETRONIO, with full commentary (1950); by V. BRANCA, with full commentary (1951–52); by C.S. SINGLETON (1955); by N. SAPEGNO (1956); and by M. MARTI (1958). On the text see M. BARBI, *La nuova filologia e l'edizione dei nostri scrittori* (1938); M. SAMPOLI SIMONELLI, "Il Decameron: problemi e discussioni di critica testuale," *Ann. Sc. norm. sup. Pisa*, vol. 18 (1949); V. BRANCA, "Per il testo del Decameron," *Studi di filologia italiana*, vol. 8 and 11 (1950–53); V. BRANCA, *Tradizione delle opere di Giovanni Boccaccio* (1958); *Concordanze del Decameron*, by A. BARBINA (1969).

SCHIAFFINI, *Tradizione e poesia nella prosa d'arte italiana della latinità medievale a Giovanni Boccaccio*, new ed. (1943); E.G. PARODI, *Lingua e letteratura*, ed. by G. FOLENA (1957). On the development and history of criticism, see G. PETRONIO, "Giovanni Boccaccio," in *I Classici italiani nella storia della critica*, ed. by W. BINNI (1954).

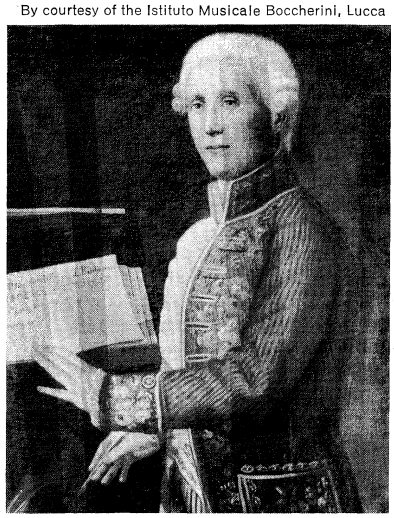
(U.Bo.)

Boccherini, Luigi

An excellent cellist and a prolific writer of instrumental music, Luigi Boccherini helped to develop a comparatively new musical form, the string quartet (two violins, viola, cello), and he created the quintet for strings only (two violins, viola, two cellos; or two violins, two violas, cello), as well as the quintet with strings and piano. He wrote about 500 works, including more than 100 quartets and 50 trios. He also wrote sacred music, symphonies, and concerti, particularly for his own instrument. A typical musician-traveller of the 18th century, Boccherini's style developed through his artistic contacts in Lucca, Rome, Vienna, Milan, Paris, and Madrid. Both forceful and gentle, his power of musical expression dissolved the previous generation's musical formalism into beauty and gracefulness. The Spanish theoretician Antonio Eximeno called him "the delight of Europe." Although Boccherini's work has frequently been compared to that of Joseph Haydn, his music often lacks his contemporary's characteristic forward drive and virility. Gentle warmth, often with a hint of melancholy, and superlative elegance are perhaps the qualities that best distinguish Boccherini's music.

The third child of a double-bass player, Leopoldo Boccherini, and Maria Santa Prosperi, Luigi Rodolfo was

By courtesy of the Istituto Musicale Boccherini, Lucca



Boccherini, portrait by an unknown artist, 1790.

born in Lucca, Italy, on February 19, 1743. At a very early age he was put under the care of the musical director of the local cathedral. When he reached the age of 13, there was nothing more he could learn there; consequently, he was sent to Rome to study with the renowned cellist Giovanni Battista Costanzi, musical director at St. Peter's. In Rome he was influenced by the polyphonic tradition —*i.e.*, music with two or more interweaving melodic parts—stemming from the works of Giovanni da Palestrina and the instrumental music of Arcangelo Corelli. At the vespers in Rome's churches, he was attracted by those symphonies that ended with a minuet—the dance that he later loved to idealize rather than stylize.

Study in Rome

In 1757 Boccherini and his father were invited to play in the Imperial Theatre orchestra in Vienna; where young Boccherini had the chance to absorb the musical classicism, dominated by the personality of Christoph Willibald Gluck, which was rising in the Austrian capital. On his second journey to Vienna (1760), Boccherini, at 17, made his debut as a composer with his *Six Trios for Two Violins and Cello*, G. 77–82 (Opus 1 in Boccherini's autograph catalog), which were appreciated by the renowned Gluck. During his third stay in that city (1764), a public concert by Boccherini was enthusiastically received.

In spite of his success, Boccherini grew homesick for Lucca, to which he returned (August 1764), having obtained a permanent position with the local church and theatre orchestras there. As a composer, he took part in the religious celebrations in the Church of Sta. Croce and other festivities. Around 1765 he composed various oratorios at Lucca. Boccherini was also in Lombardy in 1765, in the orchestra of Giovanni Battista Sammartini. Through his association with this Milanese composer, the 22-year-old Boccherini strengthened the new "conversational" style of the quartet: the cello's line was now as important as the counterpoint (*i.e.*, the intertwining of independent melodic lines) of the violin and viola. Boccherini had a chance to put into practice this conquest with an extraordinary string quartet made up of outstanding Tuscan virtuosi.

After his father's death (1766), he decided to leave Lucca for good. His destination, agreed upon with the violinist Manfredi, one of the Tuscan virtuosi, was Paris—a happy choice since France welcomed Italian musicians. The French publishers Grangé, Venier, and Chevardière published Boccherini's compositions of the previous years (*Six String Quartets*, G. 159–164 [Boccherini's Opus 2], and *Six Duets for Two Violins*, G. 56–61 [Boccherini's Opus 3], of 1761) and the new ones (*Six Trios for Two Violins and Cello*, G. 83–88 [Boccherini's Opus 4], and *Symphony in D Major*, G. 500, of 1766 and *c.* 1766?), and musical Paris competed for the young man from Lucca. From his contact with Mme Brillon de Jouy, the harpsichord player, were born the wonderful *Six Sonatas for Harpsichord and Violin*, G. 25–30 (Boccherini's Opus 5). Boccherini's style spread throughout Europe, and his *Cello Concerto No. 6 in D Major*, G. 479 (*c.* 1768?), became the model for Mozart's *Violin Concerto in D Major*, K. 218 (1775). Such vital contact and enthusiasm were interrupted when the Spanish ambassador to Paris persuaded Boccherini to move to Madrid. Attracted by this hopeful and flattering offer, he began his long segregation at the intrigue-ridden court of Charles III. The King's brother, Infante Don Luis, conferred on him a yearly endowment of 30,000 reals as a cellist and composer and wanted to keep Boccherini with him even when, after a marriage that met with opposition, he was forced to renounce the throne and retire to the Las Arenas castle, several miles from Madrid. Far away from the intrigues of the scornful Prince of the Asturias (afterward Charles IV) and from jealous court musicians, Boccherini worked in tranquillity and also performed in a quartet formed by members of the aristocracy. During this period he wrote his well-known *Six String Quartets*, G. 177–182 (Boccherini's Opus 15, Opus 11 in some editions, composed 1772).

Move to Madrid

Madrid became Boccherini's second home. There he married Clementina Pelicho, who bore him five children. At the Infante's death (1785), the King granted him a pension of 12,000 reals. He received another pension from Frederick William II of Prussia, who was an ama-

teur cellist. Boccherini had a long, friendly relationship with Frederick and dedicated to him a symphony and dozens of trios, quartets, and quintets. Lastly, the Duchess of Osuna appointed him conductor of her private orchestra at the Puerta de la Vega Palace in Madrid. To his prodigious instrumental production, Boccherini added vocal compositions: the *Stabat Mater*, G. 532 (1781), the zarzuela (a form of comic opera) *La Clementina*, G. 540 (composed 1786), with libretto by Ramon de la Cruz, and the Christmas *Villancicos*, G. 539 (1783). Though faithful to traditional classical musical forms, Boccherini was also receptive to Spanish popular music. He became, in fact, the musical representative of the "Goya epoch," the age of the great Spanish painter Francisco Goya (1746–1828), who was one of Boccherini's friends.

Having lost his first wife, Boccherini married Joaquina Porreti (1787). From 1787 to 1797, he was probably in Berlin, at a post provided by Frederick William II, but historical evidence for his stay there is lacking. In 1798, the new king of Prussia withdrew Boccherini's pension, the Duchess of Osuna moved to Paris, and Boccherini's financial stress was aggravated by poor health. His trusting nature was shaken by the greed of the Parisian publisher Pleyel, and his life was saddened by the death of his second wife and two daughters during an epidemic. After living for some years in straitened circumstances, his situation was improved briefly by the patronage of Lucien Bonaparte, who had been appointed in 1800 as ambassador of the French Republic in Madrid. After 1801 he fell into greater poverty, and in 1804 he was forced to live in one room with his three surviving children. His last complete work, the *String Quartet No. 90 in F Major*, G. 248, was composed that year. He died on May 28, 1805, in Madrid and was buried in the Church of San Justo. In 1927 Boccherini's remains were moved to the Church of S. Francesco in Lucca.

In 1969 the French scholar Yves Gérard published his *Thematic, Bibliographical, and Critical Catalogue of the Works of Luigi Boccherini*. Numbers preceded by "G." are the numbers assigned by Gérard according to type of composition and are not in chronological order.

MAJOR WORKS

OPERA: *La Clementina*, G. 540 (composed 1786).

ORCHESTRAL MUSIC: 20 symphonies; four cello concerti.

CHAMBER MUSIC: 125 string quintets; 12 quintets for piano and strings; 18 quintets for flute or oboe and strings; 102 string quartets; 60 string trios; 27 violin sonatas; six cello sonatas.

CHURCH MUSIC: *Stabat Mater*, G. 532, for three voices and strings (first version completed 1781, second version 1800); mass sections for four voices and instruments; *Christmas Cantata*, G. 535 (Boccherini's Opus 63, composed 1802); various motets.

GERARD, *Thematic, Bibliographical, and Critical Catalogue of the Works of Luigi Boccherini* (1969), with 580 compositions.

(Gu.B.)

Body Cavities and Membranes, Human

The entire body has many cavities—the brain cavity within the head, for example, discussed in the article SKELETAL SYSTEM, HUMAN; the sinuses, described in the article SINUS; the space within the stomach and intestines (see DIGESTIVE SYSTEM, HUMAN) and that within the urinary bladder (see EXCRETORY SYSTEM, HUMAN). The present article is focussed on the major cavities within the trunk: the chest, or thoracic cavity, and the abdominal cavity, together with the membranes that line these cavities and cover the organs and structures within them. The chest and the abdominal cavity contain most of the important organs concerned with respiration, circulation, and digestion. The article also includes a discussion of the principal diseases and disorders that affect these two cavities.

Thoracic cavity. The thoracic cavity, second only in size to the abdominal cavity, contains the lungs, the middle and lower airways—the tracheobronchial tree—the heart, the vessels transporting blood between the heart and the lungs, the great arteries bringing blood from the heart out into the general circulation, and the major veins into which the blood is collected for transport back to the heart. The chest also contains the esophagus, the channel for food from the throat to the stomach (see Figure 1).

The chest and the pleura

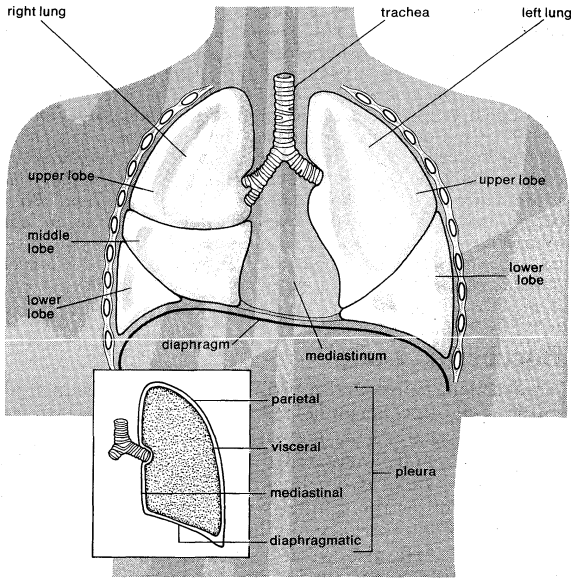


Figure 1: Chest cavity and pleura.

The chest cavity, like the abdominal cavity, is lined with a serous membrane, so called because it exudes a thin fluid, or serum. This portion of the chest membrane is called the parietal pleura. The membrane continues over the lung, where it is called the visceral pleura, and over part of the esophagus, the heart, and the great vessels: the mediastinal pleura, the mediastinum being the space and the tissues and structures between the two lungs. Because the atmospheric pressure between the parietal pleura and the visceral pleura is less than that of the outer atmosphere, the two surfaces tend to touch, friction between the two during the respiratory movements of the lung being eliminated by the lubricating action of the serous fluid. The pleural cavity is the space, when it occurs, between the parietal and the visceral pleura.

Inside the thoracic cavity is another smaller cavity, the pericardial sac, which contains the heart and the beginnings of the great vessels that enter and leave the heart (see CARDIOVASCULAR SYSTEM, HUMAN).

The structure and vessels of the pleura

The pleura is a continuous sheet of endothelial, or lining, cells supported by a thin base of loose connective tissue. The membrane is well supplied with blood vessels, nerves, and lymph channels. The vessels of the visceral part of the pleura are intimately related with those of the lungs and bronchi: its arteries are branches of the bronchial arteries, and its veins mingle with the pulmonary network of capillaries. Beneath its inner side is a network of tiny lymph channels, or capillaries, that penetrate the lung substance, or parenchyma, and drain to the lymph nodes at the hilus of each lung, the point of entrance and departure for bronchi, blood vessels, and nerves.

Diseases affecting the pleura and pleural cavity, other than primary tumours, are brought by the blood vessels or may spread from contiguous structures. The pleural cavity may be contaminated by rupture of either the visceral pleura or the parietal pleura.

Accumulation of fluid in the pleural cavity is called hydrothorax. If the fluid is bloody, it is termed hemothorax; and if it contains pus, pyothorax. The accumulation of fluid may or may not be accompanied by air. When air is present, the prefix pneumo is attached to each of the names mentioned—*e.g.*, hydropneumothorax, etc.

Hydrothorax; pneumothorax; pleurisy

The penetration of air into the pleural cavity from outside, as from a penetrating wound of the chest, or from within, by rupture of dilated alveoli (air sacs of the lung) or of a cyst, will produce a pneumothorax, converting this cavity into a positive pressure chamber and collapsing the lung, which in turn will lead to lessened oxygenation of the venous blood. The collapse may also have a deleterious effect upon the heart.

Pleurisy is a term applied to the inflammation of the pleura, usually diffuse, affecting one or both sides. Two forms are distinguished: (1) simple, dry, or fibrinous pleurisy; and (2) exudative pleurisy, in which the pleural membrane gives off excessive fluid. Since the pleura is well supplied by nerves, pleurisy can be extremely painful, especially as the lung moves on respiration.

If the pleurisy is severe and extensive enough, there may be an effusion, outpouring of fluid, at times infected. Pleurisy is commonly caused by infection in the underlying lung. More rarely, effusion results from diffuse inflammatory conditions such as rheumatoid arthritis. Rupture of the thoracic duct, the main channel for lymph, gives rise to chylothorax, characterized by escape of lymph into the pleural space.

The most common symptoms of persons who experience pleural effusion are pain and shortness of breath. Auscultation (listening to sounds within the organ) and percussion, diagnostic techniques utilizing the stethoscope and tapping, reveal replacement of the tympanic (drumlike) sound by a dull and solid one. The breath sounds are barely heard because of the interposition of fluid between the lung and the chest wall. Fever is usually present. The diagnosis of pleurisy is suggested by the affected person's account of his symptoms and is confirmed by clinical examination; a more precise evaluation of the amount and location of the fluid and the effects upon lungs and heart is made by X-ray examination.

The treatment of pleurisy is directed toward the evacuation of the fluid and the treatment of the underlying condition.

Epidemic pleurodynia, or Bornholm disease, an acute infection of the various tissues of the pleural cavity by the group B Coxsackie virus, is characterized by a general feeling of ill health and by pleuritis-like pain in the chest muscles and the upper part of the abdomen. This pain is usually increased by respiration and cough, and pain in other muscles is often present. The condition usually subsides in two to five days but sometimes may take weeks to disappear.

The peritoneum and the abdominal cavities

The abdominal cavity. The abdominal cavity is separated from the chest cavity by the diaphragm, a sheet of muscle and connective tissue. The cavity, lined by the peritoneum, a membrane similar to the pleura (see Figure 2), covers not only the inside wall of the abdominal cavity (parietal peritoneum) but also almost every organ or structure contained in it (visceral peritoneum). The space between the visceral and the parietal peritoneum, the peritoneal cavity, is a potential space only, normally containing a small amount of serous fluid that permits free movement of the viscera inside the peritoneal cavity. This motion is particularly true of the gastrointestinal tract. The peritoneum, by connecting the visceral with the parietal portions, assists in the support and fixation of the abdominal organs. The diverse attachments of the peritoneum divide the abdominal cavity into several compartments, of which the compartment called the lesser sac is of particular importance; it is located behind the stomach and is connected with the rest of the peritoneal cavity, the greater sac, by the foramen (opening) of Winslow.

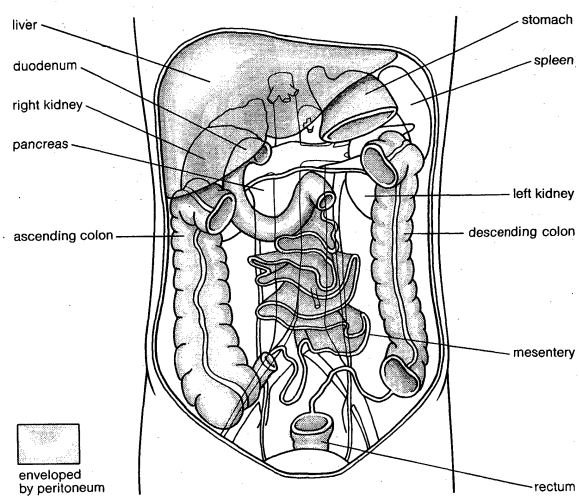

Figure 2: Abdominal cavity, showing relationship of the peritoneum and the abdominal viscera.

Some of the viscera are attached to the abdominal walls by broad areas of peritoneum, as is the pancreas. Others —*e.g.*, the liver—are attached by folds of peritoneum and ligaments, usually poorly supplied by blood vessels.

The peritoneal ligaments are actually rather strong peritoneal folds, usually connecting viscera to viscera or viscera to the abdominal wall; their name usually derives from the structures connected by them (*e.g.*, gastrocolic ligament, connecting the stomach and the colon; the splenocolic ligament, connecting the spleen and the colon), or from their shape (*e.g.*, round ligament, triangular ligament).

The mesenteries are folds of peritoneum that are attached to the wall of the abdomen and enclosing viscera. They are richly supplied with vessels that carry blood to or from the organs that they enfold. The three most important mesenteries are the mesentery for the small intestines; the transverse mesocolon, which attaches the transverse portion of the colon to the back wall of the abdomen; and the mesosigmoid, which enfolds the sigmoid portion of the colon.

The omenta are folds of peritoneum enclosing nerves, blood vessels, lymph channels, and fatty and connective tissue. There are two omenta: the greater omentum hangs down in front of the small intestine like an apron; the lesser omentum is much smaller and extends between the stomach and the liver.

Diseases of the peritoneal membranes. Ascites is the accumulation of fluid in the peritoneal cavity. This fluid contains relatively small numbers of cells, differing in this respect from the fluid associated with peritonitis. The most common causes of ascites in the following order are cirrhosis of the liver with portal hypertension (liver disease involving destruction of liver cells, formation of scar tissue, hardening and contraction of the liver, and elevation of blood pressure in the portal vein); heart failure; tumour invasion of the peritoneum; and escape of chyle (lymph laden with emulsified fats).

Fluid in cavity

The presence of fluid in the peritoneal cavity is not noticeable until such a volume is attained as to distend the abdomen. The accumulation of fluid will produce pressure against the abdominal viscera and veins and also against the thoracic cavity by pressing upon the diaphragm. Treatment is directed toward removal of the cause. Decrease in portal vein pressure in many cases relieves the ascites that accompanies cirrhosis. Chylous ascites is best treated by closure of the leaking lymphatic vessel. Adequate treatment of the heart failure will usually produce regression of the ascites that the heart failure has caused.

Peritonitis, like pleurisy, is usually secondary to an inflammatory process elsewhere, which may come from an adjacent structure or organ; may be introduced from the outside by surgery or by injury; may come from organs in the abdomen, or may be borne by the bloodstream or the lymphatics. The most common origin of peritonitis is the gastro-intestinal tract. Peritonitis may be acute or chronic, generalized or localized, and it may be due to one agent or to a number of them. It is secondary to perforation of the intestines, for example. The severity of the reactions is related, at least in part, to the extent of the peritoneal contamination. In localized peritonitis, the surrounding structures, mainly the greater omentum, will enclose the infected area and will temporarily control the infection. If no treatment is started, the infection may progress throughout the entire abdominal cavity. Often the period in which the peritonitis is localized is short,

and the peritoneal inflammation becomes generalized with great rapidity.

Control of the source of inflammation, either by surgical or by medical means, is followed either by remission of all evidence of peritoneal inflammation or infection or by formation of localized abscesses inside of the peritoneal cavity. Antibiotic therapy has considerably decreased the incidence of the latter complication. When an abscess does develop, antibiotic therapy and adequate external drainage are necessary. The most frequent sites for development of these abscesses are the spaces beneath the diaphragm and the pelvic cavity.

Adhesions between layers of peritoneum are commonly due to abdominal operations but may result from infections in the abdomen or the pelvis. Loops of small bowel or sigmoid colon may become caught between adhesions or between these and the abdominal wall or organs or may even become twisted, with resultant partial or total obstruction of the intestine. If the obstruction interferes with the blood supply, it may cause death of a section of the bowel. Obstruction of the bowel causes cramping abdominal pain and often causes nausea and vomiting. The obstruction is generally eliminated by surgery; in rare cases it disappears spontaneously.

Use of peritoneum in removal of waste products from the blood

Absorptive properties of the peritoneum. The peritoneum has a wide surface and is able to absorb water and substances in solution. This property has proved to be a liability in certain situations—for example, the membrane is known to absorb toxins arising from obstruction and strangulation (cutting off the circulation) of the intestine—but has been useful in the treatment of kidney disease. In the latter situation, the peritoneum has been used, like the semipermeable membrane of the artificial kidney, to remove waste products from the blood.

Torsion and infarction of the omentum. The omentum can become twisted either without known cause or as a result of adhesions, tumours, inflammation, or hernia. The twisting of the omentum may press on the blood vessels and cause mild interference with the blood supply or, in its severe form, may cause infarction (tissue death) in a part of the omentum. The first and predominant symptom is pain in the lower part of the abdomen. When the amount of infarcted omentum is rather large, the mass can be felt. Signs of acute inflammation are present. In treatment, the dead tissue is removed by surgery, and the underlying cause is corrected.

Boethius

Anicius Manlius Severinus Boethius, Roman scholar, philosopher, theologian, and statesman, is best known for his *De consolatione philosophiae* (Eng. trans., *The Consolation of Philosophy*, 1963). When the barbarians were invading the Western Roman Empire in the late 5th and early 6th centuries and cultural life was declining and the future of Rome was unclear, Boethius was one of a few in the upper classes who set about transmitting the texts of ancient thought to posterity.

The most succinct biography of Boethius and the oldest was written by Cassiodorus, his senatorial colleague, who described him as the accomplished orator in both Greek and Latin who delivered a fine eulogy of King Theodoric, who also wrote on theology, composed a pastoral poem, and was most famous as a translator of works of Greek logic and mathematics.

Other ancient sources, including Boethius' own *De consolatione philosophiae*, give more details. He belonged to the ancient Roman family of the Anicii, which had been Christian for about a century and of which Emperor Olybrius had been a member. Boethius' father had been consul in 487 but died soon afterward, and Boethius was raised by Quintus Aurelius Memmius Symmachus, whose daughter Rusticiana he married. He became consul in

Boethius, detail of a miniature from a Boethius manuscript, 12th century. In the Cambridge University Library, England. (MS Ii.3.12(D)).
By courtesy of Cambridge University Library, England

510 under the Ostrogothic king Theodoric, who had usurped the imperial rule of Italy. Although little of Boethius' education is known, he was evidently well trained in Greek. His early works on arithmetic and music are extant, both based on Greek handbooks by Nicomachus of Gerasa, a 1st-century-AD Palestinian mathematician. There is little that survives of Boethius' geometry, which was based on Euclid, and there is nothing of his astronomy.

Aristotelian translations and Christian theological works

It was his scholarly aim to translate the works of Aristotle with commentary into Latin, and all the works of Plato "perhaps with commentary," to be followed by a "restoration of their ideas into a single harmony." Boethius' dedicated Hellenism, modelled on Cicero's, supported his long labour of translating Aristotle's *Organon* (six treatises on logic) and the Greek glosses on the work.

Boethius had begun before 510 to translate Porphyry's *Eisagogē*, a 3rd-century Greek introduction to Aristotle's logic, and elaborated it in a double commentary. He then translated the *Katēgoriai*, wrote a commentary in 511, the year of his consulship, and also translated and wrote two commentaries on the second of Aristotle's six treatises, the *Peri hermeneias* ("On Interpretation"). A brief ancient commentary on Aristotle's *Analytika Protera* ("Prior Analytics") may be his too; he also wrote two short works on the syllogism. Instead of elucidating his translation of Aristotle's *Topika*, Boethius wrote a commentary on the *Topica* of Cicero, which was already familiar to Latin readers.

About 520 Boethius put his close study of Aristotle to use in four short treatises in letter form on the ecclesiastical doctrines of the Trinity and the nature of Christ; these are basically an attempt to solve disputes that had resulted from the Arian heresy, which denied the divinity of Christ. Using the terminology of the Aristotelian categories, Boethius described the unity of God in terms of substance and the three divine persons in terms of relation. He also tried to solve dilemmas arising from the traditional description of Christ as both human and divine, by deploying precise definitions of "substance," "nature," and "person." There is also a titleless treatise, a brief confession of the Catholic faith, not quite so Aristotelian in its idiom as the other four, the authenticity of which has been disputed. Indeed, doubt has at times been cast on all of Boethius' theological writings because in his logical works and in the later *Consolation*, Christian idiom is nowhere apparent. The 19th-century discovery of Cassiodorus' biography, however, confirmed

Boethius as a Christian writer, even if his philosophic sources were non-Christian. The idiom of his theological writing suggests that there, too, as in the logic and the arts, he kept close to Greek models; for it was in the Greek part of the empire that heretical disputes and new terminology had arisen.

About 520, Boethius became *magister officiorum* (head of all the government and court services) under Theodoric. His two sons were consuls together in 522. Eventually, Boethius fell out of favour with Theodoric. The *Consolation* contains the main extant evidence of his fall but does not clearly describe the terms of the accusation against him. After the healing of a schism between Rome and the church of Constantinople in 520, Boethius and some other senators may have been suspected of communicating with the Byzantine Emperor, who was orthodox in faith whereas Theodoric was Arian. Boethius openly defended the senator Albinus, who was accused of treason "for having written to the Emperor Justin against the rule of Theodoric." The charge of treason brought against Boethius was aggravated by a further accusation of the practice of magic, or of sacrilege, which the accused was at great pains to reject. Sentence was passed and was ratified by the Senate, probably under duress. In prison, awaiting execution, Boethius wrote his *De consolatione philosophiae*.

Content of the *Consolation*

The *Consolation* is the most personal of Boethius' writings, the crown of his philosophic endeavours. Its style, a welcome change from the Aristotelian idiom that provided the basis for the jargon of medieval Scholasticism, seemed to the 18th-century English historian Gibbon "not unworthy of the leisure of Plato or Tully." The argument of the *Consolation* is basically Platonic. Philosophy, personified as a woman, converts the prisoner Boethius to the Platonic notion of Good and so nurses him back to the recollection that, despite the apparent injustice of his enforced exile, there does exist a *summum bonum* ("highest good"), which "strongly and sweetly" controls and orders the universe. Fortune and misfortune must be subordinate to that central Providence, and the real existence of evil is excluded. Man has free will, but it is no obstacle to divine order and foreknowledge. Virtue, whatever the appearances, never goes unrewarded. The prisoner is finally consoled by the hope of reparation and reward beyond death. Through the five books of this argument, in which poetry alternates with prose, there is no specifically Christian tenet, no certain biblical quotation. It is the creed of a Platonist, though nowhere glaringly incongruous with Christian faith. The most widely read book in medieval times, after the Vulgate Bible, it transmitted the main doctrines of Platonism to the Middle Ages. The modern reader may not be so readily consoled by its ancient modes of argument, but he may be impressed by Boethius' emphasis on the possibility of other grades of Being beyond the one humanly known, and other dimensions to the human experience of time.

After his detention, probably at Pavia, he was executed in 524. His remains were later placed in the church of S. Pietro in Ciel d'Oro in Pavia, where, possibly through a confusion with his namesake, St. Severinus of Noricum, they came to receive the veneration due to a martyr, and a memorable salute from Dante.

Influence of Boethius

When Cassiodorus founded a monastery at Vivarium, in Campania, he installed there his Roman library, and included Boethius' works on the liberal arts in the annotated reading list (*Institutiones*) that he composed for the education of his monks. Thus, some of the literary habits of the ancient aristocracy entered the monastic tradition. Boethian logic dominated the training of the medieval clergy and the work of the cloister and court schools. His translations and commentaries, particularly those of the *Katēgoriai* and *Peri hermeneias*, became basic texts in medieval Scholasticism. The great controversy over Nominalism (denial of the existence of universals) and Realism (belief in the existence of universals) was incited by a passage in his commentary on Porphyry. Translations of the *Consolation* appeared early in the great vernacular literatures, with King Alfred (9th century) and Chaucer (14th century) in English, Jean de Meung (a 13th-century poet) in French, and Notker Labeo (a monk of around the turn of the 11th century) in German. There was a Byzantine version in the 13th century by Planudes and a 16th-century English one by Elizabeth I.

Thus the resolute intellectual activity of Boethius in an age of change and catastrophe affected later, very different ages; and the subtle and precise terminology of Greek antiquity survived in Latin when Greek itself was little known

Boğazköy

Boğazköy is the site of the ancient capital of the Hittites, a people who established a powerful empire in Anatolia and northern Syria in the 2nd millennium BC. The site lies about 125 miles (200 kilometres) by road east of Ankara, Turkey. The official modern name of the village is Boğazkale; it is incorporated as a township (Turkish *belediye*) and is the administrative centre of a county (*bucak*) in the district (*ilçe*) of Sungurlu, province (*il, vilâyet*) of Çorum. Before its recent renaming the place was called Boğazköy (Gorge Village) after its most conspicuous natural feature; this name, under which it became known, is still widely used.

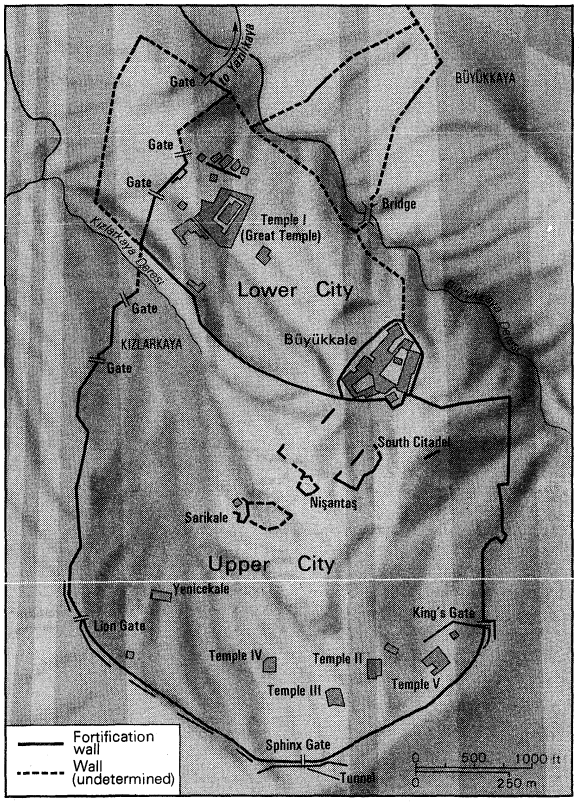
Topography

The ancient city. The ancient city occupies a section of a mountain slope at the southern end of a small fertile plain. It lies between two deeply cut stream beds, filling the angle between their converging courses. Their confluence at the level of the plain (elevation about 3,100 feet) marks the northernmost point of the city area, which rises toward the south by about 1,000 feet (300 metres) on a length of 1¼ miles (two kilometres). The eastern valley narrows in some places to form a real gorge.

The earliest settlement in the city area dates to the 3rd millennium BC, in the so-called Early Bronze Age. There are no written documents that would reveal the identity of the first settlers. Remains of this period were found on top and at the northwest foot of the high hill dominating the east side of the city, known as Büyükkale (Great Fortress), which later became the acropolis of the Hittite kings.

The earliest written sources found at Boğazköy are clay tablets inscribed in cuneiform writing in the Old Assyrian language. They attest the presence of Assyrian merchants on the site, which at that time was called Hattus. The largest Assyrian trade colony was at Kanesh (Kültepe, near Kayseri). Whereas the latter flourished from around 1950 to 1850 BC and, after a destruction, re-emerged sometime around 1820 and lasted through another two generations, that of Boğazköy is contemporary with only this later period.

Hattus was the name of the city also in the language of the early inhabitants of the "Land of Hatti," a language still little understood and not belonging to any known family. Scholars call it Hattic to distinguish it from Hittite, the name of the Indo-European official language of the Hittite kingdom. Just as in other parts of the world, the Indo-European speakers must have been invaders



Plan of Boğazköy.

After *Hattusha: The Capital of the Hittites* by Kurt Bittel, copyright © 1970 by Oxford University Press, Inc.; reprinted by permission

who conquered the older population, but the exact date and the details are unknown, except that individuals bearing Indo-European Hittite names are attested before 1850 in Kanesh in documents of the older Assyrian colony. In Hattus the population or its rulers may still have been "Hattians" even during the later colony period, but there is no proof of it. The houses of the merchants were in the lower city, north of the site of the later Great Temple. The town extended up to Büyükkale, probably culminating in the palace of the local king. Both this town and the merchants' houses were destroyed, probably by King Anittas of Kussara (after 1800). A Hittite text ascribed to Anittas tells of his conquests in Anatolia and how he defeated King Piyusti of Hattus, destroyed the city, and put a curse on the site.

The Indo-European speakers added the vowel *a* to the city name and declined it according to their language; thus the nominative case became Hattusas. The first mention of the name in the form of Hattusa is on a tablet from Mari, on the middle Euphrates, datable to the time of Hammurabi (or Hammurapi; 1792–50); possibly this refers to the city before its destruction by Anittas.

The Old Hittite city

About the middle of the 17th century BC, another king of Kussara, disregarding Anittas' curse, made Hattusa his capital; while his own name was Labarnas, he became known as Hattusilis I, "The one from Hattusa." He is the first ruler of whom there are authentic texts in the Hittite language and one of the founders of the Old Hittite kingdom. One of his successors, Hantilis, is said to have fortified the city. The line of the Old Hittite city wall can be followed today: it surrounds the northern terraces and follows the edge of the eastern valley up to Büyükkale, which must then have been the acropolis; in the west it descends along a side valley to the lower terrace.

Hattusa remained the capital throughout Hittite history with few interruptions. The sources tell of one destruction of the city by enemies around 1380 BC. Soon afterward, King Suppiluliumas I not only restored the city but, by his conquest of most of Anatolia and of Syria to the Lebanon, made it the capital of a real empire. Scholars have wondered how this empire could be ruled from such a remote place. Apart from tradition, it must have been the natural advantages of the site—plentiful water and the protection provided by the terrain—that kept the dynasty at Hattusa. King Muwatallis (around 1300 BC) is said to have transferred the capital to the south "upon the command of the gods." The real reasons behind this move are not known, and his successor brought the government back to Hattusa where it remained to the end.

In the New Kingdom, or Empire, Period (*c.* 1400–*c.* 1190 BC) the city was extended toward the south: the wide arc of the city wall, running from Büyükkale up to the top and down along the western valley, dates from the New Kingdom. The inclusion of these southern hills strengthened the fortification system considerably, especially by the sophisticated construction of the highest section. Here a deep fosse, or moat, and a high earth rampart carrying the wall protected the city against the hills to the south, while a corbelled tunnel, called Yerkapu (Ground Gate), a paved glacis (or defensive slope), and flights of steps aided the defenders. The gates with sculptural decoration also belong to this period: the King's Gate in the southeast (whose relief of a warrior god is in the Ankara museum) and the Lion Gate in the southwest.

Ara Guler

Lion Gate, southwest section of Boğazköy, New Kingdom, or Empire, Period (*c.* 1370–1290 BC).

Although temples are mentioned in the Old Kingdom, the actual temple ruins all date from the New Kingdom. Four temples in the upper city belong to the extension just mentioned. Also the Great Temple in the lower city, in the shape revealed by excavation with its large complex of subsidiary buildings, is a work of the empire. The acropolis, Büyükkale, was completely rebuilt in a monumental manner during the same period.

A further extension of the city wall across the gorge so as to enclose the plateau of Büyükkaya, the "Great Rock" east of the valley, belongs to the 13th century, as do the reliefs and structures at the rock sanctuary, Yazılıkaya, about a mile from the city on the slope of the eastern mountains.

Residential quarters have been excavated only in small parts. Large sections of the city area are taken up by temples and other official buildings, while other parts are too precipitous for building. It is therefore not possible to estimate the population of the city.

Destruction

With the downfall of the Hittite Empire (*c.* 1190 BC) the city was destroyed; traces of burning are found in all parts. The site, it seems, remained vacant for a long time. The next settlement, mainly on Büyükkale and in the lower city, was in size and layout much more modest than the Hittite capital. Through pottery and other finds, this settlement is linked to the Phrygians, to whose kingdom the region belonged in the 8th century BC. These post-Hittite settlements saw several rebuildings and lasted into the Hellenistic Age (3rd to 1st centuries BC), when a tribe of the Galatians, Celtic invaders from Europe, settled in the region. There are only scattered remains of Roman and early Christian times, after which the place

was again uninhabited until the foundation of the village of Boğazköy in the 18th century AD.

Excavations. Boğazköy was discovered in 1834 by the French explorer Charles Texier, who saw Yazılıkaya and those remains of the ancient city that were above ground. After visits by British and German travellers, it was another Frenchman, Ernest Chantre, who in 1892–93 made the first soundings and found the first cuneiform tablets there. The language in which these texts were written was not known at the time, but its identity with that of the so-called Arzawa letters found in Tell el-Amarna in Egypt was soon recognized. This led the Berlin Assyriologist Hugo Winckler to undertake excavations in 1906 together with Theodore Makridi (Bey) of the Istanbul Museum. This first season yielded 2,500 fragments of tablets from the west side of Büyükkale, including some in Akkadian; these showed that Boğazköy was the capital of the kings of Hatti. Winckler and Makridi returned in 1907, 1911, and 1912. In 1907 another German expedition under Otto Puchstein excavated and surveyed the fortifications and temples. After World War I new excavations were started by the German Archaeological Institute and the German Orient Society, with Kurt Bittel as field director. They continued from 1931 to 1939 and again after World War II. These excavations established the stratigraphy and, thereby, the history of the site, besides yielding many more tablets from several locations on Büyükkale and the area of the Great Temple. The excavators had to remove the post-Hittite structures in order to reach the Hittite levels, and they covered all levels earlier than the Hittite Empire with earth again in order to present and preserve as much as possible of the remains of the city of the 13th century BC (see also ANATOLIA, ANCIENT).

BIBLIOGRAPHY. KURT BITTEL, *Hattusha: The Capital of the Hittites* (1970), is a comprehensive description of the city and its history and remains, with an extensive bibliography. See also E. AKURGAL, *The Art of the Hittites* (Eng. trans. 1962).

(H.G.G.)

Bogotá

Bogotá (Santa Fé de Bogotá) is the capital of the Republic of Colombia and of the Department of Cundinamarca. The mountain-rimmed city is built on the eastern margin of a fertile plateau 8,660 feet (2,640 metres) above sea level in the Eastern Cordillera of the Andes mountains. In the city, skyscrapers of the 1970s stand side by side with churches of the 1600s. High-powered automobiles share modern expressways with mule carts. These and other unlikely contrasts are evidence of the city's successful transition from the 17th to the 20th century in one giant leap. Beautiful artisan handicrafts, the world's finest emeralds, excellent international hotels and restaurants, and the scenic grandeur of its mountain landscape (including the 475-foot falls of the Río Bogotá [Funza], at Tequendama 20 miles away) have made Bogotá a prime tourist attraction in South America. The area of the city is 46 square miles (120 square kilometres), and its population in 1971 was 2,500,000. The Special District of Bogotá, consisting of the city of Bogotá and six other cities or boroughs (Bosa, Engativá, Fontibón, Suba, Usaquén, and Usme) has an area of 600 square miles.

History. In April 1536, Gonzalo Jiménez de Quesada, an Andalusian lawyer and writer, set out from Santa Marta on the Caribbean Sea with more than 900 men to explore the sources of the Río Magdalena. In two years his company, drastically reduced, reached the cooler slopes of the central cordillera. Once upon the mountain plateau, they approached Bacatá, the main seat of the Chibcha Indians. Tribal resistance proved no match for Quesada's men, who soon enslaved the Chibchas, burned their temples, and carried off their gold.

In 1538 a civil government was organized with two mayors and a city council of seven members who served under a lieutenant governor. The settlement was christened Santa Fé de Bacatá: Santa Fé after Quesada's birthplace in Spain, and Bacatá for the original Indian name, which was soon corrupted to Bogotá. Bogotá's fate

Origin of name

was closely allied to that of the viceroyalty of Nueva Granada, of which it was made the capital city, soon becoming a centre of Spanish colonial power in South America. Once the territory achieved independence from Spain in 1819, Bogotá was made capital of Gran Colombia, a confederation that included the present republics of Venezuela, Ecuador, Panama, and Colombia. During the troubled history of the confederation and down to the present time when only the Republic of Colombia remains of the original territory, Bogotá has remained the capital city.

Turbulent struggles for political power in the capital city, as well as its geographical isolation, stunted Bogotá's growth and prosperity in the 19th century. Development proceeded at a modest pace prior to World War II. In April 1948, following the assassination of the leader of the Liberal Party and likely presidential candidate Jorge Eliécer Gaitán, the central part of the city was severely damaged by riots. A wave of chaotic violence subsequently known as the *bogotazo* swept the city immediately and spread to the Colombian countryside. After the invocation of martial law in the city, the rioting subsided, and rural dwellers still threatened by uncontrolled violence fled to the city for security. Undercurrents of unrest existed in Bogotá until 1958 when the Liberal and Conservative parties reached a settlement and most of the violence in the country was quelled.

The contemporary city. *The city site and plan.* The city lies on a high sloping plain at the western base of two mountains, Guadalupe and Monserrate, upon the crests of which stand two imposing religious shrines. From a broad avenue at the base of the mountains, streets slope downward to the west, carrying streams of cold water from the mountains. North–south streets cross these at right angles, the blocks forming large terraces. Aside from a few avenues (which have proper names), all of the streets are laid out in this gridiron pattern—those running east to west being known as *calles* and those going from north to south as *carreras*. The city today extends nine miles from the southern suburbs of Bello Horizonte and San Isidro to the extreme northern ones of Santa Bárbara and Usaquén. The old municipal area is still the centre of the city and the site of the federal government. This central section merges naturally with the poorer residential suburbs to the south and the commercial and business districts to the north, beyond which are the richer suburbs, becoming progressively more expensive the further they are from the city's centre. Traditional suburbs such as Teusaquillo, Chapinero, and Chico were originally separate towns that the city engulfed. Today, there are no clear boundaries between suburbs. Many businesses and most of the finer shops have located in the northern suburbs. Until the mid-1960s, Carrera 56, three miles from the eastern edge of the city, was considered to be the western extremity of Bogotá, but suburbs have continued to sprout up further west as far as the new Eldorado Airport, about seven miles from the eastern edge. These areas include low and middle income housing developments such as Minuto de Diós and Bonanza. Several plazas, often dominated by churches, are located throughout the city.

Suburbs

Climate. Although Colombians consider Bogotá to be in the country's cold zone, its mean annual temperature is about 58° F (14° C) and averages less than a 2° F (1° C) difference between the coldest and warmest months. Rainy seasons occur in April and May and from September to December. During these periods the mountain plateau is subject to moderate but often continuous rainfall. Temperate cereals, vegetables, and fruits are plentiful year round on the savanna ringing the city and provide half of its food supply.

Transportation. Until airplanes flew over its surrounding wall of mountains, Bogotá was one of the least accessible capitals in the world. Today it is the hub of air travel in Colombia and the home of Avianca (Aerovías Nacionales de Colombia), the first commercial airline in South America. Railroads connect Bogotá with the Caribbean coast and to sections of the departments of Boyacá and Santander to the east, but any trip by rail to Colom-

The cathedral on the Plaza Bolívar, Bogotá.
Hector Acebes—Photo Researchers

bia's western cities and the Pacific coast must be made via Puerto Berrío on the Río Magdalena. Bogotá is on the Colombian section of the Pan-American and Simón Bolívar highways and has road connections with all major Colombian cities.

Although automobiles are expensive in Colombia, Bogotá is jammed with them. In recent years traffic arteries have been widened in the downtown area, bypassing heavily congested sections, and a highway now crosses the city from south to north, built as part of the massive road improvement that began in 1968 in preparation for the visit of Pope Paul VI to Colombia in 1969. The city's public transportation consists of several interconnecting bus routes, metered taxicabs, and *colectivos*, or cabs with a fixed route and fare.

Population. Bogotá's population has increased fourfold in 20 years, from 660,280 in 1951 to 2,539,100 in 1971. The urban slums in the south of Bogotá testify to the scourge of that rapid growth. It has been estimated that more than 50 percent of the city's inhabitants were born elsewhere but migrated to the city in search of better living conditions. Substantial numbers of Indians, mestizos (persons of mixed white and Indian ancestry), and mulattoes (persons of mixed white and Negro ancestry) are represented in the population. Caste and class are still dominant features of Bogotá society, yet boundaries have tended to blur, and some social mobility exists.

Close to Spain in its religious orientation, Bogotá is one of the world's strongholds of orthodox Roman Catholicism, and has been an archiepiscopal see since 1564.

Architecture and housing. Its classical cathedral and several other early churches in the Baroque and Rococo style preserve some of the finest examples of colonial architecture in South America. Today, almost every architectural period and style exists in Bogotá. Public buildings of the late 19th century follow the Neo-Gothic, and recent office buildings exhibit the clean, functional lines of the International style. In spite of expanded building programs, housing in the city was unable to keep up with the influx of squatters and settlers beginning in the late 1940s, and thousands of such residents still live in squalid slums.

Economic life. Although Bogotá is the commercial, cultural, and political centre of Colombia, it does not completely dominate a dependent interior like the capital cities of most Latin American countries. It is the home of the country's tire, chemical, and pharmaceutical industries and accounts for 50 percent of the country's industry in volume of sales, but its chief activities are commercial. Over 30 banks have their main branches in Bogotá, including the central bank, the Bank of the Republic. A stock exchange was established in 1928.

Government. In 1954 Bogotá was made a Special District for administrative purposes, while it remained the capital of the Department of Cundinamarca. Bogotá is governed by a mayor appointed by the governor of the department. The mayor chooses the municipal secretaries of government, treasury, and public works. Together, they carry out the laws and orders of a popularly elected municipal council. Bogotá is also the seat of the department's elected assembly. It is the site of the national capitol, and many government offices and agencies are located in the city.

The Bogotá Special District

Utilities, health, and safety. Although the growth of electric power and water supply in Bogotá has made prodigious increases in the last 20 years, it has still not been enough to keep up with the mushrooming population. Power has been rationed at various times since the 1960s, and temporary blackouts are not uncommon. A pipeline to bring Bogotá fresh water from the neighbouring Department of Boyacá was scheduled for completion in 1972.

Bogotá has several public and private hospitals and many outstanding clinics. All employers are required by law to supply free health care and free group life insurance for their employees.

Since 1961 all civil police units in Bogotá have been staffed by the national police. The city is also the headquarters for the Department of Administrative Security (DAS)—a national security investigation force. Bogotá has a volunteer fire department with selected neighbourhood substations.

Education. Education receives a high priority in Bogotá, although standards of quality are not uniform. There is a plentiful supply of private schools, most of which are distributed in the northern suburbs and many of which are run by religious orders. The number of public schoolrooms has been increasing, and the city's goal is to provide elementary and secondary education to anyone who seeks it.

Higher education

Of Bogotá's several excellent universities, the Academia Javeriana and the Universidad de Santo Tomas de Aquino held the standings of public universities as far back as the early 17th century.

The media. Bogotá has five morning and two evening newspapers, each representing one of the major political parties. There are numerous local radio stations and three television stations. Of the two government-owned television stations, one is used for classroom educational programs during the day and for adult education at night. All media are government controlled.

Recreation and culture. Beautiful, spacious parks adorn the city and its outskirts. The city is filled with motion-picture theatres, for movies are the most popular form of public entertainment. A prime attraction for Bogotanos and tourists are the tram and cable car that climb more than 1,800 feet to the church and shrine atop Monserrate. Soccer, bullfighting, and automobile, bicycle, and horse racing always draw enthusiastic spectators to scheduled events.

Traditional cultural institutions in Bogotá, aside from the universities, include the Botanical Institute, the National Conservatory of Music, the National Museum, the National Astronomical Observatory, National Library, and the Columbus Theater, a showcase for opera, ballets, and plays of national and foreign companies. In recent years the city has been enriched by the establishment of another excellent library, a planetarium, a museum of natural history, several modern art galleries, and the Gold Museum, which houses the world's largest collection of pre-Colombian gold objects.

BIBLIOGRAPHY. There are no existing books in print in English exclusively devoted to Bogotá. General sources of information with some information on the city include THOMAS E. WEIL *et al.*, *Area Handbook for Colombia*, issued by the U.S. Department of the Army, rev. ed. (1970), a thorough work with up-to-date statistics and information; C.H. HARING, *The Spanish Empire in America* (1963), a good treatment of the ecclesiastical and political development of Colombia during the colonial period; and R.H. DIX, *Colombia: The Political Dimensions of Change* (1967).

(J.Sa.)

Bohemia and Czechoslovakia, History of

Bohemia (Czech: Čechy; German: Böhmen) is a geographical and historical unit in central Europe, bounded on the south by Austria, on the west by Bavaria, on the north by Saxony, and on the east by Silesia and Moravia. It existed for many centuries as the largest and richest province of a kingdom of the same name. Its links with Moravia, established in the early Middle Ages, were closer than those with territories acquired by the kings of later days. In 1918 Bohemia was included in the Republic of Czechoslovakia as its westernmost province. Administrative divisions have never affected too deeply its structure and the life of its inhabitants. Natural boundaries following mountain ranges and other geographical features have usually coincided with the political frontier; attempts to split Bohemia or to reduce its size by annexation have never met with lasting success.

This article is divided into the following sections:

I. Bohemia to 1914

EARLY HISTORY

The prehistoric people north of the Middle Danube were of uncertain origin. The Boii, a Celtic people, left distinct marks of a fairly long stay, but its time cannot be firmly established. The Latin name of the country, from which its names in major Western languages are derived, is of Celtic origin. The Celtic population was supplanted by Germanic tribes. One of them, Marcomanni, inhabited Bohemia; others settled in adjacent territories. No outstanding event marked the Marcomanni departure.

Movements of ethnic groups

Archaeological discoveries and incidental references to Bohemia in written sources indicate that the movements of ethnic groups were not always abrupt and turbulent but that the new settlers began to enter the territory before the earlier inhabitants had left it. It can be assumed, therefore, that the Slavic people were coming in groups before the southward migration of the Germanic tribes. In the 6th century Bohemia and the neighbouring territories were inhabited by the Slavs.

While mountains and forests offered protection to Bohemia, the tribes in the lowlands north of the Danube and along its tributaries were hard pressed by the Avars of the Hungarian plains. Attempts to unite the related Slavic tribes for resisting the Avars were successful only when directed by such strong personalities as the Frankish merchant Samo, who gained control of a large territory in which at least part of Bohemia was included. His death in 658 ended the loosely knit state. A more auspicious era dawned after Charlemagne defeated the Avars in the late 8th century.

There followed a period of comparative security, in which the concentration of the Slavs into political organizations advanced more promisingly. Soon after 800 three areas emerged as potential centres: the lowlands along the Nitra River; the territory on both sides of the Lower Morava (German: March); and central Bohemia, inhabited by the tribe of the Czechs. In time, the Czechs, protected from foreign intruders, rose to a dominant position. Governed by rulers descended from the mythical plowman Přemysl and his consort Libuše, the Czechs brought much of Bohemia under their control before 800 but failed to defeat the tribes in the east and northeast. Apart from occasional disturbances, such as Charlemagne's invasions (805), the Czech domain was not exposed to war and devastation, and little of the life there came to the notice of clerics who were recording contemporary events in central Europe.

Unification of greater Moravia. The Moravian Basin, through which ran a trade route from the Baltic to the Adriatic, became the scene of lively activities by princes of unknown origin. The first of them, Mojmír I, probably began to rule after Charlemagne's death (814) and maintained friendly relations with Louis I the Pious. Around 833 Mojmír attached the Nitra region to his domain. His successor (after 846), Rostislav, consolidated the country and defended it successfully. His relations with the Eastern Frankish Empire (since 843 under Louis the German) were determined by political considerations and by the advance of Christianity into the Slavic areas. The bishoprics of Regensburg, Passau, and Salzburg competed in trying to convert the central European Slavs but achieved only limited success. The Archbishop of Salzburg consecrated a church at Nitra around 828. In 845 Regensburg baptized 14 chieftains from Bohemia. Mojmír's Moravia had apparently more frequent contacts with Passau than with Salzburg. Recent archaeological discoveries indicate that missionaries made noticeable progress before 860; stone churches were built as places of Christian worship at Mikulčice and elsewhere.

Competition of bishoprics

Religious conflicts. But Rostislav was dissatisfied with the Frankish clergy and asked the Byzantine emperor Michael III for Slavic-speaking preachers. A group of clerics headed by two brothers of Greek origin, Constantine and Methodius, arrived from Constantinople in 863. They not only preached in Slavic but also translated the sacred books into that language and used them in divine services. To Constantine is attributed the creation of the first Slavic alphabet (Glagolitic). After some two and a half years the two brothers journeyed to Rome. There Constantine entered a convent, taking the name of Cyril; he died in 869. Methodius received the Pope's sanction for his work in Moravia and in Pannonia, Moravia's southern neighbour. The two territories were organized as a province and connected with the ancient archbishopric of Sirmium, restored by the Pope. Methodius angered the Frankish clergy, who regarded his archdiocese as their missionary field. He was captured and imprisoned until 873; he then returned to Moravia and put himself under the protection of Rostislav's successor Svatopluk. But relations between the ruler and the Archbishop were not harmonious. After Svatopluk's conciliation with the Franks at Forchheim (874), clerics of the Latin rite appeared again in Moravia, interfering with the Archbishop's work. In 880 Methodius obtained from Pope John VIII a formal sanction of his work, including the Slavic liturgy.

Political expansion. Svatopluk distinguished himself in the conduct of political affairs. After the death of Louis the German (876), he acquired large territories with Slavic population. He annexed some and left local princes who recognized his suzerainty in others. Such was apparently the case of the Czech prince Bořivoj I. Propagation of Christianity followed Svatopluk's advances. According to legends, Bořivoj was baptized by Methodius and then admitted clerics of the Slavic rite to his principality. But, while the Archbishop was engaged in missionary work in the annexed territories, advocates of the Latin rite, headed by a Frankish cleric, Wiching, bishop of Nitra, strengthened their position in Moravia. During Methodius' lifetime the Slavic clergy had the upper hand; but after his death (885) Wiching banned Methodius' disciples from Moravia and most of them moved to Bulgaria. Pope Stephen V reversed his predecessor's policy and forbade the Slavic liturgy.

Svatopluk continued his policy of expansion for several more years. But soon after 890 he made the East Frankish king Arnulf his enemy. Arnulf's expedition into Moravia in 892 opened a period of troubles, which increased when Arnulf made an alliance with the Magyars of Hungary. Svatopluk's successor, Mojmír II, tried unsuccessfully to protect his patrimony; sometime in 905–908 greater Moravia ceased to exist as an independent country.

The Přemysl rulers of Bohemia (895–1306). The Prince of Bohemia made an accord with Arnulf (895) and warded off the danger of invasion. The domain over which the descendants of Přemysl ruled from the Prague castle was, in the early 10th century, the largest unit in Bohemia. The tribal chieftains who opposed centralistic tendencies exercised control over the eastern and northeastern districts, but the extent of their power is not known. The most powerful of them, the Slavníks residing at Libice, remained defiant until the end of the 10th century.

Bohemia maintained close relations with neighbouring Bavaria. Both countries were threatened for several decades by the Magyars, and other developments in their vicinity also affected political and social life. The most important of these was the rise in Germany of the Saxon dynasty, which began with Henry I the Fowler; the imperial coronation of Otto I, in Rome (962), marked the restitution of the Holy Roman Empire, with which Bohemia was linked, thereafter, for many centuries. Bohemia's reorientation toward the Saxon dynasty began under the grandson of Bořivoj, Prince Wenceslas (Václav, ruled 921–929); it was symbolized by the dedication of a stone church at the Prague castle to a Saxon saint, Vitus. Both Slavic and Latin legends praise Wenceslas as a fervent believer but tell little about his political activities. He was murdered by his younger brother Boleslav. The legends present the murder as an outburst against Wenceslas' devotion to the new faith, but the conspiracy probably had also a political motivation.

Restitution of the Holy Roman Empire

Boleslav I (ruled 929–967) reigned as a Christian prince; his daughter married Prince Mieszko I of Poland and helped spread the gospel in that country. Boleslav attempted, unsuccessfully, to loosen the ties with the Saxon dynasty. Boleslav II (ruled 967–999) used friendly relations with the Pope and the Emperor to enhance his prestige. He attached new territories east of Bohemia to his father's annexations. In 973 a bishopric was founded in Prague and subordinated to the Archbishop of Mainz. The first bishop, Thietmar, was from the Saxon land but knew the Slavic language; he was succeeded in 982 by Adalbert (Vojtěch), a member of the Slavník family. Adalbert's promotion can be viewed as an attempt to harmonize relations between the Prague and Slavník princes, but that result did not materialize. Legends hint that Adalbert encountered considerable opposition when attempting to raise the standards of religious life in his diocese, and tension between the rival dynasties showed no signs of abating. In 895 Boleslav II moved against the Slavníks and broke their power. Adalbert enjoyed some initial success among the heathen Prussians on the shores of the Baltic but then suffered a martyr's death in 997.

Annexation of Moravia. Struggles among the descendants of Boleslav II plagued the country for about 30 years and reduced considerably its power. Most of the territories attached to Bohemia in the 10th century were lost. Prince Břetislav I, a grandson of Boleslav II, led a successful expedition into Moravia; he conquered only a minor portion of the former greater Moravia, but it was large enough to constitute a province, and it was linked from then on indissolubly with Bohemia. But the ambitions of Břetislav, who ascended the throne in 1034, ran higher. He invaded Poland in 1039 with only temporary success; he incurred the indignation of the German king Henry III and was forced to evacuate the conquered territory and to make an oath of fealty (1041). In the latter part of his reign, Břetislav cooperated with Henry III, thus protecting his domain against armed intervention.

The entire territory of Bohemia and Moravia was regarded as a patrimony of the Přemysl House, and no emperor attempted to put a foreign prince of his own choice on the throne. But the ruling family grew large, and after Břetislav's death (1055) it became entangled in competition for primacy. For about 150 years the course of public life in Bohemia was largely determined by dissensions among the adult princes, some of whom ruled in portions of Moravia under Prague suzerainty. The emperors and the landowning magnates exploited the conflicts to promote their selfish interests. A main problem was the absence of any strict law of succession; the principle of seniority usually conflicted with the reigning prince's desire to secure the throne for his oldest son.

The territory's minor obligations toward the emperors was a handicap under weak princes or when the male members of the ruling family were at odds, but a strong prince could turn friendly relations with the empire to his advantage. Břetislav's second son, Vratislav II (ruled 1061–92), as a compensation for services rendered, obtained from Emperor Henry IV the title of King of Bohemia (1085). Another able ruler, Vladislav I, gained the dignity of a cupbearer to the Emperor (1114), one of the highest court offices; and as its holder the Prince of Bohemia became one of the electors who chose the Holy Roman Emperor. Vladislav II (ruled 1140–73) participated in the campaigns of Frederick I Barbarossa in Italy. He was named king and crowned by the Emperor at Milan in 1158.

Active participation in imperial policies and military campaigns reduced markedly the Czech's isolation, caused by Bohemia's geographical position. Other contacts were made with foreign merchants and by clerics from abroad or travelling from Bohemia to Rome and to famous shrines. By the early 11th century the Latin rite prevailed. Cosmas of Prague, who recorded in his chronicle the history of Bohemia to 1125, was an ardent supporter of the Latin liturgy. Western orientation of the hierarchy and of the monastic orders was documented by the prevalence of Romanesque architecture, of which notable examples could be found in Prague and in the residences of appanage princes (lesser members of the ruling family). In social stratification and in economy the country reached such a degree of consolidation that it withstood, without serious damage, struggles that ravaged it in the late 12th century.

Frederick I Barbarossa helped foment discord among Přemysl's descendants. In 1182 he reduced the dependence of Moravia on the Prague princes and subordinated that province to the imperial authority. In 1187 he exempted the Prague bishop, a member of the Přemysl family, from the jurisdiction of the ruling prince and made the bishopric an imperial fief. These decisions had no lasting significance, however, and the Přemysl patrimony survived. The period of trials closed with Frederick's death (1190). Frequent subsequent changes on the imperial throne lessened the danger of intervention. During the same period the Přemysl family was reduced to one branch, so that the problem of succession lost its pressing importance. In 1198 Přemysl Otakar I received the royal title for himself and his descendants from one of the competitors for the imperial crown. A solemn confirmation occurred in 1212, when Frederick II issued a charter known as the Golden Bull of Sicily, which regulated the relationship between Bohemia and the empire. The king's obligations were reduced to a minimum, but as elector he was able to exercise perceptible influence, ranking first among the temporal members of the college of electors.

The Golden Bull of Frederick II

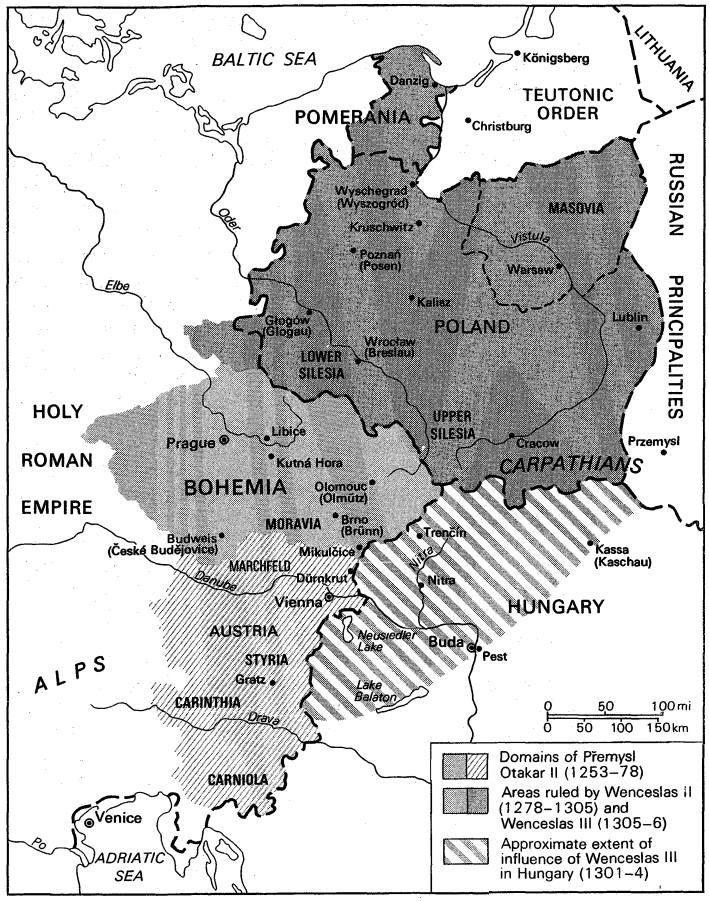
Political and economic growth. Under Otakar I and his successors, Bohemia moved from depression to political prominence and economic prosperity. The original socioeconomic structure was giving way to a more developed stratification. The clergy gained independence from temporal lords in 1221. The landowning class, made up of wealthy lords and less-propertied squires, claimed freedom in administering their domains and a more active role in public affairs. In the early 13th century the population of Bohemia and Moravia increased noticeably by immigration from overpopulated areas in

Germany. Many of the German-speaking newcomers were encouraged by the kings to found urban communities or to develop mining, especially of silver. The landowning magnates and the ecclesiastical institutions followed the royal example and settled the immigrants on their estates. There thus came into existence an urban middle class that enjoyed valuable privileges, especially the use of German law, and that became only slowly amalgamated with the native population. Apart from the townsfolk, German farmers moved into Bohemia and Moravia and transformed the less attractive border districts into prosperous areas. German immigration continued under Otakar I's successor, Wenceslas I (ruled 1230–53), and reached its peak under Přemysl Otakar II (ruled 1253–78). Bishop Bruno of Olomouc, in cooperation with the King, promoted colonization of large tracts in northern Moravia.

Otakar II was a strong and capable ruler who obtained possession of the Austrian lands through marriage and, in 1260, was invited by the nobility of Styria to become their lord. Personal bravery and financial resources facilitated his penetration into other Alpine provinces. Before his opponents could combine forces to check his advance, Přemysl Otakar II had exercised influence in Carinthia as well as in some territories along the Adriatic coast. His expansion aroused hostility of the kings of Hungary; but even more dangerous was Rudolf, count of Habsburg, who was elected king of the Romans in 1273 and, to get foothold in central Europe, claimed the Austrian lands as vacant fiefs of the empire. War followed and ended in Otakar's defeat in 1276. Unwilling to accept the loss of Austria as final, Otakar began a new campaign. Not only Rudolf's army but also Hungarian troops moved against the Czech forces, and a group of noblemen, mostly from southern Bohemia, sided with the enemy. Otakar was too weak to resist the unexpected coalition, and, on August 26, 1278, he lost, at Dürnkrut on the Marchfeld, both the battle and his life.

Otakar's only son, Wenceslas II (ruled 1278–1305), was too young to take over control immediately. During the period following Otakar's death (remembered as the evil years), Wenceslas was a mere puppet in the hands of ambitious lords; but in 1290 he emancipated himself from the tutelage and ruled with more success than had his father. The country was recovering quickly from both political and economic depression, and it again played an active role in international relations. Instead of resorting to wars, Wenceslas engaged in negotiations and soon achieved success in Upper Silesia. This was a prelude to his penetration into Poland, which culminated in 1300 with his coronation as its king. Diplomatic dexterity and enormous wealth quickly enhanced Wenceslas' prestige. In 1301 he was considered a candidate for the vacant throne of Hungary, but he recommended his son as a candidate instead. Meanwhile, the mines in various parts of the country, especially at Kutná Hora, yielded so much silver that the king was able to reform the monetary system and issue coins (grossus), which soon circulated within and outside his kingdom. But Wenceslas II's acquisitions were lost soon after his death; his son Wenceslas III took over Bohemia but was assassinated on his way to Poland (1306). Thus ended the long rule of the Přemysl family.

The end of the Přemysl dynasty



Přemyslid expansion under Přemysl Otakar II and his successors (1253–1306).

THE LATE MIDDLE AGES (1310–1526)

The Luxembourg dynasty (1310–1437). After a four-year struggle for the throne, the Bohemian magnates decided for John of Luxembourg, son of Henry VII, the king of the Romans. John, only 14, married Elizabeth (Eliška), the second daughter of Wenceslas II. John confirmed the freedoms that the Bohemian and Moravian nobles had usurped during the interregnum and pledged not to appoint aliens to high offices. But a group of advisers, headed by Archbishop Petr of Aspelt, followed John to Prague and endeavoured to uphold the royal authority. In the resulting conflict a powerful aristocratic faction scored a decisive victory in 1318. Its leader, Jindřich of Lípa, virtually ruled over Bohemia until his death in 1329. John found satisfaction in tournaments and military expeditions, and he attached to Bohemia some adjacent territories; the extension of suzerainty over the Silesian principalities was his most significant achievement. He was assisted late in his reign by his oldest son, Wenceslas, who was brought up at the French royal court, where he changed his name to Charles. Charles endeavoured to raise the prestige of the monarchy but was hindered by John's jealousy and by lack of cooperation among the nobility. In 1346 both John, then blind, and Charles joined the French in an expedition against the English. John fell at Crécy.

The reign of Charles I. John and Charles benefitted from friendly relations with the popes at Avignon. In 1344 Clement VI elevated the See of Prague and made Arnošt of Pardubice its first archbishop. Clement VI also promoted the election, in 1346, of Charles as the king of the Romans. In Bohemia, Charles ruled by hereditary right. To raise the prestige of the monarchy, he cooperated with the nobility and the hierarchy. He made Bohemia the cornerstone of his power and, by a series of charters (1348), settled relations between Bohemia, Moravia, and other portions of his patrimony. He acquired several territories in the vicinity at opportune times by purchase or other peaceful means. At the end of his reign, four incorporated provinces existed in union with Bohemia: Moravia, Silesia, and Upper and Lower Lusatias. Charles also confirmed earlier documents defining the position of Bohemia in relation to the empire. In 1355 he was crowned emperor in Rome as Charles IV. After consultation with the electors, Charles issued the Golden Bull, which readjusted the problems of the empire, especially the election of the emperor.

Coronation as Charles IV

Under Charles, Prague became headquarters of the imperial administration. By the foundation of a new district (*nové město*), Charles facilitated expansion of the city and a rapid increase in its population; about 30,000

persons lived there by the latter part of his reign. In 1348 he founded in Prague a university with four traditional divisions (theology, law, medicine, and liberal arts); its members were grouped into four nations (Bohemian, Bavarian, Saxon, and Silesian-Polish). Prague attracted scholars, architects, sculptors, and painters from France, Italy, and German lands; the most distinguished among them was the architect Petr Parléř (died 1399), a native of Swabia. The flourishing of the late Gothic architectural style left a deep mark on both the royal residence and the countryside. Under Charles, Bohemia was spared entanglements in war and reached a high level of prosperity, shared by the upper classes and the peasantry. Charles was anxious to save the power and possessions accumulated since 1346. He succeeded in getting his son Wenceslas crowned king of the Romans in 1376. He also made provisions for dividing the Luxembourg patrimony, with the understanding that its male members would respect Wenceslas as their head. After Charles's death (1378) a smooth transition to Wenceslas' reign appeared to be assured. The country mourned Charles as "the father of the country."

Opposition to Wenceslas IV. His heir began to rule, without opposition, as Wenceslas IV. Though not without talents, he lacked his father's tenacity and skill in arranging compromise, and in less than a decade the delicate balance between the throne, the nobility, and hierarchy was upset. In a conflict with the church, represented by Archbishop Jan of Jenštein, the King achieved temporary success; the Archbishop resigned and died in Rome (1400). The nobility's dissatisfaction with Wenceslas' regime was serious, mainly over the selection of candidates for high offices, which wealthy families regarded as their domain and to which Wenceslas preferred to appoint gentry or even commoners. The struggle was complicated by the participation of other Luxembourg princes, especially Wenceslas' younger brother Sigismund. The nobles twice captured the King and released him after promises of concessions. But Wenceslas never took his pledges seriously and the conflict continued. Simultaneously with the troubles in Bohemia, discontent with Wenceslas was growing in Germany. In 1400 the opposition closed ranks; the Electors deposed Wenceslas and elected Rupert of the Palatinate as emperor.

Religious reform movement. The turn of the century was a watershed in reform endeavours in Bohemia. The movement arose around 1360 from various causes, one of which was the uneven distribution of the enormous wealth accumulated by the church in a comparatively short time. Moral corruption infected a large percentage of the clergy and spread also among the laity. Prague, with its large number of clerics, suffered more than the countryside. Both the King and the Archbishop showed favours to zealous preachers like Conrad Waldhauser and Jan Milíč of Kroměříž, but exhortations from the pulpit failed to turn the tide. The Great Schism in Western Christendom after 1378 weakened the central authority. Disharmony between Wenceslas and Jan of Jenštein, archbishop of Prague, hindered the application of effective remedies. In the late 14th century the reform movement was centred at Chapel Bethlehem (Betlémské Kapli); its benefactors stressed preaching in Czech as the main duty of its rector.

Appointment of Jan Hus to Bethlehem

The second, more dramatic, period of the reform movement began with the appointment in 1402 of Jan Hus to the Bethlehem pulpit. A scholar, he combined preaching in Bethlehem with academic activities and thus was able to reach the Czech-speaking masses and to group around himself scholars and students dedicated to the idea of reform. The university was split, because foreign members followed the conservative line. Another cause of division was the popularity of John Wycliffe, an English ecclesiastical reformer, among the Czech masters and students. Hus did not follow Wycliffe slavishly but shared with him the conviction that the Western church had deviated from its original course and was in urgent need of reform. Hus enjoyed the goodwill of Archbishop Zbyněk Zajíc of Hazmburk. But the atmosphere in Prague deteriorated rapidly; the German members of the university allied with Czech conservative prelates, led by Jan Železný ("the Iron"), bishop of Litomyšl. Because Wenceslas favoured the reform party, its opponents pinned hopes on Sigismund, king of Hungary; Wenceslas was childless, and Sigismund had a fair chance of inheriting Bohemia.

In the winter of 1408–09, a strong group of cardinals convened a general council at Pisa, which deposed the two rival popes and elected Alexander V to fill the vacancy. Wenceslas sympathized with the cardinals and invited the university to join him. When the Germans did not respond favourably, he issued, in January 1409 at Kutná Hora (Kuttenberg), a decree reversing the traditional distribution of votes. Thereafter, the three "foreign" nations had one vote and the Bohemian nation had three. The Germans rejected the decree and moved to Leipzig, where some of them unleashed a polemical campaign attributing to Hus more influence on the King than he actually had and depicting him as the chief champion of Wycliffe's ideas. Meanwhile, Alexander V issued a bull virtually outlawing Hus's sermons in Bethlehem and authorizing rigid measures against discussion of Wycliffe's ideas. Hus and his collaborators continued their activities. Neither Wenceslas nor any of the Czech prelates were experienced enough to achieve reconciliation between the church authorities and the reform party, and Bohemia was drawn into a sharp conflict. In 1412 Pope John XXIII became involved in a war with the King of Naples and offered indulgences for contributions to the papal treasury. When Hus and his friends attacked the questionable practices of papal collectors in Prague, John put Prague under interdict. Hus, hit by the sentence of excommunication, left Prague and moved to the countryside under the protection of benevolent lords.

In 1414 the Pope, acting in harmony with Sigismund, since 1411 the king of the Romans, called a general council to Constance. Hus went there hoping to defend himself against accusations of heresy and disobedience. A safe conduct from Sigismund did not protect him in Constance. Late in November he was imprisoned and was kept there even after the Pope, who had lost control of the council, had fled and been condemned by the cardinals. In the spring of 1415, Hus was called three times before the council to hear charges, supported by depositions of the witnesses and by excerpts from his own writing. The council paid no attention to Hus's protests that many of the charges were exaggerated or false. Hus refused to sign a formula of abjuration; he was then condemned and handed over to temporal authorities for execution. He was burned at the stake on July 6.

Execution of Hus

Some scholars reduced to a small number the points on which Hus had deviated from the official doctrine. But his followers, not interested in doctrinal subtleties, reacted emotionally against the council, Sigismund, and the conservative clergy. A wave of indignations swept over Bohemia and Moravia, and this movement, taking the name Hussite from the martyred leader, grew rapidly. A letter of protest, signed by 452 members of the nobility, was dispatched to Constance in September 1415. The condemnation and burning of Hus's friend Jerome of Prague (May 1416) increased the discontent.

Hus had not evolved a system of doctrine nor had he designated his successor. The most faithful of his disciples, Jakoubek of Stříbro, was not strong enough to keep the movement under his control. Ideological differentiation set in and resulted in divisions and polemics. The moderate Utraquists were entrenched in Prague; the radicals came mostly from smaller boroughs and the countryside. The Germans in Bohemia and in the incorporated provinces remained faithful to the church, and, thus, the deep-seated ethnic antagonism was accentuated.

Struggle between Sigismund and the Hussites. After the death of Wenceslas IV (1419), political issues gained in importance. The Hussites were resolutely opposed to Sigismund, but the Czech Catholics and the Germans were willing to recognize him. Sigismund, determined to break the Hussite opposition, initiated a period of bitter struggles that lasted more than ten years. Sigismund had

the support of opponents of Hussitism within the kingdom, of many German princes, and of the papacy. Invasions of Bohemia assumed the character of crusades but were pushed back by the Hussites, who pulled together in time of danger.

The moderate Utraquists and the radicals reached agreement on the fundamental articles of their faith. The radicals built themselves a centre, given the biblical name Tábor. The accord, concluded in 1420 in the nation's capital, became known as the Four Articles of Prague; it stressed that: (1) the word of God should be preached freely; (2) the communion should be administered in both kinds to clerics and laymen; (3) worldly possessions of the clergy should be abolished; (4) public sins should be exposed and punished. A wide range of disagreements between Prague and Tábor was left open and often resulted in mutual accusations and embitterment. A third party arose in northeastern Bohemia, around a newly founded centre at Oreb, but it had a much smaller following than either Prague or Tábor.

Meetings were held at which attempts were made to give the country a national government; the most significant was an assembly at Čáslav (June 1421). A regency council was set up, but it lacked sufficient authority; and the virtual master of the country was the leader of the "warriors of God," Jan Žižka. He was originally attached to Tábor, but he became disgusted with the endless disputes of its theologians and left the radical stronghold to organize a military brotherhood in northeastern Bohemia (1422); its members became so devoted to Žižka that after his death (1424) they called themselves Orphans.

Žižka strove tenaciously for two goals—the protection of Bohemia from Sigismund and the suppression of the enemies of the law of God within Bohemia and Moravia. He scored brilliant victories in battles against Sigismund's forces but could not unite the country under his banner. A Catholic minority, stronger in Moravia than in Bohemia, resisted the overtures of the Hussite theologians and Žižka's attacks. After Žižka's death, his heirs, headed by Prokop Holý the Shaven, lost interest in protracted warfare with Catholic lords and undertook instead foraging raids into the German territories bordering on Bohemia. But, whenever a crusade menaced Bohemia, the radical military brotherhoods joined the conservative forces to push back the invader. The last encounter at Domažlice was bloodless; the crusaders fled in panic upon hearing of the Hussite strength.

Meanwhile, a general council of the church met at Basel in 1431 and determined to find a peaceful settlement. At a conference at Cheb (1432), the delegates from Basel and Hussite spokesmen resolved that in controversial matters "the law of God, the practice of Christ, of the apostles and of the primitive church" would be used to determine which party holds the truth. The Hussite envoys reached Basel and opened debate on the cardinal points of their doctrine. It soon became clear, however, that the council was unwilling to abide by the Cheb agreement and that theologians representing the Tábor and Orphan brotherhoods would not acquiesce to a lean compromise. A drastic change occurred in Bohemia in 1434. In a fratricidal battle at Lipany in May, combined Catholic and Utraquist forces defeated the radicals and took over the control of the country. Under the leadership of Jan Rokycana, dealings with the council advanced markedly. The final agreement came to be known as the Compacts (Compactata); it followed the Four Articles of Prague but weakened them with subtle clauses (*e.g.*, the council granted the Czechs the communion in both kinds but under vaguely defined conditions). After the promulgation of the Compacts (July 1436), an agreement followed with Sigismund. But he died in 1437, and Bohemia was neither united in religion nor consolidated politically.

The Compacts

Various forces hindered religious pacification. The Catholic clergy refused to respect the Compacts, because they were not sanctioned by the pope, and would not accept Rokycana as archbishop. The radical parties, although gravely weakened at Lipany, existed as an uncompromising opposition in Rokycana's rear. His bid for recognition was also defied by the right Utraquist wing, which had seized the key positions during Sigismund's brief reign.

The Hussite preponderance (1437–71). Sigismund had no son, and the problem of succession caused a split among the nobility, which had been enriched during the revolutionary era by the secularization of church properties and had grown accustomed to the absence of monarchy. The conservatives accepted Sigismund's son-in-law Albert II of Austria, but the more resolute Hussites favoured a Polish candidate. Albert's death in 1439 ushered in another interregnum. In January 1440 an assembly was held to set up provincial administration for Bohemia; its composition demonstrated clearly the steady rise in the importance of the wealthy lords, functioning as the first estates. The lesser nobility, recognized as the second estate, was numerous; although the percentage of Catholics among the lords was rather high, the second estate was predominantly Hussite and conscious of its contributions to the Hussite defense. The upper classes recognized the royal boroughs as the third estate but were more and more reluctant to share power with them. In the January assembly the political alignments were not identical with religious divisions. Some moderate Catholics cooperated with the Utraquist majority, headed by Hynek Ptáček of Pirkštejn; a group of conservative Utraquists joined the Catholic lords, among whom Oldřich of Rožmberk held the primacy. The actual leader of the conservative bloc was Menhart of Hradec, nominally an Utraquist. No one was elected governor of Bohemia. Instead, in the counties into which Bohemia was subdivided, leagues were organized to promote cooperation of local lords, knights, and royal boroughs, irrespective of religious orientation.

The problem of succession became urgent when Albert's widow, Elizabeth, gave birth to a boy, baptized Ladislas and called Ladislas Posthumus. Several foreign princes showed an interest in the throne, but in 1443 the estates recognized Ladislas' claims. As he resided at the court of his guardian the German king Frederick III, the interregnum was extended. Ptáček, who headed the majority, died in 1444, and the party acclaimed George of Poděbrady as its leader. For several years the destinies of Bohemia were determined by efforts of Oldřich of Rožmberk and his allies to obstruct George's endeavours. Apart from political and economic stabilization, George strove for a papal sanction of the Compacts and for the confirmation of Rokycana as archbishop. George realized that Menhart's domination of Prague was a more serious obstacle than Rožmberk's intrigues; in 1448 George attacked and took Prague without bloodshed. Rokycana also entered the city and took over from the archconservatives, the Utraquist (or Lower) consistory. Although Frederick III was of the same religion as Rožmberk, he realized that an alliance with George would improve Ladislas' chances; in 1451 Frederick designated George as governor of Bohemia. From that position of strength, George moved energetically against both the Rožmberk coterie and the remnants of the radicals, entrenched at Tábor.

In October 1453 Ladislas was crowned king in the Church of St. Vitus, and George served as his chief adviser. Ladislas had been brought up as a Catholic, and German was his mother tongue. George hoped the King could re-establish Bohemia's connection with the incorporated provinces, especially the populous and rich Silesia. Ladislas died suddenly in November 1457. Several foreign princes competed for the throne, but the estates of Bohemia reaffirmed the elective principle and decided unanimously for George (March 1458).

Election of George of Poděbrady

Although attached to the Utraquist party, George endeavoured to rule as a king of "two peoples": the Utraquists and the Catholics; the Czechs and the Germans. He was anxious to be crowned according to the rites prescribed by Charles IV. George's son-in-law, King Matthias of Hungary, sent two bishops to Prague; George took a secret oath in their presence, by which he obliged himself to defend the true faith and to lead his people

from errors, sects, and heresies. Because the Compacts were not mentioned, George did not hesitate to make his pledge; since the agreement with the Council of Basel, the Utraquists considered the communion in both kinds as a lawful concession and not a heresy. Because both the election and coronation took place in Prague, George's principal concern was to have his title recognized by the estates of the incorporated provinces. He was mostly successful, but he had to accept the friendly help of papal envoys to get at least a provisional recognition by the Catholic and predominantly German city of Breslau (Wrocław) in Silesia (1459). During the next three years George enhanced his prestige both at home and abroad. Feeling that no lasting peace could be achieved without the speedy settlement of religious issues, George attempted in 1462 to have the Compacts sanctioned by Pope Pius II. Instead of approving the Compacts, the Pope declared them null and void. When informed of the Pope's action, George held a solemn assembly in Prague in August and affirmed his devotion to the communion in both kinds. Although neither the Pope nor the King showed any intention of retreating from his position, armed conflict was not inevitable, and several princes, including Frederick III, were willing to use their influence to arrange a compromise. But the new pope, Paul II, was elected in 1464 and soon adopted an aggressive policy that encouraged George's foes, especially the city of Breslau. A group of Catholic noblemen from Bohemia, headed by Zdeněk of Šternberk, formed a hostile league at Zelená Hora (1465) and entered into negotiations with Breslau and other Catholic centres. Shortly before Christmas 1466 the Pope excommunicated George and released his Catholic subjects from their oath of allegiance. In spring 1467 George's troops attacked the rebel forces. George was, on the whole, successful in desultory campaigns against the castles of the insurgents, but his position became more awkward in the spring of 1468 when Matthias of Hungary brought support to the Czech rebels. The Hungarians invaded Moravia and, by tying down a considerable portion of the royal army, they facilitated rebel successes in other parts of the kingdom. In May 1469 the opposition proclaimed Matthias king of Bohemia. In 1470 George achieved some successes over his rivals, but he was unable to consolidate them because of deteriorating health. He died on March 22, 1471, mourned both by the Utraquists and loyal Catholics.

Rejection of Compacts by the Pope

The Jagiellonian kings (1471–1526). Emperor Frederick III had observed benevolent neutrality. And George had also derived comfort from the friendly disposition of Casimir IV, the Jagiellonian king of Poland. Contacts with the Polish court continued after George's death and resulted, in May 1471, in the election of Casimir's son, known in Bohemia as Vladislav II, as king of Bohemia. Vladislav was supported by George's partisans irrespective of religious affiliation. George's foes adhered to Matthias, who possessed Moravia, Silesia, and the Lusatias. Vladislav's forces were not strong enough to defeat the rival, and an agreement concluded in 1478 enabled Vladislav to consolidate his position in Bohemia but left Matthias in temporary possession of the incorporated provinces. After Matthias' death (1490) Vladislav was elected king of Hungary (as Ulászló II); thus, he was able to reunite the incorporated provinces with Bohemia. Vladislav's successor was his only son, Louis, a sickly boy of 9 at his father's death.

Decline of royal authority

The reign of the two Jagiellonians was marked by a decline of royal authority. Vladislav II had been brought up as a Catholic and made no secret of his dislike of the Utraquist rites. But by his coronation oath he obligated himself to respect the Compacts. As long as Matthias was alive, Vladislav was supported chiefly by the Utraquists. After 1490 he spent more time in Hungary than in Bohemia, as did Louis. In this latter period the Catholic lords attached themselves to the royal court and exercised strong influence on public affairs of Bohemia.

The Jagiellonian era, when compared with the times of stronger monarchs, appears to have been an unbroken chain of aristocratic feuds and rivalries in which personal ambitions triumphed over patriotic sentiments, but a closer examination reveals brighter spots and concrete examples of constructive cooperation. The king stood aloof, and the Catholic and Utraquist factions of the estates concluded an agreement at Kutná Hora (March 1485) that reaffirmed the Compacts, recognized the existing divisions in Bohemia, and forbade attempts by either party to extend its sphere of influence at the expense of the other. The accord lasted until 1516 but was renewed in 1512 as "of perpetual duration." The Unity of the Czech Brethren, which had come into existence in 1457–58 as a new expression of Hussite rigourism, was not granted legal protection. In 1508 Vladislav II issued a stern decree, ordering persecution of the Unity, but it was not applied too rigidly.

The provincial diet rather than the royal court held primacy under the Jagiellonians, especially when the kings resided at Buda. The lords dominated the diet and were supported by the lesser nobility when attempting to limit royal power or when introducing restrictive measures against the lower classes. Both the mighty lords and the less propertied knights viewed with displeasure the political aspirations of the royal boroughs, their competitors in commerce and production. The diets passed several resolutions to remove the third estate from the positions acquired during the Hussite revolution. Because the boroughs obtained little help from the sovereign and his officers, the nobility encountered little resistance. A land ordinance adopted by the diet in 1500 limited considerably participation of the boroughs in the diet. The boroughs were also hit by several decrees, approved by the diet (especially those of 1487 and 1497), by which the landowners attached the peasantry to their estates. They thus reduced the possibility of migration into the towns and deprived the towns of cheap labour.

The boroughs, prosperous and self-confident, resisted the limitations and sought allies wherever they could be found. They obtained some concessions under Vladislav II, but a general compromise was made by the diet held in 1517 by which the boroughs joined concessions in political and administrative matters and surrendered some of the earlier privileges on which their economic prosperity was based. The higher estates tacitly recognized the right of the royal boroughs to participate in the diet as the third estate but reserved for themselves the positions on the board of provincial officers, including that of the vice chamberlain, who, in the king's name, supervised municipal administration. Although the boroughs gained some reasonable satisfaction, the landowning nobility was permitted to engage in production of articles that were previously the monopoly of the royal boroughs.

Compromise between the nobles and the boroughs

The agreement of 1517 did not end feuds and conflicts among the aristocratic factions and their partisans in the lower classes. In 1522 King Louis I left Hungary for Prague, intending to heighten the royal authority. With the help of loyal lords, in February 1523, he relieved Zdeněk Lev of Rožmitál of the office of supreme burgrave and appointed Karel of Minstrberk, a grandson of George of Poděbrady, to that key position in provincial administration. But, soon after the King's departure, Rožmitál resumed political activity and searched for allies. Religious controversies that flared up soon after Luther's attack on indulgences (October 1517) increased tensions in Bohemia. Rožmitál posing as a staunch supporter of the old faith, ingratiated himself with the King and regained his office. Louis, fully occupied with Hungarian affairs, was preparing for a campaign against the Turks. Meeting the Sultan's army with inadequate forces, Louis was defeated; he drowned in the marshes near Mohács while retreating from the battlefield (August 29, 1526).

HABSBURG RULE (1526–1914)

The Habsburgs to 1848. Ferdinand I of Habsburg, the husband of Louis' sister Anne, presented his claims to the vacant throne. He made substantial concessions to the Bohemian magnates and was elected king in October 1526; the coronation took place in February 1527. Fer-

dinand ruled also in other countries and, beginning in 1531, he assisted his brother, the emperor Charles V, in imperial affairs. After Charles's resignation (1558) Ferdinand was elected emperor. He considered Bohemia his most precious possession.

The dynasty and the estates (1526–1620). Early in his reign, Ferdinand was frequently absent; but, when in Bohemia, he endeavoured to dilute his precoronation pledges and curtail the privileges of the estates. He was obliged by the coronation oath to observe the Compacts and to treat the Utraquists as equal with the Catholics. But since 1517 Bohemia had been open to ideas emanating from Wittenberg and other Reformation centres. Lutheranism had adherents among the Utraquists and among the German-speaking inhabitants of Bohemia and Moravia. The Unity of the Czech Brethren resisted successfully repeated attempts at its extermination; although not protected by the Compacts, the Unity increased in numbers and was shielded by sympathetic landowners, some of whom became members. The teachings of radical reformers also had echoes in Ferdinand's domains.

An opportunity to settle controversial problems arose in 1547. During the Schmalkaldic War (1546–47), between the Habsburgs and the Protestant Schmalkaldic League, the estates of Bohemia pursued an inconsistent policy, and, after the Habsburg victory at Mühlberg (April 1547), Ferdinand moved quickly against them. The high nobility and the knights suffered comparatively mild losses. But the royal boroughs virtually lost their political power and were subordinated more rigidly to the royal chamber. Another target of the King's wrath was the Unity; significantly, Ferdinand's vindictive policy did not apply to Moravia, the estates of which were more cooperative during the Schmalkaldic War than those of Bohemia. After 1547 the Unity flourished in Moravia; its members, driven from Bohemia, moved to Moravia or emigrated to Poland.

Ferdinand's moves against the Bohemian estates

The Diet of 1549 approved Ferdinand's request that his firstborn son, Maximilian, be accepted as the future king. Ferdinand also resumed his scheme of religious reunion on the basis of the Compacts, but he soon realized that few Utraquists adhered to that outdated document. The majority, called Neo-Utraquists by modern historians, professed Lutheran tenets as formulated by Martin Luther's associate, Philipp Melanchthon. Disheartened by the meagre results of his policy, Ferdinand turned toward the Catholic party to consolidate its organization. He introduced the newly founded and militant Society of Jesus into Bohemia (1556) and obtained from Rome consecration of Antonín Brus of Mohelnice as archbishop (1561). Shortly before his death, Ferdinand succeeded in getting from Pius IV a sanction of the communion in both kinds, but the Pope insisted on so many restrictions that his bull satisfied only the Utraquist extreme right.

Maximilian II (ruled 1564–76) was reluctant to grant free exercise of the Lutheran faith, which the majority of the estates requested in 1571. After several years of futile efforts, the estates adopted a more flexible policy. Both the Czech Neo-Utraquists and the German-speaking Lutherans came together and prepared a summary of their faith, known as the Bohemian Confession; it agreed in the main points with the Augsburg Confession. The Brethren cooperated with the adherents of the Bohemian Confession but preserved both their doctrine and their organization. In 1575 Maximilian II approved the Bohemian Confession, but only orally; it was commonly assumed that his oldest son, Rudolf, who was present in the session, would respect his father's pledge.

The early stage of Rudolf II's (ruled 1576–1612) long reign was simply an extension of Maximilian's regime. But in 1583 Rudolf transferred his court from Vienna to Prague, bringing with him the high offices and foreign envoys; the Bohemian capital became once more an imperial residence and a lively political and cultural centre. Rudolf, brought up in Spain, had sympathy only for the Roman Catholic faith. Because the crown possessions were too small to yield adequate income, he depended mostly on the estates, whose majority was Protestant; only the provincial diets had the power to approve increased taxation and to grant subsidies for interminable wars against the Turks. The Catholic party, stronger among the lords than among the lesser nobility and burghers, came under the influence of militant elements, trained in Jesuit schools, and listened attentively to the papal nuncios and Spanish ambassadors. Because of its long antipapal tradition and its political prominence, Bohemia had an important place in the strategy of the Counter-Reformation. The Catholics singled out the Unity as their first target. Although numerically weak, the Brethren exercised a strong influence on Czech religious life and developed lively literary activities (in Rudolf's reign they produced a translation of the Bible from the original languages, which was printed in a hamlet of Kralice on the domains of the lords of Žerotín and which came to be known as the Kralice Bible). The Catholics sought to create a breach between the majority party of the Bohemian Confession and the Unity.

The Counter-Reformation in Bohemia

By a succession of new appointments, Catholic radicals around 1600 occupied the key positions in the provincial administration of Bohemia; their head, Zdeněk Vojtěch of Lobkovice, served as the supreme chancellor and enjoyed Rudolf's confidence. In 1602 Rudolf issued a rigid decree against the Unity, which was enforced not only in the royal boroughs but also on the domains of fervent Catholic lords. The Brethren and also the more resolute adherents of the Bohemian Confession realized that the days of peaceful coexistence were gone. They closed ranks under the leadership of Václav Budovec of Budov, a prominent member of the Unity. Dissatisfaction with Rudolf's regime was growing rapidly in other Habsburg domains. His younger brother, Matthias, made contacts with the Austrian and Hungarian opposition; the Moravian estates, headed by Karel the Elder of Žerotín, joined Matthias. In 1608 rebel forces advanced to Bohemia; Rudolf was unable to resist them, and he made peace and transferred to Matthias the dissatisfied provinces. The Protestant estates of Bohemia used Rudolf's weakness for their purposes. Although reluctant, Rudolf issued, in July 1609, a charter, known as *Majestát* (Letter of Majesty), that granted freedom of worship to the Catholics and to the party of the Bohemian Confession, with which the Brethren closely cooperated. Some passages of the charter were vague, and so the Protestant and Catholic estates concluded an agreement, stipulating that future conflicts should be settled by negotiation. The Catholic radicals, too weak to upset the agreement, were unwilling to accept the *Majestát* as the final word in religious controversies.

In 1611 Rudolf was deposed, and Matthias was crowned king of Bohemia. Because he was childless, the question of succession was debated both in the court circles and among the estates. In 1617 Matthias presented his nephew Ferdinand of Styria to the Diet of Bohemia as his successor. The resolute faction among the Protestant nobility was caught unprepared and acquiesced in Ferdinand's candidacy; he was accepted and crowned in the Church of St. Vitus. Opposition grew quickly to Ferdinand, who was suspected of cooperation with the irreconcilable opponents of the *Majestát.* In the spring of 1618 the Protestant estates decided on an action. Two governors of Bohemia, William Slavata and Jaroslav Martinic, were accused of violation of the *Majestát;* after an improvised trial they were thrown from a window of the Royal Chancellery (May 23, 1618) but escaped with minor injuries. The act of violence, usually referred to as the Defenestration of Prague, sparked a rebellion in Bohemia. The estates replaced the board, or royal governors, with 30 directors, who assembled troops for defensive purposes and gained allies in the predominantly Lutheran Silesia and in the Lusatias; the estates of Moravia were reluctant to join. The death of Matthias (March 1619) changed the situation profoundly. The directors refused to admit Ferdinand II into Bohemia. In Moravia the militant Protestant party overthrew the provincial government, elected 30 directors, and made an accord with Bohemia. At a general assembly of representatives of all five provinces, a decision was made to form a federal system. Ferdinand II was deposed, and

The Defenestration of Prague

Frederick V, elector of the Rhine Palatinate, a son-in-law of James I, king of England and Scotland, was offered the crown. He accepted and early in November 1619 was crowned king according to an improvised Protestant rite. Frederick's chances for success were slight; the population of Bohemia, especially the peasantry, was unenthusiastic in its support of the rebellion. Frederick received some financial help from the Netherlands, but German Protestant princes hesitated to become involved in a conflict with the Habsburgs, among whose allies were not only Catholic Bavaria but also Lutheran Saxony. In late summer 1620 Maximilian I of Bavaria coordinated the Catholic forces; although short, the battle on the White Mountain, at the gates of Prague (November 8, 1620), had a decisive effect and delivered Bohemia to Ferdinand II. Frederick and his chief advisers fled from Bohemia. Fighting continued in 1621 at some isolated places and in Moravia, but no one succeeded in pushing back Ferdinand's troops.

In imposing penalties Ferdinand treated Bohemia more harshly than the incorporated provinces. On June 21, 1621, 27 leaders (three lords, seven knights, and 17 burghers) were executed. Landowners who had participated in any manner in the rebellion had much of their property confiscated. The upper estates and the royal boroughs were ruined; they ceased to function as centres of economic and cultural activities. Ferdinand rescinded the *Majestát* and declared his intention to promote the program of re-Catholicization of Bohemia and Moravia. The Society of Jesus, banned in 1618 by the directors, returned triumphantly and acted as the vanguard in the systematic drive against the non-Catholics, including the moderate Utraquists.

Under absolutist rule (1627–1848). In 1627 Ferdinand II promulgated the Renewed Land Ordinance, a collection of basic laws for Bohemia that remained valid, with some modifications, until 1848; he issued a similar document for Moravia in 1628. Ferdinand settled, in favour of his dynasty, issues that had disturbed Bohemian public life since 1526: the kingdom was declared hereditary in both the male and female branches; the king had the right to appoint supreme officers; in the provincial diet the higher clergy was constituted as the first estate, and all the royal boroughs were represented by one delegate only; the diet lost legislative initiative and could meet only upon the king's authorization to approve his requests for taxes and other financial subsidies; the king could admit foreigners to permanent residence; the use of German besides the traditional Czech was authorized. No faith other than Roman Catholicism was permitted.

Royal decrees pertaining to religion granted the upper classes the right to choose either conversion or emigration. A rather high percentage decided for the latter and settled abroad, mostly in Saxony. Many peasants left the country illegally, especially during the Protestant invasions of Bohemia. The Czech's most significant representative abroad came to be a scholar, John Amos Comenius. The majority of the population remained in the homeland and gradually converted to the Roman faith.

Conversion of the Czechs to the Roman faith

The Jesuits became the most important force in Czech spiritual life. Their leading school, the Clementinum, was, in 1654, united with the remnants of the ancient Charles University. The Jesuits controlled not only higher education but also literary production. With an increasing number of Czech novices, the Society could reach the common people, whose majority spoke only the Czech language.

The vacated places among the upper social classes were gradually filled by newcomers, most of whom obtained land as a compensation for services rendered to Ferdinand II and his successor, Ferdinand III (ruled 1637–57); some enterprising individuals purchased land in Bohemia either during or after the Thirty Years' War (1618–48). The old families and the newcomers had in common their attachment to the Roman church and to the dynasty; they intermarried and became amalgamated over the next several decades. German became the language in which public affairs were transacted. But language was not the only barrier separating the peasantry and lower middle class from the propertied noblemen and burghers. Both the victorious church and the wealthy laymen regarded the Baroque style as the most faithful expression of their religious convictions and their worldly ambitions. For about 100 years, the Baroque dominated in architecture, sculpture, and painting and influenced literature, drama, and music. The external appearance of Prague and the smaller boroughs and towns changed markedly. In the countryside sumptuous aristocratic residences contrasted sharply with the modest dwellings of the peasantry.

Leopold I (ruled 1657–1705) soon became involved in long and costly wars against the Turks and the French. Although Bohemia was not threatened by either of his enemies, its population had to share the financial burdens; the landed nobility was reluctant to accept financial obligation, so the major part of the contributions was expected to come from the burghers and the peasants. The urban communities, which had been impoverished during the Thirty Years' War, made no progress toward social and economic recovery. The lot of the peasantry was so heavy that risings occasionally flared up, though with no chance of success. For the common people the short reign of Joseph I (ruled 1705–11) brought some relief, but under his brother and successor, Charles VI (ruled 1711–40), their plight reached appalling dimensions. The court and the residences of the ranking aristocrats consumed vast sums of money, which had to be squeezed from the depopulated towns and poorly managed domains. At this time, alienation of the masses of people reached its apex.

Retention of autonomy under Habsburgs

The Habsburgs, ruling over Bohemia from 1620 to 1740, did not insist on its close union with their other domains. The kingdom of Bohemia, though under an absolutist regime, retained its autonomy. The two Lusatias were ceded in 1635 to Saxony; Bohemia, Moravia, and Silesia retained their provincial administration. Members of the local nobility were appointed to high offices. The supreme chancellor of Bohemia served as a link between the kingdom and the sovereign and resided in Vienna to facilitate communication with the court and various central agencies attached to it.

Most of the reforms of Charles's daughter Maria Theresa (ruled 1740–80), although motivated primarily by dynastic interests, improved the living conditions of the population. Soon after her accession Bavaria and Prussia invaded the Habsburg territories. Charles Albert, elector of Bavaria, occupied a major part of Bohemia and was acclaimed king by a fairly strong party among the estates; but he could not establish himself permanently, and in 1742 he pulled his forces back. Three wars fought against Frederick II the Great of Prussia in 1741–63, mostly in Bohemia and Moravia, were more serious and costly; finally, Maria Theresa acquiesced in the loss of the major part of Silesia. Small duchies that she was able to retain were constituted as a crown land of Silesia and remained closely connected with Moravia and Bohemia.

Realizing that the system inherited from Charles VI was the main source of weakness, Maria Theresa launched a program of administrative reforms (1749); its principal point was a closer union of the Bohemian crown land with the Alpine provinces. The Queen's staunchest opponents were members of the landowning nobility who, up to that time, had controlled the provincial administration. In 1763 Maria Theresa made some concessions but would not abandon her centralistic policy. The opposition did not remain united. The conservative faction remained unreconciled to the new course, but more flexible individuals accepted high positions in Vienna or in the provincial capitals and helped to build up the system, which Joseph II (ruled 1780–90) inherited from his mother and subordinated more rigidly to the sovereign's will and discretion.

Maria Theresa, partly under the influence of her husband, Francis Stephen of Lorraine, had adopted the idea of curtailing the privileges of the upper social classes so as not to conflict with the interest of the state, of which the ruler was the supreme representative. Joseph II had grown up in this enlightened atmosphere, and, when con-

fronted with conservative opposition as king, he went far beyond his mother's limits. Apart from the administrative reforms, the judicial and fiscal systems were revamped to serve the enlightened monarch more adequately. The state extended its influence in such other fields as education, religion, landowner–tenant relationships, the economic recovery of the royal boroughs, and a more adequate distribution of the burden of taxes. The reforms did not aim at total abolition of social and economic distinctions, but they generally improved the lot of the lower middle class and of the peasant. Two decrees of 1781 made Joseph popular among the masses: he abolished restrictions on the personal freedom of the peasants, and he granted religious toleration. After the long period of oppression, these were hailed as beacons of light, although they did not go so far as enlightened minds expected. The edict of toleration in Bohemia and Moravia was not followed by a mass defection from the Roman church, partly because it did not refer to either the Utraquism or the Unity but authorized worship according to either the Augsburg or Reformed Confession.

Joseph's conservative successors, Leopold II (ruled 1790–92), Francis I (ruled 1792–1835), and Ferdinand V (Ferdinand I of Austria; ruled 1835–48), left intact the centralistic system inherited from Maria Theresa and Joseph II, but they did engineer gradual transition from the manorial system to the full ownership of land by the peasants. They made peace with the landowning nobility, seeing in it their most faithful ally; but the provincial diets of Bohemia and Moravia still had no more than a decorative function. A fairly large number of persons of rank distinguished themselves as patrons of learning, lovers of theatre and music, promoters of new and more profitable methods in agriculture, and, in the early 19th century, as pioneers of industry. In these activities they made contacts with gifted men of middle-class or of peasant origin, gave them financial support, and shielded them from the ubiquitous police and rigid censorship. Provincial loyalties were stronger than ethnic differentiation, which emerged as a new factor in Bohemia around 1800, partly out of opposition to the centralistic tendencies of the Vienna court, partly under the impact of the French Revolution. Institutions destined to play an important role in the Czech national renascence, such as the Royal Bohemia Society of Sciences or the National Museum (1818), were bilingual and drew support both from the propertied German population and from a small fraction of the Czechs who became conscious of their origin, of the brighter periods, and of their kinship with other Slavic peoples.

Czech national renascence

From absolutism to constitutionalism (1848–1914). In 1848 the German-speaking population of Bohemia and Moravia had a distinct advantage over the Czechs. The upper classes of these two provinces were almost entirely German and the rural areas in which, after 1620, the Germans gained predominance extended from the mountain ranges deep into the lowlands, once purely Czech. There were, however, limited opportunities for Czechs of middle-class or peasant origin, who prepared for more lucrative occupations through higher studies or who acquired special skills. Some improvement could be observed in the last stage of Habsburg absolutism, from about 1830 onward. The efforts of scholars, writers, clergymen, and schoolmasters, aware of their Czech origin, stirred a national consciousness among the common people. Not only the countryside but also the urban communities witnessed an awakening. The Habsburgs, symbolized by Prince Metternich, tolerated no political activities but did not hinder cultural activities, the printing and distribution of nonpolitical books in Czech, theatrical performances, and gatherings for other than political purposes. The Czechs had their social and intellectual elite, small in numbers but devoted to the national cause; they were shielded by a group of aristocrats, who thus manifested opposition to Vienna.

Similar conditions existed in the Hungarian counties inhabited by the Slovaks. Contacts between these two ethnic groups were hindered by the existence of provincial boundaries, but the groups were close enough to permit cultural exchanges. Up to 1840 the Czech language, regenerated by such eminent linguists as Josef Dobrovský and Josef Jungmann, was used by both Czech and Slovak authors. But the growing national awareness gave rise to endeavours to develop a literary language for the Slovaks in order to reach people with no more than elementary training. The literary Slovak gradually replaced the Czech. Thus, the mounting wave of nationalism, instead of cementing the traditional relationship, created conditions for differentiation and for the establishment of two closely related but distinct ethnic units.

Revolution of 1848. In opposing Metternich's oppressive regime, the Czech intellectuals were allied with the progressive forces among the Germans. When the revolutionary wave reached Bohemia and swept away its outdated institutions in March 1848, leaders of the two nationalities worked together in an attempt to shift from absolutism to constitutionalism. Both parties had a vague notion that Bohemia should return to its autonomous status and become a constituent part of the regenerated monarchy, but they could not resolve specific problems. The Germans saw advantages in cooperating with their kinsmen in other Habsburg lands; moreover, they were keenly interested in the idea of German unification, debated in the German constituent assembly at Frankfurt. The Czech voters looked to František Palacký as their leader; he had written several volumes of *A History of the Czech People* and was a respected political thinker. He was assisted by Karel Havlíček Borovský, a journalist, and by František Rieger, a student of political science and economics. The Czech leaders sensed danger in the schemes laid before the Frankfurt assembly and in plans for a modernized but highly centralized Austria. Their primary concern was the Diet of Bohemia, and, at times, they included among their desiderata a general assembly of deputies from Bohemia, Moravia, and Silesia, to stress a continuity of modern political efforts with the ancient kingdom. But, despite some support from the aristocratic circles, the Czechs were unable to change the movement toward centralization.

Movement toward centralization

A good deal of vacillation in and after 1848 was caused by the inability of Palacký and others to harmonize the emphasis of historical rights with genuine devotion to the principle of nationality. In late spring 1848 the idea of an elected diet for Bohemia was obscured by a loftier project, an assembly of spokesmen of the Slavic peoples from all parts of the Habsburg Empire. No matter how sincerely Palacký and other prominent figures professed their loyalty to the ruling house, the Slavic congress was viewed with displeasure by the Germans and the Magyars and was finally dispersed by the archconservative Alfred, Fürst zu Windischgrätz, who ordered that no election for the provincial diet could be held. The Czech leaders recognized that the constituent assembly meeting in July 1848 in Vienna was the only representative body before which they could express their aspirations. They participated in the late summer and early autumn sessions and worked with even more vigour when the assembly reconvened at Kroměříž (Kremsier). They made themselves allies of all factions that attempted to prepare the ground for a constitutional and federal system. Rieger, in particular, rose to the occasion when defending the principle that all power comes from the people. But the draft of a constitution for the Habsburg monarchy ran counter to ideas prevailing among the advisers of the new king Francis Joseph I (ruled 1848–1916). Early in March the Kroměříž assembly was dispersed. The Habsburg government, headed by Felix, Fürst zu Schwarzenberg, ruled for some time in accordance with a constitution drafted by the crown advisers; but, on December 31, 1851, Francis Joseph abolished the last vestiges of constitutionalism and began to rule as absolute master.

The regime, allied with the church and supported by the army, police, and bureaucracy, was rigid and effective but tolerated no opposition. Its weakness was revealed, however, by the poor show of its armies in a war with Sardinia in 1859. In October 1860 Francis Joseph issued a diploma burying the absolutist rule and inaugurating a constitutional era. But it soon became clear that no

scheme forwarded by the crown advisers could reconcile the federalist tendencies with the monarch's desire to concentrate as much power as possible in Vienna.

Division of Czechs and Slovaks. After a war with Prussia and Italy in 1866, Francis Joseph sought a solution that would promise speedy recovery and the stabilization of internal affairs. The monarchy was transformed, in 1867, into a dual system. The Magyars obtained the dominant position in Hungary; in the conglomeration of other provinces, which was briefly called Austria, the Germans were the strongest single group, followed by Czechs, Poles, and other nationalities. The dual system passed through successive crises but remained in existence until 1918.

Like other nationalities the Czechs resumed political activities after the promulgation of the October Diploma. Palacký was recognized as a dominant figure, but the actual leadership passed into Rieger's hands. Two courses were open to the Czechs: to apply the principle of nationality or to emphasize historical continuity. Palacký and Rieger decided for the latter and were supported by their conservative collaborators; clearly they had no chance for success without a close alliance with the conservative landed aristocracy, to which the electoral system granted a strong position in the provincial diets and in the parliament. But this alliance was exploited by Rieger's progressive opponents. Differentiation within the National Party began in 1863 and continued more rapidly after 1867. The Czechs, irrespective of ideological orientation, opposed the dual system and boycotted institutions that Austria received after the promulgation of a new constitution in December 1867. After two stormy years, an attempt was made to devise a solution that would give Bohemia autonomy within the Austrian half of the monarchy. In agreement with the historically minded nobility, Rieger negotiated in 1870 and 1871 with the Vienna cabinet and consented to a compromise. But Francis Joseph, although originally sympathetic, yielded to heavy pressure from many sides in October 1871 and refused to sanction the compromise. No attempt was made after 1871 to revive the project.

Internal differences in National Party

Despite the setback, Rieger was able to retain leadership for some 20 more years. Most official statements in either the Vienna Chamber of Deputies or in the provincial diets of Bohemia and Moravia contained a formal declaration in favour of the state right. The idea of restitution of the kingdom of Bohemia to its former rank, similar to that of Hungary, was never given up; but its chances of realization declined with the consolidation of the dual system, and Francis Joseph showed no intention of going to Prague to be crowned with the ancient crown of St. Wenceslas. After 1871 the Czech political leadership was confronted with a dilemma: whether to boycott the parliament and the diets or to join the government majority for concessions in education and economic life. In 1874 the National Party split; the progressive wing, commonly called the Young Czechs, gained in popularity among the urban middle class and well-to-do peasants. Rieger found it more and more difficult to defend his alliance with the big landowners, because it brought no tangible results and obstructed the flow of progressive ideas. The Young Czech deputies insisted on its dissolution and were applauded by their supporters, to whom progress in education, emancipation from clerical influences, and improvement of living standards were more vital than the continued emphasis on unforfeited state right. The Old Czechs lost ground in the 1880s and suffered a total defeat in the parliamentary election of 1891.

German–Czech rivalry. The most determined opponents of the state right scheme in 1871 and thereafter were the spokesmen of the German-speaking population of Bohemia and Moravia, later known as the Sudeten Germans, who realized the losses they would suffer with any decentralization of Austria. In the Vienna parliament they cooperated with their kinsmen from the Alpine provinces and helped determine the composition of the cabinets. An alliance between Austria-Hungary and Hohenzollern Germany (1879) increased their sense of belonging to one of Europe's strongest ethnic units. But their population was losing in Bohemia and Moravia in proportion to the Czechs. The losses were not spectacular and were largely neutralized by Vienna's reluctance to change the traditional practices of giving preference to German over Czech candidates in civil service and especially in the army. The electoral system for the provincial diet, introduced in 1861, was not changed, although the right to vote in parliamentary elections was extended several times to benefit less propertied voters. The immediate cause of Rieger's fall was dissatisfaction over concessions he was willing to make to the Germans in 1890. Thereafter, no attempt was made to achieve general agreement on problems of coexistence of the two ethnic blocs. The largest and richest crown land, in fact, became a trouble spot second, after 1908, only to the southern Slavic provinces.

But the Young Czech leaders were soon caught in the same dilemma that had plagued Rieger. Solemn declarations of adherence to the state right scheme were followed by bargaining with the prime ministers, who sought potential members of a government coalition and offered tempting concessions, including Cabinet posts. Graf Kazimierz Badeni, who headed the Austrian Cabinet in 1895–97, promised administrative measures that would sanction wider use of Czech in Bohemian civil service and law courts. But he encountered vigorous opposition, organized by German nationalists, in the parliament and lost the Emperor's confidence. He resigned, and his successor recognized the futility of trying to adjust the outdated laws in favour of the Czechs, whose members in relation to the Germans amounted to almost two-thirds.

The changing social and economic stratification also sped the decline of the Young Czechs. They unsuccessfully courted industrial workers, who were more attracted by the Social Democrats and voted for their candidates. Václav Klofáč, a talented journalist, after several years of cooperation with the Young Czechs, founded the National Socialist Party. The peasants, dissatisfied with the increasing influence of big business and the upper middle class, turned away from the Young Czechs after 1890. An agrarian movement soon became the Young Czechs' most dangerous rival, because the peasants predominated in the Czech-speaking areas of Bohemia and Moravia. The young Czech political program was pervaded by liberal principles, which included anticlericalism; that made it unpalatable to the conservative groups, which favoured close cooperation with the Roman Catholic Church and which were stronger in Moravia than in Bohemia. Finally, voters led in Moravia by Adolf Stránský and in both provinces by Tomáš Garrigue Masaryk came to feel that the Young Czechs were not seriously carrying out the progressive ideas included in their program. Parties that developed out of ideological opposition were small when compared with the Agrarians, the Socialists, and the Young Czechs; but their ideas reached the noncommitted voters. The grant of universal manhood suffrage in 1906 greatly improved the chances of parties appealing to the less propertied voters; instead of helping to consolidate the parliament, it caused such differences that the prime ministers, following each other in quick succession, found it increasingly difficult to form a solid majority block. Thus, from the election in 1907 to the outbreak of World War I in 1914, the Chamber of Deputies could easily be bypassed by the court and by the ministries of Foreign Affairs and War, over which Francis Joseph exercised stronger control than other constitutional rulers. The dual monarchy, instead of experiencing regeneration, was moving toward more dangerous involvements in international affairs and, finally, toward catastrophe.

Decline of the Young Czechs

II. Czechoslovakia since 1914

THE REPUBLIC OF CZECHOSLOVAKIA (1918–45)

The struggle for independence (1914–18). World War I brought about a total estrangement between the Germans and the Czechs and Slovaks within the country. The Germans lent full support to the war effort of the

Central Powers, but among the Czechs the war was unpopular. Opposition to the war, however, was uncoordinated, because Czech political leaders were unable to agree on a program. In December 1914 Tomáš Garrigue Masaryk, a representative in the Vienna parliament, left Prague to organize activities that could not be developed at home because of the suspension of civil rights and political persecution. After staying some months in neutral countries, Masaryk moved to London. In 1915 he had been joined in Switzerland by his former student Edvard Beneš and by Josef Dürich, a member of the conservative Czech Agrarian Party. Masaryk at first had rather vague notions of the tasks ahead of him. But, after conferring with distinguished experts in central European affairs, he eventually came to advocate a program of political union of the Czechs and Slovaks. A young Slovak astronomer, Milan Rastislav Štefánik, offered his support. Masaryk established contacts with the Czechs and Slovaks living in Allied and neutral countries, especially the United States. In 1916 a Czechoslovak National Council was created under Masaryk's chairmanship. Its members were anxious to maintain contacts with the leaders at home in order to avoid disharmony, and an underground organization called the Maffia served as a liaison between them.

At home the military regime headed by Archduke Frederick curbed the press, forbade public meetings, and imprisoned those suspected of disloyalty. Among those arrested were the pro-Russian Young Czech leader Karel Kramář and the economist Alois Rašín. Dissatisfaction among the Czech soldiers on the Eastern front became more articulate in 1915, and whole units often went over to the Russian side.

Moderate reform under Charles I

Francis Joseph died in November 1916 and was succeeded by Charles I. The new emperor abolished the most irritating restrictions on the freedom of expression and granted amnesty to political prisoners. In the spring of 1917 he called the parliament to session. Charles's reforms, although in many respects gratifying, called for more intensive activities abroad in order to convince the Allied leaders that partial concessions to the Czechs were inadequate to the problems of postwar reconstruction. The position of the Slovaks was not getting better, and the Hungarian government showed no inclination to reorganize the kingdom in accordance with the principle of nationality. Two major events coincided with Charles's new course in home affairs and with his discreet exploration of the chances of a separate peace: the Russian Revolution (March 1917) and the United States declaration of war on Germany. In May 1917 Masaryk left London for Russia to speed up organization of a Czechoslovak army. While small units of volunteers had been formed in the Allied countries during the early part of the war, thousands of prisoners of war were now released from Russian camps and trained for service on the Allied side. A Czechoslovak brigade participated in the last Russian offensive and distinguished itself at Zborov in July 1917.

United States encouragement

From the United States came moral encouragement, but Pres. Woodrow Wilson's early statements pertaining to the peace aims were rather hazy. Several weeks after the United States declaration of war on Austria-Hungary, President Wilson promulgated his celebrated Fourteen Points (January 8, 1918), the tenth of which called for "the freest opportunity of the autonomous development" for the peoples of Austria-Hungary.

After the Bolshevik Revolution, the National Council decided to transfer Czechoslovak troops from Russia to France. As other routes to the West were blocked, they started moving toward Vladivostok but got involved in struggles between the Bolsheviks and the Conservative forces for the control of the Siberian railroad. Their achievements, noticed favourably in the Allied press, gave the Czechoslovak cause wide publicity, and Masaryk left Russia for the United States, where, in May 1918, he gained solid support from Czech and Slovak organizations. A declaration favouring political union of the Czechs and Slovaks was issued at Pittsburgh, Pennsylvania, on May 31, 1918 (called the Pittsburgh Convention).

In 1918, dealings with the Allies progressed more successfully. Not only the Siberian campaigns but also increased activities at home were used to get the struggle for independence endorsed by the Allied governments. A demand for a sovereign state "within the historic frontiers of the Bohemian lands and of Slovakia" was made in Prague at the Epiphany Convention (January 6, 1918) and repeated later with more vigour. In May 1918 not only the Czechs but also the Slovaks made statements to which Masaryk and his collaborators could point when pressing for an official recognition. The anti-Austria resolution, adopted at the Congress of Oppressed Nationalities at Rome (April 1918), helped in disarming conservative circles in the Allied countries who opposed a total reorganization of the Danubian region. After several encouraging statements came the recognition by France of the Czechoslovak National Council as the supreme body controlling Czechoslovak national interests; the other Allies soon followed the French initiative. On September 28, 1918, Beneš signed a treaty whereby France agreed to support the Czechoslovak program in the postwar peace conference. To preclude a retreat from the earlier Allied declarations, the National Council constituted itself as a provisional government (October 14, 1918). On October 18 Masaryk and Beneš issued a declaration of independence simultaneously in Washington and Paris. Events were moving rapidly toward total collapse of the Habsburg monarchy. The last attempt to avert it, the manifesto issued by Emperor Charles on October 16, 1918, brought no positive results. After that, Vienna had no choice but to accept President Wilson's terms. The surrender note, signed by Count Gyula Andrássy, last foreign minister, was accepted as a sanction of the idea of independence. The Prague National Committee proclaimed a republic on October 28, and, two days later, the Slovak National Council at Turčiansky Svätý Martin acceded to the Prague proclamation.

The establishment of Czechoslovakia (1918–25). Despite all efforts to maintain contacts between the leaders abroad and those at home, the early years of the republic were hindered by differences of opinion and occasional frictions. Masaryk returned to Prague on December 21, 1918. Beneš stayed in Paris and was joined by Karel Kramář, prime minister since November 1918. The Slovak leader Štefánik decided to return home but died in an air accident in May 1919. Masaryk and Beneš conducted external relations, and the leaders of five major parties controlled home affairs.

Boundary settlements after war

Of the many tasks facing the new government, negotiations at the peace conference, though complicated by dissensions among the great powers, were the least onerous. The frontiers separating Bohemia and Moravia from Germany and Austria were approved, with minor rectifications, in favour of the republic. The Slovak boundary was also felt to be satisfactory. The dispute over the Duchy of Teschen strained the relations with Poland; the partition of the duchy in 1920 was opposed by powerful Polish groups, and the Polish senate did not ratify the treaty. The northeastern counties of prewar Hungary (Carpathian Ruthenia) were attached to the new state. The area was inhabited by Slavic peoples, the majority of whom were keenly aware of their kinship with the Ukrainians.

Consolidation of internal affairs proceeded slowly. The winter of 1918–19 was critical. The most urgent task of the new government was to replace the wartime economy by a new system. The network of railroads and highways had to be adjusted to the new shape of the republic, stretching from the Cheb (Eger) region in western Bohemia to the Carpathians in the east. The first minister of finance, Alois Rašín, saved the Czechoslovak currency from catastrophic inflation, and his death in February 1923, after being shot by a young revolutionary, was a shock to the new republic.

In the chaotic conditions prevailing in central Europe after the armistice, a parliamentary election appeared to be impossible. The Czech and Slovak leaders agreed on the composition of the National Assembly. The Assembly's main function was the drafting of a constitution.

The new, democratic constitution was adopted on February 29, 1920, and was modelled largely after that of the French Third Republic. Supreme power was vested in a bicameral National Assembly. The Chamber of Deputies and the Senate had the right to elect, in a joint session, the president of the republic for a term of seven years. The Cabinet was made responsible to the Assembly. Fundamental rights of the citizens, irrespective of ethnic origin, religion, and social status, were defined generously.

Opposition from Sudeten Germans

Large segments of the population gave wholehearted support to the republic; the most resolute opposition, however, came from an ethnic minority that soon came to be known as the Sudeten Germans. The age-old antagonism between Germans and Slavs, accentuated during the war, prevented cooperation during the opening stages of the republic. The Germans issued protests against the constitution but participated, nevertheless, in parliamentary and other elections. In 1925 two German parties—the Agrarian and Christian Socialist—joined the government majority, thus breaking the deadlock. Disagreement with the trend toward centralism was the main source of dissatisfaction among the Slovak Populists, a clerical party headed by Msgr. Andrej Hlinka. Calls for Slovak autonomy were counterbalanced by other parties seeking closer contacts with the corresponding Czech groups; the most significant contribution to that effort was made by the Agrarians under Milan Hodža and by the Social Democrats under Ivan Dérer. The strongest single party in the opening period, the Social Democracy, was split in 1920 by internal struggles; in 1921 its left wing constituted itself as the Czechoslovak section of the Comintern. After the separation of the Communists, the Social Democracy yielded primacy to the Agrarians. The Republicans, as the peasant party was called officially, became the backbone of government coalitions until the disruption of the republic; from its ranks came Antonín Švehla (prime minister 1921–29) and his successors.

Political consolidation (1925–35). Foreign relations were largely determined by wartime agreements. Czechoslovakia adhered loyally to the League of Nations. Treaties with Yugoslavia and Romania gave rise to the Little Entente. France was the only major power that concluded an alliance with Czechoslovakia (January 1924). Relations with Italy, originally friendly, deteriorated after Benito Mussolini's advent to power in 1922. Czech anticlerical feeling precluded negotiation of a concordat with the papacy until 1928, when an agreement was worked out providing for settlement of the most serious disputes between church and state. But it was Germany that most strongly influenced the course of Czechoslovak foreign affairs. The relations between the two neighbours, correct but cool, improved slightly in 1925 after the Locarno Pact, a series of agreements among the powers of western Europe to guarantee peace. In the milder climate of the late 1920s, a third party, the Social Democrats, joined the German activists. Attempts to change the attitude of the Slovak Populists met with partial success. Reorganization of public administration in 1927, while marking a retreat from rigid centralism, did not go far enough to meet demands for Slovak autonomy. Monsignor Hlinka and his chief collaborator, Msgr. Josef Tiso, tenaciously pursued the program of decentralization and only at short intervals supported the Prague government.

Impact of Great Depression

When the impact of the Great Depression reached Czechoslovakia, soon after 1930, the highly industrialized German-speaking districts were hit more severely than the predominantly agricultural lowlands. The ground was thus prepared for the rise of militant nationalism. Parties supported by middle-class German voters and persisting in opposition to Prague gained in popularity. Soon after Hitler's rise to power, in 1933, efforts were made to organize noncommitted voters, especially hard-pressed businessmen. On October 1, 1933, Konrad Henlein, a gymnastics teacher, launched his Sudeten German Patriotic Front. Professing loyalty to the democratic system, he asked for recognition of the German minority as an autonomous body. In 1935 Henlein changed the name of his movement to the Sudeten German Party so as to enable its active participation in the parliamentary election (May 1935). The party captured nearly two-thirds of the Sudeten German vote and became a political force second only to the Czech Agrarians.

Moving toward the abyss (1935–38). A stable interlude of little more than two years followed the landslide victory of the Sudeten Germans. In December 1935 Masaryk retired from the presidency, and Beneš was elected his successor by an overwhelming majority, including Hlinka's party. A treaty with the Soviet Union in 1935 enhanced the sense of national security. The program of the Communist Party was determined not only by this treaty but also by the general reorientation of the Comintern, which now urged cooperation with anti-Fascist forces in popular fronts. The Czechoslovak Communists did not, however, seek Cabinet posts. The erection of an elaborate system of fortifications along the German frontier modelled on France's Maginot Line was commonly interpreted as an unwritten pledge of the French army to aid Czechoslovakia in the event of an unprovoked attack. Their capture would have given (and did give) the Germans the key to the French defense system. In February 1937 Prime Minister Milan Hodža made significant progress toward gaining the cooperation of those segments of the German population that were attached to the principles of democracy. The hope that Czechoslovakia would be able to withstand pressure from the Third Reich seemed, for a while, to be justified.

Hitler and eastward expansion of Germany

But, soon after the death of Masaryk, in September 1937, Hitler embarked on his program of eastward expansion. As early as November 1937, he informed his military chiefs of his intention to move against Austria and Czechoslovakia. After the annexation of Austria in March 1938, the Czechoslovak crisis became acute.

The Czechoslovak leaders divided their energies. Prime Minister Hodža devoted all his talents to a search for a compromise that would satisfy the Sudeten Germans and held long conferences with Henlein's lieutenants. President Beneš, assisted by his foreign minister, Kamil Krofta, maintained contacts with foreign powers. Henlein played his hand so skillfully that the influential circles, especially in London, believed that he was a free agent and not Hitler's stooge. The advocates of "appeasement," then rapidly gaining ground in Great Britain and in France, failed to realize that the Sudeten German negotiators had no intention of compromise and acted on instructions from Berlin. The main task of Henlein's party was to give Hitler a better chance to dislocate the republic without recourse to war. To invalidate critical comments from London and Paris, Beneš consented late in July to the mission of Lord Runciman, whose avowed purpose was to observe and report on conditions within the country.

The crisis culminated in September 1938. Armed with information supplied by Lord Runciman, British Prime Minister Neville Chamberlain visited Hitler at Berchtesgaden and Godesberg. Chamberlain assured Hitler that the German objectives could be achieved without fighting. The French consented to Chamberlain's policy, thus abandoning their former commitments. The Soviet Union was under no treaty obligation to assist Czechoslovakia, since the treaty of 1935 was to be operative only if the French would honour their pledges. Thus, the stage was set for a meeting between Hitler, Mussolini, Chamberlain, and Edouard Daladier, at Munich on September 29, 1938. They agreed on a document enjoining the Prague government to cede to the Third Reich all districts of Bohemia and Moravia with 50 percent or more of Germans; October 10 was set as the deadline for the transfer of these territories. Although presented as a measure to make Czechoslovakia more homogeneous and viable, the pact and its ruthless implementation sealed the fate of the country.

From Munich to the disruption of the republic (1938–39). Beneš resigned the presidency rather than agree to the German annexation. After several weeks he left Prague, first for London and then for Chicago. The lead-

ers who took over had to face mounting difficulties. The annexations completed according to the Munich timetable were not Czechoslovakia's only territorial losses. Poland obtained the Duchy of Teschen as a reward for its menacing attitude during the Munich crisis. By the Vienna Award (November 2, 1938) Hungary was granted large portions of Slovak and Ruthenian territories. By all these amputations Czechoslovakia lost about one-third of its population. Communications were totally disrupted, and the country was rendered defenseless.

The chances of recuperation were greatly reduced by the rapid growth of centrifugal tendencies. The Slovak Populists, headed since Hlinka's death by Monsignor Tiso, presented Prague with urgent demands for autonomy, which the government accepted. A similar request came from Carpathian Ruthenia. A cumbersome system composed of three autonomous units (the Czech lands, Slovakia, and Ruthenia) united by allegiance to the Prague government was introduced late in the fall. On November 30, 1938, Emil Hácha was elected president; an Agrarian leader, Rudolf Beran, formed the federal Cabinet. Under German pressure the complicated party system was changed drastically. The right and centre parties in the Czech lands formed the Party of National Unity; the Socialists organized the Party of Labour. In Slovakia the Populists absorbed all other political groups. Despite all efforts of the loyal elements, stabilization of political and economic life made little progress. Moreover, the public knew little of the confidential negotiations being conducted in Vienna and Berlin by Tiso's aides, who went along with Hitler's preparation for the final takeover. In the early months of 1939, Tiso's group prepared the ground for the secession of Slovakia, and, on March 14, 1939, the Slovak National Assembly voted for independence. On the same day, Hácha and his foreign minister, František Chvalkovský, journeyed to Berlin, where they were informed of Hitler's decision to annex Bohemia and Moravia; on the following day, Czechoslovakia was proclaimed a protectorate of the Third Reich.

The struggles at home and abroad (1939–45). The basic laws regulating the status of Bohemia and Moravia were drafted hastily, and many loopholes were left in them to facilitate German intervention. Hitler installed a Reich Protector in Prague as his personal representative. He was assisted not by Konrad Henlein but by Karl H. Frank, a Sudeten German notorious for his brutality. The Cabinet under President Hácha operated with limited rights and powers. Matters that in any way touched on the Third Reich, especially the war effort, were excluded from Czech jurisdiction and handled either by the Reich Protector or by direct order from Berlin. For some two years the protectorate kept the semblance of an autonomous body. But in September 1941 Reinhard Heydrich replaced Konstantin von Neurath as Reich Protector and inaugurated a reign of terror. After Heydrich's assassination (May 1942) the Germans virtually took over the country. Hácha stayed on as president, but the Cabinet was reconstructed in such a manner that it served only as a screen behind which the Germans carried out retaliatory measures and exploited the country's economy for their own purposes. Mass executions, consignment of Czech patriots to concentration camps, and recruitment of young people for work in Germany or behind the front continued until the collapse of the Nazi regime.

Reich Protector in Prague

Several months after the proclamation of the protectorate, Beneš moved from Chicago to London to resume his political activities. His position was originally rather awkward, as neither French nor British statesmen were keen on dealing with him. But, after the fall of France, in spring 1940, the British prime minister, Winston Churchill, granted Beneš recognition; a provisional government, with Msgr. Jan Šrámek as prime minister, began to function in London. In July 1941 Great Britain and the Soviet Union granted Beneš and his government-in-exile full recognition. Beneš maintained underground contacts with Prague and, until Heydrich's assassination, exercised indirect influence on the protectorate government. But Beneš' main occupation was with diplomacy. He devoted a good deal of energy to get the Munich Agreement denounced as invalid. While London and Washington were reluctant to make statements that might prejudice the outcome of the future peace conference, Moscow did not hesitate to condemn the past and open bright prospects for cooperation in the war and in the postwar reconstruction. In the desire to reap benefits of a timely decision for cooperation, Beneš visited Moscow in December 1943 and signed a treaty of alliance for 20 years, the terms of which far exceeded the pact of 1935. Not only the treaty but also conversations with Klement Gottwald, the leader of the Czechoslovak Communists, from then on determined both the policy of the exiles and the underground movement in the protectorate and in Slovakia. The Communist groups, passive before the Nazi invasion of the Soviet Union, now became intensely active and gradually seized the leadership from other clandestine organizations. They played a significant part in the Slovak uprising (late summer 1944) and in the activities of Czech patriots (spring 1945). It was of decisive importance that the Red Army penetrated deep into the territory of the republic several months earlier than the Western Allies were able to cross the traditional borderline between Germany and Bohemia. In March 1945 Beneš and other political figures journeyed from London to Moscow to make a final accord with Stalin and Gottwald. A program of postwar reconstruction was worked out under decisive Communist influence and a Cabinet was formed with Zdeněk Fierlinger as prime minister. The new government, set up at Košice in Slovakia on April 3, 1945, exercised jurisdiction in the eastern portion of the republic; in Moravia and Bohemia, fighting continued until early May. Underground activities, guided by the Czech National Committee, were intensified. On May 5 the people of Prague launched an uprising against the German troops concentrated in central Bohemia and fought them bravely for four days. Their appeals for Allied help were largely ignored. The U.S. general George S. Patton, though sympathetic, did not move from Plzeň, complying with instructions from Gen. Dwight D. Eisenhower. On May 9 the forces of the Soviet general Ivan Konev entered Prague. Thus, the Soviet Union secured both a military and political victory.

Communist role in underground

CZECHOSLOVAKIA SINCE 1945

The uneasy interim (1945–48). The new regime at Košice did nothing in foreign or in home affairs that would conflict with the 1943 treaty of alliance with the Soviet Union. Immediately after the end of fighting, a purge of those suspected, rightly or wrongly, of collaboration with the Nazis was carried out with utmost severity. The main target was the Sudeten Germans, whose transfer to Germany was sanctioned at the Potsdam Conference on August 2, 1945. A small fraction were allowed to stay in the republic. The transfer of the Magyars was discontinued after an agreement with Hungary. Since the Carpathian Ruthenia was ceded to the Soviet Ukraine, the republic became ethnically more homogeneous than it had been prior to 1938. The Slovak and Czech parties accused of either subservience to Hitler or of irresolute policy before Munich were not allowed to resume activities. The strongest among the former was the Slovak Populists, among the latter the Agrarians. Five major parties agreed on basic principles and established the National Front; they were the Communists (Czech and Slovak), Czech National Socialists, Czech People's Party (Catholic), Social Democrats, and Slovak Democrats. In the early period the government ruled by decrees, the most important of which called for the nationalization of key industries and banks. "National committees" were established on the village, town, district, and provincial levels; and on October 28, 1945, a provisional National Assembly was formed and unanimously endorsed a program of gradual transition from capitalism to Socialism.

Both in the local committees and on the higher levels, the Communists recognized other parties as equal partners. But by skillful manoeuvring the Communists es-

tablished themselves as the dominant element not only in the political assemblies but also in a large number of other organizations including the trade unions. The press, though ostensibly free, operated under invisible restrictions, and, on a number of vital problems, no open exchange of view was tolerated. In foreign affairs, national interests were subordinated to those of Moscow.

Communist election victory

The election of the Constituent Assembly in May 1946 revealed the proportional strength of the Communist and non-Communist movements. The Communists, stronger in Czech lands than in Slovakia, polled approximately 38 percent of the vote, making them the strongest party in its country, and, in accordance with parliamentary practices, Klement Gottwald became the prime minister. Seats in the Cabinet were distributed among the members of the National Front. Jan Masaryk, the son of T.G. Masaryk, retained the portfolio for foreign affairs that he had held in London; Gen. Ludvík Svoboda, whose troops had fought on the side of the Red Army, continued to serve as minister of defense. But not more than one year was allowed to pass in continuous efforts to keep the National Front in a reasonable balance. In June 1947 the United States invited Czechoslovakia to participate in the European Recovery Program (Marshall Plan). The Prague government accepted the offer in the belief that the Soviet Union would adopt a friendly attitude. But several days later Stalin warned the Czechoslovak delegation that any participation in the Marshall Plan would be interpreted in Moscow as a hostile act. Thereupon, the government reversed its decision. Seemingly, nothing hindered continued cooperation within the National Front. But the appearances were deceptive. Few people were aware of President Beneš' deteriorating health, an important factor in view of his key position.

With the term of the Constituent Assembly due to expire late in the spring of 1948, all parties opened campaigning for the coming election. Several ugly incidents in the Czech lands and in Slovakia caused uneasiness in democratic ranks, but the leaders of the parties were convinced that they had been motivated only by the Communist determination to increase the number of seats. A decision not to wait for the outcome of the election was made by the Communist leaders in utmost secrecy sometime before the end of 1947, and a timetable was set up to synchronize Communist policy with the tactics of other parties. The crisis came to a head in February 1948, precipitated by the decision of the minister of the interior, Václav Nosek, to replace non-Communists in the security forces by party members. Attempts of other leaders to change the Communist policy came to nothing. On February 20, 1948, the ministers of three parties—National Socialist, People's, and Slovak Democratic—resigned in protest and in the belief that the Social Democrats would eventually back them and that the president would take a firm stand against the Communists' tactics. But the Social Democratic leadership, weakened by discord, did not take the expected action. The Communists, advised in their policy by Valerian Zorin, who had gone to Prague ostensibly to supervise shipments of wheat from Russia, mobilized the worker's militia in Prague and other centres. Minister of Defense Ludvík Svoboda expressed his sympathy with the Communist aims. Action committees were organized in the factories, workshops, and offices to protect the Socialist cause. Messages from all parts of the country poured to the Hradčany Castle urging Beneš to drop the resigning ministers. He yielded to the pressure, and, on February 25, 1948, approved a list of Cabinet members submitted to him by Gottwald. In the new Cabinet the Communists held one-half of the portfolios; the other half was made up of members of other parties, which by now had been thoroughly purged. Jan Masaryk remained in office, but on March 10 he was found dead in the courtyard of his residence at Černín Palace. It was strongly suspected that he had been murdered, though his death was made to look like suicide.

The People's Democracy (1948–60). The new regime was ruled under the aegis of the Communist-dominated Renewed National Front (RNF). The Social Democrats, headed by Zdeněk Fierlinger, merged with the Communists in June 1948. The National Socialists and the People's Party continued in existence but with drastically reduced membership. The party of Slovak Regeneration replaced the Democrats. Several nonpolitical organizations were also admitted to the RNF. For several months the action committees were busy purging the civil service, army, mass organizations, and cultural institutions. Most non-Communist leaders fled to Paris, London, or the United States. On May 9, 1948, a new constitution was promulgated codifying the principles of a "people's democracy." Beneš disagreed with some articles and resigned on June 7; he died on September 3, 1948.

Resignation of Beneš

On June 14 the National Assembly elected Gottwald as president. Antonín Zápotocký, since 1945 the leading figure in the trade unions, headed the Cabinet. Rudolf Slánský continued as the secretary general of the Communist Party. The new leadership pushed ahead the February program of socialization. In October 1948 the first five-year plan set the lines for a thorough transformation of national economy, stressing rapid development of heavy industry above the production of consumer goods. Two subsequent plans (1954–58 and 1959–63) were drawn along similar lines, increasing the targets for metallurgy and heavy machinery. A law creating uniform agricultural cooperatives was passed in February 1949, but its application was hindered by farmers' opposition. Czechoslovakia joined the Council for Mutual Economic Assistance (Comecon), set up in 1949 as a counterpart to the European Recovery Program (Marshall Plan).

Gottwald and his aides loyally followed Stalin's line and were determined to crush any kind of opposition. Peasant and urban middle-class reluctance to accept a new social and economic order was suppressed by stern measures. Potential centres of discontent were destroyed by mass arrests and spectacular trials before "people's courts." The religious bodies, especially the Roman Catholic Church, were among the principal targets. In October 1949 a state office for church affairs was set up. In exchange for nationalization of church properties, the state accepted obligation to support the clergy from public funds. The main cause of conflict was the oath of allegiance. While the non-Catholic churches eventually complied with the request, the Catholic hierarchy persisted in its opposition. Several trials were held in 1950 and 1951 with the bishops, superiors of religious orders, as well as members of the lower clergy, as defendants. The monasteries were closed and the monks and nuns either imprisoned or forced to seek other occupations. Between August and October 1950, most of the bishops were moved from their residences; some of them were sentenced to prison terms. In March 1951, five prelates were finally induced to take the oath of allegiance. Other vacancies were filled from the ranks of "patriotic priests."

Political opposition was thrown into confusion by the escape to foreign lands of almost all pre-February leaders and by the elevation of pliable figures to mostly imaginary posts. But the omnipresent security forces sniffed out underground activities and attacked them mercilessly. In late spring 1950, Milada Horáková, a prominent figure in the feminist movement was brought, along with several others, before the people's court; one of them, Záviš Kalandra, an ardent Socialist, was accused of Trotskyism. The Communists soon discovered that their enemy was not alone to be sought in bourgeois or clerical centres. After Tito's feud with Moscow and the execution of László Rajk in Hungary, the high party echelons were put under surveillance. The demotion, in March 1950, of Vladimír Clementis from the foreign ministry was followed by an action against his two friends—Laco Novomeský, a poet of distinction, and Gustáv Husák, since 1946 a chairman of the Board of Trustees for Slovakia. The purge of the party proceeded with increasing vigour. In December 1951 Rudolf Slánský fell from grace; he and ten of his associates, including Clementis, were sentenced to death in November 1952. In April 1954 Gustáv Husák was sentenced to life imprisonment.

Party purges

The death of Gottwald (March 1953) brought no

change in the party's policy. The new president, Antonín Zápotocký, was personally more popular but showed no intention to inaugurate a milder course. The head of the Cabinet, Viliam Široký, a Slovak, was a staunch Stalinist, as was the acting secretary, Antonín Novotný. After a reorganization of the party's upper echelons, Novotný became its first secretary. Purges and public trials continued in 1954. The unveiling (May 1, 1955) of a huge Stalin monument on heights overlooking Prague showed that the Czechoslovak Communist Party was persisting in the policy that came soon to be known as the "cult of personality." The 20th Congress of the Communist Party of the Soviet Union and the policies of Stalin's successor, Nikita Khrushchev, were merely recorded in the Czechoslovak press. The conservative tendencies were strengthened by the election of Novotný to the presidency after Zápotocký's death in November 1957.

With closed ranks and concentration of power in the political bureau, the party carried out unpopular measures that were resented not only by whatever was left of the middle class but also by the working people. A monetary reform in May 1953 wiped out savings and caused disastrous inflation. The main industrial centres of Plzeň, Kladno, and Ostrava seethed with discontent, but security forces were strong enough to keep the situation under control. The collectivization of land was resumed in 1956 with greater energy, and by 1960 about 90 percent of cultivable land had been converted into either agricultural cooperatives or state farms. At about the same time the last vestiges of private business and of liberal professions disappeared. The educational system was tied to the party and adjusted to the Soviet pattern. In the creative arts so-called Socialist Realism was proclaimed the official creed. In July 1960 the constitution of May 1948 was replaced by a new charter, which gave the country the title of Czechoslovak Socialist Republic (CSSR). Like its model, the Soviet constitution of 1936, the Czechoslovak charter subordinated the state to the party and its complex machinery.

Reform endeavours (1960–67). Outbreaks of dissatisfaction in Poland and a Hungarian rising in 1956 played into the hands of the old-line Czechoslovak leaders. Neither Khrushchev nor his successors, Leonid Brezhnev and Aleksey Kosygin, insisted on replacement of the Stalinists by people of their own choice. Opposition was born in the party ranks and manifested itself in such a manner that Novotný's clique hesitated to adopt the measures to which Gottwald had resorted in 1950. The national economy did not develop as successfully as the official statements prognosticated. The third five-year plan (1961–65) had to be scrapped, and for several years production was regulated by short-term plans. In January 1965 the Central Committee adopted a more flexible system of planning and relaxed the bureaucratic control over management. The project was debated by the 13th Party Congress (May 31–June 4, 1966) and was put into effect on January 1, 1967. Although reluctant to admit that grave errors had been committed, the political bureau sanctioned revision of the purge trials from Gottwald's era. A commission was set up and made public its findings in August 1963. Among those fully rehabilitated was Vladimír Clementis. Rudolf Slánský and some of his associates were rehabilitated legally, but their expulsion from the party was confirmed. In 1965 a slight improvement occurred in church–state relations. Archbishop Josef Beran, promoted to cardinal, was allowed to leave for Rome, where he died in 1969. Bishop František Tomášek was appointed apostolic administrator of the archdiocese of Prague. Other bishops were allowed to return to their sees, but no general agreement with the Vatican was reached. Novotný sacrificed some of the most unpopular figures to relieve the tension. In September 1963 a moderate Slovak, Jozef Lenárt, replaced Viliam Široký as prime minister.

Improvement of church–state relations

Systematic efforts to bring intellectual life into harmony with party policy did not meet with full success despite heavy concentration on that wide field. Coercive measures alternated with attempts to win good-will by material advantages, but scholarly and creative activities could not be so easily curbed as the press or education in government-controlled schools. The universities and other institutions of that rank lost their traditional autonomy in 1950. Both the teaching staff and student body were purged in Gottwald's era; new appointments and admissions were rigidly supervised. In 1952 the Czechoslovak Academy of Sciences (with a branch at Bratislava) was founded as a centre for research. Its institutes launched learned journals and series of publications and provided opportunities for a large number of scholars, many of whom earned international recognition. Writers, artists, composers, actors, and film producers were organized into unions, over which the party exercised control through pliable officers. Despite all precautions, news of the 20th Congress of the Communist Party of the Soviet Union and the gradual de-Stalinization reached Czechoslovakia and had lively echoes among intellectuals, young and old. The second congress of the Union of Czechoslovak Writers (1956) was pervaded by an invigorating atmosphere. Novotný's regime imposed restrictions of all kinds but did not achieve more than a temporary restitution of the former uniformity. Concessions, which the party leadership could not avoid in other spheres of national life, could not be put off indefinitely when intellectual activities came up for discussion. Liberalization was not sanctioned by official declaration, but it was pioneered by talented members of that generation that had joined the party prior to 1948, endorsed wholeheartedly the Communist program, but was increasingly resentful of stifling regimentation. The fourth congress of the Union of Czechoslovak Writers (June 1967) took a resolute stand against censorship and the party's efforts to interfere with creative processes. Retaliatory measures, aimed especially at the Union's weekly *Literární noviny*, supplied further evidence of Novotný's determination to remain at the helm. Although governed by the same basic laws as the Czech lands, Slovakia did not follow their implementation in exactly the same path. The constitution of 1960 attempted to restrict the power of the Board of Trustees and other autonomous bodies. The policy of centralization encountered more and more articulate opposition. In the end, Slovak resentment of Novotný's regime precipitated a crisis.

The "Prague Spring." The critical phase of the reform movement began early in January and closed late in August 1968—the so-called "Prague Spring." The movement became nearly synonymous with the name of Alexander Dubček, since April 1963 the first secretary of the Slovak Communist Party. Dubček was elected to succeed Novotný as the first secretary of the Czechoslovak Communist Party on January 5, 1968. Other changes both in the party and state administrations followed in rapid succession. Oldřich Černík became the prime minister and Josef Smrkovský, chairman of the National Assembly. Two vice premiers rose to prominence: Ota Šik, an advocate of decentralization in industrial enterprises; and Gustáv Husák, an ardent champion of Slovak nationalism. Under ever increasing pressure, Novotný retired from the presidency and was succeeded by General Svoboda. Early in April the party announced a program outlining reforms in political, economic, and cultural matters. Despite changes in the top level, the conservative wing of the party still held a strong position in the Central Committee and other party organs. In order to secure more support, Dubček called an extraordinary congress for September. Special committees were formed to prepare material for that session.

The rise of Dubček

Dubček's activities were supported by the press and other media. Students and writers enthusiastically joined the efforts to give "human face" to Socialism. Not only the non-Communist members of the National Front but also nonparty intellectuals felt encouraged to take active part in public affairs. The movement was not uniform. While the Slovaks put the need of federalization above other concerns, the Czechs insisted on a complete rehabilitation of persons afflicted by "violation of socialist legality" and on better guarantees of freedom of expression. The new leadership adopted a sympathetic attitude to the fresh currents in public life without, however,

giving up the idea that the Communist Party must retain its dominant position.

It was apparent, however, that the conservative wing had not lost backing among the rank and file and in the cumbersome apparatus created by Gottwald and his successors. From the countries of the Warsaw Pact, warnings were heard more often than applause. Walter Ulbricht and Władysław Gomułka were less cautious than Soviet statesmen in assessing the new trends. Several meetings and exchanges of visits occurred in the spring. Early in May, Dubček, Svoboda and other prominent officials journeyed to Moscow to dispel suspicions; they gave consent to army manoeuvres of the Warsaw Pact to be held in Czechoslovakia in summer. A group of senior officers arrived in Prague late in May to complete preparations for the war games.

As spring advanced, it became clear that the official decisions and the reforming zeal of the radicals were no longer in harmony. The Central Committee endorsed the April Action Program in principle but modified some of its concrete stipulations. These retrogressive steps were balanced by other measures, such as relaxation of censorship and a law providing for the rehabilitation of victims of political persecutions. Both groups reacted promptly. Diehards headed by Vasil Bilak widened their contacts with corresponding groups in the Warsaw Pact countries. The champions of liberalization on June 27 published a manifesto, the "Two Thousand Words," signed by more than 70 prominent persons. Although the party Presidium promptly disavowed the manifesto, the Soviet, Polish, and East German presses intensified their hostile campaign. The critical period opened.

Army manoeuvres began on June 20 and were officially closed on July 2. The movements of the Soviet units, ostensibly heading eastward, caused a good deal of anxiety. Symptoms of uneasiness multiplied rapidly. The Soviet, Bulgarian, East German, Hungarian, and Polish leaders met in Warsaw in mid-July to review the situation. Dubček replied promptly to their letter and reaffirmed his loyalty to the Warsaw Pact. But the exchange of messages did not dispel suspicions. On July 29 the Soviet Politburo met with the Czechoslovak delegation at a border railroad station, Čierna nad Tisou. The agreement reached there was vague, allowing for different interpretation of its articles. On August 3 the same men who attended the Warsaw conference met with Dubček and his group at Bratislava; the statement issued there contributed nothing new to the controversy. Seemingly, the differences were settled to mutual satisfaction. But events occurring on both sides increased the tension. In Czechoslovakia the liberalization continued; problems handled in other Communist countries behind closed doors were ventilated publicly and with unprecedented audacity. To fasten the ties with countries not present in either Warsaw or Bratislava, Dubček invited Tito and President Ceausescu to Prague; Tito arrived on August 11, Ceausescu, on August 15. They were received with great enthusiasm. Ulbricht requested a meeting with Dubček; Marshal Andrey Grechko went to East Germany for a conference with the defense minister, General Hoffman. Criticism of "a noticeable intensification in Prague of subversive activities by anti-Socialist forces," published in *Pravda* on August 18, portended nothing good.

Foreign invasion

In the night of August 20–21, the troops of the five Warsaw Pact countries, namely, the Soviet Union, Poland, Hungary, Bulgaria, and the German Democratic Republic, crossed the Czechoslovak frontier and took over the country with amazing efficiency. Late on August 21 Dubček and some of his aides were taken away to an unknown destination. The arrival of foreign troops aroused spontaneous reaction among the population. Attempts to form a pliable Cabinet came to nothing. On August 23, President Svoboda, accompanied by six notables, left for Moscow. Dubček and his aides were transferred there and participated in negotiations. An agreement on "normalization of the situation" was eventually reached; the Czechoslovak delegation returned to Prague on August 27. During the absence of the top leaders, the population had been guided by radio and television; other sources of information were underground newspapers, leaflets, and posters urging people to avoid clashes with foreign troops. The National Assembly held sessions during the critical period. On August 22 an extraordinary congress of the party, which had been scheduled for September 9, was hastily convened; 1,192 out of 1,543 elected delegates met in a Prague suburb and debated reports of the committees. In Slovakia, Vasil Bilak was, on August 28, replaced by Husák as the first secretary. In a public statement Husák expressed doubts concerning the validity of the extraordinary congress; his rise to prominence began.

Normalization and consolidation (1968–71). Forces of the smaller countries soon withdrew, but reduced Soviet units remained quartered in strategic positions. A treaty on their stationing was signed on October 16, 1968, and then endorsed by the National Assembly. Soviet leaders increased efforts to obtain an additional sanction of their military intervention. The August events were to be harmonized with the principles defined in a *Pravda* article (September 26) and called henceforth the Brezhnev Doctrine. Except for some replacements, Dubček's team retained the leading positions both in the party and state. Attempts were made to put the less objectionable points of the April program into effect and thus restore people's confidence. On October 28, the 50th anniversary of the republic, the law concerning federalization of the country was approved; it was signed in Bratislava on October 30. It brought about noticeable changes in every sector of public life. New posts both in the party and in the government were created and filled to give the Slovaks parity with the Czechs. Dubček's repeated efforts to recapture people's sympathy missed the mark. The population was guided more by instinct than by official proclamations. Its hero became Jan Palach, a student who on January 16, 1969, set himself on fire in protest against the erosion of freedom in Czechoslovakia. But his heroic deed did not bring about a significant change; the bulk of the population was rapidly losing interest in public affairs; material problems and everyday worries took precedence over big issues affecting the country.

Demotion of Dubček

The Soviet determination to obtain an additional approval of the August events was the strongest factor in shaping Czechoslovak policy in 1969 and thereafter. Since Dubček's statements were found evasive, he was gradually moved from the top level to total insignificance. In April 1969 the foremost champion of the "new realism," G. Husák, took over as the first secretary and found enough support in Moscow and at home to silence the opposition, which was entrenched in cultural organizations and educational institutions. Černík's fall in January 1970 marked the end of another chapter. Czechoslovak ties with the Soviet Union were tightened in May 1970 by a 20 years' treaty of friendship, cooperation, and mutual aid. The most important development at home was a thorough purge of the party, which went on until the end of 1970.

The final step toward "normalization" was made by Husák at the 24th Soviet Party Congress in Moscow (March–April 1971). Husák admitted that Socialism in Czechoslovakia had been in danger and that the armed intervention by members of the Warsaw Pact "saved his country from civil war and counterrevolution." The Czechoslovak Party Congress (late May 1971) reaffirmed Husák's declaration and annulled the extraordinary assembly of August 1968. The congress approved the list of new members of both the Presidium and the Central Committee of the party; Husák was acclaimed as secretary general. The large scale purge was sanctioned; the principle of permanent purge opened the door to continuous search for unreliable elements. In the presence of delegates from the five Warsaw Pact countries, Czechoslovakia was fully rehabilitated and readmitted into the Moscow-led bloc as a loyal and dependable member.

BIBLIOGRAPHY. Standard works in Czech, Slovak, English, German, and French are listed in PAUL L. HORECKY (ed.), *East Central Europe: A Guide to Basic Publications* (1969). The following books supply information on various

aspects of national history of the Czechs and Slovaks. Although outdated in some points, R.W. SETON-WATSON, *History of the Czechs and Slovaks* (1943), can be used for general orientation. S.H. THOMSON, *Czechoslovakia in European History*, 2nd ed. (1953), is arranged topically rather than chronologically and treats the basic issues. The perennial problem of Czech–German coexistence is presented by E. WISKEMANN in *Czechs and Germans*, 2nd ed. (1967). JOZEF LETTRICH, *History of Modern Slovakia* (1955), has as its main theme the Czech–Slovak relationship in the era of democracy. R.R. BETTS devoted most of his *Essays in Czech History* (1969) to the Hussite movement. Two books by F. DVORNIK, *The Making of Central and Eastern Europe* (1949) and *Byzantine Missions Among the Slavs* (1970), although dealing with general issues of medieval Slavic history, contain information on early Bohemia and its rise as an independent country. R.E. WELTSCH, *Archbishop John of Jenstein (1348–1400)* (1968), is a biography of the third archbishop of Prague and sheds light on state–church relations around 1390. From among several books of M. SPINKA, *John Hus: A Biography* (1968), should be mentioned as the best summary of the reformer's life and teachings. H. KAMINSKY, *A History of the Hussite Revolution* (1967); and F.G. HEYMANN, *John Žižka and the Hussite Revolution* (1955), have much in common; but while the former analyzes competently the ideas of the Hussite leaders in relation to political events, the latter describes the defense of the Hussite inheritance by Žižka and his followers. F.G. HEYMANN, *George of Bohemia, King of Heretics* (1965); and O. ODLOZILIK, *The Hussite King* (1965), cover much the same ground, the era of consolidation under the moderate Hussite leadership. There is no outline in English of Czech religious history in the 15th and 16th centuries. Two solidly documented monographs contribute to the knowledge of the "third party," the Unity: PETER BROCK writes on *Political and Social Doctrines of the Unity of Czech Brethren in the Fifteenth and Early Sixteenth Centuries* (1957); and J.K. ZEMAN traces the contacts of two groups, *The Anabaptists and the Czech Brethren in Moravia, 1526–1628* (1969). R.J. KERNER, *Bohemia in the Eighteenth Century* (1932, reprinted 1969), has a general survey of post-White Mountain developments, but its main emphasis is on social and economic conditions under the "Enlightened despots." The book of essays, edited by PETER BROCK and H. GORDON SKILLING, *The Czech Renascence of the Nineteenth Century* (1970), examines significant episodes in the development of modern Czech nationalism. Three of its contributors published monographs on specific features of Czech national life in the 19th century: S. PECH on *The Czech Revolution of 1848* (1969); J.F. ZACEK on *Palacký: The Historian As Scholar and Nationalist* (1970); and S.B. KIMBALL on *Czech Nationalism: A Study of the National Theater Movement, 1845–1883* (1964). The book of essays *Czechoslovakia: Twenty Years of Independence*, ed. by R.J. KERNER, appeared in 1940 as a record of the achievements of the Czechoslovak democracy. D.H. PERMAN, *The Shaping of the Czechoslovak State* (1962), is an excellent survey of peace negotiations pertaining to the creation of the republic. R. LUZA, *The Transfer of the Sudeten Germans: A Study of Czech-German Relations, 1933–1962* (1964), connects topically with Wiskemann's book and carries the story into the post-Munich era. V. MASTNY, *The Czechs Under Nazi Rule* (1971), is a succinct account of the early period of the German control of Bohemia and Moravia. Many books appeared in recent years on the Communist movement in Czechoslovakia, some of them hastily compiled and quickly antiquated. Three serious studies illustrate the earlier period: P.E. ZINNER, *Communist Strategy and Tactics in Czechoslovakia, 1918–1948* (1963); J. KORBEL, *The Communist Subversion of Czechoslovakia, 1938–1948* (1959); EDWARD TABORSKY, *Communism in Czechoslovakia, 1948–60* (1961). Three well-informed authors introduce the rather complicated story of liberalization and its gradual suppression after August 1968: T. SZULC, *Czechoslovakia Since World War II* (1971); W. SHAWCROSS, *Dubček* (1970); P. WINDSOR and A. ROBERTS, *Czechoslovakia, 1968* (1969). The debate of the merits of the movement symbolized by Alexander Dubček goes on.

(O.O.)

Bohemond I, Prince of Antioch

Norman adventurer, crusading leader, and prince of Antioch, Bohemond was one of the most important figures in the First Crusade. History records him as a handsome man, a warrior of genius, and a gifted diplomat.

Son of Robert Guiscard (the Wily) and his first wife, Alberada, Bohemond was christened Marc but nicknamed after a legendary giant named Bohemond. The nickname proved well taken because physically Bohemond was the ideally tall and strong knight—in the words of a contemporary, "a wonderful spectacle." His boyhood home was in southern Italy, where his Norman father Robert had gone as a mercenary and had risen to the rank of duke of Apulia and Calabria. Here Bohemond became involved in his father's wars and learned his trade as a fighter and leader. This early training must be inferred, however, as Bohemond's childhood is poorly recorded. His date of birth is placed between 1050 and 1058. In 1079 he was in command of a unit of his father's army. Meanwhile, his stepmother, Sigelgaita, bore his father's heir-to-be, Roger Borsa; thus, Bohemond no doubt felt early in life that he would have no patrimony because of his half-brother and so would have to seek lands and fortune in the weakened condition of the Greek empire.

In 1081 Bohemond, in command of his father's army, captured Avlona, a town south of Durazzo; but in this same year Alexius I Comnenus became ruler of the Byzantine Empire and challenged the Norman threat. For over three decades Alexius and Bohemond were rivals. In the opening struggle, 1081–85, Bohemond and his father came close to dismembering the Greek empire in the West. The Norman army won a few brilliant victories, but the persistence of Alexius drove Bohemond from Larissa in Thessaly in 1083, and the death of his father in 1085 left Bohemond without a patrimony and with little hope of success against Byzantium. In the next four years Roger Borsa allowed Bohemond to gain a foothold in Bari (about 65 miles northwest of Brindisi), where he awaited another chance to move decisively against Alexius.

Rivalry with Alexius I Comnenus

The chance came when Pope Urban II launched the First Crusade in November 1095 by offering rewards in both this world and the next for those who wrested the Holy Sepulchre from the Saracens. When the word reached Bohemond, he set off for the East. Bohemond and his small band of Normans crossed the Greek lands in the winter of 1096–97 with few incidents; and on passing through Constantinople, he made friendly, though cautious, terms with the emperor Alexius. The latter managed to extract oaths from most of the leaders, including Bohemond, and helped them cross the Bosporus, speeding them with promises of aid if they would return to the sovereignty of the Emperor the Byzantine lands recaptured from the Muslims. In the ensuing campaigns against the Turks, Bohemond distinguished himself at Nicaea, Dorylaeum, and Antioch, which was besieged from October 1097 until June 3, 1098. The city of Antioch fell to the crusaders through his cunning and his negotiations with a traitor, Fīrūz. After a brief, unsuccessful countersiege by the Turks, during which Bohemond more or less assumed command, the crusaders dawdled away the summer and fall.

Bohemond assumes the rule of Antioch

When the crusading army marched southward to Jerusalem in January 1099, Bohemond was left the de facto possessor of Antioch, although his claim was not openly supported for fear of violating the oath of Alexius. The Norman leader did not participate in the capture of Jerusalem but did, for the sake of appearances, journey later to the Holy Sepulchre. With the departure of many crusaders for their homelands, Bohemond was left with his city, hemmed in by Alexius to the north and the Muslim world to the east. Following sorties against Aleppo, Bohemond made the mistake of moving against the emir of Sebastea (Sivas), to the north of Antioch. The "little God of the Christians," as he was termed by the Turks, fell into an ambush and was captured and held in chains for months.

Released in 1103, he returned to Antioch and its problems. In 1105 Bohemond was in Bari to enlist reinforcements for his struggle with the Greeks. In September 1105 he went to Rome to interview the Pope and then journeyed, early in 1106, through France. There, babies were named for him, crowds heard him denounce the perfidious Alexius, and shrines received sacred relics from his hands. In the spring of 1106 Bohemond married Constance, the daughter of Philip I of France, in a brilliant ceremony at Chartres.

Bohemond, who 30 years before had been a landless young man, now stood at the pinnacle of his career. By September 1107 he was ready to launch his crusade against the Greeks and within a month had landed a large army at Avlona. In the months that followed, Durazzo held firm against the Normans, and Bohemond met with misfortune in Albania. In this impasse Alexius, anxious to end the war, offered Bohemond Antioch and other Greek cities in return for vassalage. In accepting these terms, Bohemond suffered humiliation even though he retained control of Antioch. He had used the crusade against Alexius, however, to further his ambition for an empire that stretched from Apulia to Antioch and had thereby cheapened the crusading idea.

The years following this peace of discord are poorly recorded. Constance bore Bohemond two sons, one of whom later became Prince of Antioch. Bohemond probably sought to raise another army, but he died on March 7, 1111. His combat with the Greeks was ended, and his rival Alexius followed him in death in 1118. Nicknamed for a giant, Bohemond had fought against gigantic odds and at death bequeathed to his heirs one of the important crusader states, the Principality of Antioch.

BIBLIOGRAPHY. R.B. YEWDALE, *Bohemond I: Prince of Antioch* (1917), offers the best biography of Bohemond; R.L. NICHOLSON, *Tancred: A Study of His Career and Work in Their Relation to the First Crusade and the Establishment of the Latin States in Syria and Palestine* (1940), supplements the work of Yewdale; K.M. SETTON and M.W. BALDWIN (eds.), *A History of the Crusades*, vol. 1 (1955), is the best general work on Bohemond.

(J.H.Hi./L.L.H.)

Böhme, Jakob

Jakob Böhme, a German philosophical mystic who summed up various Renaissance and Reformation mystical views in his writings, became one of the most influential leaders in later intellectual movements. Through his religious and mystical writings he exerted a profound influence on movements such as idealism and romanticism, and on the views of such modern thinkers as Nikolay Berdyayev and Paul Tillich. His influence was also important in the development and expansion of the Quakers, German Pietism, and theosophy.

Böhme, woodcut by Hugo Bürkner (1818–97).

Early mystical experiences

Böhme was born in 1575, at the end of the Reformation period, in the Upper Lusatian (German) village of Altseidenberg. After receiving a rudimentary education, he went, in 1594 or 1595, to nearby Görlitz, a town where controversies over Reformation issues seethed. Here crypto-Calvinists (Lutherans charged with maintaining Calvinist views), Anabaptists (radical Protestants), Schwenkfeldians (followers of the Reformer Schwenkfeld), Paracelsian physicians (followers of the occultic physician Paracelus), and humanists vied with orthodox Lutherans. Martin Möller, the Lutheran pastor of Görlitz, was "awakening" many in the conventicles that he had established. At these religious meetings traditional materials, both early Christian and medieval German, were studied by a varied group of persons.

In 1600, newly married and just established with a shoemaker's bench of his own, Böhme, probably stimulated by Möller, had a religious experience within the period of a quarter hour wherein he gained an empirical and speculative insight that helped him to resolve the tensions of his age. The strain between medieval and Renaissance cosmologies (dealing with the order of the universe), the perennial problem of evil, the collapse of feudal hierarchies, and the political and religious bifurcation of the time found resolution in Böhme's rediscovery, as he said, of the dialectical principle that "in Yes and No all things consist." Basically Lutheran ("we shall fear and love God," as Luther's Small Catechism states), this principle became with Böhme a *Realdialektik* ("real dialectic"), a wide-ranging polarization of empirical or natural reality.

The Aurora his first writing

Germinating for several years, the insight led him to commit his thoughts to paper, at first for his own use. The manuscript was entitled *The Aurora* (1612) and was written in stages. Called by Böhme a "childlike beginning" it was a conglomeration of theology, philosophy, and what then passed for astrology, all bound together by a common devotional theme. Circulating among Böhme's friends, a copy of *The Aurora* fell into the hands of Gregory Richter, successor to Martin Möller as pastor, who condemned the shoemaker's pretensions to theology. Richter brought the matter up with the Görlitz town council, which forbade further writing on Böhme's part.

A period of silence ensued during which Böhme's ideas matured and his outer affairs prospered. He read the "high masters" as well as other unnamed books that were lent to him by the circle of neighbours and friends who were awed by the book-writing intellectual cobbler. These friends—some physicians, and others of the nobility—introduced Böhme to speculative alchemy, especially to the writings of the Swiss physician Paracelsus (*c.* 1490–1541) that were then quite popular. The alchemical and mystical views of Paracelsus further inspired Böhme's interest in nature mysticism and gave him the terminology which, in a partly integrated way, dominated his next period.

Although he never worked in a laboratory himself, Böhme did use its alchemical terms to describe both his nature mysticism and his subjective experiences, which he sought to integrate into a common framework. During this period Böhme wrote at least six tracts that were circulated guardedly among his friends, creating an influential and respected reputation for him. This second period of writing activity began in 1619, the year when the Thirty Years' War (1618–48) was beginning to gain momentum; in fact, Böhme himself was in Prague (Czechoslovakia) when the Winter King, Frederick V of the Rhine Palatinate, entered. The various strident controversies of the age forced Böhme into a period of religious apologetics wherein he had to protest his orthodoxy against accusations, more implied than actual, of Calvinism (Reformed views), chiliasm (belief in the 1,000-year reign of God's people at the end of history), and rabid sectarianism. Reconstructing his theological views, he wrote a series of devotional tracts dealing with penitence, resignation, regeneration—traditional themes of German mysticism. In 1622 his friends had several of these devotional tracts printed in Görlitz under the title *The Way to Christ*, a small work joining nature mysticism with devotional fervour. Publication of this tract brought about the intense displeasure of Richter, who incited the populace against Böhme.

In 1623, the year of his maturity, he wrote two major works: *The Great Mystery* and *On the Election of Grace.* The former explained the creation of the universe as told in Genesis in terms of the Paracelsian three principles (including the mystical elements "salt," "sulfur,"

and "mercury"), thus joining Renaissance nature mysticism with biblical religion. The latter, more philosophical, gave exposition in terms of dialectical insight to the problem of freedom that Calvinist predestination (the view that man's destiny is foreknown by God) was then making acute. This theme later was taken up by the idealist philosopher Friedrich Schelling and by a German theologian, Franz von Baader, whose commentary *On the Election of Grace* is still held in high regard by scholars.

Later career

Böhme continued his writing at hectic pace, perhaps freed from business obligations by financial help from his friends. Between 1619, when he defiantly renewed his writing, and 1624, when he died, he produced at least 30 works. His defiance of the town council of Görlitz brought him further difficulty and he was banished, being cited to the Elector's court in Dresden, where, to all appearances, he found vindication because he returned to his home. Although vindicated by the theologians who had examined his views, he was not free from the rancorous moods of his neighbours who were instigated in their attacks by Richter. Esteemed by his friends among the nobility, physicians, and intellectuals, he fled to one of the neighbouring castles where he clearly was the central figure in some kind of secretive group. There he fell sick and, sensing that his end was near, he was taken back home to Görlitz where, attended by his wife and sons, he began to weaken. He was examined by ecclesiastical authorities, found orthodox enough to be given the sacrament, and on November 21, 1624, in a mood of charismatic expectancy, he died.

BIBLIOGRAPHY. The 17th-century translation of Böhme into English by J. ELLISTONE and J. SPARROW, *The Works of Jacob Behmen*, 4 vol., reprinted in the 20th century, is considered to have more grace and elegance than modern translations of some tracts by J.R. EARLE and J.J. STOUDT. The 1730 German edition of the collected works, edited by J.W. UEBERFELD and reprinted in facsimile during the 1950s by W.E. PEUCKERT, remains the best text, although in modernized German; valuable biographical matter may be found in vol. 10. The most serviceable English biography utilizing modern materials is J.J. STOUDT, *Jacob Boehme: His Life and Thought* (1968), based on the standard German biographical works by W.E. PEUCKERT, *Das Leben Jakob Böhmes* (1924); and R. JECHT, *Jakob Böhme, Gedenkgabe der Stadt Görlitz* (1924). The best modern interpretation is A. KOYRE, *La Philosophie de Jacob Boehme* (1929); the most profound is E. BENZ, *Der vollkommene Mensch nach Jakob Böhme* (1937).

(J.J.S.)

Bohr, Niels

One of the foremost scientists of the 20th century, Niels Henrik David Bohr was the first to apply the quantum theory (that the energy of a system at the atomic or molecular scale can take on only certain discrete values) to the problem of atomic structure. He was a guiding spirit and major contributor to the development of quantum physics for almost 50 years.

Early life in Denmark and Britain

Bohr was born in Copenhagen on October 7, 1885, the son of Christian Bohr, professor of physiology at the University of Copenhagen, and Ellen Adler Bohr, whose family was prominent in Danish banking. His scientific interests and abilities were evident early and were encouraged and fostered at home. As a 22-year-old student at the University of Copenhagen he won a gold medal from the Royal Danish Academy of Sciences and Letters for his precise experimental study of the surface tension of water. In 1911 Bohr received his doctorate for a thesis on the electron theory of metals. He then went to England intending to continue this work with J.J. Thomson at Cambridge, but soon moved to Manchester to join Ernest Rutherford's group studying the structure of the atom.

His first great work began with a study of the theoretical implications of the nuclear model of the atom proposed by Rutherford. Bohr was among the first to see the importance of the atomic number (a number assigned to each element and equal to the electric charge on the nuclei of its atoms) in characterizing the physical and chemical properties of the elements. In 1913 he combined the concept of the nuclear atom with the quantum theory of Max Planck and Albert Einstein in a theory that accounted quantitatively for the lines observed in the spectrum of light emitted by atomic hydrogen. To do so, he departed radically from classical physics, postulating that any atom could exist only in a discrete set of stable energy states, that radiation would be emitted only when the atom made a transition between two of these states, and that the frequency of this radiation depended only on the difference in energy between initial and final states. This meant that the atom could neither absorb nor emit energy continuously but only in finite steps or quantum jumps.

Bohr.

Bohr was married to Margrethe Nørlund in 1912, at just the time when he was working out his bold new ideas. He stayed on at Manchester, with some interruptions, until 1916 when he returned to Copenhagen as professor. In 1920 he became director of the newly created Institute for Theoretical Physics, a position he held until his death. Bohr's work on atomic structure was recognized by the Nobel Prize for Physics in 1922.

Bohr elaborated his ideas in the early 1920s to explain the atomic basis of the periodic table of the elements and many atomic properties. More than any of his contemporaries, however, Bohr stressed the tentative and symbolic nature of the atomic models that were used, since he was convinced that an even more radical change in physics was still to come.

By the time that change arrived, with the quantum mechanics of 1925–26 by Werner Heisenberg, Erwin Schrödinger, Max Born, Wolfgang Pauli, Paul Dirac, and others, Bohr's institute had become the world capital for atomic physics. A steady stream of people flowed into Copenhagen to work on quantum theory with Bohr, work that was carried on by intense discussions as well as lengthy calculations. Out of these discussions came a physical interpretation of the new mathematical description of nature, linking it with the procedures and results of the experimental physicists. Bohr expressed the characteristic feature of quantum physics in his principle of complementarity:

Principle of complementarity

> Evidence obtained under different experimental conditions cannot be comprehended within a single picture, but must be regarded as complementary in the sense that only the totality of the phenomena exhausts the possible information about the objects.

This Copenhagen interpretation of the meaning of quantum physics, with its altered view of the meaning of physical explanation, was generally accepted by scientists, but Albert Einstein, among others, held out against it until the end of his life. He and Bohr often discussed the fundamental questions of physics over the years, and Einstein's challenging objections played an important part in the evolution of Bohr's ideas.

During the 1930s Bohr continued to work on the epistemological problems raised by the quantum theory, and also contributed to the new field of nuclear physics. His concept of the atomic nucleus, which he likened to a liquid droplet, played an essential part in the understanding of nuclear fission (the splitting of a heavy nucleus into two parts, almost equal in mass, with the release of a tremendous amount of energy).

Role under German occupation

When Denmark was overrun and occupied by the Germans in 1940, Bohr did what he could to maintain the work of his institute and to preserve the integrity of Danish culture against Nazi influences. In 1943, under threat of immediate arrest (Bohr's mother had been Jewish and his anti-Nazi views were no secret), he escaped to Sweden with his family by fishing boat with the help of the Danish resistance movement. He and his son, Aage, also a theoretical physicist and Bohr's eventual successor as director of the institute, took part in the projects for making a nuclear fission bomb, first in England and then in Los Alamos, New Mexico. Bohr's concern about the terrifying prospects for humanity produced by such atomic weapons was evident as early as 1944, when he tried to persuade Churchill and Roosevelt of the need for international cooperation in dealing with these problems. Although this did not succeed, Bohr continued to argue for rational, peaceful policies, advocating an "open world" in a public letter to the United Nations in 1950. Bohr was convinced that free exchange of people and ideas among countries was necessary to achieve control of nuclear weapons. He led in promoting such international efforts as the First International Conference on the Peaceful Uses of Atomic Energy, Geneva (1955), and in creating the European nuclear physics laboratory (CERN). Among his many honours, Bohr received the first U.S. Atoms for Peace Award in 1957.

In his later years Bohr tried to point out ways in which the idea of complementarity could throw light on many aspects of human life and thought from biology and anthropology to the age-old problems arising from the fact that man both acts and is the spectator of his actions. Bohr had a major influence on several generations of physicists, deepening their approach to their science and to their lives. He himself was always ready to learn from his younger collaborators. He drew strength from his close family ties with his sons, his wife, and his younger brother, Harald, a famous mathematician in his own right and Bohr's closest friend.

Niels Bohr died peacefully on November 18, 1962. Bohr's works include *The Theory of Spectra and Atomic Constitution* (1922), *Atomic Theory and the Description of Nature* (1934), *Atomic Physics and Human Knowledge* (1958), and *Essays, 1958–1962, on Atomic Physics and Human Knowledge* (1963). The last two include, respectively, his wonderful accounts of his relationships with Einstein and Rutherford.

BIBLIOGRAPHY. There is no definitive biography of Bohr; however, STEFAN ROZENTAL (ed.), *Niels Bohr: His Life and Work As Seen by His Friends and Colleagues* (1967), contains much biographical material. See also the article by LEON ROSENFELD in the *Dictionary of Scientific Biography*, vol. 2, pp. 239–254 (1970), an authoritative account of Bohr's life and work with bibliographical references; RUTH MOORE, *Niels Bohr: The Man, His Science and the World They Changed* (1966), a popular biography; WERNER HEISENBERG, *Der Teil und das Ganze* (1969; Eng. trans., *Physics and Beyond: Encounters and Conversations*, 1971), contains much material on Bohr and his work, by one of his leading collaborators; MAX JAMMER, *The Conceptual Development of Quantum Mechanics* (1966), a history of quantum physics with technical details on Bohr's work through 1927; and BRYCE S. DEWITT and R. NEILL GRAHAM, "Resource Letter IQM–1 on the Interpretation of Quantum Mechanics," *Am. J. Phys.*, 39:724–738 (1971), an annotated bibliography placing some of Bohr's contributions in perspective.

Bolingbroke, Henry St. John, 1st Viscount

A prominent English politician in the reign of Queen Anne (1702–14) and, later, a major political propagandist in opposition to the Whig Party then led by Sir Robert Walpole, Bolingbroke was also a historian of some talent and a would-be philosopher in touch with many of the trends of the European Enlightenment. Intelligent and widely read, he was also noted for his handsome appearance, graceful manners, and brilliant conversation. Clear and forceful in speech and in print and imperious in temperament, he captivated some of the finest minds of his age. On the other hand, he was a notorious libertine and a poor manager of men who tended to lose his nerve in a crisis, and his unscrupulous ambition betrayed him into serious political errors and gained him a reputation for treachery.

Bolingbroke, oil painting attributed to Alexis-Simon Belle, probably 1712. In the National Portrait Gallery, London.

The eldest son of Sir Henry St. John (afterward 1st Viscount St. John; pronounced sin' jun), he was born on September 16, 1678, probably in Wiltshire; he was possibly educated at a Dissenting academy rather than at Eton and Oxford, as has been claimed. In 1698–99 he travelled in Europe, and in 1700 he married Frances Winchcombe. In 1701, he entered Parliament, where he soon won a reputation by his superb oratory and his support of partisan Tory measures, including attacks on the previous Whig ministry and on the Protestant Dissenters, who were the Whigs' staunchest allies. His conduct soon brought him to the notice of the government, and, after he was made secretary at war (1704), he was converted, temporarily, to the moderate policies of Robert Harley, one of Queen Anne's principal ministers. For four years, he worked hard to provide the Duke of Marlborough with troops and equipment for the War of the Spanish Succession against France and then resigned with Harley (February 1708) when they failed to prevent the Whigs from dictating government policy. Failing to gain a seat in the 1708–10 Parliament, he urged Harley to ally with the Tory Party as the best means to defeat the Whigs.

Alliance with Harley

In 1710 St. John became northern secretary of state in Harley's new ministry, but he soon emerged as an opponent of Harley's moderation and a rival to his authority. His efforts to control the government's policies and to supplant Harley (after 1711 the earl of Oxford) were largely unsuccessful. Oxford had initiated secret peace negotiations with France, but, even after he had learned of these and had forced his way into the discussions, St. John (after 1712 Viscount Bolingbroke) was not able to dictate the terms that were finally settled at the Treaty of Utrecht (1713). In Parliament, Bolingbroke was no more successful in leading a Tory rebellion against Oxford. He won over some Tories by such partisan measures as the Schism Act (1714), which aimed at depriving the Dissenters of their schools, but he failed to persuade the majority to support his leadership and was unable to give the Tories a clear lead on the disputed succession to Queen

Anne. Oxford was eventually dismissed on July 27, 1714, but the Queen's death, on August 1, ruined Bolingbroke's hopes of replacing him.

Exile in France

Dismissed from office by George I and fearing impeachment because of his role in the peace negotiations with France and his intrigues with the Jacobites (the supporters of James III, the Old Pretender), Bolingbroke fled to France (March 1715) and became the Old Pretender's secretary of state in July. This enabled the British government to pass an act of attainder against him by which his property and civil liberties were taken away. As a result, Bolingbroke's political future depended upon a successful Jacobite rebellion. Despite Bolingbroke's hard work, the attempted Jacobite rising in 1715 was a dismal failure. Amidst bitter recriminations, Bolingbroke was dismissed by the Old Pretender and at once sought to ingratiate himself with the Whig government in England. In 1717 he wrote a *Letter to Sir William Wyndham* (not published until 1753) to defend his actions since 1710 and to persuade the Tories to abandon the Jacobite cause. Not surprisingly, he found it difficult to persuade men to forget his recent conduct.

Forced to remain in exile, Bolingbroke sought other outlets for his talents. Mixing with aristocrats and scholars, including Voltaire, he embarked on biblical, historical, and philosophical studies and wrote several works, including *Reflections upon Exile* and *Reflections Concerning Innate Moral Principles*. Shortly after the death of his first wife, he married a French widow, the Marquise de Villette (1719).

After years of petitioning the British government and of trying to assist it with his limited influence at the French court, Bolingbroke was pardoned in 1723. He did not, however, resettle in England until 1725, when an act allowed him to buy a small estate at Dawley, near London; his attainder was never fully reversed, and he was unable to regain his peerage or reclaim his seat in the Lords. He imputed this exclusion from parliamentary life to the animosity of Sir Robert Walpole. Though his own frustrated ambition clearly motivated his long campaign against Walpole's political ascendancy, he was also concerned by the way Walpole appeared to monopolize power by the excessive use of bribery and corruption. While charges of such behaviour were exaggerated, there was enough truth in them to build up a formidable opposition to Walpole. At the centre of a literary circle that included Jonathan Swift, Alexander Pope, and John Gay, Bolingbroke waged an influential propaganda campaign. His major contributions to *The Craftsman*, an opposition journal, were the "Remarks on the History of England" (1730–31) and "A Dissertation upon Parties" (1733–34), both of which sought to end the old Whig–Tory disputes and to weld the disparate elements of the opposition to Walpole into a new Country Party, which would protect the independence of Parliament against the encroachments of a corrupt government.

Despite occasional successes, Bolingbroke was unable to bring down Walpole or create a united opposition party. In 1735 he retreated to France, where he continued his studies in philosophy and history, lamenting his countrymen's lack of patriotism in the struggle against Walpole. After a short visit to England in 1738, his hopes revived of a new opposition party that was gathering at Leicester House around George II's son Frederick, prince of Wales. For this group, he wrote *The Idea of a Patriot King*. It was his most famous work, but it offered no real solution to the problems of defeating Walpole or of creating a "patriot" party. In any event, Prince Frederick did not live to become king, and Walpole's final defeat, in 1742, was not engineered by Bolingbroke.

In his last years, Bolingbroke lacked any real political influence, though he still made vain efforts to create a patriot ministry. He was further embittered by his discovery, in 1744, that Alexander Pope had secretly printed 1,500 copies of *The Idea of a Patriot King* for publication. When, in 1749, Bolingbroke published a corrected version of this work, he was bitterly attacked for taking the opportunity to reveal Pope's earlier breach of faith. Bolingbroke's failing health was further undermined by his distress at his wife's death (March 1750). He himself died at Battersea of a facial cancer on December 12, 1751. Though he died a neglected figure, the posthumous publication of his works in 1754 stirred considerable controversy. His unorthodox religious views were at last made public and were denounced on all sides. Modern scholars have paid much less attention to his philosophical works, but he is widely regarded as one of the best contemporary analysts of the politics of the Whig supremacy.

DICKINSON, *Bolingbroke* (1970), now the standard life, based on extensive research and seeking to integrate and interpret Bolingbroke's political career and intellectual development; W.S. SICHEL, *Bolingbroke and His Times*, 2 vol. (1901–02, reprinted 1968), an old-fashioned biography, which is not very good on interpretation but which quotes much useful source material; G. HOLMES, *British Politics in the Age of Anne* (1967), a brilliant analysis, based on exhaustive research; I. KRAMNICK, *Bolingbroke and His Circle* (1968), a stimulating study of the political ideology of the age of Walpole.

(H.T.D.)

Bolívar, Simón

Simón Bolívar, soldier-statesman to whom six Latin-American republics owe their freedom from Spanish rule, is regarded by many as the greatest genius the Hispanic-American world has produced. A man of international renown in his own day, his reputation has steadily increased since his death. There are few figures in European history and none in the history of the United States that display the rare combination of strength and weakness, character and temperament, prophetic vision and poetic power that distinguish Simón Bolívar. As a consequence, his life and his work have grown to mythical dimensions among the people of his continent.

Bolívar, engraving by C.G. Childs (1793–1871).

Bolívar, the son of a Venezuelan aristocrat of Spanish descent, was born to wealth and position on July 24, 1783, in Caracas. His father died when the boy was three, and his mother died six years later. His uncle administered his inheritance and provided him with tutors. He was an unruly child, and only one of his teachers had a lasting influence on him. This was Simón Rodríguez, a disciple of Jean-Jacques Rousseau, who introduced Bolívar to the world of 18th-century liberal thought, which produced on him a deep and lasting effect.

Education in Europe; marriage

At the age of 16, Bolívar was sent to Europe to complete his education. For three years he lived in Spain and in 1801 married the daughter of a Spanish nobleman, with whom he returned to Caracas. The young bride died of yellow fever less than a year after her marriage. Bolívar

often pondered on the effect her tragic death may have had on him and believed that it was the reason for his taking up a political career while still a very young man. In 1804, when Napoleon was approaching the pinnacle of his career, Bolívar returned to Europe. In Paris he met his friend and tutor, and under Simón Rodríguez' renewed guidance steeped himself in the writings of such European rationalist thinkers as Locke, Hobbes, Buffon, d'Alembert, and Helvetius. In addition, he read Voltaire, Montesquieu, and Rousseau. The latter two had the deepest influence on his political thinking, but Voltaire coloured his philosophy of life. In Paris he also met the German scientist Alexander von Humboldt, who had just returned from his voyage through Hispanic America, and who told Bolívar that he believed the Spanish colonies were ripe for independence. This idea took root in Bolívar's imagination and on a trip to Rome, standing on the heights of the Monte Sacro, he made a vow to liberate his country.

One other experience enriched his intellect at this time: he watched the extraordinary performance that culminated in Napoleon's coronation in 1804 as emperor of the French. Bolívar's reaction to the coronation wavered between admiration of the accomplishments of a single man and revulsion at Napoleon's betrayal of the ideals of the Revolution. The desire for glory was one of the permanent traits in Bolívar's character, and there can be little doubt that it was stimulated by Napoleon. The example of Napoleon was, nevertheless, a warning that Bolívar heeded. In his later days he always insisted that the title of "liberator" was higher than any other and that he would not exchange it for that of king or emperor. In 1807 he returned to Venezuela by way of the United States, visiting the eastern cities.

Independence movement. The Latin-American independence movement was launched a year after Bolívar's return. It was touched off by Napoleon's invasion of the Iberian peninsula. The Spanish people resisted the intruder, and a junta assumed governmental powers during the absence of the legitimate king. Napoleon also failed completely in his attempt to gain the support of the Spanish colonies, who claimed the right to nominate their own officials. Following the example of the mother country, they wished to establish juntas to rule in the name of the deposed Spanish king. Many of the Spanish settlers, however, saw in these events an opportunity to sever their ties with Spain. Bolívar participated in many conspiratorial meetings, and when the governor of Venezuela, Vicente Emparán, reprimanded him, he answered boldly that he had declared war on Spain and could not withdraw. On April 19, 1810, Emparán was officially deprived of his powers and expelled from Venezuela, and a junta took over. To obtain help, Bolívar was sent on a mission to London, where he arrived in July. His assignment was to explain to England the plight of the revolutionary colony, to gain recognition for it, and to obtain arms and support. Although he failed in his negotiations on all counts, his English sojourn was in other respects a fruitful one. It gave him an opportunity to study the institutions of the United Kingdom, which remained for him models of political wisdom and stability. More important, he fostered the cause of the revolution by persuading the exiled Francisco de Miranda, who in 1806 had attempted to liberate Venezuela singlehandedly, to return to Caracas and to assume command of the independence movement.

The mission to London

Venezuela was in ferment. In March 1811 a national congress met in Caracas to draft a constitution. Bolívar, though not a delegate, threw himself into the debate that aroused the country. In the first public speech of his career he declared "Let us lay the cornerstone of American freedom without fear. To hesitate is to perish." After long deliberation the national assembly declared Venezuela's independence on July 5, 1811. Bolívar now entered the army of the young republic, whose commander in chief was Miranda. In the short time since their London meeting, however, the two men had drifted apart. Miranda called Bolívar a "dangerous youth," and Bolívar had misgivings about the ability of the aging general. When the Spaniards rallied to retain control of the colony, Bolívar was placed in charge of Puerto Cabello, a port vital to Venezuela. Treasonable action by one of Bolívar's officers opened the fortress to the Spanish forces, and Miranda, believing the loss of Puerto Cabello fatal to any future military action, entered into negotiations with the Spanish commander in chief. An armistice was signed (July 1812) which left the entire country to the mercy of Spain. Miranda was turned over to the Spaniards—some authorities say at Bolívar's instigation—and spent the rest of his life in Spanish dungeons.

Determined to continue the struggle, Bolívar obtained a passport to leave the country and went to Cartagena in New Granada (present-day Colombia). There he published the first of his great political statements: *El Manifiesto de Cartagena.*

Cartagena manifesto

> I am a son of unhappy Caracas, miraculously escaped from its political and material ruins, who . . . has come here to follow the banner of freedom.

His reference to miraculous escape refers to the catastrophic earthquake of March 26, 1812, which took a tremendous toll of lives in Caracas and other towns. He did not hesitate to point out the underlying causes for Venezuela's downfall: "Not the Spaniards, but our own disunity had led us back into slavery. The most important error committed by Venezuela upon entering the political theatre, was, without doubt, the fatal adoption of a system of tolerance, a weak and inefficient system, . . ." Bolívar had now emerged as the champion of strong government for the nascent republics of Hispanic America.

His plea was answered by the people of New Granada, and he was named commander of an expeditionary force whose task was to liberate Venezuela. In a sweeping hard-fought campaign he vanquished the Spaniards in six pitched battles and regained control of the capital. On August 6, 1813, he entered Caracas, was given the title of liberator, and assumed political dictatorship.

But the war of independence was just beginning. The majority of the people of Venezuela were hostile to the forces of independence and weary of the sacrifices imposed. A cruel, anarchic, murderous civil war broke out. Bolívar himself resorted to extreme measures, such as the "war to the Death" and the shooting of prisoners. But his severity failed in its object. In 1814 he was once more defeated by the Spanish, who had drawn the *llaneros*, the cowboys of the Orinoco Valley, into the war. The Spanish had converted the *llaneros*, led by José Tomás Boves, into an undisciplined but savagely effective cavalry that Bolívar was unable to repulse. Boves captured Caracas in 1814 and subjected the city to terrible atrocities. Thus ended the second Venezuelan republic. Bolívar narrowly escaped Miranda's fate. He managed to reach Cartagena, where he was commissioned to oust a separatist faction from Bogotá and succeeded in doing so. He then laid siege to the New Granadan port city of Cartagena, but failed to unite the revolutionary forces, and fled to Jamaica.

In exile he turned his energies toward gaining support from Great Britain, and in an effort to convince the British people of their stake in the freedom of the Spanish colonies, he wrote the greatest document of his career: *La Carta de Jamaica* ("The Letter from Jamaica"). "The bonds," wrote Bolívar, "that united us to Spain have been severed." He was not dismayed that the Spaniards had in certain instances won the upper hand. "A people that love freedom will in the end be free." Bolívar outlined a grandiose panorama from Chile and Argentina to Mexico. "We are," he said proudly, "a microcosm of the human race. We are a world apart, confined within two oceans, young in arts and sciences, but old as a human society. We are neither Indians nor Europeans, yet we are a part of each." What kind of government should emerge from the cataclysm of the independence movement? "The American states need the efforts of paternal governments to heal the wounds and scars made by despotism and war." He proposed constitutional republics, modelled on the government of Great Britain, with a hereditary upper house, an elected lower house,

"The Letter from Jamaica"

and a president chosen for life. The last provision, to which Bolívar clung throughout his career, constituted the most dubious feature of his political thinking.

In "The Letter from Jamaica" Bolívar showed himself as a great internationalist. Looking forward to the day when the representatives of all Hispanic-American nations would gather in a central location such as Panama, he wrote,

> How ineffable it would be if the Isthmus of Panama should become for America what the Straits of Corinth were for the Greeks. May God grant that we can some day enjoy the good fortune of opening a congress of representatives of the republics, kingdoms, and empires that would discuss peace and war with the rest of the nations of the world.

By 1815, however, Spain had sent to its seditious colonies the strongest expeditionary force that had ever crossed the Atlantic. Its commander was Pablo Morillo. Since neither Great Britain nor the United States would promise aid, Bolívar turned to Haiti, a small republic that had freed itself from French rule, where he was given a friendly reception, as well as money and weapons.

Liberation of New Granada. Three years of indecisive defeats and victories followed. In 1817 Bolívar decided to set up headquarters in the Orinoco region, which had not been devastated by war and from which the Spaniards could not easily oust him. He engaged the services of several thousand foreign soldiers and officers, mostly British and Irish, established his capital at Angostura (now Ciudad Bolívar), began to publish a newspaper, and established liaison with the revolutionary forces of the plains. Their leader, José Antonio Páez, recognized Bolívar's authority, and by 1819 the latter was firmly in command of the entire region. In the spring of that year he conceived his master plan of attacking the Spanish position on its western flank. He had previously centred his hopes on the liberation of Caracas, but he now concentrated on the bolder project of an attack on the Spanish viceroyalty of New Granada. In the plains of Casanare a force of patriots had withstood all Spanish attempts to destroy them. Their leader, Francisco de Paula Santander, made contact with Bolívar, who operated in the eastern part of the plains, and on June 12, 1819, the armies of Bolívar and Santander met and merged.

Páez and Santander

Bolívar's attack on New Granada will always be considered one of the most daring in military history. The route of the small army (about 2,500 men, including the British legion) led through the plains, but it was the rainy season and the rivers had become lakes. For seven days, said one of Bolívar's aides, they marched in water up to their waists. Ten navigable rivers were crossed, most of them in cowhide boats. But the journey through the plains seemed child's play in comparison with their ascent of the Andean mountains that stood between Bolívar and the city of Bogotá. Bolívar had chosen to cross the pass of Pisba, which the Spanish considered an inconceivable approach. An icy wind blew across the heights of the pass, and many of the scantily clad troops died of cold and exposure. But fatigue and loss were more than outweighed by the advantage gained in descending unopposed into New Granada. When the Spaniards recovered from their surprise, it was too late to throw Bolívar back. A series of skirmishes followed, culminating in the crucial Battle of Boyacá on August 7, 1819, when the bulk of the royalist army surrendered to Bolívar. Three days later he entered Bogotá. It was the turning point in the history of northern South America.

Indefatigably Bolívar set out to complete his task. He appointed Santander vice president in charge of the administration and in December 1819 made his appearance before the congress that had assembled in Angostura. Bolívar was made president and military dictator. As he said, the union of New Granada and Venezuela had been his goal since his earliest fighting days. He urged the legislators to proclaim the creation of a new state: the republic of Great Colombia, and three days later La República de Colombia was established. It was a federation and, since two of its three departments, Venezuela and Quito (Ecuador), were still under royalist control, it was only a paper achievement. Bolívar knew, however, that victory was finally within his reach. A revolution in Spain had forced the Spanish king to recognize the ideals of liberalism on the home front, and his action quite naturally discouraged the Spanish forces in South America. Bolívar persuaded Morillo to open armistice negotiations, and the two warriors met in a memorable encounter at Santa Ana, signing, in November 1820, a treaty that ended hostilities for a six-month period. When fighting was resumed, Bolívar found it easy, with his superior manpower, to defeat the Spanish forces in Venezuela. The Battle of Carabobo, June 1821, opened the gates of Caracas, and Bolívar's homeland was at last free. In the autumn of the same year a congress convened in Cúcuta to draft a constitution for Colombia. Its provisions disappointed Bolívar. Although he had been elected president, he thought the constitution too liberal in character to guarantee the survival of his creation. As long as more urgent assignments claimed his attention, however, he was willing to put up with its weak structure. Leaving the administration to Santander, he asked permission to continue his military campaign.

Creation of Great Colombia

At the end of a year, Ecuador was liberated. In this campaign Bolívar was assisted by the most brilliant of his officers, Antonio José de Sucre. While Bolívar engaged the Spaniards in the mountains that defended the northern access to Quito, capital of modern Ecuador, Sucre marched from the Pacific coast to the interior. At Pichincha on May 24, 1822, he won a victory that freed Ecuador from the Spanish yoke. On the following day the capital fell and Bolívar joined forces with Sucre on June 16.

It was in Quito that the Liberator met the great passion of his life, the vivacious and beautiful Manuela Sáenz. She was the ideal woman for a gallant soldier like Bolívar, the perfect mixture of Amazon and courtesan. An ardent revolutionary, she freely admitted her love for the Liberator and accompanied Bolívar from the battlefields to the presidential palace.

Liberation of Peru. The territory of Colombia had now been completely recovered from Spain and its new government recognized by the United States. Only Peru remained in the hands of the Spaniards. It was the Peruvian problem that brought Bolívar and the Argentinian revolutionary José de San Martín together. San Martín had done for the southern part of the continent what Bolívar had accomplished for the north. In addition, he had already entered Lima and proclaimed Peru's independence. But the Spanish forces retreated into the highlands, and San Martín, unable to follow them, decided to consult with Bolívar. On July 26, 1822, the two men met in the port city of Guayaquil, Ecuador, and their conference has been a source of controversy ever since. What took place has never become known, except in the form of either biased or fragmentary information. Apparently San Martín came to request military aid from Bolívar, and in addition he wanted to reach an understanding on problems of boundaries and the political future of Latin America. There was scant sympathy between the two. Bolívar, brilliant, ambitious, self-centred, was convinced that he was the "chosen son," singled out by providence to complete the independence of his people. San Martín was stoic, taciturn, self-effacing, and moderate. His failure to influence Bolívar was almost a foregone conclusion, and on his return from Guayaquil he resigned his office in Lima and went into exile. Whether he took this action to give Bolívar a free hand or out of a sense of personal frustration, is still not clear.

Meeting with José de San Martín

The avenue leading to Bolívar's ultimate ambition was now open. In September 1823 he arrived in Lima. The Spanish Army occupied the Sierra east of Lima and its position was considered unassailable. But for Bolívar, after the trials he had successfully passed, this was no deterrent. Men, horses, mules, and ammunition were systematically assembled to form an army, and in the summer of 1824 he ascended into the high mountain country. Once more, as chief of staff, Sucre was his able assistant. The first major battle, at Junín, was easily won by Bolívar, who then left the successful termination of

the campaign to Sucre. On December 9, 1824, the Spanish viceroy lost an important battle and surrendered with his entire army.

Bolivia. Bolívar was now president of Colombia and Peru. Only a small section of the continent—Upper Peru—was still defended by royalist forces. The liberation of this region fell to Sucre, and in April of 1825 he reported that the task had been terminated. The new nation chose to be called Bolivia after the name of the Liberator. For this child of his genius, Bolívar drafted a constitution that showed once more his authoritarian inclinations: a lifetime president, a legislative body without power, and a highly restricted suffrage. Bolívar was devoted to his own creation, but as an instrument of social reform it was a failure.

Treaties of alliance

Bolívar had now reached the high point of his career. His power extended from the Caribbean to the Argentine-Bolivian border. He had conquered severe illness, which during his sojourn in Peru had made him practically an invalid for months at a time. Another of his favourite projects, a league of Hispanic-American states, came to fruition in 1826. He had long advocated treaties of alliance between the American republics, whose weakness he correctly apprehended. By 1824 such treaties had been signed and ratified by the republics of Colombia, Peru, Mexico, Central America, and the united Provinces of Río de la Plata. In 1826 a general American congress convened in Panama. Compared with Bolívar's original proposals, it was a fragmentary affair, since only Colombia, Peru, Central America, and Mexico sent representatives. The delegation from the United States never reached Panama. The four nations who attended signed a treaty of alliance and invited all other nations to adhere to it. A common army and navy were planned, and a biannual assembly representing the federated states was projected. All controversies among the states were to be solved by arbitration. Despite its meagre results, the congress of Panama laid the cornerstone for future hemispheric solidarity and understanding. The Organization of American States and the United Nations can look to Bolívar as one of the first statesmen in the world sincerely interested in advocating and implementing international cooperation.

But Bolívar was aware that his plans for hemispheric organization had met with only limited acceptance. His contemporaries thought in terms of individual nation-states, Bolívar in continents. In the field of domestic policy he continued to be an authoritarian republican. Many of his followers offered him the crown, but the Liberator preferred his old title to that of "Simón the First." He thought of himself as a rallying point, and anticipated civil war as soon as his words should no longer be heeded. Such a prophecy, made in 1824, was fulfilled in 1826.

Civil war. Venezuela and New Granada began to chafe at the bonds of their union. The protagonists in each country, Páez in Venezuela and Santander in New Granada, opposed each other, and at length civil war broke out. Bolívar left Lima in haste, and most authorities agree that Peru was glad to see the end of his three-year reign and its liberation from Colombian influence. In Bogotá, Bolívar found Santander upholding the constitution of Cúcuta and arguing that Páez be punished as a rebel. But Bolívar was determined to preserve the unity of Colombia and was therefore willing to appease Páez, with whom he became reconciled early in 1827. Páez bowed to the supreme authority of the Liberator, and in turn Bolívar promised a new constitution that would do justice to Venezuela's desire for regional independence. He took over the presidency and called for a national convention that met in April 1828. Bolívar refused to influence the elections, with the result that the liberals under the leadership of Santander gained the majority. Bolívar had hoped that the constitution of Cúcuta would be revised and presidential authority strengthened, but the liberals blocked any such attempts. A stalemate developed. Arguing that the old constitution was no longer valid and that no new one had taken its place, Bolívar assumed dictatorial powers. He flattered himself when he said that "the whole nation recognizes my authority," but he soon learned the bitter truth. A group of liberal conspirators invaded the presidential palace on the night of September 25, and Bolívar was saved from the daggers of the assassins only by the quick-wittedness of Manuela Sáenz. But though this attempt on his life had failed, the storm signals increased. Bolívar's precarious health began to fail. Peru invaded Colombia with the intention of annexing Guayaquil. Once more Sucre saved Colombia and defeated the Peruvians at Tarqui. A few months later, one of Bolívar's most honoured generals, José María Córdoba, staged a revolt. It was crushed, but Bolívar was disheartened by the continued ingratitude of his former adherents. France, England, and the United States tried to intervene in the domestic affairs of the country. In the fall of 1829, Venezuela seceded from Colombia.

Assassination plot

Reluctantly, Bolívar realized that his very existence presented a danger to the internal and external peace of the nations that owed their independence to him, and on May 8, 1830, he left Bogotá planning to take refuge in Europe. Reaching the Atlantic coast, he learned that Sucre, whom he had trained as his successor, had been assassinated. Bolívar's grief was boundless. In vain a military uprising in Bogotá called him back. The projected trip to Europe was cancelled, and at the invitation of a Spanish admirer, Bolívar journeyed to his estate near Santa Marta. Ironically his life ended in the house of a Spaniard, where on December 17, 1830, he died of tuberculosis.
