The German Enlightenment intensified opposition to supernaturalism (belief in an order of existence beyond the observable universe) in order to affirm the necessity of reason and the self-sufficiency of nature against any notion of transcendence. The official theologians became alarmed at this movement and reacted against the philosophers. Even Immanuel Kant, the founder of transcendental, or critical, Idealism, came into conflict with the civil and religious authorities for his *Die Religion innerhalb der Grenzen der blossen Vernunft* (1793; Eng. trans., *Religion Within the Limits of Reason Alone*, 1960), which he later defended in a work published in 1798. In that same year the *Atheismusstreit* ("conflict over atheism") broke out. Friedrich Karl Forberg, an unknown philosopher, published an essay in a periodical of which his friend Johann Gottlieb Fichte, an important German Idealist, was a coeditor. In the essay, Forberg reduced religion to a "practical belief" in the moral order of the world: to have religion is to act as if a just and moral world were possible. Fichte himself conceived of God as the simple, active, moral world order. For this theory Fichte was formally accused of atheism and in 1799 was dismissed from the University of Jena. When Fichte was accused of atheism, Friedrich Jacobi, a contemporary German philosopher who was trying to protect himself, claimed that the danger of atheism was rooted primarily in the influence of Benedict de Spinoza, a 17th-century Rationalist. In so doing, Jacobi was attacking as an atheist not only Fichte but also F.W.J. von Schelling, an Idealist who was influenced by Spinoza, for his notion of God as nature, as "absolute productivity and the sacred original force of the world." The influence of Spinoza was found again in the thought of G.W.F. Hegel, an early-19th-century Idealist, who wrote that "without the world God is not God," and in the work of Friedrich Schleiermacher, a German Protestant theologian of the same period, who in his later years synthesized his thought in the formula "there is no God without a world, just as there is no world without God." The partial atheism of transcendental Idealism was denounced shortly after Hegel's death in 1831 by many of his followers, especially Ludwig Feuerbach, an anti-Christian German philosopher, who in 1839 appraised the development of modern thought and stated that the duty of the modern age was the humanization of God, the transformation of theology into anthropology. Marxist atheism carried the atheism of Feuerbach to its radical extreme by accusing religion of being the "opium of the people" and the principal cause for the alienation and exploitation of man. The final step in this Germanic atheistic revolution was the "will to power" of Friedrich Nietzsche, a Dionysian thinker of the late 19th century, who openly professed the need for the death of God so that the superman (*Übermensch*) could arise.

20th-century development of atheism

The dominant form of atheism in the 20th century has been "radical humanism," which interprets the being of man solely within the confines of the human, or behavioral, sciences. According to the theory of Sigmund Freud, the founder of psychoanalysis, religion—as the affirmation of the transcendental principle and of the spirituality and immortality of man—is just the result of neurotic frustration. Logical Positivism—according to

which scientific knowledge is the only kind of factual knowledge and all traditional metaphysical doctrines are meaningless—also has arrived at the radical negation of God, either because the Absolute is judged to be a concept without meaning or because it is declared to be unknowable. Existentialism has tended to protest against any force in the face of which human beings are regarded as helpless playthings. In the wake of Nietzsche, the German Existentialists Karl Jaspers and Martin Heidegger emphasized the thoroughly ambiguous nature of religious transcendence, but without denying its importance for man; the atheism of the French Existentialists, however, has been even more radical: according to Jean-Paul Sartre, the idea of God is self-contradictory, and, according to Albert Camus, the affirmation of God involves the negation of human reason.

In 1933 a document called the *Humanist Manifesto* was published in the United States; it was substantially a profession of anthropological atheism based on the theory of evolution. The definition of humanism given by the drafter of the *Manifesto* was rather vague: "Humanism is faith in the supreme value and self-perfectibility of human personality." Among the signatories were several of the leading U.S. philosophers, including John Dewey. The movement grew out of the Pragmatism—the philosophical doctrine that the meaning of conceptions is to be sought in their practical consequences—of William James and others at the beginning of the century. An account of the movement in 1949 fully bore out the diagnosis that the new humanism—which was proclaimed as "the real American philosophy"—was a synthesis of scientism (the theory that the methods used in the natural sciences should be used in all fields of investigation), evolutionism, and vitalism (the theory that life processes possess a unique force different from all other forces found outside living things).

The development of atheism in the Western world, therefore, has followed the ascent of man toward the conquest of earthly ideals in which man himself is considered the subject, the source, and the primary object of values.

Critical examination of atheism. The presence of atheism appears to be coextensive with the history of human civilization. The tension between atheism and theism theoretically constitutes the first and fundamental alternative for man; on this choice depend the individual's understanding of the world and of his destiny and his development of a code of life. According to the Bible, the first generations of men did not practice any form of worship or religion; it was Enosh, son of Seth, who was the first to invoke the name of God. For this reason Giambattista Vico, an 18th-century Italian philosopher of history, spoke of the animal state of the first men. But atheism has appeared at very different levels of culture and has assumed very diverse forms. Thus, in India the *Bhagavadgītā* developed the metaphysical Idealism of the Brahman—the impersonal world spirit—of the *Upaniṣads*, the chief documents of ancient Hinduism, into a sort of theism that includes the idea of creation. But Sāṇkhya (the ancient philosophy of numbers), Buddhism, and Jainism profess an animistic atheism in which the universal energy (*karma*) activates both the soul and matter; and also the Buddhist teaching of Nirvāṇa, the ultimate goal of life, implies the negation of a personal God. The atheism of the ancient Chinese wise men was founded on the absolute moralism professed in the 5th and 6th centuries BC by Confucius and on the notion of the original goodness and dignity of human nature that was expressed almost 200 years later by Confucius' follower Mencius. The other great Confucianist of Chinese antiquity, Hsün-tzu, asserted that moral standards are the creations of society that exert a civilizing influence upon the individual, molding him into a disciplined and morally conscious human being.

Atheism's diverse forms in diverse cultures

In the religion of the Bible, the first duty of man is to know and venerate God; atheism is regarded as the highest folly. According to the author of Psalms 14, "The fool says in his heart, 'There is no God,' " and his foolishness consists in the thought that God cannot reach the sinner while he is committing his fault. Also included as atheists are all polytheistic pagans who worship worthless idols. Even the pessimism found in the book of Ecclesiastes has been accused of atheism, although the author expressly declared faith in God and in his Providence. In the New Testament, St. Paul condemned as stupid and unpardonable all those who, after viewing the world, shut their eyes to the manifestations of God in it and refuse to serve him.

The situation of atheism in the classical Greco-Roman world was extremely ambiguous because of the tension between the anthropomorphic notion of the gods and the notion of God as the transcendent first principle, between the religion of the state with its indigenous divinities and the religion of the Creator of the world, the Father of all men, present to all and yet transcendent. Each understanding of God was accused of being atheistic by adherents of the opposing understanding. Further confusion was raised because some ancient Greek and Roman philosophers professed atheism in their doctrines but in practice acknowledged, or at least did not dispute, the official religion and thus avoided any formal accusation of atheism. But other philosophers, such as Plato and Aristotle, the most important thinkers of the ancient world, criticized the polytheism of the popular religion, did not accept the subordination of philosophy to the religion of the state, and tended toward a monotheism with the transcendent principle; they were accused of atheism and in some cases—an example is Socrates, the great Athenian teacher—were condemned for their impiety.

It is not surprising, then, that the Christians, who refused to acknowledge the religion of the state and adored their God as the only true God and Jesus Christ as the God-man, were accused of atheism. The Christians were considered to be the new enemies of the established religion of the state, and this accusation appears to be the primary reason for their persecution by the Roman emperors until the edict of Constantine in 313 granting toleration for all religions. For their part, the Christians accused of atheism not only the pagans who did not believe in their God but also heretics who defended unorthodox doctrines about God. St. Augustine, the greatest thinker of Christian antiquity, formulated a theological judgment of atheism that embraced the whole course of human history extending to the end of time in his doctrine of the two cities, the city of God (*civitas Dei*) and the city of the world (*civitas terrena*), according to which men are divided into the "faithful," who strive for eternal life, and the "impious," who are "lovers of the world."

Atheism as a purgative for religion

Often the psychological origin of atheism, in its philosophical forms, is a critical reaction to superstition, to the multiplicity and variety of religions, and to the aberrations of magical practices and pseudomystical extravagances. Without doubt, atheism in many of its historical forms has been the purgative for such kinds of religion and has thus been historically an indispensable agency for keeping sound and deepening the knowledge of God. This cathartic function of atheism has influenced the thinking of several important 20th-century Protestant theologians. According to Karl Barth, the Swiss theologian, atheism is parallel to mysticism insofar as it replaces the contents of conceptualistic dogmas with a void in which knowledge and object are one and the same. The starting point of faith and of theology, according to Rudolf Bultmann, a German theologian and New Testament scholar, is the destruction of the concept of God by philosophy so that the thinking of the philosophers, who must ignore the God of the Bible, may then, perhaps, come closer to revealing the divine God. Paul Tillich, a German–U.S. philosopher and theologian, asserts that, in the destruction of the metaphysical God accomplished by modern philosophy, man ultimately encounters the theology of the living God in the form of an absolute faith that is without visible authority and without content and that far surpasses the assent of dogmatic theism or atheism. Therefore, the radical atheists (for example, Nietzsche) become the primary witnesses of God, and atheism, in the judgment of these theolo-

gians, becomes intrinsically impossible. The Roman Catholic second Vatican Council (1962–65), in its constitution on the church in the world, admits that modern and contemporary atheism has been in part a reaction to the conduct of those believers who "neglect their own training in the faith, or teach erroneous doctrine, or are deficient in their religious, moral, or social life, and must be said to conceal rather than reveal the authentic face of God and religion." Atheism is thus seen as a historical fault of Christians because of their infidelity to the precepts of love of God and of neighbour. It was the hope of the council that the shock of realizing that atheism has been the result of the scandal of indifferent Christians could and would provoke a return to authentic Christianity.

Theoretical atheism is bound closely to the particular way the philosopher explains the material and formal causes, or bases, of all beings. These explanations govern the approach he takes to the conception of the One and to the relation between reason and faith. Thus, the material pantheism—that God is the prime matter, or potentiality, of all things (*Quod Deus est materia*)—of David of Dinant, a 12th-century Scholastic philosopher, and the formal pantheism—that God is the formal principle of all things (*Quod Deus est omnia*)—of Amalric of Bene, another 12th-century philosopher at Paris, were considered professions of atheism. Al-Ghazālī, the 11th-century Islāmic theologian, in his *Incoherence of the Philosophers*, complained that "skeptical, nihilistic, and sensualistic philosophers" profess atheism. The same accusation was made against all those—including Averroës, the great 12th-century representative of Islāmic philosophy in Spain—who professed the eternity of the world, thereby implying the existence of uncreated matter, and who denied the freedom of human actions, the divine knowledge of singulars, and the immortality of individual souls. In his response to al-Ghazālī, Averroës did not reject the validity of faith but rather affirmed the primacy of reason over faith. The theories of Averroës—especially that there is only one single intellect, or "intellective soul," for the whole of humanity, that Divine Providence does not reach down to individual men, that there is no individual immortality, and that there is a separation-opposition between reason and faith (the "double truth" doctrine, according to which conclusions in natural philosophy were said to be true, while, simultaneously, conclusions affirming the contrary in theological argument were said to be true)—were preserved in Latin Averroism, a term that designates the thought of a number of Western Christian philosophers who, in the later Middle Ages and during the Renaissance, drew their inspiration from Averroës' interpretation of Aristotle. Latin Averroism was undoubtedly the most significant source of atheism during the Renaissance.

Atheism and its refutation as reflections of their times

As the positions of atheism have varied according to the doctrinal background out of which they developed, so the dialectic of the accusations and condemnations of atheism has been a reflection of the cultural situation of the time. Thus, in 1600 Giordano Bruno, an Italian thinker and writer, whose excursions into many areas of investigation constantly brought him into collision with orthodox opinion, was burned at the stake as an atheist for his pantheistic theory that all life is ultimately derived from matter and for his denial of positive religion. In France, François Rabelais, the 16th-century author of *Gargantua and Pantagrue* (1532, 1534), a bitter satire on the effects of popular religion, and other contemporary authors were accused of atheism. In England, Christopher Marlowe, a dramatist, and Sir Walter Raleigh, an author and explorer, were formally accused of atheism in 1593. Marlowe was brought to trial for blaspheming against the truth of the faith and was killed during the course of the proceedings, although it does not seem that he ever openly professed atheism. There is also no clear proof that Raleigh was an atheist, although the Jesuit pamphleteer Robert Parsons complained of his "School of Atheism" in 1592. Raleigh was, however, an enthusiastic reader of skeptical philosophy. There was more substantial argument for the accusation of atheism brought against Thomas Hobbes, a 17th-century British political philosopher. In *Leviathan*, his masterpiece, Hobbes declared that the traditional doctrines of the divine Logos, or wisdom, and of the divine attributes were nonsense and condemned religion as superstition intended to defend the laity from true moral and political institutions.

Critical judgments against modern atheism were directed at the starting points of the speculative systems of the philosophers. Thus, in the 17th century both the Jesuit historian Jean Hardouin and the Calvinist theologian Gisbertus Voetius accused Descartes and his followers of atheism because they conceived of God as *ens infinite perfectum* ("infinitely perfect being") and pure universal form. Spinoza was accused of atheism because he identified God, the one and only substance, with the world. The classical text of rational atheism is considered to be the *Ethics* of Spinoza, who is also considered to be the founder of modern biblical interpretation and demythologization—uncovering the meaning underlying the literary and mythological forms of the Bible. The works of many 17th- and 18th-century English clergymen and theologians, especially Samuel Clarke and Joseph Butler, were aimed at Deism, which denied the unique position of the Judeo-Christian tradition as a divine revelation. In an effort to halt the rising tide of disbelief and atheism, Robert Boyle, a British physicist and chemist who died in 1691, provided in his will for the Boyle Lectures for the defense of Christianity "against those who are notoriously unbelievers, such as the atheists, the deists, the pagans, the Jews, and the Mohammedans." The lecture series, which is still continued, was begun in 1692 by Richard Bentley, a clergyman and classical scholar, who delivered a "refutation of atheism," arguing especially against that form of cryptoatheism that had its starting point in the notion of "thinking matter" and questioning the return to pagan morals and the rejection of the Christian message of salvation.

The anthropological origin of atheism

Although every form of atheism can be traced back to a particular ideology (for example, the cosmic form of the Renaissance, the ethical form of the Deistic Enlightenment, the anthropological form of modern Idealism), in reality atheism always has an anthropological origin, or a tendency to found truth and the value of existence within man. Modern radical atheism is founded on the principle of immanence: human subjectivity—the presence of the self to itself—is the foundation of the truth of being. The atheisms of Marxism, of Existentialism, of Logical Positivism, and of Pragmatism can all be considered as precipitating causes of the modern principle of immanence. But all immanentistic concepts radically eliminate the possibility of the Absolute and thereby also empty man's being of its originality by reducing man to a simple function of his historical situation. Therefore, there is a return to discussion of the need for a "resurrection of metaphysics," or the need for consideration of some transcendent principle, in the writings of Heidegger.

There is also a need to distinguish philosophy from science and even more from morality and religion. According to Positivistic, humanistic, and especially Marxistic atheism, scientific and technological progress (particularly the exploding knowledge about outer space) has destroyed the need for religion. It can be answered, however, that the progress of science has brought man to a deeper and more precise knowledge of the magnitude of the universe and of the complexity of its laws (especially in the fields of microphysics and microbiology); but according to such eminent 20th-century physicists as Max Planck, Albert Einstein, and Werner Heisenberg, man merely discovers these laws, and they presuppose an infinite intellect. The resources capable of catastrophic effects that modern technology has put at man's disposal render more pressing the need to affirm the transcendence of moral and religious values if man wishes to help and not to destroy his own species.

Furthermore, the foundation of the concept of freedom has come to be understood as demanding absolute au-

tonomy. According to Existentialism and secular humanism in their multiple forms, the negation of theological transcendence is necessary in order to guarantee the absolute character of freedom; so state such thinkers as Dewey and Sartre. This radical existential freedom, however, has real meaning only if it is based on each individual's ability to choose his own happiness according to an absolute criterion of good and evil. According to the Christian Existentialist Søren Kierkegaard and the Jewish thinker Martin Buber, such a choice means being and putting oneself "before God."

The problem of evil

Finally, the existence of evil has been at all times the strongest argument on the existential level in favour of the denial of God. Evil refers either to physical evils (such as natural disasters and cataclysms, poverty and war, sickness and death) that deprive man of sensual happiness or especially to moral evils (such as errors and injustices, betrayals and hostilities, hate and violence) that oppress the spirit of man. The horror of evil is that it often strikes the weak and the innocent. How are such phenomena compatible with the existence of an omnipotent and good God? To this question the theist observes that the denial of God and of immortality does not change the sorrow and suffering but only aggravates the situation by depriving the suffering individual of any hope of liberation from evil and by depriving the innocent individual of any right to obtain justice from an absolutely perfect and independent judge, whom men have called God. Christianity further claims that sorrow and suffering have been sanctified by the example of the Passion and death of Jesus Christ.

During the 1960s, in a movement arising under the convergent influence of the German theologians Paul Tillich and Dietrich Bonhoeffer, a "theology without God" was proclaimed. According to one of the theologians espousing it—most of whom are of the English-speaking world—the "death of God" is not a metaphysical category but a cultural one; contemporary man, in this view, is just not fitted to understand any real repentance through an exterior principle like the transcendent God: "Bonhoeffer invites us to accept the world without God as given and unalterable." According to the same author the second idea that marks Bonhoeffer's influence and importance is his plea for a nonreligious or religionless Christianity. Because the world has grown up and transcended its dependency situation, "the God of religion, solving otherwise insoluble problems, meeting otherwise unmeetable needs, is impossible and unnecessary." A last and more profound ground of this "theological atheism" is the kenotic movement, according to which the God who died in Christ is the God who thereby gradually ceases to be present in living form, emptying himself of his original life and power. According to another of the "death of God" theologians, Thomas J.J. Altizer, the death is, thus, "an inevitable consequence of the movement of God into the world, of spirit into flesh."

The possibility of universal atheism and even the atheism of large masses in wealthy modern society have placed all men really for the first time face-to-face with the basic alternative of being either with God or against God. But even for sophisticated modern man the decision is complicated by the danger of nuclear catastrophe, which threatens to destroy all the values of civilization, man himself, and his cosmos.

BIBLIOGRAPHY

Notion of atheism: *Encyclopaedia of Religion and Ethics*, vol. 2, pp. 173–190 (1928); *Reallexikon für Antike und Christentum*, vol. 1, pp. 866–870 (1950); *Die Religion in Geschichte und Gegenwart*, vol. 1, pp. 670–678 (1957); G. KLAUS and M. BUHR, *Philosophisches Wörterbuch*, vol. 1, pp. 125–129 (1969); and *Enciclopedia filosofica*, 2nd ed., vol. 1, col. 557–562 (1968), are five expositions indispensable for viewing atheism from the point of view of the history of religion, the ancient Christian culture, contemporary theology, and Marxist and contemporary philosophy. J.M. ROBERTSON, *A Short History of Freethought*, 3rd ed. rev., 2 vol. (1915); L. STEPHEN, *A History of English Thought in the Eighteenth Century*, 2nd ed., 2 vol. (1902), are two fundamental works to follow the development of atheism in the various modern philosophical schools. E.S. BRIGHTMAN, *A Philosophy of Religion* (1946); M. SCHELER, *Vom Ewigen in Menschen* (1954; Eng. trans., *On the Eternal in Man*, 1960); and *Philosophische Weltanschauung* (1954; Eng. trans., *Philosophical Perspectives*, 1958), are important studies for a psychological analysis of atheism.

History of atheism: F. MAUTHNER, *Der Atheismus und seine Geschichte im Abendlande*, 4 vol. (1920–23), contains the story of atheism in the Western world, according to the traditional criteria of the positivistic method. See also J. PRESSER, *Das Buch "De tribus impostoribus"* (1926), a primary source for the background and development of modern atheism; H. BUSSON, *Le Rationalisme dans la littérature de la Renaissance (1533–1601)*, new ed. (1957), a fundamental study of atheism from the Middle Ages through modern times; and C. FABRO, *Introduzione all'atheismo moderno* (1964; Eng. trans., *God in Exile: Modern Atheism*, 1968), a critical and speculative analysis of the atheistic essence of modern thought.

Representatives of contemporary atheism: JOHN DEWEY, *A Common Faith* (1934); R. ROBINSON, *An Atheist's Values* (1964); and R. GARAUDY, *Dieu est mort* (1962), represent contemporary secular atheism. DIETRICH BONHOEFFER, *Widerstand und Ergebung* (1951; Eng. trans., *Letters and Papers from Prison*, 1953); T.J.J. ALTIZER and W. HAMILTON, *Radical Theology and the Death of God* (1966); J.A.T. ROBINSON, *Honest to God* (1963); L. DEWART, *The Future of Belief* (1966); THOMAS W. OGLETREE, *The "Death of God" Controversy* (1966); W. HAMILTON, *The New Essence of Christianity* (1966); and G. VAHANIAN, *The Death of God* (1966), are representatives of so-called theological atheism. E. BLOCH, *Atheismus im Christentum* (1968), is an exposition of Marxist atheism; and C. FABRO, *L'uomo e il rischio di Dio* (1967), is a critical evaluation of these modern responses to the problem of God.

(C.F.)

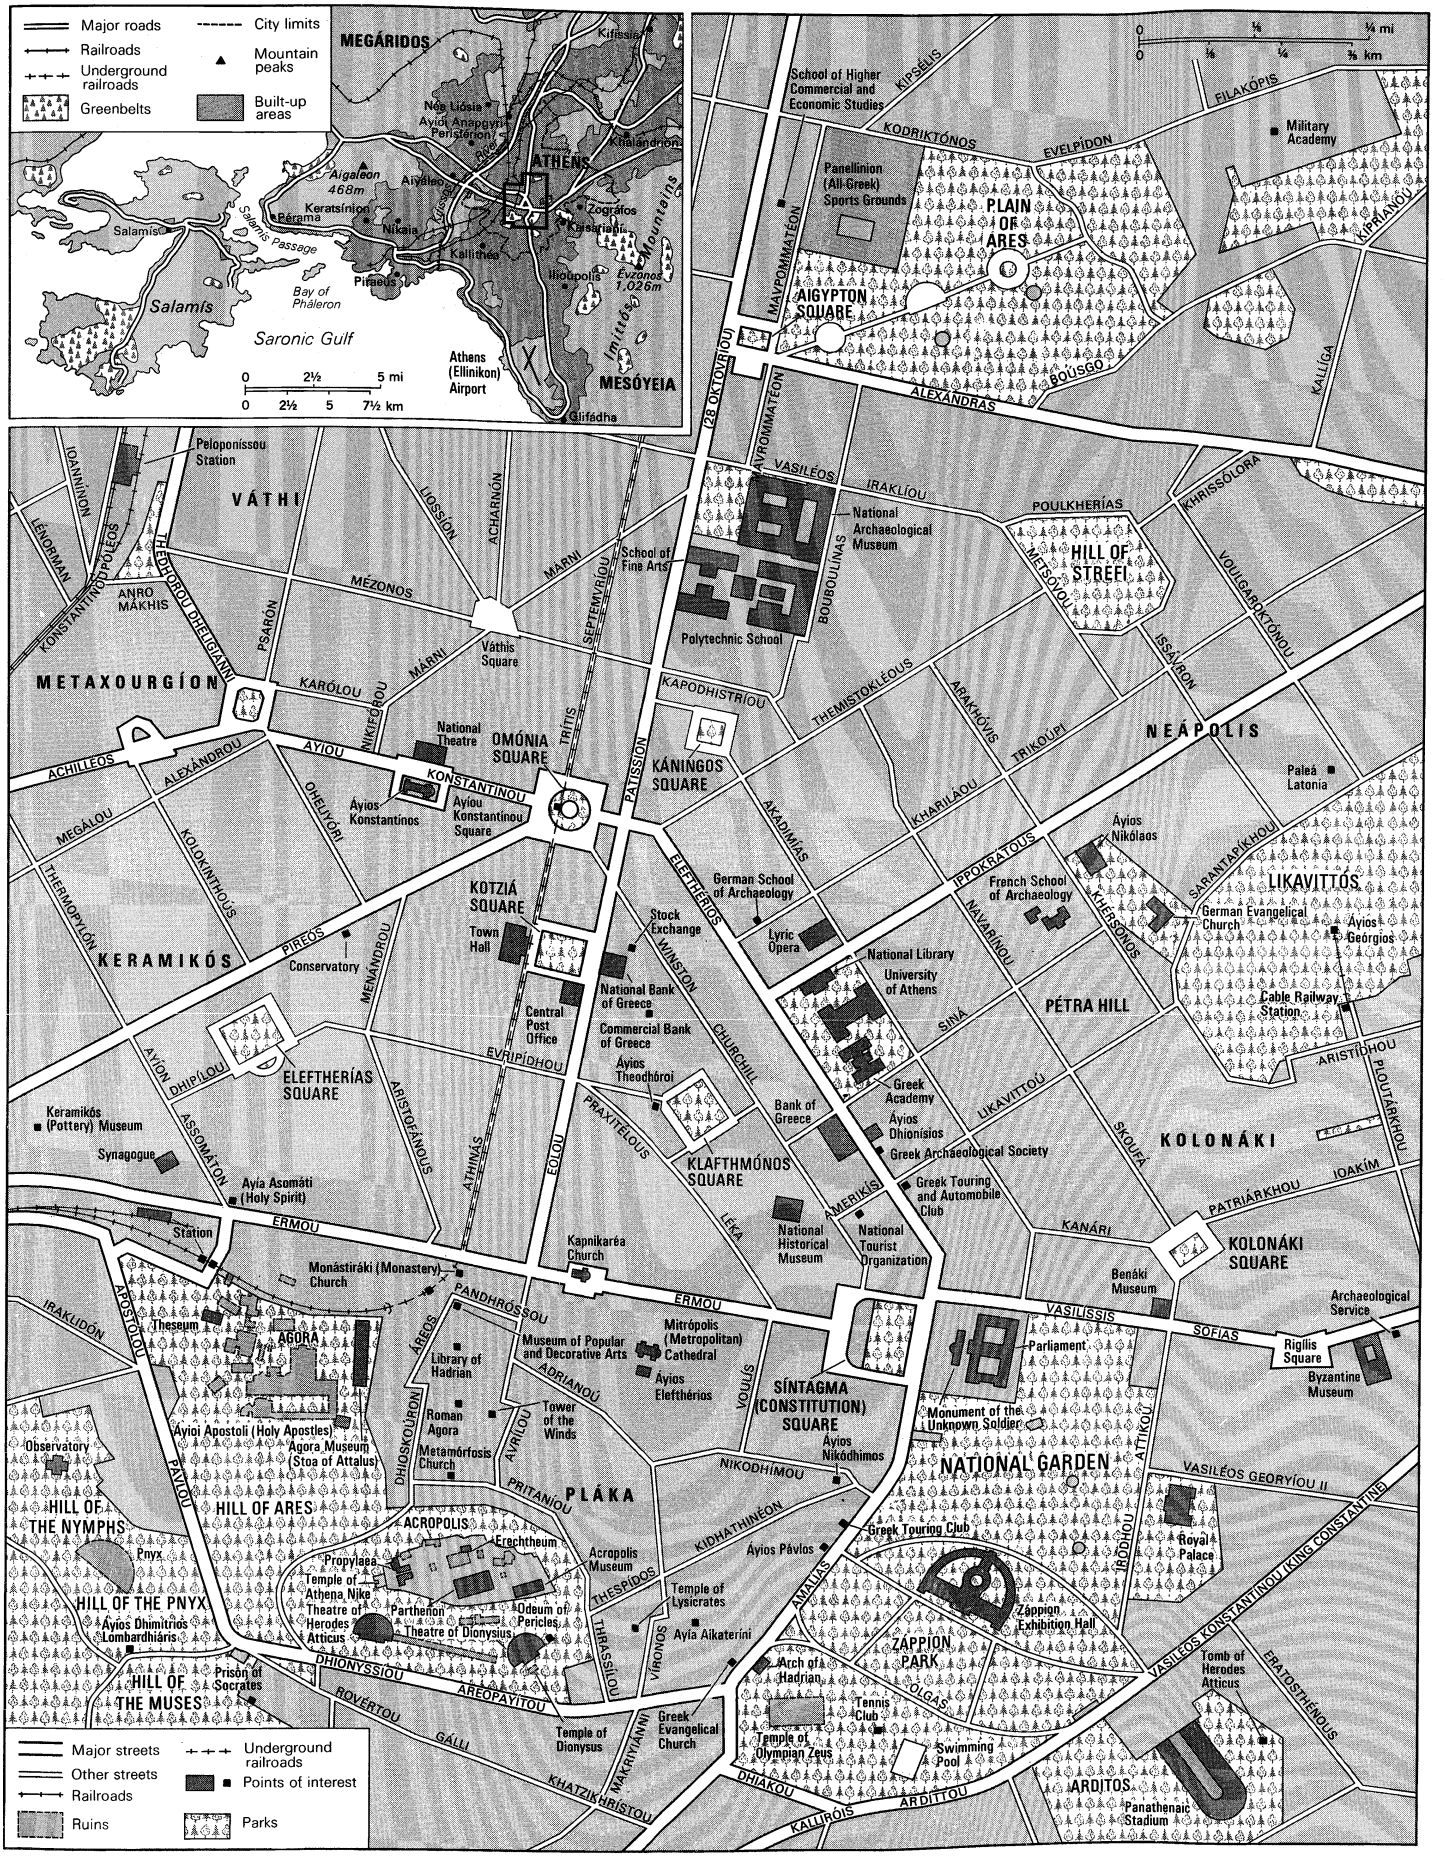
Athens

The capital of the kingdom of Greece and generally considered the nursery of Western civilization, Athens (Greek Athínai) lies five miles from the Bay of Phaleron, an inlet of the Aegean (Aigaion) Sea where Athens' port, Piraeus (Piraiévs) is situated, in a mountain-girt arid basin divided north–south by a line of hills. Greater Athens has an area of 167 square miles (433 square kilometres) and was the home of a little more than 2,500,000 people in the early 1970s. The central city, the old municipality, had over 862,000 inhabitants. The Kifisós River, a trickle in summer, flows through the western half; and the Ilisós River, often actually dry, traverses the eastern half, while the surrounding mountains of Párnis, 4,635 feet (1,413 metres), Pentelicus (Pendéli), 3,631 feet (1,107 metres), Hymettos (Imittós), 3,365 feet (1,026 metres), and Aigáleon, 1,535 feet (468 metres), add to the impression of barrenness. Yet such considerations are superficial when compared with the fecundity of Athens' spiritual bequests to the world, such as its philosophy, its architecture, its literature, and its political ideals.

THE ATHENIAN LEGACY

The Acropolis. Many of these concepts (all, if the theatre of Herodes Atticus may be regarded as an embodiment of the city's literature) are expressed in and around the Acropolis, the natural focus of Athens. Rising some 500 feet above sea level, with springs near the base and a single approach, the Acropolis was an obvious choice of citadel and sanctuary from earliest times. That it could be something more is evidenced in the Parthenon, one of the brightest jewels in mankind's treasury, let alone Athens'. As deceptively simple as Socrates' conversation, this columned, oblong temple is the expression—without a trace of strain or conflict—of a human ideal of clarity and unity. The architectural genius is concentrated in the exterior, for within was a shelter for the goddess Athena—the patroness who lent her name to the city—not a place for mass worship. Its spiritual quality, the sensation of being almost afloat, is enhanced by the lack of a single, straight, vertical line in the peristyle (the colonnade surrounding a building or court); each vertical is almost imperceptibly bowed, theoretically meeting some 11,500 feet up in the sky. The columns, of diminishing thickness toward the centre of the colonnade, with diminishing space between them, lean toward the centre,

The Parthenon



Central Athens and (inset) its metropolitan area.

too; all these differences are virtually invisible to the beholder. Even the 20 flutings (grooves) of each column diminish in width as they rise, and the humblest details of craftmanship are perfect.

On the northeast corner of the interior are faint traces of Christian wall paintings, dating from the temple's service as the Church of St. Mary, and in the southeast corner of the porch is the stair leading to the minaret that poked through the roof when the building was a Turkish mosque. The Parthenon was also used as a powder magazine, when, on September 26, 1687, Venetian artillery, attacking the Turks from the Hill of the Muses, scored a direct hit. A member of the party with the field commander, General Königsmark, wrote, "How it dismayed His Excellency to destroy the beautiful temple which had existed three thousand years!" Conversely, Francesco Morosini, the commander in chief, when reporting to the Venetian government, called it "a fortunate shot." Wishing to bring home more than just good news, he also tried to lower Athena's horses in the centre of the west pediment, but his men's dexterity was not as highly developed as their marksmanship and the masterpieces smashed to bits on the rock below.

The Turks regained possession of the Acropolis the following year, and later began selling "souvenirs" to Europeans. The Duc de Choiseul, lately French ambassador in Constantinople, picked up a piece of the frieze and two metopes (space between two triglyphs, or ornaments in the frieze). Fourteen years later the British ambassador, Lord Elgin, arrived with an imperial decree permitting him to pull down Turkish houses on the Acropolis to seek fragments of sculpture. Among the 50 pieces he took home (the shipping charges were £75,000, a huge sum for those days) was most of the remaining Parthenon sculpture, which he later sold to the British Museum for £35,000. The Greeks have forgiven the clumsiness of the Venetian engineers, the accuracy of her cannoneers, and the vandalism of the Turks, but still nurture rancour against Elgin. His lordship also removed one of the caryatids (draped female figures serving as columns) from the Erechtheum, a temple of Athena called after a shrine dedicated to the legendary King Erechtheus or to Poseidon Erechtheus, but replaced her with a plaster cast. From London he graciously sent a town clock for Athens, duly erected in the Agora (marketplace) and lost in the fire of 1885.

Plan of the Acropolis, Athens.

The Erectheum (5th century BC), which later became a church under the Byzantines and subsequently the Turkish commander's harem, was originally dedicated to both Athena and Poseidon and was the most venerated of the Acropolis temples.

The Propylaea, the matchless entryway into the Acropolis, was the only opening in the surrounding wall. Just in front of it and to the left is the 27-foot-high pedestal for the thank-offering to Agrippa, the victor of the Battle of Actium, who interceded for Athens, which had supported the loser, Mark Antony. To the right was the temple of Athena Nike (Giver of Victory), 27 feet long and 18½ feet wide, which stood untouched until the Turks demolished it in 1686 to use the stones as defenses against the Venetians. In 1836 it was badly restored, and 100 years later its foundations began to slip into previously undiscovered Turkish cisterns, revealing the 6th-century foundations, of Peisistratus' earlier shrine to Artemis Epipyrgidea (Artemis on the Tower). The temple was then more accurately reconstructed. The northern wing of the Propylaea, the Pinakotheke, was used by the Frankish dukes, who reconstructed the interior to make a two-story building. In the 12th century, Greek Orthodox bishops lived in the Pinakotheke, and in the 14th century, the Acciajuoli dynasty of Athenian dukes from Florence turned the Propylaea into a fortified castle with a Tuscan tower, which Heinrich Schliemann, the German archaeologist who discovered Troy, paid to have dismantled in 1875.

The Pinakotheke

When the Turks, who had occupied Athens since 1456, departed, they left the monuments in a state of ruin, the ground covered with garden plots, and 300 small huts. After Greece won its independence, Otho, the first king of the Hellenes, had everything that postdated the classical period swept away, set scholars to work identifying the remains, and encouraged some reconstruction.

According to Pausanias, the Greek traveller and geographer of the 2nd century AD, the colossal, 30-foot-high bronze seated statue of Athena Promachos (Athena Who Fights in the Foremost Ranks), by the 5th-century Athenian sculptor Phidias, was set up in the open behind the Propylaea, her gleaming helmet and spear visible to mariners off Cape Sunium (30 miles away). The 6th-century Byzantine emperor Justinian carried her off to Constantinople, just as Phidias' ivory and gold statue of Athena had been taken from the Parthenon by his predecessor Theodosius II. Both of these masterpieces were lost to other looters in the Crusaders' sack of Constantinople in 1204. Other statues stood in profusion amid small temples, such as the sculptor Myron's group of Marsyas and Athena, his Perseus, and his heifer; Phidias' Lemnian Athena and his Pericles; and a gigantic bronze effigy of the Trojan horse. There was an altar to Athena Hygeia (the Health Giver), a precinct sacred to the goddess Artemis Brauronia (named after a statue of her, brought from the town of Brauron), the Pandroseum (a building named after Pandrosos, a girl associated with Athena in legend), where the sacred olive tree of Athena grew, and beyond the Parthenon the great altar of Athena.

Other notable buildings. Below the Acropolis sanctuary, on the southwest slope of the hill, Herodes Atticus, a rich Roman, built a 5,000-seat odeum as a memorial to his wife in AD 161. A conventional Roman theatre, save that the semicircular auditorium was hollowed out of the rock, it was roofed in cedar and had a three-story facade of arches. Repaired but roofless, it is now used for the Athens summer festival of music and drama. A 300-yard-long portico stretching toward the theatre of Dionysius had been built some 300 years earlier. The Dionysiac theatre itself, scooped out of the south slope early in the 5th century, replaced the Agora stage as the drama centre. It also replaced the Pnyx as the meeting place for the popular assembly. Rebuilt many times, the ruined theatre now visible is largely Roman, the last construction work on the stage probably dating from the early 3rd century AD. The Dionysia, the spring festival, which drew crowds from many parts of Greece and colonies in Asia Minor and Italy, was held in this theatre, which had 13,000 seats in 67 rows. The jury had larger front seats and the ecclesiastical dignitaries small stone thrones, on which their titles can still be read. Three tragic and four comic plays were presented in competition for the prize. Production costs were met by private sponsors who, when their choruses won the prize tripod, displayed it in an elaborate memorial in the Street of Tripods to the east of the theatre. The only one of these monuments still standing is that of Lysicrates, erected 335/334 BC, a small circular temple 21½ feet high, its six columns an early example of the Corinthian order. Preserved through incorporation into a convent (in which the English poet Lord Byron had a study), the monument influenced British Georgian and Regency architecture through the engravings of the Edin-

burgh artist "Athenian" Stuart. Farther east lay the Odeum of Pericles, and to the west are traces (420 BC) of the precinct of Asclepius, the god of healing, which took the form of a hospital portico for patients and temples decorated with votive reliefs.

On the Hill of Ares, the god of war, to the right of the descent from the Propylaea, a legendary jury of gods spared Ares from execution for the murder of the sea god Poseidon's son. Trials for homicide continued to be heard on this hill through the ages, and the Supreme Court of Greece still bears the name.

Other hills in Athens

Across Apostólou Pávlou (Apostle Paul Avenue) are the Hill of the Nymphs, where an Austro-Greek, Baron Sina, built an observatory in 1842; the Hill of the Muses, crowned with the remains of the marble monument to Philopappus, a Syrian who was Roman consul in the 2nd century AD; and the middle hill, the Pnyx, meaning "tightly crowded together," the meeting place of the Ecclesia, the assembly of 18,000 citizens who heard the great Athenian orators. (In fact, attendance of over 5,000 was rare, but it would still have been crowded.)

The Agora. The avenue leads down to the Agora, which the American School of Classical Studies started restoring in 1931, paying $2,500,000 compensation to the several hundred families living there. Financed by, among others, the Rockefeller Foundation, the Marshall Plan, and the Greek government, the work went on until 1960. It includes what has been called "the pitiless replica of a 180-columned portico of the 2nd century BC," which serves as a museum.

At the approaches to the Agora is the best preserved of all Greek temples, the Theseum (5th century BC). Although virtually intact and absolutely genuine, it has all the deadness of a latter-day reproduction. The beauty, the mystery, and the genius that render the Parthenon incandescent eluded the architects and builders of the Theseum.

The Horologium and the Orthodox cathedrals. Another monument is the octagonal, 42-foot-high marble Horologium of Andronicus of Cyrrhus, usually called the Tower of the Winds because each side bears a weather-beaten figure of the wind from that particular compass point. It used to have a sundial, a water clock for telling the hour on cloudy days, and a weather vane. The Turks left it unchanged, believing it to be the tomb of two local prophets, Sakhratis and Aflatun (Socrates and Plato).

In the shadow of the 19th century, Neo-Byzantine Greek Orthodox Cathedral (Mitrópolis) nestles the old Mitrópolis, Áyios Elefthérios, one of three genuine Byzantine churches still surviving. It is red brick like the others and tiny, its Pentelic marble ruddied with age, its outer walls artfully, if promiscuously, decorated with classical Greek tidbits: panels, votive tablets, and morsels of frieze. Like its sisters, this retired cathedral is charming, unassuming, and comforting. (B.E.)

THE EARLY HISTORY OF ATHENS

The city in antiquity. *Factors inducing settlement.* The climate of Athens is benign: frost is rare (the minimum temperature is 32° F, 0° C) and snow seldom lies, while the summers, though hot (maximum temperature is 99° F, 37° C), are dry, and a fresh northeasterly wind often blows by day. The nights are always cool. All of this permits outdoor activity the year around and has had an important effect on both the style of architecture and the life and political institutions of the city.

Evidence of early inhabitation

The site of Athens has been inhabited since the Neolithic Period (before 3000 BC). Evidence for this has come from pottery finds on and around the Acropolis but particularly from a group of about 20 shallow wells, or pits, on the northwest slope of the Acropolis, just below the Klepsydra spring. These wells contained burnished pots of excellent quality, which show that even at this remote period Athens had a settled population, with high technical and artistic standards. There are similar indications of occupation in the Early and Middle Bronze ages (3000–1500 BC).

The earliest buildings date from the Late Bronze Age, particularly about 1200 BC when the Acropolis was the citadel. Around its top was built a massive wall of Cyclopean masonry (a type of construction using huge blocks without mortar). The construction of this wall probably marks the union of the 12 towns of Attica (the department in which Athens lies) under the leadership of Athens, an event traditionally ascribed to Theseus. The palace of the king was in the area of the later Erechtheum, but almost no traces of it have been identified. The town, insofar as it was outside the Acropolis, lay to the south, where wells and slight remains of houses have been found. The principal cemetery lay to the northwest, and several richly furnished chamber tombs and many smaller ones have been discovered in the area that later became the Agora.

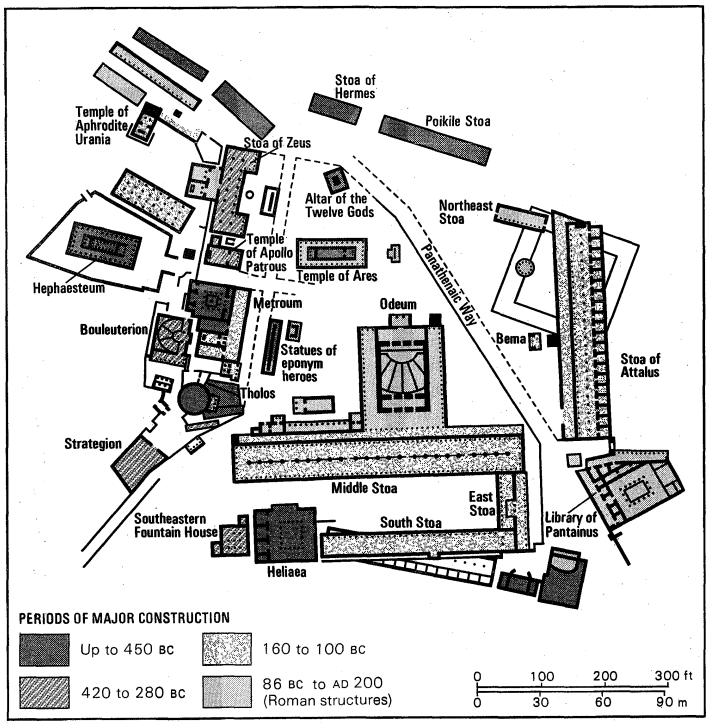
Whether through the strength of its walls, the valour of its citizens, or its geographical position away from the main route to the Peloponnesus, Athens seems to have weathered the Late Bronze and Early Iron ages, troubled times, better than other, more important centres. There is no evidence of complete or widespread destruction, as at Mycenae and Pylos; in fact, the pottery styles show an unbroken development through sub-Mycenaean (a style later than the Mycenaean but not yet Greek) to Protogeometric (the earliest phase of Geometric) and Geometric (a style of pottery in vogue from 1000 BC to 750 BC). Furthermore, there is positive evidence that from about 1000 BC the city began to expand in a northwesterly direction, into the area that had previously been confined to cemeteries. Wells appear, indicating occupation by the living, and any graves in the area are increasingly confined to restricted plots or placed along the roads outside the town limits. The Agora and some of the public buildings seem, to judge from scattered notices in later writers, to have been located west and northwest of the Acropolis. Though there are few remains of buildings, the wealth and prosperity of the city can be appreciated from late Geometric graves found in the area of the later Dipylon and Erian gates. These graves were adorned with large vases, sometimes over five feet high, richly decorated with geometric patterns and having figured scenes of battles, processions, and funeral ceremonies.

Changes in the 6th century BC

Athens' expansion. The 6th century BC was a period of phenomenal growth, particularly during the tyranny of Peisistratus and his sons (*c.* 560–510 BC). On the Acropolis, the old primitive shrines began to be replaced with large stone temples. About 580 BC a temple to Athena, known as the Hekatompedon, or "Hundred-Footer," was erected on the site later to be occupied by the Parthenon. The pediments (triangular spaces forming the gable) of this temple were decorated with large-scale sculpture in gaily coloured, porous limestone, representing groups of lions bringing down bulls, and with snaky-tailed monsters in the angles. These sculptures are now displayed in the Acropolis Museum. In 566 BC Peisistratus reorganized the Panathenaic Games in honour of Athena on a four yearly basis. About 530 BC a large peripteral temple (one having a row of columns on all sides) to Athena Polias (Guardian of the City) was erected near the centre of the Acropolis, on the site of the old Bronze Age palace. It had marble pedimental sculpture representing the battle of the Gods and Giants. Besides these two major temples there were five smaller buildings, treasuries and the like, and a wealth of votive offerings in marble, bronze, and terra-cotta. The Acropolis was now a full-fledged sanctuary.

This change from citadel to sanctuary is also reflected in the arrangement of the entrance at the west. Instead of a winding path suitable for defense, there was, from about the middle of the 6th century BC, a broad ramp, designed as a ceremonial approach, leading up to the gate. This basic change of attitude toward the Acropolis must mean that the whole lower town was now surrounded by a fortification wall, and the Acropolis was no longer needed for defense. The ancient historians Herodotus and Thucydides tell of such a wall, but no trace of it has been found, and its course and date are uncertain.

In the lower town, too, the 6th century was a period of great growth and change. The old Agora, below the western approach to the Acropolis, was now inadequate, and



Ground plan of the Athenian Agora.

a new one was therefore laid out in the low ground to the northwest. This was accomplished by demolishing houses and filling in wells and gullies, to create a broad, open square, which was used for gatherings of all sorts: political, judicial, religious, and commercial. Dramatic contests were held here, too, before the construction of a separate theatre. Various public buildings and shrines were erected around the borders of the square, including the Basileios (Royal) Stoa, where the archon Basileus, one of the chief magistrates of the city, had his headquarters, the Old Bouleuterion (or Council House), and a large enclosure (100 feet square), which probably housed the Heliaia, the largest of the popular lawcourts. At the southeast corner of the square a small fountain house was built, which received water from outside the city through a conduit of terra-cotta pipes.

Building of the new Agora

In 480 BC this flourishing city was captured and destroyed by the Persians. The Acropolis buildings were burned, and the houses in the lower town mostly destroyed, except for a few that had been spared to house the Persian leaders.

Athens at its zenith. When the Athenians returned, in 479 BC, they immediately rebuilt their fortification wall larger than before. About 20 years later the famous Long Walls were built, connecting the city with its port, Piraeus, four miles away. They were parallel over most of their course, forming a corridor 550 feet wide. These walls played a vital part in Athens' history during the Classical period, for they allowed it to carry the supplies brought in by its powerful fleet in safety to the city, even when enemy forces roamed the Attic countryside.

For 30 years after the Persian destruction, the Athenians built only fortifications and some secular buildings in the Agora, notably the Stoa Poikile, or Painted Colonnade, with its famous paintings by Polygnotus and Micon, one of which represented the Battle of Marathon. The Tholos, the round building that served as the headquarters of the executive committee of the council, was also built at this time. Lack of attention to the Acropolis was partly the result of the oath, sworn before the Battle of Plataea in 479 BC, that sanctuaries destroyed by the Barbarians would not be rebuilt but left as memorials of their impiety. In 449 BC, however, peace with Persia was at last officially established, and the oath was annulled. Athens, moreover, now had ample funds, for the silver mines in the Laurium (Lavrion) Hills of southern Attica were in full production. These mines had always been exploited, but in 483 BC a big strike was made, the proceeds of which were used to build the ships that won the battle of Salamis, in 480 BC. Thereafter, the mines remained productive throughout the 5th and 4th centuries, providing Athens with the sinews of its strength in the great Classical age. Another source of revenue was the tribute that the allies had been paying, as members of the Delian League, to prosecute the war against Persia. Athens had been collecting and administering this money and now, even though the war was officially over, continued to collect it in spite of the protests of the allies, who degenerated into subjects of Athens. Pericles deemed it proper, over the protests of his opponents, to use this money on beautifying the city; in this way he could keep the money in circulation and provide jobs for the whole population. Thus began one of the largest and most enduring works programs in history.

Peace with Persia

In a period of 40 years the Acropolis was entirely rebuilt in gleaming white marble quarried from Mt. Pentelicus, ten miles north of the city. The first great work was the Parthenon, begun in 447 BC and finished, except for some details, in 438 BC. The architects were Ictinus and Callicrates, and Phidias was in charge of the whole artistic program. The building was considerably larger than was usual, having eight columns across the ends and 17 on the long sides, against six by 13 for the average temple. It was richly decorated with sculpture, having a running frieze all around the top of the cella (the walled-in chamber within the colonnade) wall outside, and sculptured metopes and sculptured pediments. Inside the cella stood the cult statue, the great gold and ivory figure of Athena, the work of Phidias. No sooner was the main work on the Parthenon completed than the Propylaea was begun. This was the monumental gateway with five doors at the head of the approach, designed by the architect Mnesicles. Its large outer vestibule was covered by a marble ceiling, supported by marble beams with a free span of 18 feet, about which Pausanias wrote, "the Propylaea has a ceiling of white marble which in the beauty and size of the stones remains supreme even to my time." Work on the Propylaea was nearly finished when stopped by the outbreak of the Peloponnesian War in 432 BC, but, as things began to go well for Athens, the little temple of Athena Nike was erected on the bastion in front of the Propylaea, perhaps in 425 BC. At the time of the Peace of Nicias (421 BC), or perhaps a year or two earlier, the Erechtheum was begun. This was a small Ionic temple of highly irregular plan, which housed various early cults and sacred tokens. When the building was about half-finished, work was suddenly interrupted, probably because of the disastrous Athenian expedition to Sicily (415–413 BC), but it was resumed in 409 BC, and the building was completed in 406 BC. The final defeat of Athens two years later put an end to all building, but the Acropolis had been completed, and in later centuries only secondary buildings and monuments were added.

The building of the Erechtheum

The second half of the 5th century also saw some building activity in the lower town. Even before the Parthenon, work was begun on the temple of Hephaestus (the Greek god of fire), the Theseum, which still stands on a low hill. In the Agora itself, a new Bouleuterion was built, and two colonnades, the Stoa of Zeus and the South Stoa, were constructed. On the south slope of the Acropolis, next to the theatre, Pericles built an odeom, a large enclosed concert hall, its roof supported by a forest of columns. Of the theatre itself there are no identifiable remains, but the arrangements were no doubt quite simple, and it is known that a theatre existed on this spot from the late 6th century BC because of the old temple of Dionysus (the god of wine) nearby, which dates from the same period. A sanctuary of Asclepius was founded on the south slope of the Acropolis in 420 BC.

Athens was slow in recovering from its defeat in the Peloponnesian War, but in 394 BC its admiral, Conon, won a decisive naval victory over Sparta off Cnidus, on the west coast of Asia Minor. As a result he rebuilt the Long Walls, which the Spartans had demolished to the

music of flutes ten years before, believing they were inaugurating the freedom of Greece. The walls of Piraeus were also rebuilt, and those of the city were repeatedly strengthened in the course of the 4th century, notably by the addition of a ditch or moat as protection against siege machinery.

Building in the late 4th century

Apart from military works, there was little building in 4th-century Athens until the years 338–322 BC, when the orator Lycurgus was in control of the state finances and there was great activity. On the Pnyx, the broad-backed hill west of the Acropolis where the Athenian popular assembly had met since the reforms of Cleisthenes (a 6th-century constitution maker), a large auditorium was constructed. At the same time, two large stoas were started on the terrace above. The theatre of Dionysus was rebuilt and greatly enlarged, with stone seats to accommodate the crowds. (Lycurgus did another service to the theatre by having definitive copies made of the old plays.) The Panathenaic stadium was also built about then, partly with state funds and partly by private contributions: the land was donated by a certain Deinias, and one Eudemus of Plataea provided 1,000 yoke of draft animals to level the ground. The period was one of lavish private expenditure in other fields as well. The tripods won in choral contests were displayed on elaborate monuments, sometimes even resembling small temples: the best preserved of these is that of Lysicrates (334 BC), a small round building with six Corinthian columns. Tombs also became increasingly elaborate, often portraying the whole family in high relief. In 315 BC a stop was put to all this extravagance by the sumptuary laws of Demetrius of Phalerum.

Meanwhile, the philosophy schools flourished. Plato (*c.* 428–348/347 BC) established himself in the Academy, a gymnasium that had existed since at least the 6th century BC in the great olive grove about a mile west of the city. Plato himself had a house and garden near by. Aristotle and his Peripatetics occupied the Lyceum, another gymnasium, just outside the city to the east, and his successor Theophrastus lived near by. Antisthenes and the Cynics used the Cynosarges gymnasium to the southeast of the city. Zeno held forth in the heart of the city, in the Stoa Poikile, or Painted Colonnade, in the Agora, and his followers were therefore known as Stoics. Epicurus and his followers had a house and garden in town.

Apart from its temples and public buildings and its great avenues, however, Athens seems to have made a poor impression. A 3rd-century-BC visitor complained that the city was dry and ill-supplied with water, that it was badly laid out because of its great antiquity, and that most of the houses were mean. The streets were in fact narrow and winding, and the houses, it is true, presented a blank wall to the street except for the entrance door, but then they were built around a central courtyard, off which the various rooms opened. There was often an upper story, and the court had a well. Water brought in by the aqueducts was not considered good because it was hard (containing salts of magnesium or calcium) and caused rheumatism. Waste water was carried off in an elaborate system of underground drains beneath the streets. (For related information, see GREEK CIVILIZATION, ANCIENT.)

Hellenistic and Roman times. Athens in Hellenistic and Roman times depended for its embellishment less on its own resources than on the generosity of foreign princes. One of the Ptolemies (rulers of Egypt) gave a gymnasium, erected near the sanctuary of Theseus, and the Ptolemies were probably also instrumental in the founding of the sanctuary of the Egyptian gods Isis and Sarapis. More important were the donations of the Attalids of Pergamum (a dynasty of Asia Minor); Eumenes II (197–159 BC) gave a large, two-story colonnade on the south slope of the Acropolis near the theatre. His brother Attalus II (159–138 BC), who had studied at Athens under the philosopher Carneades, head of the New Academy, likewise gave a colonnade. This was a large, elaborate, two-story building more than 350 feet long with a row of shops at the rear. It was located on the eastern side of the Agora and has been reconstructed in modern times (1953–56) to serve as the Museum of the Agora excavations. The Stoa of Attalus was the first element in a large-scale reconstruction of the Agora. It was followed in quick succession by three buildings, the Middle Stoa, the East Building, and the South Stoa, which together formed a separate South Square in the southern half of the Agora.

Donations of the Attalids

The capture of Athens by the Roman general Sulla in 86 BC was accompanied by great slaughter and much destruction of private houses, but the only public building to be destroyed was the Odeum of Pericles, burned by the defenders of the Acropolis lest its timbers be used by the enemy. The Odeum was rebuilt on the same plan a few years later, through the generosity of King Ariobarzanes of Cappadocia.

Under the Roman Empire, Athens enjoyed imperial favour. A spacious market for the sale of oil and other commodities was laid out east of the old Agora with funds originally provided by Julius Caesar and supplemented by the emperor Augustus. In the old Agora itself, a new odeum, or concert hall, was built in the middle of the square by Marcus Agrippa, the emperor's son-in-law and one of his chief lieutenants. A large building, perhaps a law court, was also erected at the northeast corner. At the southeast corner of the Agora a handsome library was erected about AD 100, the gift of one T. Flavius Pantainus and his family. It was decorated with a group of marble sculpture representing Homer flanked by the Iliad and the Odyssey. On the Acropolis a small round temple was erected to the goddess Roma and the emperor Augustus.

Hadrian's devotion to Athens

The emperor Hadrian (AD 117–138) completed the great temple of Olympian Zeus, started over 600 years earlier by the Peisistratids. This temple formed the chief ornament of the new eastern suburb of Athens, and Hadrian gave the area a monumental entrance through a gateway, the inscriptions on which proclaimed, on one side, "This is the Athens of Theseus, the old city," and, on the other, "This is the city of Hadrian, not of Theseus." Hadrian also built a library, a gymnasium, and a Pantheon (a sanctuary of all the gods). His aqueduct, which brought water from the mountains to the north, has been reconditioned and still serves the modern city.

In the reign of Valerian (AD 253–260), the walls of Athens, which had been neglected since Sulla's capture of the city in 86 BC and had fallen into ruin, were rebuilt, and the circuit was extended to include the new suburb northeast of the Olympieion. This was done because of the threat of a barbarian invasion, but when that invasion came, in AD 267, the walls were of no avail. The Heruli, a Germanic people from northern Europe, easily captured Athens, and though the historian P. Herennius Dexippus rallied 2,000 men on the city outskirts, they could only resort to guerrilla tactics. The lower town was sacked, and all the buildings of the Agora were burned and destroyed. The Acropolis, however, may have held out; at least there is no evidence of extensive damage at this time.

This sack of Athens is comparable only to that by the Persians in 480 BC, but now the reaction was quite different. The Athenians abandoned the outer circuit and established a new and much smaller line north of the Acropolis, leaving even the Agora area outside the walls. This new wall, which, on the evidence of coins, was built in the reign of Probus (AD 276–282), consisted of material taken from ruined buildings in the lower town.

Athens remained confined within this narrow circuit for several generations, but in the 4th and 5th centuries experienced a revival. The old outer circuit of the walls was restored, and many new buildings were erected. Athens at this time was still the cultural capital of the Greek world and a stronghold of Paganism. Its schools of philosophy, which retained their ancient names, however different their outlooks may have been, flourished, attracting students from all parts. These included the emperor Julian the Apostate and two Fathers of the Church, Basil and Gregory Nazianzene. While the schools existed, Athens remained a place of consequence, but when they were closed by the emperor Justinian in AD 529, Athens sank to the level of a small provincial town. Power and

wealth had long since moved to Constantinople, the new centre of the Greek world.

The Byzantine and Turkish periods. Christianity started early in Athens, with the visit of the apostle Paul in AD 51 and the conversion of Dionysius the Areopagite, a former archon and member of the Court of the Areopagus that had heard Paul's defense of his teachings. The little Christian community did not flourish, however, and Athens remained a stronghold of older ways. In the 5th and 6th centuries, however, after the formal establishment of Christianity and the abolition of pagan worship, churches began to be built. These were sometimes ancient temples converted to Christian worship; for example, the Parthenon, the Erechtheum, and the temple of Hephaestus (the "Theseum"). Newly built churches had a basilica plan and a wooden roof, but these now survive only in foundations. In all, some 22 churches of this period are known.

Effects of Christianity on Athens

The 7th to 10th centuries were dark times for Athens. The city is almost never mentioned in the history of the period, and archaeological remains are few. In the 11th and 12th centuries a measure of prosperity returned, and the taste of Athenians then can be gauged by the number of small stone and brick churches surviving, built on the Byzantine cross-in-square plan, such as the Kapnikaréa, and those of the Saint Theodore and the Holy Apostles.

Athens fell to the Crusaders in 1204, remaining in Latin hands for 250 years. The town's outward appearance changed little, except that the Parthenon, now a Catholic not an Orthodox cathedral, received a campanile (bell tower).

When the Turks captured Athens in 1456, the Parthenon became a mosque, and its campanile was turned into a minaret. Other mosques were built in the lower town, but in general the age of gunpowder was to prove disastrous for Athenian architecture, especially on the Acropolis, which was still virtually intact as late as the mid-17th century. (E.V.)

THE MODERN CITY

Athens, when approached from the Middle East, is the first European city, with tall buildings, newspaper kiosks, modern shops, and modishly dressed women. Approached from Europe, it seems, if not exactly the first Oriental city, at any rate not quite European, in its ill-fitting, locally tailored modernity. The European notes a medley of characterless concrete and out-of-style dress, with the smell of spitted meat and spices in narrow streets as clamorous as bazaars and unpaved roads a few streets from the centre.

The Athenian character. Nevertheless, it is wrong to say that Athens is a mixture of East and West: it is Greek and, more particularly, Athenian. The Athenians, after all, nurtured Western civilization. Yet, some three centuries after the death of Pericles (429 BC), they entered upon a period of bondage that lasted almost 2,000 years. Athens was freed in 1833, and in the following 135 years was the scene of 14 revolutions, another brutal foreign occupation, and a civil war of especial savagery. This long history of passion and suffering has had considerable effect on the Athenian character. The core of that character is an implacable will to survive, buttressed by a profound sense of loyalty (especially to the family) and patriotism. The church, which is directed by a Synod sitting in Athens, was a main force in keeping alive the Greek language, tradition, and literature when such things were forbidden, and most people still support it.

The 2,000-year bondage

The millennia of oppression, instead of driving the Athenian into obtuse moroseness, have honed his wit and rendered him tough but supple, while centuries of privation have only preserved his warmth and generosity. The long oral tradition, alive even under the invader, has reflected and stimulated a taste for rich talk. Of course, the poetic impulse to make a good story better leads to considerable exaggeration in daily conversation, suiting a vanity that goes with a sharp-edged sense of personal and family honour and the spoiling of children. The ancient heroes, too, were vain about both themselves and honour, boasting as much about outwitting the enemy as about outfighting him. Cunning, as in the Odyssey, is still a virtue here.

Athens' development as a modern capital. One-quarter of the nation's population, half its urban population, lives in Athens, and, despite sporadic efforts at decentralization, the city remains the capital in every sense. Since 1833, when Athens became the capital of an independent Greece, the population of the country has increased 12 times, that of Athens 150 times.

In 1833, indeed, there was almost no Athens at all. During the fight for independence, it had been entirely evacuated in 1827, and six years later held perhaps 4,000 people in the straggle of little houses on the north slope below the Acropolis. The newly imported King of the Hellenes, Otho, the 18-year-old son of Ludwig I of Bavaria, was installed in the only two-story stone house, while his German architects hurried ahead with plans for a palace and a new Athens far out in the fields.

Below the well-sited but very plain palace, a large garden square, Síntagma (Constitution) Square, was laid out. Today it is garnished in the tourist season with some of Europe's most luxurious cafe chairs, and at all seasons is hemmed in by tall new buildings and elderly luxury hotels. Broad avenues were created and are still the city centre's principal thoroughfares (Winston Churchill [formerly, Stadium] and Elefthérios [formerly, Venizélos and Panepistimíou] streets), between which an orderly grid of narrow side streets was laid out. The housing that developed was generally the sort of architecture familiar in Victorian London: solid, porched, rather imposing, the later imitations graceless and monotonous. In Athens it is called the Othonian style, but there is little of it left as the centre encroaches on old residential areas.

Once the new capital was established, the city grew at a regular rate of about 7 percent a year, soon reaching 50,000 inhabitants, a figure not much exceeded in the days of Athens' greatest power and glory. By 1907 the municipality had a population of 167,479, Omónia Square had been built at the western end of the two main streets, with other broad avenues radiating from it, but it did not develop as the hoped-for balance to Síntagma.

By now the railway to Piraeus (the port of Athens) had been built, its station near the antique Agora and its tracks laid over the Painted Stoa. Indeed, the city plan projected a logical growth southward along this axis, but a real-estate developer beckoned northward—the National Museum is now out this way—and the newly rich followed. The palace garden almost touched the Arch of Hadrian and the 15 mammoth columns (some of them seven feet ten inches in diameter) of the temple of Olympian Zeus, last of the Classical buildings built in Athens, and beyond lay empty fields. The slopes of Mt. Likavittós, outside the town limits, were still pine-clad.

Since then, the garden has become one of the painfully rare public parks in Athens. Likavittós now rears up in the middle of the city (as if Hyde Park or Central Park were a 1,112-foot [339-metre] mountain), its lower slopes built upon, and many of the trees felled for a road leading to a cog railway and restaurant.

Along Elefthérios (Venizélos) Street rose the Academy of Athens in marble from Mt. Pentelicus, its pediments and colonnades gilded. Its new neighbours were the University of Athens (re-founded in 1837), the colonnade adorned with paintings, and the National Library. All were done in Greek Revival style by the Court's German architects. A new Royal Palace was built during 1891–97, a little southeast of the old (which is now a Parliament house) on Herodes Atticus Street. This leads to the 70,000-seat Panathenaic Stadium, reconstructed by an expatriate Greek millionaire in time for the revival of the Olympic Games in 1896.

Population. In 1921 the orderly progress of Athens was overturned and haphazard development began, for ethnic minorities were exchanged between Greece and Turkey, and approximately 1,500,000 Greeks, most of them penniless, came "home" from Asia Minor. Despite government efforts to resettle them elsewhere, many swarmed into shanty towns around the fringes of Athens and Piraeus, and the area's population soared from 473,-

000 to 718,000. The city is still clearing slums that began as refugee colonies. After this, the city began to spread in two directions, south toward Piraeus and north toward the village of Kifissia, which first became a smart suburb when Herodes Atticus built his villa there in the 1st century BC. The 1940 census showed 481,000 inhabitants in Athens proper, and 1,124,000 in the Athens Basin.

In the decade before the next census, hideous things happened in Athens. During the German occupation, a truck toured the streets picking up the bodies of starvation victims, and the city began to fall apart from lack of maintenance. When the Germans left, part of the Allied-equipped Resistance refused to lay down its arms, and the civil war began. For a while the government held only the Parliament building, neighbouring embassies, and a part of Constitution Square, while the palace garden was used as a common grave.

Housing. Shortly after, a construction boom began, which had still not stopped by the early 1970s. New apartment houses pushing up everywhere erased old social boundaries, though the Kolonáki district on the southeast slope of Likavittós remained an enclave of respectable fortunes, and villages that had been attached to the city in the previous expansion lost their physical and political identities. A network of major highways was thrown up. The west side of the historic olive grove by the Kifisós River was shorn, and hillside greenery began to disappear under housing, either unauthorized or made legal through political skullduggery. Open space vanished, without provision for parks, playgrounds, or even schools, and Athens spread down to the sea by Glifada, joining up with Piraeus. Piraeus itself was transformed from one of the world's celebrated honky-tonk ports into a clean, new-built, flower-decorated city.

Enlargement of the city's master plan

The Athens master plan was enlarged several times to keep pace with spread, which in 1964 already attained 75 square miles (195.6 square kilometres), with a built-up area of 17 square miles outside the plan altogether. Land values in the centre quadrupled, then octupled, and rose proportionately elsewhere. Traffic increased almost to the saturation point at rush hours, and the city continued to sprawl over the plain. As international tourism increased, Athens Airport, with 3,008,000 passengers in 1970, was expanded and modernized, and 25,000 hotel beds were still 5,000 too few in 1971's peak season.

The city water supply from an artificial lake at Marathon was insufficient to supply new building construction and the Mornos River 110 miles to the east was dammed and tapped. Installation of a modern sewer system was undertaken, together with controls to check the floods that roar into Athens when heavy rains pour off the denuded mountains.

Economic life. *Commerce and manufacturing.* Since World War I Athens has become the hub of all mercantile business, export and import. With the Piraeus, it is the most important manufacturing town in Greece. There are cloth and cotton mills, distilleries, breweries, potteries, flour mills, soap factories, tanneries, chemical works, and carpet factories. Exports include tobacco, wine, oil, currants, marble, and, recently, bauxite and magnesite. Publishing enterprises are important. The principal imports are coal, grain, and manufactured articles.

Transportation and shipping. By 1970 Athens accounted for more than half the nation's telephones, more than half its cars, trucks, and buses, and half the jobs in industry and handicrafts. Average earnings were three times higher than the national average. Furthermore, between 1967 and late 1970, the number of merchant ships registered in Greece (mostly at Piraeus) increased from 1,771 to 2,315 as Greek shipowners answered the government's call to bring their foreign-registered ships home (though 3,561 Greek ships remained under other flags). Likewise, shipping receipts rose in the same period from $182,400,000 to $269,760,000. In 1970 alone, 130 shipping offices opened in refurbished Piraeus, while on weekends, shipping magnates sailed to the nearby islands of Hydra and Spetse in chrome-fitted luxury yachts, flying Panamanian and Liberian flags. It hardly seemed to matter where the official city limits stood, since Athens was overrunning everything: the population at the 1971 census was 2,530,207.

Environmental and modernization problems. The brilliant Attic light is now dimmed by the pall of pollution hovering over the city. To discourage new factories from adding to the problem and to stimulate modernization of other regions' economies an industrial wage tax was imposed in the Athens area, and a reduction of up to 40 percent tax on turnover was offered to new factories set up in other areas.

Old Athens

The older Athens has not entirely disappeared in all this hubbub. Older men may have given up smoking hookahs (pipes passing through water) in shadowy cafes but not their 33-bead *kombouloi* ("worry beads"), a tension-dissipating addiction acquired from the Turks.

Old Athens also lives on in the six streets sidling off Monastiraki, by the excavated Agora. Here are tiny open-fronted shops hung with tinseled folk costumes, boots apparently captured from German soldiers in 1944, and all the monuments of Athens reproduced in copper, plaster, plastic, and paint. There is an alley of antique dealers, a street of smithies, one of hardware merchants, and another of wildly assorted miscellany.

Close to this lively quarter is the Pláka, on the north slope of the Acropolis. Small, one-story houses, dating from about the time of Independence, are clustered together up the hillside in peasant simplicity. There are appropriately tiny squares, with *tavernae*, once celebrated for their folk music, dancing, and simple fare. There are vine-covered pergolas and some unpaved streets too narrow for cars. The baths built by the Turks still function morning and afternoon, but the *bouzouki*, local relative of the lute, is giving way to the electric guitar, the *taverna* signs are multilingual, and the ubiquitous kitchen chair is being replaced by the plastic-ribbed restaurant seat. Progress laps at the Pláka like a vengeful sea, but the Acropolis is just up above, just under the stars. (B.E.)

Atheriniformes

The order Atheriniformes contains 15 families of marine and freshwater spiny-finned fishes, including the flying fishes, needlefishes, silversides, and cyprinodonts. The last group, the Cyprinodontidae, is an abundant tropical

and subtropical family that includes the guppies, mollies, swordtails, and many other aquarium fishes. In addition to the Atheriniformes, this article will treat the three smaller related orders Beryciformes, Zeiformes, and Lampridiformes, the most primitive groups of the superorder Acanthopterygii or spiny-finned fishes.

GENERAL FEATURES

Beryciforms and zeiforms are mostly deep-bodied fishes of small to moderate size, a foot or less in length. The lampridiforms include a few rare, deep-bodied forms, notably the disk-shaped opah, which may reach more than 300 pounds in weight, but the majority are much elongated, ribbonlike fishes, including the giant oarfish, *Regalecus*, which reaches eight metres (25 feet) in length and is the probable source of many sea-serpent legends. The atheriniform silversides, flying fishes, needlefishes, and halfbeaks tend to be slender, elongate fishes, up to two or three feet in length. The cyprinodonts and their relatives are diminutive and include some of the smallest vertebrates. Many cyprinodonts are important as experimental animals in biological research and as useful predators in the control of insect-borne diseases.

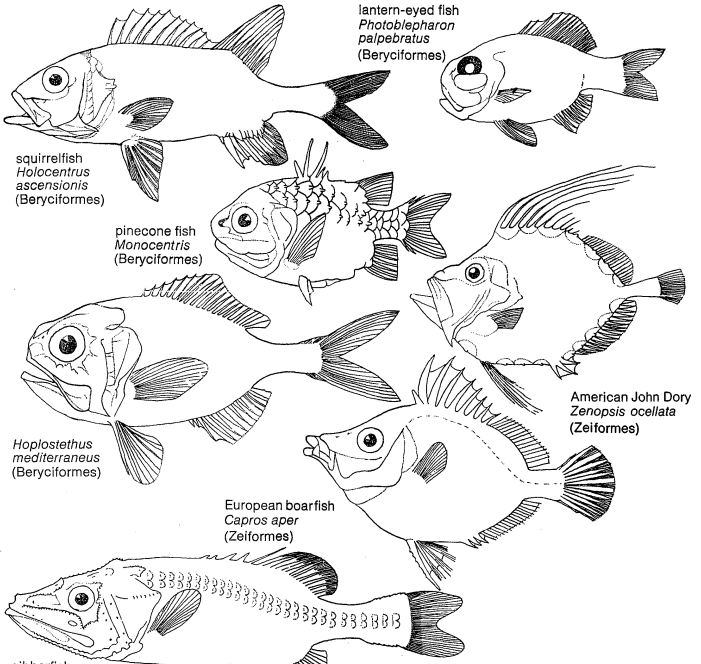

Figure 1: Body plans of Beryciformes and Zeiformes.

NATURAL HISTORY

Most beryciforms, zeiforms, and lampridiforms are inhabitants of the open oceans, usually living at considerable depth, and little is known of their natural history. All appear to produce numerous small eggs. The best known of the beryciform groups are the squirrelfishes and soldierfishes (family Holocentridae), abundant around coral reefs in warm seas. Typical of beryciforms, they are red in colour, with large eyes. Holocentrids are nocturnal, sheltering in crevices during the day and emerging at night to feed. They are notable sound producers, having special drumming muscles attached to the swim bladder, and many have connections between the swim bladder and the ear to improve hearing: presumably these sounds and their reception play some part in courtship. In holocentrids the young (larva) is quite unlike the adult, with a projecting spiny snout and enlarged spines in front of the gill cover. There is a pronounced metamorphosis (a major change in body plan on reaching maturity). It is probable that some of the deep-sea beryciforms undergo similar metamorphoses; the larva of the fanged *Caulolepis* was for many years placed in a different family from the adult, and the genus *Kasidoron*, recently discovered and placed in a distinct family, may be only the larva of *Gibberichthys*. Another family of beryciforms found near the surface is the Anomalopidae, or "strange-eyes," so-called because of a large luminous organ lying directly below the eye, which is switched on by muscular eversion, turning the inside outward (in *Anomalops*) or by the withdrawal of a pigmented cover (in *Photoblepharon*). The Monocentridae, the bizarre pinecone fishes, are another beryciform group with luminous organs, in this case located on the chin. The majority of beryciforms are generalized predators, but a few coral-reef forms are grazers.

Luminescent organs

Among zeiforms, at least one species, *Zeus faber*, produces sounds by drumming muscles and breeds inshore. Little is known of the biology of the oceanic forms, but some certainly undergo metamorphosis, especially the Oreosomatidae, whose larvae are studded with large, spinous tubercles. All zeiforms are highly compressed fishes, with stiff bodies and long dorsal and anal fins: probably they swim by undulating these fins rather than by flexing the body. This slow, stealthy mode of swimming, coupled with their highly protrusile mouths, adapts them for stalking and engulfing prey.

The lampridiforms are all oceanic fishes. Metamorphosis is recorded in dealfishes and oarfishes, the young of which have rather deep bodies and greatly elongated finrays. All are slow swimmers, and the larger forms, the opah and the oarfishes, which are characteristic of surface waters, use their protrusile, toothless mouths as traps for small, planktonic (free-floating) organisms. The deep-sea forms have feebly toothed jaws and are predators. A remarkable modification in one lampridiform, *Lophotus*, is the presence of an ink sac, discharging a viscous, black secretion into the hindgut, thence into the water. These fishes probably use their ink as a defense mechanism, as do squids. *Stylephorus*, a highly modified deep-sea lampridiform, has projecting, telescopic eyes.

Among atheriniforms there is an extraordinary variety of locomotor, reproductive, and ecological adaptations. Locomotor modifications are most marked in the flying fishes, but the origin of the "flying" habit can be traced in flying fish relatives such as the halfbeaks, garfishes, and skippers. All are surface fishes of the open ocean and are capable of leaping or skipping on the surface, sometimes for considerable distances, thus allowing them to escape predators. The tail (caudal) fin is usually asymmetrical, with the lower lobe longer than the upper, and while the body is out of the water the lower lobe vibrates as a scull driving the fish along. True flying fishes have a similar asymmetrical tail, but the pectoral fins are inserted high on the shoulders and are greatly enlarged, with long, stiff fin rays supporting a web of skin. In the most highly evolved flying fishes, the pelvic fins are also enlarged and winglike. The fish accelerates under water by rapid vibration of the tail and fin, with the paired fins furled. On breaking surface, the pectoral fins are expanded, but the lower lobe of the tail remains in the water, sculling rapidly and accelerating the fish. The pelvic fins are then expanded, lifting the tail out of the water and initiating gliding flight. As airspeed is lost, the fish may fall back into the sea or furl its pelvic fins, dropping the lower lobe of the tail into the water and picking up speed for a further glide. Up to five repeated takeoffs have been observed, producing a total flight time of almost half a minute and covering several hundred yards.

Flying fishes

Marine atheriniforms are mostly predators, the predatory habit being most highly developed in the garfishes and needlefishes, with their long, formidably toothed jaws. Freshwater atheriniforms are generally adapted

for feeding at the surface, on insect larvae and small crustaceans.

All atheriniforms are characterized by the production of few, large, adhesive eggs, by mating in pairs, usually accompanied by sexual dimorphism (*i.e.*, the sexes markedly different), and many groups exhibit various reproductive specializations, the most advanced of which is viviparity (the production of functional young, instead of eggs). The young are normally miniatures of the adult and there is no metamorphosis. Sauries, needlefishes, flying fishes and marine halfbeaks are pelagic (*i.e.*, inhabiting open ocean) and breed either in the open sea (sauries, flying fishes) or near the shore (needlefishes, halfbeaks), the eggs often attaching to floating objects by adhesive filaments. The freshwater halfbeaks are mostly viviparous and have an elaborate courtship behaviour.

Atheriniforms of the suborder Atherinoidei fall into two groups, the silversides (Atherinidae and their close relatives) and the more specialized phallostethoids. The silversides are mainly freshwater fishes and show some reproductive specializations in courtship behaviour and sexual dimorphism (coloration and fin shape). They breed near the shore, attaching the eggs to plants. The grunion (*Leuresthes tenuis*) breeds on the California coast, schooling in the surf at extreme spring high water and spawning on the shore, where the female buries the eggs in the sand. The eggs hatch when they are exposed by the next spring tide, two weeks later. In phallostethoids, males have a fleshy, asymmetrical intromittent organ, the priapium, under the throat, formed from the modified pelvic fins. Although fertilization is internal, viviparity is not known to occur.

Breeding specializations of cyprinodonts

Even the most primitive atheriniforms in the suborder Cyprinodontoidei show the usual reproductive specializations of the group: sexual dimorphism and complex behaviour patterns in courtship and spawning. In the Mexican topminnows (Goodeidae) viviparity has developed, the embryos absorbing nourishment within the oviduct of the mother by means of threadlike outgrowths. In the live-bearers (Poeciliidae), an abundant group in the American tropics and subtropics, sexual dimorphism affects many parts of the body. Males have a complex intromittent organ, the gonopodium, formed of modified anal fin rays. One member of the group is oviparous, shedding the eggs while the embryo is only partially developed, but in the guppies, mollies, and swordtails, where the male is much smaller than the female and more brightly coloured, the young are born fully developed, and a series of broods, at about monthly intervals, may result from a single fertilization. In wild cyprinodont populations the sex ratio is frequently unusual, with many females to each male. In *Jenynsia* and *Anableps* (the four-eyed fish) the gonopodium and female reproductive opening are asymmetrical. Both dextral and sinistral forms occur within a species, dextral males mating with sinistral females and vice versa.

Ecological adaptations in atheriniforms are most marked in freshwater species. Cyprinodonts are among the hardiest of fishes and survive in the most rigorous environments. Some cyprinodonts have become adapted to life in hot springs in Africa and America and seem capable of surviving water temperatures approaching the coagulation point of protoplasm. Others survive in stagnant, almost or completely deoxygenated waters, either by taking in water at the surface film, or by breaking surface and gulping air, although no accessory respiratory structures are developed. Some cyprinodonts have overcome the rigours of a seasonal tropical habitat by becoming annuals, growing rapidly and reaching sexual maturity in small temporary bodies of water during the wet season, and on the approach of the dry season, mating and burying the eggs in the mud. The eggs can survive droughts for up to five years, hatching rapidly with the onset of the succeeding wet season. Perhaps another response to rigorous environments is the occurrence in some cyprinodont populations of functional hermaphrodites, capable of self-fertilization and hence of maintaining a population from one surviving parent.

FORM AND FUNCTION

The fishes discussed here share a number of anatomical features typical of the more advanced teleosts. These include a closed swim bladder; separation of the parietal bones by the supraoccipital; jaws that protrude to some extent, with the maxillary bone (toothless except in a few beryciforms) acting as a lever to move the large premaxilla; the pectoral fins inserted high on the flank and the pectoral girdle without a mesocoracoid arch; and a tail skeleton supported by two or less vertebrae. Otherwise, there is considerable structural variation.

Structure of beryciforms

Beryciforms are the most primitive fishes of the four groups under discussion, exhibiting primitive features: the presence of two supramaxillary bones in the upper

From (*Lampris regius*) N.B. Marshall, *The Life of Fishes* (1965), Weidenfeld & Nicolson; (*Mirapinna esau*) P.P. Grasse, *Traite de Zoologie*, Masson et Cie, Paris; (*Kirtlandia vagrans*) D.S. Figure 2: Body plans of Lampridiformes and Atheriniformes.

jaw; an orbitosphenoid bone between the eyes; a tail fin containing 19 principal rays, which insert on six hypural bones supported, in turn, by two vertebrae. Occasionally, they have teeth on the maxillary bone (in the modern holocentrid *Myripristis* and a few Cretaceous fossils). There are many ways in which beryciforms approach the perciforms, the typical "spiny-rayed" fishes. Such resemblances are seen in a number of features: the structure of the mouth, with a normal acanthopterygian pattern of jaw muscles and ligaments; the spiny head bones and ctenoid scales (with a serrated edge); a projection called a subocular shelf on the bones below the eye, stout spines in front of the dorsal, anal, and pelvic fins; bony contact between the pelvic and pectoral girdles; and the short, deep trunk, with about 25 vertebrae. The more generalized beryciforms (holocentrids, trachichthyids, and berycids) exhibit all of these features, but in several lineages degeneration has occurred, associated with life in the deep. In such deep-sea beryciforms as the big-scale fishes (Melamphaeidae), fin spines tend to be absent, the pelvic fins have moved back to the abdomen, and the head bones and scales have become thin and flimsy. Also, in some species primitive structures such as the orbitosphenoid and supramaxillary bones are lacking, and fusions within the tail skeleton have resulted in a condition resembling that of perciforms. The swim bladder is reduced or lost in some.

Structure of zeiforms

Anatomically, the zeiforms resemble perciforms more closely. Almost the only feature that distinguishes zeiforms from perciforms is the presence, in the former, of two or three more rays in the pelvic fins, and in some zeiforms even this distinction fails to hold. Nevertheless, these extra pelvic rays and a few other features, notably the structure of the otoliths ("ear stones," used in maintaining balance), indicate that the zeiforms are beryciform relatives that have independently attained the perciform evolutionary level. Typically, the zeiform has a highly protrusible mouth, a separate spinous dorsal fin, ctenoid scales, and a short, deep trunk; the most primitive members of the order have 24 or less vertebrae.

Structure of lampridiforms

The most primitive lampridiforms are also deep-bodied fishes, with spines in front of the dorsal and anal fins, the pelvic fins directly below the pectorals, an orbitosphenoid bone in the skull, and a tail fin with 19 principal rays, in which they resemble beryciforms. Lampridiforms differ from beryciforms, however, in never having a subocular shelf or pelvic spine, in having more numerous vertebrae, and in having the upper tail fin supports fused with an independent vertebral centrum, a condition resembling that found in the cods and their relatives (Paracanthopterygii). Most lampridiforms have highly protrusile jaws in which depression of the lower jaw dislocates the maxilla of the upper, so that it moves forward bodily, carrying the premaxilla with it. This is a different method from that adopted by other acanthopterygians, hence the name allotriognaths ("strange-jaws") originally applied to the group. A parallel can be drawn between the beryciforms and lampridiforms in certain modifications exhibited by the deep-sea forms, compared with their surface-living relatives. These include the loss of fin spines, reduction in ossification, and reduction of the swim bladder. The most striking features of the more highly evolved lampridiforms, however, are peculiar to the group: great elongation of the trunk, accomplished by increase in vertebral number and elongation of the vertebrae themselves, and reduction of the tail to a small, asymmetrical or filamentous appendage.

Structure of atheriniforms

The atheriniforms are an extremely varied group. There are many structural resemblances to more advanced acanthopterygians, but these are in mosaic distribution, indicating that most have been independently acquired. The jaws of many atheriniforms are protrusile, but the structural modifications by which this is achieved are quite different from those of typical acanthopterygians. The simple, shelflike head of the maxillary bone is attached to the palate only by ligaments, not by a mobile joint. The premaxilla is longer than the maxilla and also has a simple head. Protrusion of the jaws is accomplished by twisting the maxilla and displacing its head forward; the complex system of joints and ligaments characteristic of other acanthopterygians is not developed. The palate is usually toothless, and the series of infraorbital bones incomplete, only the first (lachrymal) and last (dermosphenotic) bones being present. The skull bones are not spiny, but the scales are often ctenoid. The pelvic girdle may have a ligamentous connection with the shoulder girdle but often lies further back, and the girdles never acquire the direct contact that characterizes higher acanthopterygians. The pelvic fin has six or fewer rays, but there is no pelvic spine. The atheriniform tail skeleton is of an advanced type, usually with two large plates emanating from a single supporting centrum, as in some advanced perciforms. The caudal fin contains 17 or less principal rays. There are a few spines in front of the dorsal and anal fins in many atheriniforms, and the members of the Atherinidae and Phallostethidae have a small, separate spinous dorsal fin, but atheriniform spines appear to have evolved independently from those of true acanthopterygians.

An extreme example of adaptation to life near the air–water interface, the habitat of most atheriniforms, is the eye of *Anableps*, the four-eyed fish, so named because each eye is a double structure. The eye is set high on the head and the upper part projects above the water. The cornea is divided by a horizontal band of pigment, separating an upper, strongly convex part from a lower, flatter division. The iris has a pair of projections partially dividing the pupil into two, and the upper is effective for aerial vision, the lower for underwater vision.

Much work has been done on the genetics of atheriniforms, perhaps the most surprising result being the hatching of hybrids between *Fundulus* (Cyprinodontidae) and *Menidia* (Atherinidae), fishes placed in separate suborders. A physiological peculiarity of some marine atheriniforms, garfishes and needlefishes, is a bright green coloration of the bones and even the flesh, due to retention of a bile pigment, biliverdin.

EVOLUTION; PALEONTOLOGY AND CLASSIFICATION

Paleontology. The four orders Beryciformes, Zeiformes, Lampridiformes, and Atheriniformes are primitive groups within the superorder Acanthopterygii. The Beryciformes and Zeiformes apparently form a related group, originating in the Cretaceous, its closest relatives being the Perciformes. The Lampridiformes also originated in the Cretaceous and are of uncertain relationships, being to some extent intermediate between the Acanthopterygii and Paracanthopterygii. The Atheriniformes represent a radiation from near the base of the acanthopterygian stock, but their exact relationships within this group are not known. The present distribution of atheriniforms indicates that the group arose in fresh or brackish waters of the tropical Indo-Pacific region, but little is known of their early fossil history.

Annotated classification.

ORDER BERYCIFORMES

Spiny-rayed fishes with a pelvic spine, an orbitosphenoid, and 19 principal rays in the tail. Of the two main lineages the first contains the Holocentridae, coastal fishes of warm seas. The second is a series of oceanic families centring around the Trachichthyidae. Both groups have fossil records back to the Cretaceous, the 2 lines converging in the Middle Cretaceous.

Family Holocentridae (soldierfishes and squirrelfishes)

Circumtropical, with partly separate spinous dorsal fin. Several extinct genera, Middle Cretaceous onward.

Family Monocentridae (pinecone fishes)

Armoured, very spiny. Teeth on endopterygoid bone. Two genera; Indo-Pacific.

Family Trachichthyidae

Midwater (mesopelagic) or deepwater pelagic fishes, worldwide. Skull bones cavernous, with large mucus cavities. Several extinct genera, Middle Cretaceous onward.

Family Berycidae (*alfonsinos*)

Upper and midwaters in open ocean; worldwide. Pelvic girdle enlarged and tightly joined with the pectoral.

Family Anoplogasteridae

Deep-sea, adults with large fangs; 1 genus.

Family Diretmidae

Very deep bodied, compressed fishes; 1 genus.

Family Anomalopidae (lantern-eyed fishes)

With subocular luminous organ, found near the surface at night; 2 Indo-Pacific genera, 1 Atlantic.

Family Stephanoberycidae (prickle fishes)

Scales and head spiny, fin spines reduced; bathypelagic, worldwide; 3 genera.

Family Melamphaeidae (big-scale fishes)

Abundant deepwater open ocean fishes, worldwide; soft-bodied and black. Fossils in the Miocene.

Family Gibberichthyidae

As Melamphaeidae but with stronger fin spines. Atlantic, 1 or 2 genera.

Family Rondeletiidae (whale fishes)

Head large, no scales, fin spines, or swim bladder; bathypelagic, 1 genus.

Family Cetomimidae (whale fishes)

Mouth enormous, fins without spines, bathypelagic, worldwide.

Family Barbourisiidae (whale fishes)

No fin spines, scales reduced to minute spines, red, bathypelagic, 1 genus.

ORDER ZEIFORMES

As Perciformes but with up to 9 pelvic rays and only 12–13 principal caudal rays.

Family Caproidae (boar fishes)

Most primitive family, 21–23 vertebrae, fossils in the Oligocene; 2 genera, worldwide.

Family Zeidae (John Dories)

Deep bodied and laterally flattened. Mouth large; scales reduced; more than 30 vertebrae. Several genera, worldwide; fossils in the Eocene.

Family Grammicolepididae

Mouth very small, scales drawn out into oblique bands. Two genera, mesopelagic.

Family Oreosomatidae

Larva covered with large tubercles. Four genera, benthic (bottom dwelling); worldwide.

Families Zeniontidae and Macrurocyttidae

Two small families, the first with two genera, the second with one, too poorly known to be characterized.

ORDER LAMPRIDIFORMES

Similar to Beryciformes, but with no pelvic spine; upper hypural bones fused with their supporting centrum.

Suborder Lampridoidei

Deep-bodied forms.

Family Veliferidae

One living genus (*Velifer*) with saillike fins, 33 vertebrae. Fossils from Paleocene and Eocene, several extinct genera.

†*Families Aipichthyidae and Pharmacichthyidae*

Extinct families, each containing a single Upper Cretaceous genus; appear to be primitive lampridiforms, resembling *Velifer* in deep trunk, but with fewer vertebrae and more primitive tail skeletons.

Family Lamprididae (opahs)

One genus (*Lampris*); 15–17 pelvic rays, 46 vertebrae. Fossils from Miocene. Length to 2 m, weight to 300 kg; surface waters (epipelagic) of warm seas; widespread.

Suborder Trachipteroidei

Ribbonlike, about 100 vertebrae.

Family Trachipteridae (dealfishes)

Pelvic fins with 5–9 rays, no anal fin, jaws toothed. Length to 1.2 m; epipelagic. Worldwide in warm seas.

Family Lophotidae (unicorn fishes)

Scales lacking; pelvic fins small or absent, anal fin short. Fossils from Oligocene. Worldwide in warm seas.

Family Regalecidae (oarfishes)

Anal fin lacking; 1 pelvic ray elongated; jaws toothless; length to 9 m; weight to 300 kg. Mesopelagic, tropical.

Suborder Stylephoroidei

Family Stylephoridae

Deep-sea forms with enlarged telescopic eyes, about 50 vertebrae, 2 filamentous caudal rays. Known from only a few specimens.

Suborder Ateleopoidei

Family Ateleopidae

Specialized, deep-sea, bottom-living fishes, Indo-Pacific and Atlantic, usually placed among the primitive teleosts, but probably lampridiform.

Suborder Mirapinnoidei

Families Mirapinnidae and Eutaeniophoridae

Three species of little-known mesopelagic fishes, usually placed as a distinct order of lower teleosts (Mirapinniformes), but probably larval lampridiforms.

Suborder Megalomycteroidei

Family Megalomycteridae

Four rare, little-known, deep-sea genera, probably larval lampridiforms.

ORDER ATHERINIFORMES

Premaxilla greatly expanded between maxilla and mandible, without crossed ligaments controlling the upper jaw, infraorbital bone series incomplete.

Suborder Exocoetoidei

Lateral line complete and low on the flank in marine forms, lower pharyngeal bones fused, no parietals, 9–15 branchiostegals. Worldwide, but especially abundant in the Indo-Pacific.

Family Exocoetidae (halfbeaks and flying fishes)

Lower jaw often extended; snout not modified. Surface marine waters and freshwaters, worldwide; length to 45 cm. Fossil half-beaks in the middle Eocene.

Family Belonidae (garfishes and needlefishes)

Snout bones sutured together, both jaws elongated into a strongly toothed beak. Mostly temperate and tropical marine; a few freshwater; length to 120 cm. Fossils in the Oligocene.

Family Scomberesocidae (sauries, skippers)

Snout and jaws as in Belonidae but feebly toothed; small finlets behind dorsal and anal fins. Inshore temperate and tropical marine waters; length to 35 cm. Fossils in the Miocene.

Suborder Cyprinodontoidei

Lateral line represented by pits on the flank, 4–7 branchiostegal bones. Families mostly distinguished by reproductive specializations.

Family Oryziatidae (medakas)

Most primitive cyprinodonts; a single genus in freshwaters and brackish waters in Indonesia.

Family Adrianichthyidae

Mouth and snout enlarged and shovellike. Two genera in lakes in Celebes; length 7–20 cm. Fossils in Late Tertiary in Celebes.

Family Horaichthyidae

Small fishes with anal fin modified, in males, for clasping female in mating. One genus, freshwater, India.

Family Cyprinodontidae (killfishes or egg-laying topminnows)

Circumtropical and temperate marine and freshwater, many genera. Many popular aquarium fishes; length to 15 cm. Fossils in the Oligocene.

Family Goodeidae (Mexican topminnows)

Live-bearing, but male lacks elaborate intromittent organ found in poeciliids. About 10 genera, in rivers draining the Mexican Plateau; length to about 10 cm.

Family Jenynsiidae

Small fishes with asymmetrical genital organs; 1 genus; rivers of South America.

Family Anablepidae (four-eyed fishes)

Characterized by specialized eye structure (see above *Form and function*); 1 genus, 2 species; surface waters in rivers and estuaries of South America.

Family Poeciliidae (live bearers or viviparous topminnows)

Native to tropical and subtropical America but introduced elsewhere for mosquito control. Freshwaters and coastal marine waters. Length 1.5 to about 15 cm. Family includes mollies (*Mollienesia*), guppies (*Lebistes*), swordtails (*Xiphophorus*), any many other popular aquarium fishes, as well as the mosquito fishes (*Gambusia*).

Suborder Atherinoidei

Lateral line variable; 5–7 branchiostegal bones; separate spinous dorsal fin.

Family Melanotaeniidae

Many species; freshwater bodies of New Guinea and Australia. Compressed, deep-bodied; pointed snout; 5–20 cm.

Family Atherinidae (silversides)

Lateral line absent; pelvic fins midway along belly; length 7–70 cm. Coastal and freshwater, worldwide in warmer regions. Many genera. Fossils from middle Eocene.

Family Isonidae

Pectoral fins unusually high on body. Small marine fishes; Indian and Pacific Oceans. Two genera.

Families Phallostethidae and Neostethidae

Males with priapium, an organ derived from pectoral and pelvic girdles, functioning to clasp female. Tiny fishes (3–5 cm long); confined to freshwaters and brackish waters in Thailand, Indonesia, and Philippines.

Critical appraisal. The whale fishes (cetomimids, rondeletiids, barbourisiids) are often placed in a separate order Cetomimiformes, thought to be more primitive than Beryciformes, but their "primitive" features appear to be due only to degeneration. The stephanoberycids, melamphaeids, and gibberichthyids are usually placed in a suborder Stephanoberycoidei, all other beryciforms being placed in the Berycoidei, but the major phyletic cleft in Beryciformes seems to be between the holocentrids and the remainder, which form a related group.

Athletic Games and Contests

This article covers the historical background of athletic games and contests from their beginnings in ancient Greece through the renewal of the quadrennial Olympic Games at Athens in 1896 and their development into the pre-eminent athletic events of the world. Tables at the end of the article list the Olympic champions from 1896.

Just how far back in history organized athletic contests were first held remains a matter of doubt, but it is reasonably certain that they occurred in Greece, at least, some 1,500 years before Christ.

However ancient in origin, by the end of the 6th century BC at least four of the Greek sporting festivals, sometimes known as classical games, had achieved major importance. They were the Olympic Games, held at Olympia; the Pythian Games at Delphi; the Nemean Games at Nemea; and the Isthmian Games at Corinth. Later, similar festivals were held in nearly 150 cities as far afield as Rome, Naples, Odessus, Antioch, and Alexandria.

Classical games

The Olympic Games in particular were to become famous throughout the Greek world. There are records of the champions at Olympia from 776 BC to AD 217. The Games, held every four years, apparently continued till AD 394 when they were abolished by the Roman emperor Theodosius I. For the first 100 or 200 years, Olympic champions came from a dozen or more Greek cities—the majority from Sparta and Athens; but in the next three centuries, athletes were drawn from 100 cities in the Greek empire. And in the final 100 years or so before the games were discontinued champions came from as far afield as Antioch, Alexandria, and Sidon.

Fifteen centuries after the abolition of the Olympic Games, thought was given to organizing events of a comparable character. In 1887 the 24-year-old Baron Pierre de Coubertin conceived the idea of reviving the Olympic Games and spent seven years preparing public opinion in France, England, and the United States to support his plan. At an international congress in 1894, his plan was accepted and the International Olympic Committee was founded. The first modern Olympic Games were held in Athens in April 1896, with 13 nations sending nearly 300 representatives to take part in 42 events and 10 different sports. Seventy-six years later, more than 100 nations sent 6,000 athletes to Munich to take part in almost 200 events in more than 20 different sports. In 1976 at Montreal, the number of participants was about the same as at Munich despite the last minute withdrawal of 22 countries involving nearly 450 athletes.

The revival of the Olympic Games led to the formation of many international bodies controlling their own amateur sports and to the creation of National Olympic Committees throughout the world. By the 1960s and '70s, through the media—the press, radio, and especially television—the quadrennial Games were brought into millions of homes.

History

CLASSICAL GAMES

Greece. *The Olympic Games.* Of all the games held throughout Greece, those staged at Olympia in honour of Zeus are the most famous. Held every four years between August 6 and September 19, they occupied such an important place in Greek life that time was measured by the interval between them—an "Olympiad." Although the first Olympic champion listed in the records was one Coroebus of Elis, a cook, who won the sprint race in 776 BC, it is generally accepted that the Games were probably at least 500 years old at that time. According to one legend they were founded by Heracles, son of Alcmene. The Games, like all Greek games, were an intrinsic part of a religious festival. They were held at Olympia in the city-state of Elis, on a track about 30 yards (27 metres) wide and one stade (about 600 feet [183 metres]) long. Later, the word *stadion* was sometimes employed to describe the *dromos* (a race one length of the track) and also the arena itself.

The first Olympic champion

At the meeting in 776 BC, there was apparently only one event, the *dromos*; but other events were added over the ensuing decades. In 724 BC a two-length race, the *diaulos*, roughly similar to the modern 400-metre race, was included, and four years later the *dolichos*, a long-distance race possibly to be compared to the modern 1,500- or even 5,000-metre event, was added. Wrestling and the pentathlon were introduced in 708 BC. The latter was an all-round competition consisting of five events—the long jump, javelin throw, discus throw, foot race, and wrestling.

Boxing was introduced in 688 BC, and in 680 a chariot race. In 648 the pancratium (Greek, *pankration*), a kind of all-strength, or no-holds-barred, wrestling, was included. Kicking and hitting were allowed; only biting and gouging (thrusting a finger or thumb into an opponent's eye) were forbidden. Between 632 and 616 BC events for boys were introduced. From time to time further events were added, including contests for fully armed soldiers, for heralds, and for trumpeters. The program must have been as varied as that of the modern Olympics, although the athletics (track and field) events were limited; there was no high jumping in any form and no individual field event, except in the pentathlon.

Until the 77th Olympiad (472 BC) all of the contests took place on one day; later they were spread over four days, with a fifth devoted to the closing-ceremony presentation of prizes and a banquet for the champions. Women were not allowed as competitors or, except for the priestess of Demeter, as spectators.

The Olympic Games were originally restricted to "freeborn" Greeks. The competitors, including those who came from the Greek colonies, were "amateur" in the sense that the only prize was a wreath or garland. The athletes underwent a most rigorous period of supervised training, however, and eventually the contestants were true professionals. Not only were there substantial prizes in kind or in money but the Olympic champion was handsomely rewarded for his prowess and received adu-

Early professionalism

lation and unlimited benefits from his city. Athletes became full-time specialist performers. An ominous parallel in the course of the modern Olympic Games has been suggested.

Pythian Games. From earliest times there had been a religious festival at Delphi in connection with the oracle of Apollo. Originally the games associated with the festival were held every eight years, but in 582 BC a four-year cycle was introduced, in the third year of an Olympiad. In addition to sporting events and contests, there were competitions in singing, the playing of musical instruments, and recitation. The prize was a crown of laurel leaves.

Nemean Games. According to one legend, these games were founded by Adrastus of Argos when he led the Seven against Thebes; another founder is said to have been Heracles, after the slaying of the Nemean lion. The games, conducted on similar lines to the Olympics, were in honour of Zeus. They took place every two years, in the second and fourth years of an Olympiad. The prizes were crowns of wild celery.

Isthmian Games. These athletic and musical competitions were held in Corinth in honour of Poseidon. They took place every two years, in the same years as the Olympic and Nemean Games.

Other games. Similar games were held in cities not only in Greece proper, but in Macedonia, Egypt, Syria, Arabia, Italy, and many other areas. While there was variation in the types of events included, the pattern was much the same, and the semi-religious character of the games was retained. The games for the most part took place on fixed dates at a sanctuary and were integrated with religious ceremonies. Every Greek city of any size held what might be described as local games, while larger ventures were the combined effort of several cities or states. Participation soon became a career, and outstanding young athletes were sponsored by the city in which they lived in the hope that one day they would bring it glory by their victories.

Local games

Rome. Greece lost its independence to Rome in the middle of the 2nd century BC, and the support for the competitions at Olympia and other places fell off considerably in the next century. The Romans looked on athletics with contempt—to strip naked and to contend in public was degrading in the eyes of the Roman citizen. The Romans realized the value of the Greek festivals, however, and Augustus, who had a genuine love for athletics, staged athletic games in a temporary wooden stadium erected near the Circus Maximus. Nero was also a keen patron of the festivals in Greece. By the 4th century AD, Rome, with its population of more than 1,000,000, had well over 150 holidays for games. There was chariot racing in the hippodrome and horse racing in the Circus Maximus, with room for more than 250,000 spectators. In an amphitheatre with accommodation for 50,000, animals and human beings were maimed and slaughtered.

Indeed, public games were held in abundance—games in honour of the gods, some of which were said to go back to the foundation of the city. But through all this, athletic events occupied a secondary position. The only ones that really interested the Romans were the fighting events—wrestling, boxing, and the pancratium. The main difference between the Greek and Roman attitude was that the Roman festivals were described as *ludi* (games), the Greek as *agōnes* (contests). The Greeks originally organized their games for the competitors, the Romans for the public. One was primarily competition, the other entertainment; and it is not unreasonable to suggest that the Greeks took an "amateur" view of sport, the Romans a professional.

GAMES FROM THE 5TH TO THE 19TH CENTURY

From the fall of Rome in the 5th century to the 19th century, the history of sport is but thinly documented. Organized games and contests as religious observances and events sponsored by the state seem to have disappeared, and athletic contests and sports generally to have declined. All that the records show is that in the Middle Ages, religious festivals were often the scene of primitive games between towns and guilds. On holy days, there were national holidays, and assuredly sporting matches and contests took place on these occasions. Games of all kinds were practiced in England and practiced extensively, as the various proclamations and laws forbidding sports and the playing of games testify. In the reign of Elizabeth I, for example, a statute of Oxford University forbade the playing of football by any scholar over the age of 16 on penalty of a fine and imprisonment, and expulsion for a third offense.

Class distinction was much in evidence. The aristocracy engaged in tournaments and jousts and in hunting. Royalty played court, or royal, tennis, as the English diarist Samuel Pepys testifies:

> *Thence to the Tennis Court and there saw the King* play at tennis and others. To see how the King's play was extolled without any cause at all was a loathesome sight, though sometimes he did play right well and deserved to be commended; but such open flattery is beastly.

Pepys mentions in an entry for May 1663:

> . . . great thronging upon Banstead Downs upon a great horse race and foot race. The foot race was between Lee, the Duke of Richmond's footman and a tyler, a famous runner. And Lee hath beat him, though the King and Duke of York and almost all men did bet 3 to 4 to 1 upon this tyler's head.

The common people played football, while prizefights, bearbaiting, and cockfighting drew large crowds. Competitions between pedestrians (called "peds," that is to say, professional runners) were frequent, as were contests against the clock. At the beginning of the 19th century Captain Barclay (Robert Barclay Allardice), a famous English pedestrian, walked 1,000 miles in 1,000 consecutive hours before thousands of spectators on Newmarket Heath. There must have been hundreds of local sports meetings with competitions for men, women, and youths of both sexes. But real championships were a product of the late 19th century, and then mainly in England and the United States.

Pedestrianism

The real growth of organizations concerned with the national control of sport came in Great Britain in the latter half of the 19th century with, for example, the formation of governing bodies for association football in 1863, rugby football in 1871, athletics in 1880, boxing in 1884, and lawn tennis in 1888. The Amateur Athletic Union of the United States, the biggest national governing body in the world, was founded in 1888.

For the most part, these governing bodies were formed to control amateur sport at a time when amateur performers competed primarily for the love of competition. But the improvement in the standard of amateur performers inevitably led to public popularity, the building of stadiums to accommodate paying crowds, and the subsequent great inducements to become professional.

MODERN GAMES AND CONTESTS

It is to amateur sport that credit for the initiation of international competition is due, for while from time to time individual professional performers from one country pitted their skill against individuals from another, such encounters were rare. One can instance the boxing match in 1860 between Tom Sayers from England and John Heenan of the United States, which went to 42 rounds before the police intervened; and the sensational performances of an American Indian, who called himself Deerfoot, on the track in England in the same year. But it was the formation of the various amateur clubs in different sports from 1860 onward that led to the creation of organized international competitions. A cricket team from England visited Canada and the United States in 1859 and Australia two years later. The first Test match (*i.e.*, between representative national teams) against Australia took place in March 1877. Yale University sent a track team to meet Oxford in London in 1894, followed in 1895 by a match in New York City between the oldest American athletic club, the New York AC, and the oldest British club, the London AC. The Americans won every event.

Beginnings of international competitions

The revival of the Olympic Games in 1896 gave the real impetus to international competition and led in time to

the formation of the many national and international governing bodies.

Revival of the Olympics. The architect of the modern Olympics was Pierre de Coubertin, born in Paris on New Year's Day, 1863. As a young man he was intensely interested in literature and in education and sociology. Family tradition pointed to an army career or possibly politics, but at the age of 24 de Coubertin decided that his future lay in education. At the same time he had the idea of reviving the Olympic Games, and in 1892 he propounded his desire for a new era in international sport when on November 25th, at a meeting of the Union des Sports Athlétiques in Paris, he said:

> Let us export our oarsmen, our runners, our fencers into other lands. This is the true Free Trade of the future; and the day it is introduced into Europe the cause of Peace will have received a new and strong ally. It inspires me to touch upon another step I now propose and in it I shall ask that the help you have given me hitherto you will extend again, so that together we may attempt to realise, upon a basis suitable to the conditions of our modern life, the splendid and beneficent task of reviving the Olympic Games.

The speech did not produce any appreciable activity, but de Coubertin was not fainthearted. At a conference on international sport in Paris in June 1894 at which de Coubertin raised the possibility of the revival of the Olympic Games, there were 79 delegates representing 49 organizations from nine countries. De Coubertin himself wrote that except for his co-workers Dimítrios Vikélas of Greece, who was to be the first president of the International Olympic Committee, and Professor William M. Sloane of the U.S. from the College of New Jersey (later Princeton University), nobody had real interest in the revival of the Games. Nevertheless, and to quote de Coubertin again, "a unanimous vote in favour of revival was rendered at the end of the Congress chiefly to please me."

It was at first agreed that the Games should be held in Paris in 1900. Six years seemed a long time to wait, however, and it was decided to change the venue—what better site than Athens, the capital of Greece—and the date, to April 1896.

First games of the modern cycle

A great deal of indifference, if not opposition, had to be overcome, including a refusal by Athens to stage the Games at all. But de Coubertin and his newly elected International Olympic Committee of 14 members won through, and the Games were opened by the king of Greece in the first week of April 1896.

Regional games related to the Olympics. The International Olympic Committee (IOC) grants its patronage to certain regional games that contribute to the development of amateur sports in the areas in which they are organized; that are conducted in a dignified manner and without commercial exploitation; and that follow the policies, rules, and regulations of the IOC and the international sports federations concerned.

Three of the regional games that have received Olympic patronage were first held in 1951: the Pan-American Games, the Mediterranean Games, and the Asian Games. The Central American and Caribbean Games were first held in 1926 and the Bolivarian Games in 1938. The Far East Games, encompassing China, Japan, and the Philippines, were first held in 1913 and last held in 1930.

From time to time, often at somewhat irregular intervals, a number of area games have been staged, of which the following may be mentioned: Pan-African, Pan-Arabian, Pan-Asian, Southeast Asian Peninsular, South Pacific, Pacific Conference, Balkan, International Youth, and World Student games.

Other regional games. *Commonwealth Games.* In 1928 plans were set up for what were to be known as British Empire Games. The first meeting was held in Hamilton, Canada, in 1930, and 11 countries took part with a total of 400 competitors. The sports included lawn bowling, or bowls, in addition to the more typical events in boxing, rowing, swimming and diving, track and field, and wrestling. The 1954 games, in Vancouver, were renamed the British Empire and Commonwealth Games; in 1970 the title was changed to British Commonwealth Games, and later the word British was omitted.

Highland and Hibernian games. The Braemar Gathering, the most famous of all Highland Games, dates from the 8th century AD. About 1100, according to tradition, King Malcolm of Scotland built a hunting lodge in the highlands, at Braemar in Aberdeenshire. One day he required a courier to take some dispatches to Edinburgh. In order to obtain a suitable runner for the royal task, a gathering of local inhabitants organized a race to the top of a hill a few minutes away through scrub and heather, for a prize of a sword, a belt, and a purse of gold. The race is said to have been the first of the traditional highland hill races. By the end of the 14th century the area had been depopulated by the Black Death, and the modern games date from the 19th century, when they were revived to raise money for the relatives of men killed at the Battle of Waterloo (1815). Regular gatherings have been held since.

Events staged at most Highland Games—and there are as many as 40 such gatherings in Scotland annually—are putting the stone, throwing the hammer, tossing the caber, and the pole vault, the high jump and broad jump, wrestling, and hill races. The caber is a pole, usually from 16 to 19 feet (5 to 6 metres) long and weighing 90 to 120 pounds (40 to 54 kilograms). Distance is of no significance; the object is to carry and toss the caber so that the end of the pole in the hands of the thrower passes through an angle of 180 degrees and lands away from the thrower. "Highland" Games have not been confined to Scotland. They have been held in many parts of the world including North Carolina and Nova Scotia.

Caber tossing and wheel throwing

Hibernian Games, held originally in Ireland, are of great antiquity. The Tailtean Games at Tara, in memory of Queen Tailte, were first held in the 19th century BC and continued for many centuries until sometime in the Middle Ages. The Hibernian weight-throwing event was the *roth cleas*, or wheel feat. Legend tells of the Celtic hero Cú Chulainn, who gripped a chariot wheel by its axle, whirled it around his head, and threw it farther than could any other mortal. Wheels were later replaced by boulders attached to wooden handles; modern versions are weight throwing and hammer throwing.

Maccabiah Games. This international Jewish festival held under the auspices of the Maccabi World Union was first staged in Czechoslovakia in 1929. Meetings were held in Belgium (1930) and thereafter in Israel.

International and national contests. The revival of the Olympic Games gave an impetus to sport that gradually spread throughout the world, so that the number of encounters between countries in different sports must be many hundreds annually. It is not only the world championships in many sports, both amateur and professional, but far more the interchange of club and national teams. The tremendous growth in air travel has made such contacts possible. In track and field most countries have a number of international matches every year; and from time to time contests are set up between the United States and Europe, and the United States against the British Commonwealth. In 1977 the first World Cup of the International Amateur Athletic Federation was held in Düsseldorf, West Germany, with competitors representing African, North American, South American, Oceanian, Asian, and European countries. The tendency toward many competitions is making it increasingly difficult for a top-class performer to remain an amateur, even with the gradual loosening of the strict and now absolutely unenforceable rules. The greatest difficulty is the ever-increasing number of competitions coupled with the public demand for the best performers. This tends to make sport more of an entertainment than a recreation, and it is questionable that the demand for the superlative by the public, including the world television audience, can be combined with the traditional idea that sport is for the competitor.

The modern Olympics

ORGANIZATION

The International Olympic Committee. At the Congress of Paris in 1894, the control and development of the modern Olympic Games was entrusted to the Inter-

national Olympic Committee (IOC; Comité International Olympique), with headquarters at Mon-Repos, Lausanne, Switzerland. It is responsible for maintaining the regular celebration of the Olympic Games; seeing that the Games are carried out in the spirit that inspired their revival; and promoting the development of amateur sport throughout the world. The original committee in 1894 consisted of 14 members and de Coubertin.

Convinced that the downfall of the ancient Olympic Games had been caused by outside influences that undermined the spirit of the Games, de Coubertin felt that the revived Games would go the same way unless they were in the hands of people whose concern was to keep the spirit of amateur sport alive, and who were responsible in no way to any outside influences. Thus IOC members are regarded as ambassadors from the IOC to their national sports organizations. They are in no sense delegates *to* the committee and may not accept from the government of their country, or from any organization or individual, any instructions that in any way affect their independence.

Independence of International Committee members

The IOC is a permanent organization that elects its own members. Each member—the total is about 70—must speak French or English and be a citizen or reside in a country that has a National Olympic Committee. With a very few exceptions, there is only one member from any one country. Members were originally elected for life, but anyone elected after 1965 must retire at 72.

The IOC elects its president for a period of eight years, at the end of which he is eligible for re-election for further periods of up to four years each. Michael Morris, Lord Killanin (Ireland) was elected in 1972. Previous presidents were Dimítrios Vikélas (1894–96, Greece), Baron Pierre de Coubertin (1896–1925, France), Count Henri de Baillet-Latour (1925–42, Belgium), J. Sigfrid Edström (1946–52, Sweden), Avery Brundage (1952–72, U.S.).

The executive board of nine members holds periodic meetings with the international federations and National Olympic Committees. The IOC as a whole meets when summoned by the president, and he must convene a meeting if one-third of the members so request.

National Olympic Committees. Each country that desires to participate in the Olympic Games must have an Olympic committee accepted by the IOC. In the 1970s there were more than 120 such committees.

A National Olympic Committee is composed of at least five national sporting federations, each affiliated to an appropriate international federation. The ostensible purpose of these National Olympic Committees is the development and promotion of the Olympic movement and of amateur sport. National committees arrange to equip, transport, and house their country's representatives at the Olympic Games. According to the rules of the committee, they must be not-for-profit organizations; must not associate themselves with affairs of a political or commercial nature; and must be completely independent and autonomous and in a position to resist all political, religious, or commercial pressure.

A person who has ever competed in sports as a professional, who has ever coached sports competitors for payment, or who is engaged in or connected with sport for personal profit is not eligible to serve on a national committee. The rules provide that

> exceptions to these categories may be made by the Executive Board of the I.O.C. on the recommendation of the National Olympic Committee concerned.

National Olympic Committees that do not conform to IOC rules and regulations forfeit their recognition and their right to send participants to the Olympic Games.

IOC awards. In individual Olympic Games events, the award for first place is a gold (silver-gilt, with six grams of fine gold) medal, for second place a silver medal, and for third place a bronze medal. Solid gold medals were last given in 1912. Diplomas are awarded for fourth, fifth, and sixth places. All competitors and officials receive a commemorative medal.

Since 1974 there have been two noncompetitive awards, the Olympic Cup and the Olympic Order. The former was instituted by Baron de Coubertin in 1906. It is awarded to an association or institution that has a general reputation for merit and integrity, that has been active in the service of amateur sport, and that has made a substantial contribution to the development of the Olympic movement. The first recipient of the Olympic Cup was the Touring Club de France. It was awarded to the town of Innsbruck, Austria, for its organization of the XII Winter Games of 1976.

The Olympic Order, created in 1974, is intended for living persons, excluding active members of the IOC. There are three degrees of award—gold, silver, and bronze—to be made "to any person who has illustrated the Olympic ideal through his action, has achieved remarkable merit in the sporting world, or has rendered outstanding services to the Olympic cause, either through his own personal achievement or his contribution to the development of sport." The gold medal was awarded posthumously to Avery Brundage, for 20 years president of the IOC. Ten silver and 13 bronze awards have been made, including silver medals to Jesse Owens, winner of four gold medals at the 1936 Olympics, and to Dan Ferris, for more than 50 years a prominent administrator in United States and world track and field.

Olympic Order

Five previous awards were suspended in 1974: the Olympic Diploma of Merit, first awarded in 1905; the Sir Thomas Fearnley Cup and the Mohammed Taher Trophy, first awarded in 1951; the Count Alberto Bonacossa Trophy, established in 1955; and the Tokyo Trophy, first awarded in 1967.

The Games and participants. The Olympic Games (Summer) are held every four years. There is no age limit for competitors, and in theory no discrimination is allowed against any country or person on grounds of race, religion, or political affiliation. The Games are contests between individuals and not between countries. Separate Winter Games have been held since 1924.

The Olympic Games celebrate an Olympiad, or period of four successive years. The first Olympiad of modern times was celebrated in 1896, and subsequent Olympiads are numbered consecutively, even though no Games take place (as was the case in 1916, 1940, and 1944).

The period of the Summer Games must not exceed 15 days; the Winter Games are limited to 10 days.

The maximum number of entries permitted for individual events is three per nation. The number is fixed (but can be varied) by the IOC in consultation with the international federation concerned. In team events, only one team per country is allowed. In general, a National Olympic Committee may only enter a citizen of the country concerned.

Problems of amateurism. To be eligible to compete, a competitor must be an amateur as defined by the international body of the particular sport and also by the rules of the IOC.

The IOC rules were substantially changed in 1976 and now provide that a competitor must not have received any financial reward or material benefit in connection with his or her sports participation except as permitted by the IOC bylaws. These bylaws permit the athlete to receive personal sports equipment and clothing, travelling and hotel expenses, and compensation (authorized by a National Olympic Committee or a National Federation). Compensation may be given in case of necessity to cover financial loss resulting from absence from work or basic occupation because of preparation for, or participation in, the Olympic Games and international sports competitions.

IOC rule changes

This wide concession for payment, known as "broken time," in effect authorizes a competitor (subject, of course, to the rules of each individual International Federation, or of any national controlling body) to devote as much time as he or she wishes to training and competitions and to be recompensed to the full for any loss of earnings. The only limitation is that "in no circumstances shall payment made exceed the sum which the competitor would have earned in the same period." In the extreme, therefore, a competitor may abandon his or her normal occupation and be in fact, if not in name, a professional.

For decades, it had been generally agreed that many of the rules of amateurism were more honoured in the breach than in the observance. Originally these rules were laid down in England more than a century ago by the leisured and, in many cases, financially independent class of society. Numerous followers of amateur sport have felt that since the Olympic Games take place only once in four years, the rules governing general participation in amateur sport should be left entirely to the individual international bodies, and that the IOC should abandon any attempt to produce a series of rules applying to more than a score of different sports. The extensive changes made by the IOC in 1976 materially altered the whole position, and indicated that yet one more step had been taken toward making the Olympic Games open to all comers.

It now appears to many of those who have been closely associated with the Games that they have become too vast, too nationalistic, too expensive, and too commercial. It is felt that no longer is the important thing "to take part," but that winning a gold medal is the only thing that matters. The primary consideration appears no longer to be the competitors, more than 95 percent of whom cannot win gold medals, but the public. Entertainment now seems to supersede the enjoyment of competition, and the demand for entertainment may well be the death of amateur sport.

The Olympic sports

Programs and events. An official Olympic program must include at least 15 of the following sports: archery, athletics, basketball, boxing, canoeing, cycling, diving, equestrian sports, fencing, football, gymnastics, handball (team handball), hockey, judo, modern pentathlon, rowing, shooting, swimming, volleyball, water polo, weight lifting, wrestling, and yachting. Women can participate in the following sports: archery, athletics, basketball, canoeing, diving, equestrian sports, fencing, gymnastics, handball (team handball), hockey, luge, rowing, shooting, figure and speed skating, skiing, swimming, volleyball, and yachting. An Olympic program may also include two demonstration sports and in addition must include exhibitions and demonstrations of fine arts (architecture, literature, music, painting, sculpture, photography, and sports philately).

The particular events included in the different sports are a matter for agreement between the IOC and the international federation. For many years there were 24 events for men in track and field. In 1976, however, the men's 50,000-metre walk was excluded (on the claim that the total number of competitors in the Games must be reduced), while women's rowing events were included for the first time. It appears that although the IOC feels that in some way there must be a halt to the total number of competitors, it has not faced the fact that the only way to produce substantial reductions must be to exclude some sports. The suggestion that all team events be omitted is the kind of action that should be seriously contemplated.

The Olympic Village. The Olympic Village was first introduced at Los Angeles in 1932. The organizing committee provides the village so that competitors and team officials can be housed together and fed at a reasonable price. The villages are located as close as possible to the main stadium and other facilities, and have separate accommodations for men and women. Only competitors and officials may live in the village, and the number of team officials is strictly limited; *e.g.*, a team of 250 competitors is allowed 45 officials.

Ceremonies. *The Olympic flag.* In the stadium and its immediate surroundings, the Olympic flag is flown freely together with the flags of the nations taking part. The Olympic flag presented by Baron de Coubertin in 1914 is the prototype: it has a white background and in the centre there are five interlaced rings—blue, yellow, black, green, and red. The blue ring is on the left next to the pole. These rings represent the five continents joined together in the Olympic Movement. The Olympic motto is *Citius—Altius—Fortius* ("Faster—Higher—Stronger").

The opening ceremony. The form of the opening ceremony is laid down by the IOC in great detail, from the moment when the chief of state of the host country is received by the president of the IOC and the organizing committee at the entrance to the stadium, to the end of the proceedings when the last team files out. The rules provide that participants are not permitted to carry cameras into the arena, but this provision is always ignored.

When the head of state has reached his place in the tribune, he is greeted with the national anthem of his country, and the parade of competitors begins. The Greek team is always the first to enter the stadium, and the nations follow in alphabetical order as determined by the language of the organizing country. Each contingent, dressed in its official uniform, is preceded by a shield with the name of its country, while an athlete carries its national flag. The competitors march around the stadium and then form up in the centre of the ground facing the tribune.

The president of the organizing committee then delivers a brief speech of welcome (not more than two minutes), followed by a speech of not more than three minutes from the president of the IOC, who asks the chief of state to proclaim the Games open.

A fanfare of trumpets is sounded as the Olympic flag is raised slowly; pigeons are released, symbolically to fly to the countries of the world with the news that the Games are open.

The Olympic flame

The Olympic flame is then carried into the stadium by the last of the runners who have brought it from Olympia, Greece. The runner circles the track, mounts the steps, and lights the Olympic fire that burns night and day during the Games. In 1968 a woman carried the flame into the stadium, and in 1976 the flame was jointly borne by a male and a female athlete.

Victory ceremony. Medals are presented during the Games at the various venues and as soon as possible after the conclusion of the event. The competitors who have occupied the first three places proceed to the rostrum, with the winner (gold medalist) in the centre, the silver medalist on his or her right, and the bronze medalist on the left. The medals attached to a chain or ribbon are hung round the necks of the winners by a member of the IOC, and the flags of the nations concerned are raised to the top of the flagpoles while an abbreviated form of the national anthem of the winner is played. The spectators are expected to stand and face the flags, as do the three successful athletes.

Closing ceremony. The closing ceremony takes place after the final event, which is usually the equestrian Prix des Nations. Since the Melbourne Olympics in 1956, the closing ceremony has been a less formal affair, and after certain formalities have been observed, the athletes taking part stage their own demonstrations.

The ceremonies include a parade of six athletes from each nation, marching eight or ten abreast without distinction of nationality, and signifying the friendly bonds of Olympic sport. The president of the IOC calls the youth of the world to assemble in four years to celebrate the Games of the next Olympiad. A fanfare is sounded, the Olympic fire is extinguished, and to the strains of the Olympic anthem the Olympic flag is lowered and the Games are over.

The awarding of the Olympic Games. The honour of holding the Olympic Games is entrusted to a city and not to a country. The choice of the city lies solely with the IOC. Application to hold the Games is made by the chief authority of the city, with the support of the national government.

Applications must state that no political meetings or demonstrations will be held in the stadium or other sports grounds or in the Olympic Village, and it must be promised that every competitor shall be given free entry without any discrimination on grounds of religion, colour, or political affiliation. This involves the assurance that the national government will not refuse visas to any of the competitors. At the Montreal Olympics in 1976, however, the Canadian government refused visas to the representatives of Taiwan because they were unwilling to forgo the title of the Republic of China, under which their National Olympic Committee was admitted to the IOC.

This Canadian decision, in the opinion of the IOC, did great damage to the Olympic Games, and it was later resolved that any country in which the Games are organized must undertake strictly to observe the rules. Enforcement will be difficult unless, for example, the IOC should decide that the Games would not be held, even at the last minute, unless the rules were obeyed.

DEVELOPMENT OF THE GAMES

Since the revival of the Games, their growth in the number of competitions, of competitors, and of participating countries has been almost continuous. The history of the modern Games may be conveniently divided into three periods: (1) from the revival in 1896 to the outbreak of World War I, (2) the period between the two World Wars, and (3) the post-World War II period.

First period: 1896–1912. Of the five celebrations in the first period, the first three, Athens in 1896, Paris in 1900, and St. Louis, U.S., in 1904 were somewhat haphazard affairs. The entries were unlimited and hardly ever "national" in the sense of representing each nation's best performers. The actual events included varied considerably, and it is not possible to determine with any degree of confidence which of the events were really of Olympic significance. Women competed at golf and lawn tennis in the Paris Games and at archery in the St. Louis Games.

London, 1908

The Games of 1908 in London were the first to be organized by the various sporting bodies concerned, and were not regarded as an appendage to a world fair and controlled by the promoters. Though the holding of a Franco-British Exhibition at Shepherd's Bush, London, made possible the construction of a new stadium—the famous White City, with a crowd capacity of 66,000—the governing bodies of sport were in control. Twenty-two nations sent more than 2,000 athletes (but only 36 women) to compete in over 100 events in 21 different sports. Archery and lawn tennis were included in the 1908 program.

At Stockholm in 1912, the number of nations increased to 28, the number of competitors passed the 2,500 mark, and for the first time three swimming events for women were included. Because of World War I, no Games were held in 1916.

Second period: 1920–36. In this period, too, there were five celebrations. In less than two years after the armistice in November 1918, Belgium organized the first post-World War I Olympics, opened at Antwerp by King Albert I. Twenty-nine nations, including many new ones, sent more than 2,000 competitors to take part in over 150 events in 20 sports. Women competitors were still a mere handful (about 60). Four years later in Paris, the number of countries increased to 44, with more than 3,000 competitors for 137 events, a decrease because of a reduction in the excessive number of shooting and yachting events. For the first time more than 100 women took part, appearing in fencing as well as swimming and lawn tennis. After 1924, intrusion of professionalism in lawn tennis caused the IOC to omit the sport from future Games.

Increase of women's events

In 1928 in Amsterdam, women's track and field competitions (five events) and one event for women in gymnastics were introduced. Again there were 3,000, from 46 countries, but the number of women (290) was double that at Paris (136). Four years later the Games for the second time crossed the Atlantic, to Los Angeles, and there was a great falling off in the number of competitors —under 1,500 from 37 countries. The long journey from Europe, in those days 3,000 miles by sea and then the same distance by land, and the heavy cost were responsible for the large decreases. In 1932 the Olympic Village was first introduced. The return to Europe and to Germany produced 4,000 athletes at Berlin in 1936.

Recent games: 1948–1976. Because of World War II, no Games were held in 1940 or 1944. London was given the task of organizing the first postwar Games in 1948 with a bare three years available. This was accomplished despite extremely difficult postwar conditions, with rationing of building and other materials and supplies still in effect and a strict limitation on expenditure. The number of competing countries was 59, with 4,700 competitors of whom 385 were women. Track and field events for women were increased to nine by the addition of the 200-metre run, the broad (now long) jump, and shot put.

Finland, which had hoped to organize the 1940 Games, was host to the 1952 Games, at Helsinki. The number of countries participating rose to 69, competitors totalled within 100 of 5,000, and women topped the 500 mark.

In 1956 for the first time the venue was in the Southern Hemisphere. The Games in Melbourne were celebrated in November and December, and for the first time one of the sports had to take place in another country. Owing to quarantine regulations that prohibited the importation of horses to Australia, the equestrian events were decided in Stockholm. Again the distance from Europe reduced the competitors in Melbourne by 1,500.

In Rome four years later, however, the number of competitors passed the 5,000 mark, the number of nations rose to more than 80, and of events to 150. Originally Rome was to have staged the 1908 Games, so the city had waited over 50 years for the honour.

The Games were in Asia for the first time in 1964, at Tokyo, again in a city where the previous award (in 1940) had not been fulfilled. Once more there were record figures: 94 countries; 162 events; 5,500 competitors, 700 of them women.

There was considerable and mounting criticism when Mexico City was awarded the 1968 Games. Controversy surrounded charges that the altitude, more than 7,500 feet (2,300 metres), would adversely affect the majority of distance runners, who would not have been able to spend many months living in a comparably rare atmosphere. The number of competitors rose to more than 6,000 from 112 countries. Women numbered 800, the total events 172.

In Munich in 1972 there were nearly 200 different events, with 6,000 competitors from 124 countries. Tragedy struck the Games when Arab (Palestinian) terrorists invaded the Olympic Village and killed two and seized nine Israeli athletes as hostages for the release of 200 Arab prisoners in Israel; all nine, five of their captors, and a West German policeman were slain when police rescue attempts failed.

Montreal, 1976

In Montreal in 1976 the number of entries exceeded those of Munich, but the last minute withdrawals reduced the actual competitors by more than 400. The countries endeavoured to persuade the IOC not to permit competitors from New Zealand to take part because the New Zealand rugby team had played matches against South Africa. The IOC rejected the plea, and later decreed that "such occurrences cannot be tolerated in the future." The disqualification of weight-lifting competitors for use of anabolic steroids was another sad incident of the games. Two of the competitors were gold medallists, who were ordered to return their medals.

The Winter Olympic Games. While some skating events were included in the 1908 and 1920 Games, the Winter Games were accepted as a celebration comparable to the Summer Games and given the official blessing of the IOC in 1924. The first Winter Games were held at Chamonix, France, and consisted of 16 events. There were 16 participating countries, and the participants numbered less than 300. Subsequent Winter Games were held at St. Moritz, Switzerland (1928); Lake Placid, U.S. (1932); Garmisch-Partenkirchen, Germany (1936); St. Moritz (1948); Oslo (1952); Cortina d'Ampezzo, Italy (1956); Squaw Valley, U.S. (1960); Innsbruck, Austria (1964); Grenoble, France (1968); Sapporo, Japan (1972); and Innsbruck (1976). The 1980 Winter Games were to be held at Lake Placid.

So much dissension has arisen over the commercialism of the Winter Games that, from time to time, there has been talk of revising, or even discontinuing, them.

THE OLYMPIC RECORD

The accompanying tables of the Olympic record list the gold medal winners of each event in each of the games held since the revival of the Olympic idea in 1896. Unofficial, or demonstration, events are not included.

(H.M.A.)

Atlantic Ocean

The Atlantic Ocean is the name given to that vast stretch of world ocean that separates the continents of Europe and Africa from those of North and South America. The term, derived from Greek mythology, means the Sea of Atlas. It is second in size only to the Pacific Ocean (*q.v.*).

The Atlantic is, generally speaking, S-shaped and narrow in relation to its length. The area of the Atlantic without its dependent seas is 31,800,000 square miles (82,400,000 square kilometres), and with them, 41,100,000 square miles (106,400,000 square kilometres).

The ocean's drainage area

Although not the largest of the world's oceans, the Atlantic has by far the largest drainage area. The continents on both of its sides tend to slope toward it, so that it receives the waters of a large proportion of the great rivers of the world, including the St. Lawrence, the Mississippi, the Orinoco, the Amazon, the Río de La Plata, the Congo, the Niger, the Loire, the Rhine, the Elbe, and the great rivers of the Mediterranean and the Baltic. The total area of land draining to the Atlantic and the Arctic Sea is nearly 16,691,000 square miles (43,229,700 square kilometres), almost four times the area draining to the Pacific Ocean, and almost exactly four times the area draining to the Indian Ocean (*q.v.*).

In the north, between the island of Spitsbergen and Greenland, the waters of the Atlantic merge with those of the Arctic Ocean; in the southeast, between the southern tip of Africa and Antarctica they merge with those of the Indian Ocean; in the southwest, Drake Passage (*q.v.*) connects the South Atlantic and South Pacific oceans. The Atlantic and Pacific are also connected by the Panama Canal (*q.v.*) about 10° north of the Equator, as well as via the difficult and virtually unused Northwest Passage (*q.v.*), which runs through the Arctic Ocean to the north of North America.

A large proportion of the world's fishing grounds are located in the Atlantic. Vast mineral reserves have been located on the ocean floor as well as on the floor of the continental shelves on either side of the ocean. At the present time the greater part of the nonbiological resources being exploited consists of petroleum and gas. The North Atlantic is the most heavily travelled seaway in the world. (For associated articles, see CONTINENTAL DRIFT; CONTINENTAL SHELF AND SLOPE; OCEAN BASINS; OCEAN CURRENTS; OCEANIC RIDGES; OCEANS AND SEAS; OCEANS, DEVELOPMENT OF; for associated physical features, see BAFFIN BAY; BALTIC SEA; BARENTS SEA; BISCAY, BAY OF; BLACK SEA; CARIBBEAN SEA; DRAKE PASSAGE; ENGLISH CHANNEL; FUNDY, BAY OF; GUINEA, GULF OF; GULF STREAM; HUDSON BAY; IRISH SEA; MEDITERRANEAN SEA; MEXICO, GULF OF; NORTH SEA; NORTHWEST PASSAGE; SAINT LAWRENCE, GULF OF; SCOTIA SEA; WEDDELL SEA.)

PHYSIOGRAPHY

Extent. The Arctic Basin, which stretches from the Bering Strait across the North Pole to Spitsbergen and Greenland, connects with the Atlantic Ocean by way of the narrow, but deep, straits between Spitsbergen and Greenland. In the south, the Atlantic extends to the shores of the Antarctic continent. The Atlantic Ocean has, therefore, a share in both the seas of ice.

In contrast to the South Atlantic, the North Atlantic is rich in islands, in the variety of its coastline, and in tributary seas. The latter include the Caribbean Sea, the Gulf of Mexico, the Gulf of St. Lawrence, Hudson Bay, and Baffin Bay on the west, and the Mediterranean Sea, Black Sea, North Sea, and Baltic Sea on the east. Between Spitsbergen and Novaya Zemlya, on the one hand, and the Murmansk coast, on the other, lies the Barents Sea; between Greenland, Iceland, the Faeroes, Shetlands, Norway, and Spitsbergen lies the Norwegian–Greenland Sea. Hudson Strait in the northwest is 64 miles wide; Davis Strait to the north of it 200 miles; and Denmark Strait, between east Greenland and Iceland, 159 miles across. The passage between Iceland and northern Scotland is 518 miles wide.

Tributary seas

In the South Atlantic, on the other hand, between Cape Horn and South Africa, the ocean approaches Antarctica on a 3,965-mile front, and is much colder and rawer than the North Atlantic.

From east to west, the ocean's breadth varies considerably. From Newfoundland to Ireland it is 2,059 miles; further south it widens to over 3,000 miles, before narrowing again so that the distance from Cabo São Roque, Brazil, to Cape Palmas, Liberia, is only 1,769 miles. Southward, it again becomes broader and is bordered by simple coasts almost without islands.

Relief of the ocean floor. The foundations of knowledge of the Atlantic floor were laid in the last century when the practical needs of telegraphic engineers and the curiosity of natural scientists led to the first explorations of the abyss. Though soundings were taken by lead line or wire, real comprehension of sea floor topography was not possible until the development of continuously recording precision echo sounders after World War II. The detailed profiles produced by these instruments allowed a realistic appraisal of the ocean floor, which made the earlier probings seem vague and almost dream-like.

The Mid-Atlantic Ridge

The outstanding feature of the Atlantic floor is the Mid-Atlantic Ridge, an immense median mountain range extending throughout the length of the Atlantic, claiming the centre third of the ocean bed, and reaching 1,000 miles in breadth. This feature, though of tremendous proportions, is but the Atlantic portion of a world-encircling ridge, the Mid-Oceanic Ridge, which stretches 45,000 miles around the entire globe.

In some places the Mid-Atlantic Ridge reaches above sea level. The Azores, Ascension, St. Helena, Tristan da Cunha, Gough, and Bouvet—all volcanic islands—rise from its flank; Iceland, which rises from its crest, is rent by an extension of the median rift valley. East and west of the ridge, 12,000 to 18,000 feet below sea level, lie basins which seem on first inspection to present a rather even profile. Study reveals, however, that parts of the basin floor are as mountainous as the Mid-Atlantic Ridge, while other parts are extremely smooth. The former are rocky abyssal hills; the latter are the abyssal plains that form the upper surface of great ponds of mud which fill many of the broad depressions. Large ancient volcanoes are found singly or in rows in the basins; these rise to form seamounts and occasionally islands. As the continents are approached and the rugged Mid-Atlantic Ridge is left behind, the echo-sounding profile of a survey vessel will first reveal an abyssal plain and then the smooth, undulating surface of the continental rise.

These broad embankments, which lie at depths of 8,000 to 15,000 feet at the foot of continents, reach in widths of over 300 miles off Northwest Africa, Angola, Argentina, and the eastern seaboard of the United States. In other areas they are exceedingly narrow. The continental rise is in fact an immense refuse heap of sediments eroded from the continents through geologic time. Here, in all probability—within the 10,000- to 50,000-foot-thick accumulations—lie the largest potential reserves of petroleum on Earth.

The continental shelf

The continents have steep sides and bevelled edges; the continental slope is cut by canyons that funnel sediments from continental sources to the continental rise (consisting of debris, which has accumulated at the foot of the continental slope) below. The continental shelf is the wetted perimeter of the continent, which has only re-

cently been claimed by the sea. A few thousand years ago the ocean level was lower, and the shelf belonged to the continent; almost certainly, it will again, in the future. It is this nonoceanic part of the ocean with which man is most concerned, for here fish and minerals are exploited, and here shoals create hazards to mariners.

The Caribbean Islands and the South Sandwich Islands form great unstable island arcs, where the greatest depths of the Atlantic are found in steep-sided, narrow gashes that drop to over 30,000 feet below sea level, and over 10,000 feet below the floors of adjacent basins. Earthquakes occur continuously along the arcs as the deformation of the Earth's crust actively proceeds in these unstable belts.

The North Polar Basin and the intervening Norwegian Basin are separated from the open Atlantic by a shallow ridge extending from Greenland to Scotland upon which Iceland and the Faeroe Islands rise above sea level. The maximum depths in Denmark Strait, between Greenland and Iceland, and over the Wyville-Thompson Ridge, between the Faeroes and Scotland, are only about 1,600 feet. Lowering the sea level about 1,600 feet would expose a land bridge from North America to Europe and would completely isolate the waters of the Polar Basin from both the Atlantic and the Pacific. In the North Polar Basin relatively few soundings were made until a Russian expedition (1937–38), which landed by plane on the ice within 60 miles of the pole. After that time numerous soundings were made from the ice floes and ice islands throughout the basin. The basin, roughly elliptical, is divided into two parts by the Lomonosov Ridge, having a sill depth of 5,000 feet, which runs from the continental shelf north of Ellesmere Island through a position of 89° N 180° W, then south near the meridian of 140° E toward the New Siberian Islands. The depression on the right looking north from Ellesmere Island is smaller, but deeper—over 16,000 feet—whereas, depths in the larger basin to the left (toward Alaska) approach 13,000 feet. There are two lobes in the larger basin and some evidence of a second ridge roughly parallel to the Lomonosov Ridge. Between Greenland and Spitsbergen the sill depth is about 5,000 feet, and in the Norwegian Basin the greatest depth is about 12,000 feet.

Depths greater than 13,000 feet occur in the Caribbean Basin and in the Mediterranean Sea. The former has numerous shallow and several deep connections with the open ocean, but the Mediterrean communicates with the Atlantic only through the Strait of Gibraltar, which is about 12 miles wide and where the maximum depth on the sill is only 1,000 feet. The partial isolation of the large adjacent seas has a profound effect on the conditions in the seas and also upon those in the open ocean.

(B.C.H.)

Oceanic islands

Islands. Among purely oceanic islands without any foundation of continental rock, usually the result of volcanic action, there are Jan Mayen, Iceland, the Azores, Ascension, St. Helena, Tristan de Cunha, and Bouvet (latitude 54° 26′ S), which rise from the Mid-Atlantic Ridge, and the Canaries, Madeira, the Cape Verdes, and Fernando de Noronha (near Cabo São Roque), rising from the continental margins of Africa and South America. Volcanic islands of a different sort are those of the two great arcs, the Lesser Antilles and the South Sandwich. Partly continental and partly oceanic are the Greater Antilles in the Caribbean, and South Georgia and the South Orkneys in the Scotia Sea. Purely continental are Spitsbergen and the Bear Islands, the British Isles, Newfoundland, and the Falkland Islands.

Ice. The area of ice-covered ocean is an important variable feature of the Earth. Variations in ice extent influence, and are influenced by, large-scale circulation of atmosphere and ocean. Seasonal variations and longer term variations associated with global climatic trends are much larger in the Antarctic than in the Arctic. In the Northern Hemisphere, maximum sea ice extent occurs in April and is about 5 percent of the area of the hemisphere. The September minimum is about 25 percent less. In the Southern Hemisphere, the maximum in October, is about 8 percent of the area, while the March minimum is about 75 percent less. Typical Antarctic pack ice is under one year old and three to seven feet thick, while typical Arctic pack ice is several years old and ten to 13 feet thick, melting about three feet at the surface during summer and growing about three feet at the bottom during winter.

Pack ice is in constant motion, mainly under the influence of wind, with open leads and fracture patterns giving the appearance of a giant jigsaw puzzle. Most of the pack ice leaves the Arctic Ocean east of Greenland where the southerly drift reaches 20 miles per day. Roughly 720 cubic miles (3,000 cubic kilometres) of ice enter the Greenland Sea yearly, where most of it melts before reaching the latitude of Iceland. Large variations in ice extent are associated with global climatic trends. Following a long warming trend, there was an advance of sea ice in the 1960s, comparable to that of the last century, which threatened the economy of Iceland. The causes of these changes are unknown.

Icebergs

Icebergs are another form of ice found especially in the North and South Atlantic. In the Northern Hemisphere, the main source of icebergs is the southwest coast of Greenland, between 69° and 73° N, where the six fastest moving glaciers on Earth release over 5,000 icebergs a year into Baffin Bay. Altogether, the Labrador Current every year carries 7,000 to 8,000 icebergs south. Most of these melt before reaching the Grand Bank, but about 400 drift south of Newfoundland and about 50 reach the southern tip of the Grand Bank.

The glacial flow from Antarctica is mostly in broad streams which form ice shelves hundreds of feet thick. Fragments from the outer edges form the tabular icebergs, sometimes over 60 miles long, found in the southern ocean. Tabular icebergs are formed in the Arctic only rarely, on a smaller scale, and only in a small region of Ellesmere Island and the Franz Josef Islands. In 1972 seven manned, drifting Arctic scientific stations were situated on such ice islands. (J.O.Fl.)

GEOLOGY

The Atlantic is the youngest of the oceans. Its origin and development are now accounted for by the theory of continental drift, according to which a vast "proto-continent," Pangaea, which once "floated" on the Earth's liquid mantle, broke up in the late Mesozoic Era about 150,000,000 years ago; the rifting caused the landmasses of the Western and Eastern hemispheres to separate, opening up the Atlantic Ocean Basin. As can be seen on the map, the continental coastlines of North America and Europe, and of South America and Africa almost seem to match. If the edges of the continental shelves are matched, the fit is almost perfect. Other geological and paleontological similarities on both sides of the Atlantic have been found to substantiate the theory of continental drift and, thus, to help explain the evolution of the Atlantic.

Perhaps the most conclusive evidence bearing out this theory of origin is to be found in the existence of the Mid-Atlantic Ridge. The ridge is, in effect, a long rift zone of mountains, volcanoes, and faulted plateaus. A high-heat flow, which is associated with the extrusion of magna due to sea-floor spreading, exists in the rift zone. The crustal material on either side of the Ridge is notably younger than that on the corresponding plateaus, indicating an uprising of material from the Earth's mantle onto the crest of the ridge. The newer rock is mainly composed of gabbro (a coarse-grained rock formed deep down under heat and pressure), basalt (a rock which originally poured out at the surface in molten form), and serpentine (a common rock-forming mineral). Consequent movement of the ocean floor and of the continents in opposite directions outward from the ridge is resulting in an increasing widening of the Atlantic Basin at an estimated rate of from less than half an inch to about four inches (one to ten centimetres) a year. A corresponding spreading is occurring at an even faster pace in the Pacific Ocean; in the Atlantic, however, the slower rate of spreading causes the flanks of the ridge to be built up steeply by accumulating lava. The physiography and ge-

Movement of the ocean floor

ology of the Mid-Atlantic Ridge are now the subject of much scientific study, as is the geologic study of the Atlantic as a whole. Such investigations were undertaken only comparatively recently, since the theories of continental drift and of sea-floor spreading were not generally accepted until the later 1960s. (I.M.P.)

BOTTOM DEPOSITS

The greater part of the bottom of the Atlantic between the Arctic and the Antarctic circles is covered with globigerina ooze (a calcareous deposit consisting mainly of the shells of dead one-celled animals). At depths greater than 16,400 feet the calcium carbonate content decreases, and the calcareous deposits give way to red clay. On submarine ridges the finer material is lacking, and the shells of pteropod gastropods (mollusks of the gastropod class comprising the snails) may be sufficiently abundant to characterize the deposits as pteropod ooze. Diatom ooze (formed from microscopic unicellular algae having cell walls consisting of or resembling silica) is the most widespread deposit in the high southern latitudes but, contrary to conditions in the Pacific, is not found in northern latitudes. The bottom itself is covered with mud (oozes, globigerina, etc.), 60 percent; sand, 25 percent; and rock, gravel, and shells, 15 percent. Airborne material is abundant off the west coast of Africa where dry offshore winds carry material from the desert regions. In high latitudes ice-rafted detritus, including rock fragment, sometimes showing the effect of glacial abrasion, is an important component. The calcium carbonate content of the sediments of the Atlantic is notably greater than that at comparable depths and latitudes in the Pacific.

Turbidity currents

After World War II thousands of sediment cores, some exceeding 66 feet in length, were collected in the North and South Atlantic by means of a piston coring tube. These cores revealed the importance of turbidity currents—that is, occasional catastrophic torrents of sediment-laden, hence denser, water flowing downslope under clear water—as carriers of great quantities of sediment to the greatest depths in the Atlantic. Since the last ice age, turbidity currents have been relatively infrequent, with the consequence that the characteristic deposits laid down by them are as a rule covered by a few inches of normal pelagic sediment. Study of the shells of planktonic foraminifera (microscopic, floating, unicellular organisms) in these cores shows that the climatic changes, ice ages, and interglacial ages of the last 2,000,000 years have been recorded in the sediments as alternations of species adapted to cold or to warm water. In the 1960s the Joint Oceanographic Institutions for Deep Earth Sampling deep-drilling project penetrated the entire thickness of sediment in the Atlantic. Apparently the oldest sediments in the Atlantic Basin accumulated during the Mesozoic Era (from 65,000,000 to 225,000,000 years ago). Dating of sediment layers by radioactive decay or by examination of the traces in rocks of reversals of the Earth's magnetic poles (which occur every few million years) shows that the rate of accumulation of pelagic sediment in the Atlantic is between two-fifths and four-fifths of an inch per 1,000 years. Locally, however, the rate is much faster because of deposition by turbidity currents. (D.B.E.)

CLIMATE

Weather over the North Atlantic is largely determined by large-scale wind currents and air masses emanating from North America. In winter the Prevailing Westerly Winds at levels of 10,000 to 40,000 feet over North America meander in such a way that a northward bulge (ridge) is generated by and over the Rockies and a southward bulge (trough) over the eastern half of the continent. This geographically forced flow pattern sets the stage for the frequent deployment of cold air masses from Canada and Alaska to the Atlantic seaboard. Large temperature contrasts are thereby frequently set up between the polar outbreaks and mild air from the Pacific or tropical air from the Gulf of Mexico or Gulf Stream. Along these zones of contrast, which are called fronts, wave cyclones (low pressure areas) are formed, and these develop into strong vortices as they move toward Newfoundland and Iceland. Their growth rate largely depends on the temperature contrast, so that winter storms usually become appreciably stronger than summer storms in terms of low pressure, wind, and severe weather.

Storm patterns

These cyclonic storms carry heat, moisture, and momentum northward from the tropics and thereby siphon off the excess heat constantly generated by solar heating in the tropics. They also contribute a large share of the energy required to maintain the Prevailing Westerlies of midlatitudes, which are found to be one-half as strong and about 10° further north over the North Atlantic in summer than in winter.

Since even in winter the temperatures of air masses along the eastern seaboard vary considerably from one week to another, the number of coastal storms, their growth rate, and even their paths may vary. Thus, despite the underlying fixed geography, the North Atlantic average pressure distribution, on which the prevailing winds depend, may show large differences from one January to another. In some winters, Iceland may be dominated by prevailing high pressure in contrast to the normally low pressure, and in this case storms leaving the North American coast are blocked and shunted into the Davis Strait and to the Azores. When this happens, warm maritime air masses that normally flow into Europe and account for its mild climate are replaced by cold air from the European Arctic and from Siberia.

Thus, it is not surprising that in winter tremendous amounts of heat are extracted from the western North Atlantic by overflowing cold air masses. Although the transfer of real (sensible) heat is large, the transfer of heat by evaporative losses into the cold, dry air is about three times larger. The oceanic heat losses are soon restored by the flow of warm water associated with the Gulf Stream and other currents. The net effect of the increase in heat and moisture off the east coast is to further stimulate the growth of cyclonic storms. In the United States, an observer looking eastward from a high point over Boston may frequently see banks of large cumulus clouds (clouds showing great vertical development in the form of heaps or piles of cloud) at sea as a manifestation of rapid offshore heating when a cold air mass flows out over the warmer seas.

In latitudes 15° N to 30° N the North Atlantic is characterized by prevailing high pressure with an attendant lack of intense storms and severe weather. These high-pressure areas are part of a globe-encircling belt in which air from the westerlies to the north and from the tropics to the south sinks about 900 feet a day, and is warmed by compression so that the weather is often sunny and rainless. South of this North Atlantic high-pressure zone the Northeast Trade Winds blow with characteristic steadiness.

Although low latitudes of the North Atlantic are usually storm free, there are notable exceptions during later summer and early fall, when wavy patterns in the east winds occur and occasionally develop into tropical storm vortices or hurricanes. The hurricanes grow by the liberation of vast amounts of heat released when vapour evaporated from the warm ocean is lifted and condensed to bands of heavy showers. Hurricanes may live more than a week, travelling as severe wind vortices steered by upper air currents. Thus they frequently move clockwise around the periphery of the North Atlantic high-pressure belt and into the Prevailing Westerlies, often ending up in the Icelandic area. They have, however, occasionally struck England, and even the Azores, in modified form with abnormal upper-air wind patterns.

Hurricanes

Over the South Atlantic the belt of Prevailing Westerlies extends from about 40° S almost to Antarctica, and the South Atlantic high-pressure area is centred around 30° S. This anticyclone (circulation of winds around a central region of high atmospheric pressure) leads to Southeast Trade Winds on its north side, since the rotation of wind around the high-pressure area is opposite to that in the Northern Hemisphere, due to the Coriolis force (the effect caused by the Earth's rotation). The Southeast Trades meet the Northeast Trades in the zone

roughly centring on the Equator called the doldrums or intertropical convergence. Here heavy showers result from ascending warm, moist air that is being continually replaced by moistened trade wind air.

As in the North Atlantic, the weather is usually settled and fine in the latitudes of the high pressure but is unsettled and stormy in the higher latitudes of the Westerlies. The great storminess of the Southern Hemisphere Westerlies largely derives from the temperature contrast set up by the cold Antarctic continent and the adjacent open sea, rather than the west–east contrast described in connection with the North Atlantic storms.

While many regional weather peculiarities may be found over the Atlantic, one of the most interesting, especially to the jet-age traveller, is the large amount and variety of cloud in the Westerlies. These clouds are continually being generated by the large cyclonic storm systems, by warm, moist air masses condensing while moving northward over colder water (in advance of storms), and by rapid vertical ascent (convection) produced by cold air streaming over warm water. Extensive fog banks may frequently be seen in summer off the Grand Bank, when heated air from the continent is forced to flow over the cold Labrador Current. (J.Na.)

HYDROGRAPHY

Surface currents. The surface currents of the Atlantic Ocean primarily correspond to the system of prevailing winds with such modifications as are imposed upon the movement of the water by land boundaries. Other factors that influence the currents are regional excesses of evaporation or precipitation, regional differences in cooling or heating, friction, and the Earth's rotation. In the North Atlantic the Trade Winds maintain a fairly steady current from east to west, partly by the direct action of the wind and partly by maintaining an accumulation of warm water on the northern side of the current. A great bulk of water carried by this current continues into the Caribbean Sea and through the Strait of Yucatán into the Gulf of Mexico from which it flows out as a warm and swift current through the Strait of Florida. This current, reinforced by water which has flowed on the eastern side of the Antilles, forms the Gulf Stream (*q.v.*) off the American east coast. The Gulf Stream follows the coast closely as far as Cape Hatteras; continues at some distance from the coast; and turns more and more toward the east, flowing due east to the south of the Grand Banks of Newfoundland in latitude 40° N. In its further course, the Gulf Stream loses its identity as a well-defined current. The warm surface waters turn to the right and form part of the big eddy circulating around the Sargasso Sea (an area of the North Atlantic between the West Indies and the Azores, characterized by relatively still waters and containing gulfweed [*sargassum*] and specialized marine animals). Somewhat colder water continues toward the European coast as the North Atlantic Current. One diffuse branch turns south, and another branch turns north and splits up still more. One part, the Irminger Current, turns northwest, washes the southeast coast of Iceland and continues past the southern cape of Greenland. The waters of this current become gradually mixed with cold low-salinity water from the Arctic Ocean, but the last traces of Gulf Stream water are still found in latitude 65° N off western Greenland. Another branch of the Gulf Stream system enters the Norwegian Sea to the north of Scotland. One small portion turns south into the North Sea, but the major part follows the coast of Norway to North Cape and continues to Spitsbergen, sending minor branches into the Barents Sea. North of Spitsbergen the current submerges below the less saline waters of the Arctic and continues as a subsurface current clear across the Arctic Ocean where traces of Gulf Stream water of temperature slightly above 32° F (0° C) are found to the north of the New Siberian Islands (north of Siberia, separating the Laptev and East Siberian seas).

The Gulf Stream

The surface layer of the Arctic Ocean, throughout the year, is at a temperature close to the freezing point (at 29° F, or −1.6° C) but is of relatively low density because the salinity has been reduced by runoff from the great Siberian rivers. This cold, low-salinity water flows out from the Arctic Ocean along the east coast of Greenland where it is gradually mixed with Atlantic water. It continues around the south cape of Greenland, Cape Farvel; flows north along the west coast of Greenland; turns around again; and, after addition of cold water from Baffin Bay, flows south as the cold Labrador Current. To the south of the Grand Bank of Newfoundland, where this cold water meets the warm waters of the Gulf Stream, it is deflected toward the east and mixes with the Atlantic water. In winter this mixed water, with a salinity of almost 35 parts per thousand, is cooled to a temperature of nearly 37° F (3° C), whereby it attains a density high enough to make it sink to the bottom and spread to the south. On an average for the whole year, 5,230,000 cubic yards of water sink every second (about 86 cubic miles per day). Similarly, bottom water is formed in winter to the north of Iceland, but this has a considerably lower temperature, about 30° F (−1° C). It fills the deep basin of the Norwegian Sea but is prevented from returning directly into the Atlantic Ocean by the submarine ridge which extends from Scotland to Iceland and from Iceland to Greenland; after some intermixing, the Norwegian Basin water eventually crosses the ridge to the Atlantic.

In the southeast part of the North Atlantic, surface water flows into the Mediterranean and high-salinity Mediterranean deep water flows out along the bottom of the strait and spreads over wide areas. Along the west coast of northwest Africa, the Canary Current flows to the southwest and continues across the southern part of the North Atlantic as part of the North Equatorial Current. Low temperatures prevail on the African coast.

The currents of the South Atlantic correspond in many respects to those of the North Atlantic. The Southeast Trade Winds maintain the South Equatorial Current that flows toward the west where it divides into two branches, one that continues to the Northern Hemisphere and enters the Caribbean together with water from the North Equatorial Current, and one which turns south as the Brazil Current, a weak counterpart of the Gulf Stream. Between the Equatorial currents, the Equatorial Countercurrent flows toward the east and is particularly well-developed off Ghana, where it is known as the Guinea Current. To the south of the high-pressure area of the South Atlantic the current flows to the east and turns toward the Equator when reaching the African coast. There the Benguela Current is more pronounced than its northern counterpart, the Canary Current, and is characterized by lower temperatures near the coast, caused by more intense upwelling. Further south the Antarctic Circumpolar Current enters the Atlantic Ocean through Drake Passage, sending one branch, the Falkland Current, a counterpart of the Labrador Current, along the east coast of Argentina. The major branch of the Antarctic Circumpolar Current continues to the east into the Indian Ocean, sending another branch to the south and feeding a large clockwise eddy in the Weddell Sea.

African coastal currents

Deepwater currents. The deep and bottom water of the North Atlantic, as already stated, consists of surface water sinking between Iceland and Greenland and in the Labrador Sea, from where it spreads to the south. At depths between 3,000 feet and 6,500 feet the water that flows out from the Mediterranean spreads and can be recognized by an intermediate salinity maximum. With increasing distance from the Mediterranean the salinity decreases because of mixing with other water masses, but traces of Mediterranean water are found as far south as latitude 40° S.

In the Antarctic, bottom water with a temperature of about 31° F (−0.6° C), and salinity of 34.65 parts per thousand, is formed by sinking of water from the continental shelf. The temperature of this water is so low that its density is higher than that of the North Atlantic deep water. This water flows toward the north and can be traced as bottom water to 40° N. Surface water sinks at the Antarctic Convergence in about latitude 50° S and spreads to the north as low-salinity water. This Antarctic

intermediate water also crosses the Equator and can be traced to about 20° N. Large amounts of the Antarctic bottom water and intermediate water mix with the North Atlantic deep water, return to the south, and rise toward the surface between 50° and 60° S latitude. In rising, the deep water brings quantities of plant nutrients, phosphates, and nitrates to the surface layers, and the oceanic circulation therefore accounts for the high productivity of the Antarctic waters.

The deep and bottom waters of the Atlantic are characterized by a high oxygen content because there exists a fairly rapid circulation. The waters have sunk from the surface where they became saturated with oxygen by contact with the air.

TEMPERATURE AND SALINITY

Temperature. The distribution of the sea-surface temperature is closely related to the character of the currents. The waters of the North Equatorial Currents spread to the north and to the south when reaching the east coasts of North and South America and, correspondingly, the region of high surface temperature is wide off the American east coasts but narrow off the African coast, where the Canary Current and the Benguela Current carry cold water toward the Equator. Therefore, in latitudes about 10° S to 30° S and 10° N to 30° N the sea surface is warmer off the eastern coast than off the western, but poleward of 30° this feature is reversed. This reversal is barely evident in the South Atlantic, where the Falkland Current carries cold water up to about latitude 30° S (in August to 25° S), but is conspicuous in the North Atlantic. There the Labrador Current brings cold water to latitude 40° N, whereas the extreme branches of the Gulf Stream system carry warm water along the coast of Norway where ports remain ice-free even in latitude 71° N. The contrast between the South and the North Atlantic is related to the surface currents, which in turn reflect the action of the prevailing winds and the effect of the shape of the coasts. Where the Falkland Current meets the Brazil Current, and where the Labrador Current meets the Gulf Stream, the surface temperature changes rapidly within a very short distance. The change is particularly striking when passing from the Gulf Stream to the Labrador Current where the phenomena is called "the cold wall."

The Labrador Current

In the Tropics the surface temperature is controlled by climatological factors to such an extent that it is nearly uniform, and differences related to currents do not appear. Such differences are very marked, however, at a depth of about 650 feet, where in latitude 6° to 7° N the temperature is 50° F (10° C), whereas it is 68° F (20° C) in latitude 20° N. The existence of the cold water at shallow depths to the north of the Equator should not be interpreted as showing that deep water rises to the surface. The temperature distribution is directly related to the existence of Equatorial currents—which flow toward the west, and within which the warm water must be to the right in the Northern Hemisphere and to the left in the Southern Hemisphere.

The distribution of temperature at greater depths has already been touched upon when discussing the deep water circulation. In the North Atlantic, the temperature decreases slowly toward the bottom from a value of about 41° F (5° C) at 3,000 ft. to about 36.5° F (2.5° C) at the bottom. In the South Atlantic, up to latitude 40° S, the temperature first decreases to a minimum between 3,000 feet and 4,000 feet, increases again and reaches a maximum of 36° to 39° F (2° to 4° C) at about 6,500 feet, indicating the flow of North Atlantic deep water, and then decreases to less than 34° F (1° C) at the bottom where Antarctic bottom water is encountered. To the south of 40° S low temperatures prevail throughout, and near Antarctica a large body of water has a temperature below 32° F (0° C).

Salinity. The surface waters of the North Atlantic Ocean have a higher salinity than those of any other ocean, reaching values exceeding 37 parts per thousand in latitudes 20° to 30° N. The salinity distribution is also related to the currents but is greatly influenced by evaporation and precipitation. It has been shown that for each ocean the average surface salinity can be taken as equal to a constant basic value plus a correction that is directly proportional to the difference between evaporation and precipitation. The basic salinity value differs from one ocean to another and is highest for the North Atlantic. It is 35.5 parts per thousand for the North Atlantic and 34.5 for the South Atlantic. This difference can be explained as the effect of the intense evaporation in the Mediterranean and the outflow from that sea of high-salinity water that maintains the salinity of the North Atlantic at a higher level than that characteristic of any other ocean. On an average for every latitude range, say 0° to 5° N, and so on, the deviations from the basic value are proportional to the difference between evaporation and precipitation. Near the Equator precipitation dominates, and surface salinities of about 35 parts per thousand are encountered; but in latitudes 20° to 25° N and about 20° S evaporation greatly exceeds precipitation, and over large areas the surface salinity is above 37 parts per thousand. Proceeding poleward precipitation again becomes greater than evaporation, and, correspondingly, the surface salinity decreases, in large areas to values below 34 parts per thousand. Superimposed upon these general features are the effects of currents, which again are more striking in the North Atlantic where Atlantic water of salinity exceeding 35 parts per thousand is carried as far north as Spitsbergen in latitude 78° N, and Arctic water of salinity below 34 parts per thousand is carried south to nearly 45° N off Newfoundland. North of 40° N the sea-surface isohalines (lines of equal salinity) run nearly in a north–south direction, whereas south of 45° S they run east–west. In adjacent seas the salinity depends also upon the runoff from rivers. In the Mediterranean and the Red Sea, where the runoff is small and evaporation is great, high salinities prevail; in the Black Sea and in the Baltic, where large rivers empty, the salinity is low. In the inner part of the Gulf of Bothnia between Sweden and Finland, the water is nearly fresh. The surface water of the Polar Sea has a salinity of 30 to 33 parts per thousand because of admixture of freshwater from the great Siberian rivers.

Evaporation and precipitation

(H.U.S./R.H.Fl./C.A.B.)

MARINE LIFE

The Atlantic is divided into five water layers or zones, each harbouring a unique type of marine life. From top to bottom these are: the littoral benthic, euphotic, mesopelagic, bathypelagic, and benthic zones.

The five ecological zones

The littoral (tidal) zone, which has a maximum depth of 200 feet, contains the near-shore varieties of animals such as the oysters, clams, mussels, and burrowing animals, as well as most types of attached seaweed. Sea moss, kelp (a large brown seaweed), fucus (an olive-brown seaweed) and brown algae are the most common.

The euphotic zone (lighted surface layers), which has a maximum depth of 600 feet, is the sunlit portion of open water which harbours the organisms that manufacture 90 percent of the life-sustaining nutrients in the sea. These organisms—zooplankton (microscopic sea animals) and phytoplankton (single-celled green sea plants)—are both part of a mass assemblage of floating organisms. The vast quantities of plankton are consumed by other sea dwellers, including herring, mackerel, tuna, sharks, and baleen whales.

Below this zone is the mesopelagic (literally mid-oceanic) realm at a depth of from 660 to 3,000 feet; it is the habitat of sperm whales and of giant squids, which feed upon the organic debris that sinks down from the euphotic zone.

The bathypelagic (deep ocean) zone, which occurs at a depth of from 3,000 to 13,200 feet is permanently dark; it is here that the phenomenon of bioluminescence is found. Bioluminescent animals are those which are able to produce their own light; almost two-thirds of the fish in this zone have this characteristic. These include the anglerfish, lanternfish, and viperfish. The most common explanation for the development of bioluminescence is its use as a lure to attract prey.

The bottom, or benthic zone, which occurs at an average depth of 12,000 feet contains animals of elementary structure, including the large attached invertebrates such as the crinoids (sea lilies) and glass sponges. Certain brachiopods (bottom-dwelling invertebrates), once thought to be extinct, exist here in large numbers. These three varieties of animals consume organic matter from the upper zones. Fish are uncommon, except for poor swimmers such as the grenadier fish (related to cod) and the tripod fish (an abyssal fish which awaits its prey resting on its fins and tail). The upwelling of cold waters returns nutrients to the littoral benthic and euphotic zones, sustaining the animal life there, and so completing the ocean's life cycle.

ECONOMIC RESOURCES

Biological resources. The Atlantic Ocean contains six of the world's 14 major fishing grounds. They are roughly situated in the northwest, northeast, west central, east central, southwest, and southeast Atlantic.

Principal fishing grounds

Regions of high fertility, supporting large quantities of marine life, lie along the Atlantic seaboard of the North and South American continents. The waters of the Grand Bank off Newfoundland are among the most populous fishing grounds in the world. Here, where the waters of the Gulf Stream and Labrador Current merge, herring and menhaden (a fish resembling a shad but with a more compressed body) thrive in great numbers. The northeast Atlantic and North Sea have long been traditional fishing grounds, but are in danger of being overfished. Since the 1950s, fishing has increased south of the Equator, with large quantities of tuna, hake, and herring being caught. The waters off the Florida Keys, especially Key West, abound in shrimp and sponges. The calm Sargasso Sea, bounded on the east by the Canary Current and on the west by the Gulf Stream, is the breeding ground of all the eels of both Europe and North America. Clams, lobsters, crabs, and octopus are other important biological resources.

Mineral resources. Ever since the British "Challenger" expedition conducted a pioneering oceanographic survey from 1872 to 1876, it has been known that the Atlantic Ocean contains large stores of manganese nodules. These nodules are distributed most abundantly in the red clay bottom deposits throughout 10 percent of the pelagic (oceanic) area. Their composition is roughly 24 percent manganese and 14 percent iron; the nodules are formed of concentric layers, anywhere from several microns (a micron is a millionth part of a metre) in size to large slabs.

Large diamond deposits have also been located off the coast of South West Africa; the diamonds were washed into the ocean millions of years ago. The diamondiferous sediments vary in thickness from six to 30 feet; the stones are almost all of gem quality, and few industrial diamonds are found among them. The richest area so far located is along the southwest African coastline between Hottentot's Bay and Oranjemund.

Petroleum, natural gas, and sulfur are found in the Gulf of Mexico and off the west central coast of Africa.

Petroleum and gas reserves

Petroleum and gas represent 90 percent of the Atlantic's available mineral resources; they occur in the sediments of the continental rise.

Smaller deposits of coal and tin are found in sediments off the British Isles. Salt occurs along most of the Atlantic seaboard, and 70 percent of the world's bromine is extracted from the ocean waters. The water of the ocean itself, in desalinated form, constitutes a potential, though still extremely expensive, resource.

Resource exploitation. Exploitation in the second half of the 20th century has produced a dangerous shortage of many species of fish in several of the traditional fishing grounds. The Atlantic at the present time yields 40 percent of the world's catch of fish. The situation is most serious in the North Atlantic, where several varieties of fish, including flounders, ocean perch, cod, hake, herring, and tuna, are being overfished. South of the Equator, the yield, except for tuna and pilchard, is not yet in danger. Tuna has been the most exploited species, and, as a result, yields are becoming more and more meagre not only in the Atlantic but also in other oceans.

No comparable problem, however, faces the mining industry. A single diamond dredge, for instance, sweeps up by suction $420,000 worth of diamonds off the coast of South West Africa every day, and the resources are just beginning to be tapped. There seems to be an almost unlimited reserve of manganese nodules, but they have as yet been little exploited because it is still far more expensive to reclaim them from the sea than to mine manganese on land. Petroleum and natural gas reserves are being exploited off the coast of southern United States in the Gulf of Mexico, and petroleum resources are also being tapped in European and African territorial waters.

HISTORY

Exploration. The story of the surface exploration of the Atlantic is well known. Centuries before the age of Columbus, the Vikings in their 11th-century wooden ships charted the waters around Greenland, Iceland, and northeastern North America. After the Portuguese discovery of Madeira and the Azores in the 15th century, and the transatlantic voyage of Christopher Columbus (*q.v.*) in 1492 to 1493, Europeans of many nationalities joined in the exploration of the lands bordering the Atlantic's western shores. Not much scientific attention, however, was paid to the Atlantic until 1842, when a pioneering oceanographic study of the Atlantic and the Pacific was made by Lieutenant Matthew Fontaine Maury of the United States Navy. Maury compiled charts on winds and currents, collected other data, and prepared an extensive treatise on the Gulf Stream, thus paving the way for the further studies of the Atlantic. A Scottish naturalist, Sir Wyville Thompson, discovered the Mid-Atlantic Ridge on the "Challenger" expedition already mentioned, using temperature variations as indicators that a vast barrier existed below the surface. His findings were substantiated by a German expedition of 1925–1927, which verified the presence of a distinct mountain range.

Exploration was not, however, conducted solely from the surface. As interest in oceanography increased, such deep-sea vehicles as Trieste I, a deep-sea bathyscaph built for Jacques Piccard, a member of a well-known Swiss family of scientists and explorers, were constructed, and used to obtain further information about the ocean's depths. Many different types of submarine have also been used to gather information.

New methods of underwater research

The "Glomar Challenger," a United States deep-sea drilling ship, has made extensive surveys of Atlantic and adjacent waters; in 1970 it discovered a vast oil field 12,000 feet below the Gulf of Mexico. Yet another technique is to establish an underwater habitat in order to study marine environments for an extended period. One such habitat, the United States Sealab, has housed four aquanauts for three weeks in waters off Bermuda, enabling them to study marine life in its natural environment.

Naval predominance. Following early Portuguese and other explorations, Spain became the dominant naval power in the Atlantic in the 16th century. Later, Spain's naval supremacy was challenged by French, British, and Dutch ships. In the 19th century, Britain established a naval supremacy that endured until the first half of the 20th century, during which United States seapower developed. At the present time both the United States and the Soviet Union have powerful naval forces in Atlantic waters, and are competing with each other in oceanographic research and its applications.

NAVIGATION

The areas of congested sea traffic all lie in the North Atlantic. As ice conditions occur at certain times of the year, the International Convention for the Safety of Life at Sea was adopted in 1948 in order to systematize and regulate use of shipping lanes. Each lane is desginated for use at a certain time of year. Countries are also assigned their own routes in order to relieve traffic congestion; for instance, the United States is assigned a route far to the

Shipping lanes

south only when extreme ice conditions occur. An International Ice Patrol, formed and operated by the United States Coast Guard, maintains surveillance of icebergs. The United States Navy and the Royal Canadian Air Force fly air reconnaissance flights over both the Atlantic and Arctic oceans for the same purpose, while certain European nations maintain surveillance in the Baltic and North seas. The Soviet northern sea route, where many icebergs are to be found, is also kept under close observation. Hardly any regular ice reconnaissance flights are flown south of the Equator, but satellite observations of Antarctic ice limits were being recorded in the 1970s.

Among the many harbours on the Atlantic, the port of Amsterdam, used by ships from all over the world, is perhaps the busiest. Punta Arenas in Chile is the southernmost port in the South Atlantic, and Archangel in the Soviet Union is the northernmost North Atlantic port.

Atlas Mountains

The Atlas Mountains form the geological backbone of the countries of the Maghrib region—Morocco, Algeria, and Tunisia. They extend for more than 1,200 miles (2,000 kilometres), from the Moroccan port of Agadir in the southwest, to the city of Tunis in the northeast. Their thick rim rises to form a high sill separating the Mediterranean basin from the Sahara, thus constituting a barrier that hinders, without completely preventing, communication between north and south. Across the mountains filter both air masses and human migrations. It is, however, only in the east–west direction that the Atlas Mountains facilitate movement. These are the conditions that create at the same time both the individuality and the homogeneity of the Atlas countries. (For coverage of the three countries of the Maghrib, see the articles ALGERIA; MOROCCO; and TUNISIA; for coverage of associated physical features, see the articles MEDITERRANEAN SEA; and SAHARA.)

The mountains. The Atlas mountain system takes the shape of an extended oblong, enclosing within its ranges a whole complex of plains and plateaus.

The northern section is formed by the Atlas Tellien (Tell Atlas), so-called because it receives enough rainfall to bear fine forests. From west to east several massifs (mountainous masses) occur. The first of these is er-Rif, which forms a half-moon-shaped arc between Ceuta and Melilla; its crest line is over 5,000 feet (1,500 metres) at several points, reaching 8,058 feet (2,456 metres) at Jebel Tidirhine. Beyond the Moulouya gap the Algerian ranges begin, among which the rugged bastion of Ouarsenis (which reaches a height of 6,510 feet [1,984 metres]), the Grande Kabylie Massif which reaches 7,500 feet (2,307 metres) at the peak of Lalla Kredidja, and the mountains of Kroumirie in Tunisia are all prominent.

The southern section, which is subject to desert influences, is deservedly called the Atlas Saharien. It includes in the centre a palisade formed by shorter ranges, such as the Ksour and Ouled Naïl mountains, grouped into massifs between two mighty ranges—the Moroccan Haut Atlas to the west, and the Aurès mountains to the east. The Haut Atlas culminates in Jebel Toubkal 13,665 feet (4,165 metres), which is surrounded by high snow-capped peaks; the Aurès is formed of long parallel folds, which reach a height of 7,638 feet (2,328 metres) at Djebel Chélia.

The Atlas Tellien and Atlas Saharien merge in the west into the long folds of the Moyen Atlas and in the east join together in the Tébessa and Medjerda mountains.

Geology. If the relief of the Atlas region is relatively simple, its geology is complex. In essence, the two Atlases comprise two different structural regions.

Formation of the Atlas Tellien

The Atlas Tellien originally arose out of a basin filled with sediment, which was dominated to the north by a marginal rim, of which the massifs of Tizi-Ouzou, Collo, and Edough are the remnants. Its elevation took place during a lengthy mountain-building process, which was marked by upheavals in the Tertiary Period (which lasted from 65,000,000 to 2,500,000 years ago); over the cluster of folds that was uplifted from the rift valley were spread sheets of flysch (deposits of sandstones and clays), which were carried down from the north over the top of the marginal rim. Thus the Atlas Tellien represents an example of a young folded mountain range still in the process of formation, as is shown by the earth tremors to which it is still subject.

To the south, the Atlas Saharien belongs to another structural grouping, that of the vast plateaus of the African continent, which form part of the ancient base rock largely covered by sediments deposited by shallow seas and by alluvial deposits. The Atlas Saharien results either from the mighty folding of the substructure that raised up fragments of the base rock, such as the horst (uplifted block of the earth's crust), which constitutes the Moroccan Haut Atlas, or else from the crumpling into folds of the earth's crust during the Jurassic Period (from 190,000,000 to 136,000,000 years ago) and the Cretaceous Period (from 136,000,000 to 65,000,000 years ago).

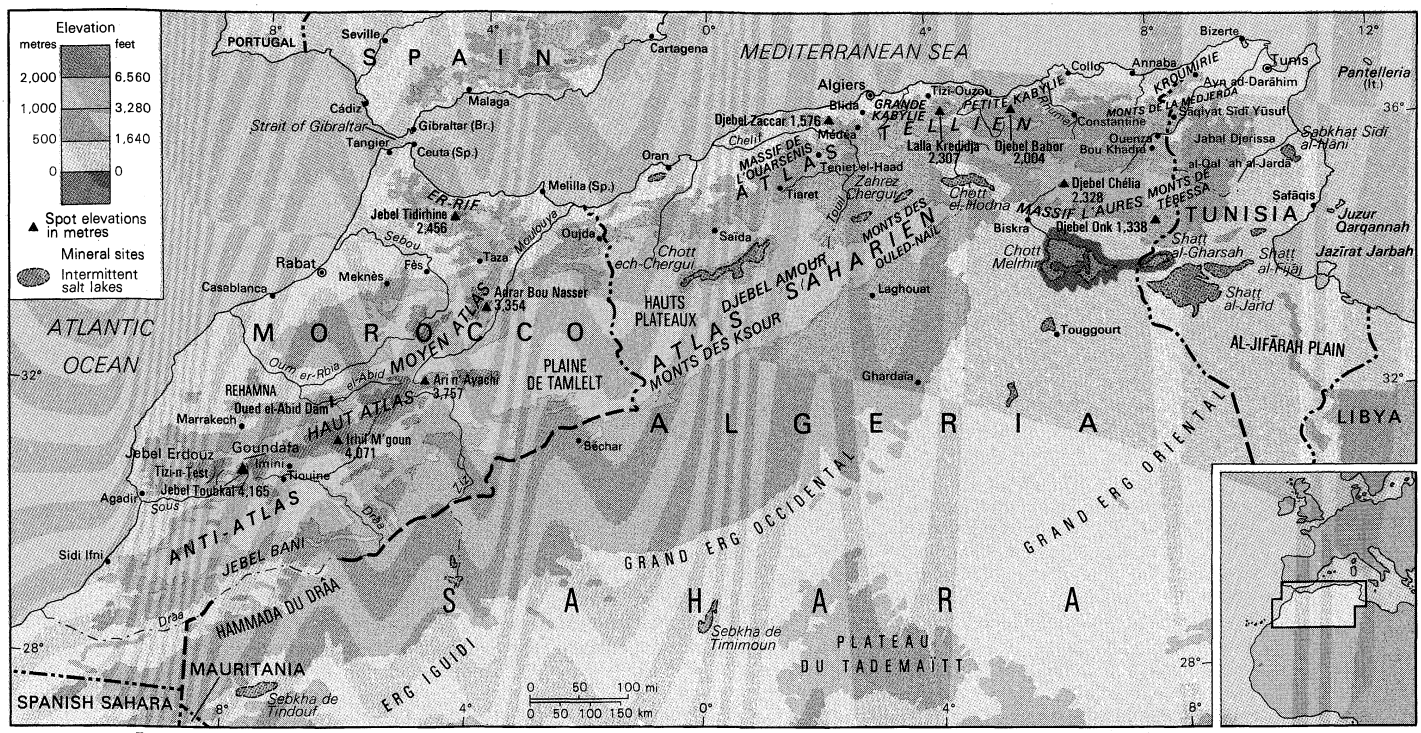
Climate. The Atlas Mountains are the meeting place of two different kinds of air masses—the humid and cold polar air masses that come from the north, and the hot and dry tropical air masses that move up from the south. To the influence of altitude and of latitude, there must therefore also be added that of aspect or exposure.

Rain is more plentiful in the Atlas Tellien than in the Atlas Saharien, and more so to the northeast than to the southwest: thus the highest rainfall is recorded in the east of the Atlas Tellien. ʿAyn ad-Darāhim in the Kroumirie mountains receives 60 inches a year; nowhere in the Anti-Atlas Mountains, which are to the south of the Haut Atlas, is the total rainfall more than 17 inches (432 millimetres) a year. In a single massif the slopes exposed to the north receive more rainfall than those exposed to the south; mountain dwellers distinguish between slopes that in the Berber language are called *amalou* (humid), and those that are dry or *assammeur*.

With increased altitude the temperature drops rapidly; despite the proximity of the sea, the coastal massifs are cold regions. At 6,574 feet (2,004 metres) the summits of Djebel Babor in the Petite Kabylie region are covered with snow for four or five months, while the Moroccan Haut Atlas retains its snows until the height of summer. Winter in the Atlas is hard, imposing severe living conditions upon the inhabitants.

Hydrology. The seasonal character of the rains, which fall in torrents, determines the characteristics of drainage in the Atlas: the runoff feeds streams that are of great erosive capacity, and that have cut their way down through the thickness of accumulated layers of sediment to form deep narrow gorges difficult to cross. The fortress of Cirta, now called Constantine, stands on a rock sculptured out by one such stream, the winding Rhumel River.

The great Maghribian wadis, or oueds, (channels of watercourses that are dry except during periods of rain)



The Atlas Mountains.

issue from the Atlas mountain ranges. Among them are the Moulouya that rises from the Moyen Atlas and the Chelif that rises from Djebel Amour. Destructive of the soils of their headstreams, they deposit their loads of silt at the foot of the mountain ranges or else leave a long line of conical deposits locally known as *dirs* (hills).

Soils. Soil worthy of the name is rare at higher altitudes in the Atlas region. Most often nothing is to be found but bare rock, debris, and fallen materials incessantly renewed by landslides. Two materials predominate—limestone, which forms ledges that are half-buried in rough debris, and marls (chalky clays) cut by erosion into a maze of ravines and crumbling gullies. The rarer sandstones favour forest growth. The best soils are the alluvia found on the terraced slopes and on the valley bottoms.

Vegetation. Erosion is aggravated by the sparseness of the vegetation covering the landscape; only 8,000,000 hectares (20,000,000 acres) of land are forested. On er-Rif, Kabylie, and Kroumirie ranges, which experience rainfall, moist forests of cork oaks cover an undergrowth of arbutus (cane apple) and heather shrub, and carpets of rockroses and lavender. When the total rainfall is below 31 inches (790 millimetres) and limestone is present, green oak and arbor vitae (a species of pine tree) cover the soil, forming light, dry forests with a thin and bushy undergrowth. The cedar predominates at higher altitudes. On the dry summits of the Atlas Saharien the vegetation is reduced to scattered stands of green oak and juniper trees.

The clearance of land for agriculture has resulted in the disappearance of the forest in the Atlas ranges; the animal life of the mountains is also in retreat. There only remain a few bands of jackals, some tribes of monkeys, and some herds of wild boar in the oak woods.

The inhabitants. The mountains, with their inhospitable environment, have provided a refuge for the original inhabitants, who have fled successive invasions. Here the Berber race has survived, preserving its own language, traditions, and beliefs, while at the same time accepting Islām to some extent. Village communities still live according to a code of customary law, known as *kanun*, which deals with all questions of property and persons. The family unit traces its descent from a single ancestor, preserving its cohesion by the sense of solidarity that unites its members; an injury to the honour of one affects the group as a whole and demands vengeance.

Villages high on mountains

The concern of Berber society to preserve its individuality is evident in the choice of habitat. Villages, which are fortified, are generally perched high up on mountain crests. Small in size, such villages are composed of the dwellings, a mosque, a threshing floor, and a place for the assembly of the elders, or *jemaa*, which governs the affairs of each community. Families live, each unit apart, in separate rooms that form a square around a closed interior courtyard.

Despite the fundamental homogeneity of Berber society, there is a considerable diversity in different mountain localities. The Shleuh (Chleuch) of the Haut Atlas in Morocco inhabit the river valleys that cut down deeply into the massif. Their villages, with populations of several hundred inhabitants in each, are often located at an altitude of more than 6,500 feet (2,000 metres). They consist of terraced houses, crowded one against the other. They are often dominated by a communal fortified threshing floor, or else are grouped around the threshing floor-plus-dwelling (*tirhamt*) of the most powerful family. The mountain slopes in the vicinity are divided up for pasturage and cultivation. In some fields dry (i.e., non-irrigated) farming is practiced for growing cereals. Land that is irrigated by diverting water from oueds yields two crops a year—cereals in winter and vegetables in summer. The Shleuh use manure from their cattle to fertilize the soil. Oxen and goats penned together on the ground floor of dwellings graze on stubble and on fallow lands around the villages. Sheep follow a pattern of transhumance (seasonal migration), grazing on low-lying land in winter and on the uplands in summer.

During the period of the French Protectorate in Morocco, profound changes occurred, transforming the way of life of the Moyen Atlas populations. The dominant pattern of transhumance gave way to the practice of agriculture. The winter descent to the *azarhar* (plains) pasture is practically a thing of the past, since the land is now under cultivation. The ascent to high pastures in summer, however, still continues. Stock farming is increasingly practiced in one place. Lumbering also brings in an appreciable income.

Where the mountain and the plain meet, the *dir* lands offer rich potentialities, thanks to a light soil and abundant water. Grouped together in large villages, the *diara* populations (*i.e.*, populations who live on the slope of the *dirs*) constitute prosperous agricultural communities.

The Rif of Morocco and the Kabyle of Algeria have

many points of resemblance. Both Berber tribes, they inhabit the same wet mountain slopes covered with oak forests, are similarly attached to a barren soil, and are both inclined to isolationism. In contrast to the way of life of the Berbers of the Haut Atlas and the Moyen Atlas, stock raising plays only a secondary role in their village life; they are not so much agriculturalists as arboriculturists, although they grow a little sorgo (a sorghum used for fodder), and their wives grow vegetables in small gardens adjoining their houses. It is, however, the fig and olive trees covering the mountain slopes they inhabit that constitute their principal resources. The Kabyles are also skilled craftsmen, working with wood, silver, and wool. Until recently they were also peddlers, selling carpets and jewelry to the people of the plains.

The Aurès Massif, standing alone in northeastern Algeria, is perhaps the most backward mountain region in the Maghrib. The Shawia (Chaouia) populations who inhabit it follow a seminomadic style of life, which is partly agricultural and partly pastoral. They live in terraced stone villages in which the houses are built in tiers, one above the other, the whole being dominated by a *guelaa*, or fortified granary. When winter comes, the inhabitants of the high valleys lead their flocks to the lowlands surrounding the massif, where they pitch tents or live in caves. Returning to the uplands in summer, they irrigate the land to grow sorghum (a cereal grass) and vegetables and maintain apricot and apple orchards, while shepherds take the sheep to pasture on the hilltops.

Despite precarious living conditions, the Atlas Mountains are densely populated—overpopulated, even, in certain localities. In the Tizi-Ouzou region of the Grande Kabylie, for example, densities reach about 780 persons per square mile. Emigration is a necessity: the mountain regions have become a human reservoir upon which the Maghribian countries draw to obtain the labour force needed for development. Commercial agriculture attracts large numbers of farm workers to the plains either on a seasonal or a permanent basis. The Mitidja Plain, for example, has been settled by Kabyles. In Morocco, the Shleuh of the Haut Atlas provide labour for the phosphate mines.

Urban growth has served to increase the volume of the migratory stream that flows down from the mountains; the cities of Algiers, Constantine, Oran, and Casablanca are to a great extent peopled by mountain folk. The shantytowns of Algiers contain numerous Kabyles, and those of Casablanca many Shleuh. Many of these urban immigrants find employment as labourers, while others become shopkeepers.

In Algeria the insecurity that became general in most mountain districts during the Nationalist uprising that preceded independence led to the departure of large numbers of people. The exodus from the mountains continued after independence, with many mountain dwellers moving into the plains to occupy houses abandoned by departing Europeans. Rural and urban activities, however, still did not provide employment for all, for many emigrants, mostly from Algeria, sought work in France. To a considerable extent the mountain populations subsist on money sent back by these migratory workers.

Transport and communications. The Atlas Mountains have their own internal system of communications. Villages are linked by paths that, avoiding the valley bottoms, follow the crest lines of the hills. Travel is on foot or by mule, although local bus transport is increasing.

The massifs constitute an obstacle to traffic; roads and railroads traverse them by means of tunnels and viaducts, which are costly to build. Traffic between Algiers and Constantine is obliged to cross the Kabylie Massif; the route runs through the Oued Isser gorges and crosses the Biban mountains at the Portes de Fer Pass. The Chiffa Gorge cuts across the route between Blida and Médéa.

The relative impenetrability of the mountains explains why they have been avoided by the main transportation routes, and why, consequently, they constitute strongholds of ancient traditionalism. Obstacles to communication should not, however, be exaggerated; the mountains also offer many natural connecting links, or passes, that facilitate movement. Such topographic accidents localize communication routes: between the desert and the plains the nomads use synclinal corridors (*i.e.*, corridors formed by folds in the rocks in which the strata dip inward from both sides toward the centre) that separate the ridges of the Atlas Saharien range. The Biskra Gap, situated between the Monts des Ouled-Naïl and the Aurès, provides a natural conduit for traffic between Constantine and Touggourt. Between Algeria and Morocco both the road and the railroad cross the Atlas at the Taza Pass, which breaks the continuity of the mountain system between er-Rif and the Moyen Atlas. Passes are natural routes across the mountain barriers, and thus strategic points. The focal point of communication in the Grande Kabylie, for example, is Tizi-Ouzou, at the Genêt Pass, which has become in effect the capital of the massif. To surmount the obstacle formed by the Ouarsenis, situated between Chelif Plain and the Sersou Plateaus, one must pass by way of Teniet el-Haad. The passes of the Moroccan Haut Atlas have also played a decisive role in the history of relations between Morocco and the vast region known as the Sudan to the south; the ancient caravan route from Marrakech to the Drâa Valley used the Tizi-n-Test Pass, which thus became of great commercial importance.

The mountain passes

Economic resources. It might be thought that the Atlas Mountains have no part to play in the future development of the Maghribian countries, but this is not so. The development of the resources of the Atlas will open new perspectives. The mountain massifs constitute catchment areas with considerable potentialities. The construction of reservoir dams not only would permit the storage of enormous amounts of water for irrigating the plains but would also generate much hydroelectric energy. In Morocco efforts are being made to exploit the potentialities of the mountain oueds. In addition to the dams across the Oued el-Abid (a wadi) on the northern slope of the Haut Atlas, dams on the southern face have been constructed across the Oued Drâa and Ziz watercourses. In Algeria, the Kabylie regions have been developed. Among the major projects completed are the Iril-Emda Dam and the underground power station at Darguinah on the Agrioun Wadi. The Namoussa Dam, which will irrigate the Annaba Plain, is now under construction.

The geological formations of the Atlas are rich in minerals. The Moroccan Haut Atlas in particular contains important deposits. Among these are the lead and zinc deposits associated with Jebel Erdouz, the copper and lead deposits now being mined at Goundafa, and the manganese deposits of Imini and of Tiouine, the output of which is transported to Marrakech by overhead cable cars. In Algeria, iron ore is extracted from the Seba Chioukh Mountains, and from Zaccar, Ouenza, and Bou Khadra, while phosphate is mined at Djebel Onk. In Tunisia, the Haut Tell mountains produce phosphate at al-qalʿah al-Jardāʾ, iron ore from Jabal Djerissa, and lead from Sāqiyat Sīdī Yūsuf. These raw materials are not processed on the spot but are either exported or else are processed in the coastal towns. The iron ore from Ouenza, for example, supplies the iron-smelting industry of Annaba.

Among forest products, cork is more important than timber; production is centred in the Kabylies, notably on the Collo Massif.

The tourist industry is also being developed, particularly in the Haut Atlas region of Morocco. In the Moyen Atlas, long snow-covered slopes suitable for winter sports are located in the vicinity of major towns. In Algeria, the establishment of industry in mountain regions is being encouraged, so that employment for the mountain dwellers will be available on the spot. A textile factory has been constructed at Drâa ben Khedda in the Grande Kabylie, while at Constantine, the principal city of the mountain regions, several industries have been established. Despite these efforts, however, contrasts between the life styles of the mountains and those of the plains and cities of the Maghrib have by no means diminished, nor are they soon likely to do so.

Atmosphere

The atmosphere that surrounds the Earth and is commonly called the air consists of layers of gases and mixtures of gases, as well as water vapour and solid and liquid particles. The mean pressure exerted by a vertical column of the atmosphere at sea level equals that of a column of mercury 760 millimetres (29.92 inches) in height. Such a column of air exerts a force, called atmospheric pressure, expressed as 1.033 kilograms per square centimetre (14.7 pounds per square inch).

Higher in the atmosphere the pressure decreases, and at an altitude of six kilometres (four miles) it is only one-half that at sea level. If this decrease in the pressure within the field of gravity were uniform throughout the depth of the atmosphere, the weight of a column of air at about 60 kilometres (40 miles) would be reduced to a thousandth (10^{-3}) that at sea level, to a thousandth of a millionth (10^{-9}) at about 180 kilometres (110 miles), and to 10^{-21} at about 420 kilometres (260 miles). The last value (10^{-21}) represents a density less than that of interstellar space. It is known, however, that the atmosphere of the Earth extends well beyond 400 kilometres (250 miles). Visual observations—of the auroras, for example—reveal the presence of luminous rays up to altitudes as great as 1,000 kilometres (600 miles). Furthermore, shortwave radio transmission has proved that the medium is sufficiently dense at an altitude of several hundred kilometres to produce enough electric charges (electrons) to reflect radio waves. Rocket probes and especially the drag encountered by artificial satellites at altitudes of several thousand kilometres have demonstrated that the terrestrial atmosphere extends to a very great distance. This extension to high altitudes occurs because of the occurrence of constituents of low mass and because of pressure and temperature conditions.

This article treats the physical and chemical properties of the several regions of the atmosphere. For further information on the interaction of the Earth's magnetic field and the atmosphere, see EARTH, MAGNETIC FIELD OF; IONOSPHERE; VAN ALLEN RADIATION BELTS; and AURORAS. See ATMOSPHERE, DEVELOPMENT OF for treatment of the origin and evolution of the present atmosphere; and WINDS AND STORMS; OCEANS AND SEAS; and CLIMATE for the role of the atmosphere at levels near the Earth and its interaction with the hydrosphere.

REGIONS OF THE ATMOSPHERE

Vertical temperature distribution

The principal regions of the atmosphere, each of which is characterized by the pattern of vertical distribution of temperatures, are the troposphere, the stratosphere, the mesosphere, the thermosphere, and the exosphere (Figure 1). In meteorological research it has long been customary to deal with two regions: the troposphere and the stratosphere.

The lower atmosphere. *The troposphere.* The region of the atmosphere in contact with the Earth's surface, the troposphere, is the realm of the clouds, rain, snow, etc., and is characterized in general by a decrease of temperature with increasing altitude. The upper limit of the troposphere, known as the tropopause, is at an altitude of about 17 kilometres (11 miles) at the Equator and only six to eight kilometres (four to five miles) at the poles. In the middle latitudes, the altitude of this limit varies with the atmospheric conditions. In high-pressure areas it is about 13 kilometres (eight miles), and it may be below seven kilometres (four miles) under low-pressure conditions.

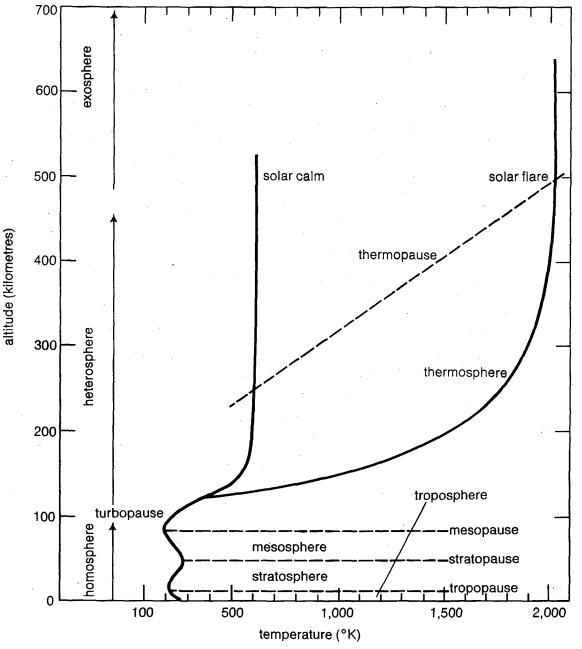

Figure 1: Regions of the atmosphere and their transitional zones.

The stratosphere and mesosphere. The second region of the atmosphere that has been closely studied, the stratosphere, is still within the reach of meteorological probes. In its lower section there is a slow, constant increase in temperature with altitude; the temperature rise becomes more rapid with increasing altitude, attaining a maximum of about 270° K (the Kelvin scale is an absolute Celsius scale; *i.e.*, 0° K equals −273° C [−460° F], which is absolute zero) at approximately 50 kilometres (30 miles), the upper limit of the stratosphere, which is known as the stratopause. The temperature of the stratopause varies less than that of the tropopause, which may decrease from 220° K at the pole to about 190° K at the Equator. There is some variation of the temperature of the stratopause with latitude and with the seasons. The troposphere and the stratosphere are clearly separated; the exchange between tropospheric air and stratospheric air requires several months, if not several years, indicating a difference in the circulation of the air within the two zones.

The middle atmosphere

Above 50 kilometres is the mesosphere or middle region, characterized by a rapid decrease of temperature to a minimum at about 85 kilometres (55 miles); this can be below 160° K in the summer at high latitudes. But, like the troposphere, the mesosphere is subject to strong seasonal variations of temperature at high latitudes. The prevailing level of the minimum temperature indicates another division in the atmosphere, known as the mesopause.

The upper atmosphere. Beyond the mesopause is an atmospheric region different in character from that of the lower regions. The first stratum of this higher region is the thermosphere, characterized by a continuous increase of temperature up to 500° K in the course of a night during minimum solar activity and to above 1,750° K in the course of a day during maximum solar activity. The altitude at which this increase of temperature ceases is the thermopause, which is at the base of an isothermal (constant-temperature) region that would extend into interplanetary space if the normal properties of a gas in hydrostatic (equal-sided) equilibrium continued to apply. In reality, the frequency of collisions between gas atoms becomes so low above a certain level, called the critical level, or baropause, or exobase, that the gas atoms can be considered to have their free-space trajectories. In this

highest region, the exosphere (outersphere), the study of the physical properties becomes the study of the movement of particles subject to gravity and capable of escaping from the atmosphere. In the exosphere, temperature no longer has the customary meaning.

Atmospheric mixtures. Of the regions described above in terms of their vertical temperature distribution, the first three—troposphere, stratosphere, and mesosphere—have the same general composition; that is, the tropospheric mixture of molecular nitrogen and oxygen is maintained in the stratosphere and the mesosphere. In combination the three regions comprise the homosphere. At the higher altitude of 100 kilometres (60 miles), in the thermosphere, molecular oxygen is strongly dissociated, and atomic oxygen becomes an important component of the atmosphere. The latter region is known as the heterosphere and is characterized also by the presence of light atoms, such as helium and hydrogen, at its higher altitudes. A relative increase of these light elements in comparison with heavier elements such as nitrogen and oxygen is a result of the absence of sufficient mixing of the air by turbulence; instead, its composition is dominated by gas diffusion in the field of gravity. The region of 100 to 110 kilometres (60 to 70 miles) is one of transition, called the turbopause; above it, an element can exhibit its own natural vertical distribution, rather than that characteristic of the general atmosphere.

Extraterrestrial effects. Above a certain level the atmosphere is subject to ultraviolet radiation, to X-rays, and to solar particles. These cause the production of electrically charged particles—that is, ions and electrons from various kinds of atoms and molecules—in the ionosphere (*q.v.*), which extends from the mesosphere to the outermost limits of the atmosphere. But the charged particles are affected by the magnetic field of the Earth and consequently behave differently from the neutral particles in the air. In regions where the pressure is high enough, as in the mesosphere and the greater part of the thermosphere, ionospheric conditions are dominated by the preponderant neutral atmosphere. But, when the numerical ratio of charged particles to neutral particles is no longer negligible, the ionosphere is characterized by conditions in which account must be taken of the electric field connecting the positively and negatively charged particles. The region in which charged particles have energies greater than those corresponding to thermal velocities and move among the lines of force of the terrestrial magnetic field is the magnetosphere. It is a vast region primarily related to the interplanetary space in which the charged particles coming from the Sun are propagated. Another important influence is an auroral zone called the auroral oval (because of its form), characterized by the occurrence of polar auroras resulting from an influx of charged particles. Within the auroral oval the solar protons produce a particular type of ionization. Thus, there is also a geographic division of the atmosphere, resulting from the presence of the terrestrial magnetic field.

The region of the ionosphere

Composition of the atmosphere. The air near the Earth's surface has a well-defined chemical composition, consisting of molecular nitrogen, N_2 (78.1 percent by volume), molecular oxygen, O_2 (21 percent), argon (0.9 percent), and a small amount of carbon dioxide, CO_2 (0.03 percent). Also contained in the atmosphere (see Figure 2) are small, variable amounts of water vapour, H_2O, and trace quantities of methane, CH_4, nitrous oxide, N_2O, carbon monoxide, CO, hydrogen, H_2, and ozone, O_3, and of helium, neon, krypton, and xenon.

Where there is sufficient mixing by turbulence, the air consists essentially of molecular nitrogen and oxygen. Only at the altitude where molecular diffusion outweighs eddy diffusion does there begin the relative impoverishment of O_2 and N_2 molecules in comparison with atomic oxygen, O (Figure 2). The mass of an oxygen atom is 16 in relative units (*i.e.*, as compared to the mass of the atom of the isotope carbon-12, which is taken as the standard unit, a mass of 12), whereas that of molecular oxygen is 32 and that of molecular nitrogen 28. The mean mass of the air of the homosphere, 29, is gradually altered above an altitude of about 100 kilometres (60 miles) to that resulting from an increasing proportion of atomic oxygen. In addition, the elements that are rare in the homosphere (for example, helium, $5/1{,}000{,}000$ of the air at sea level, and hydrogen, $1/1{,}000{,}000$ at sea level) become relatively more abundant at higher altitude. Because of their low masses (helium 4, hydrogen 1), the concentration of these atoms decreases much more slowly than that of oxygen and nitrogen in the heterosphere, where each element is independently subject to the field of gravity. Ascending into the heterosphere, the belts of molecular nitrogen and oxygen, of atomic oxygen, and of helium are encountered in that order. Finally, at its extreme limits, the atmosphere is composed of atoms of hydrogen.

Atomic mass and distribution

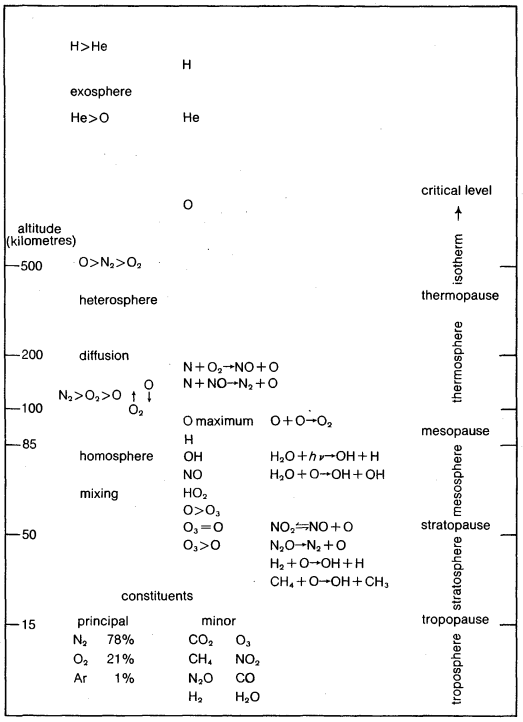

Figure 2: Distribution of principal and minor constituents of the homosphere, heterosphere, and exosphere.

THE HOMOSPHERE

It is not difficult to describe the homosphere in terms of only the concentration of its principal elements, molecular nitrogen and oxygen; however, the phenomena that occur under the influence of solar and cosmic radiation must be taken into account as well. Although most of the molecules of nitrogen and oxygen are not affected by radiations originating outside the atmosphere, the absorption of various radiations does lead to certain ionization and dissociation effects.

Galactic cosmic radiation produces a permanent ionization in the whole of the stratosphere and in the mesosphere. In the homosphere, however, ionization is strictly a secondary phenomenon; dissociation under the influence of solar ultraviolet radiation is more important.

The effects of ultraviolet radiation. Molecular oxygen, O_2, is photodissociated under the influence of radiation of wavelengths less than 2400 Å (angstroms; the angstrom is a unit of length equal to 10^{-8} centimetre) into atoms of oxygen, O. This process is the foundation of all photochemical reactions in the homosphere. Production of atoms of oxygen, O, in the stratosphere and the mesosphere leads immediately to the production of molecules of ozone, O_3, as is shown in the equation

$$O_2 + O + M \rightarrow O_3 + M,$$

in which a triple collision between a molecule of oxygen O_2, an atom of oxygen O, and a third particle, M, which may be a molecule of oxygen or of nitrogen, results in formation of a molecule of ozone, O_3.

In the homosphere, the ozone, O_3, and molecular oxy-

gen, O_2, molecules absorb all the solar ultraviolet radiation from 3000 to 1800 angstroms (ultraviolet ranges in wavelength from 100 to 3900 angstroms). Ozone absorbs primarily the radiation between 3000 and 2000 angstroms, and molecular oxygen that below 2000 angstroms. It follows that the absorption of ultraviolet radiation by ozone is the basis of the increase of temperature with altitude in the stratosphere; the ultraviolet heating is sufficient to develop a maximum temperature at the stratopause. Conversely, absorption by oxygen is very weak in the mesosphere, with the result that temperature decreases with altitude to the very low minimum found at the mesopause.

Dissociation of ozone. The presence of ozone in the stratosphere and mesosphere sets in motion a series of chemical processes. Under the influence of solar ultraviolet radiation of wavelengths below 3300 angstroms, ozone is photodissociated into molecules and atoms of oxygen in excited states. Production of an excited oxygen atom is important because it is a powerful oxidizer (*i.e.*, capable of producing chemical change by destroying normal molecules such as water vapour, methane, molecular hydrogen, and nitrous oxide).

When an excited oxygen atom is in the presence of, for example, stratospheric water vapour, H_2O, an immediate oxidation takes place, producing two hydroxyl radicals, OH (a radical is a group of atoms that occurs in the molecules of many compounds), expressed by the equation

$$O + H_2O \rightarrow OH + OH.$$

Formation of hydrogen compounds. With the dissociation of the water vapour, many compounds of hydrogen can be formed; for example, the hydroperoxy radical, HO_2, and hydrogen peroxide, H_2O_2. Furthermore, because the oxides of nitrogen NO and NO_2 are present, such compounds as nitric acid, HNO_3, can be formed. Analysis of these reactions shows that within the homosphere the existence of a mild degree of photodissociation of oxygen results in a remarkable series of reactions, which are important to the nature of the stratosphere and of the mesosphere. Accordingly, within the homosphere must be introduced the concept of the chemosphere, within which such chemical reactions occur.

Mechanisms of air mixing. One of the essential characteristics of the homosphere is that the turbulence of the air is always sufficient to maintain the same proportions of molecular nitrogen and oxygen in the mixture. Although molecular diffusion—that is, the tendency of gases of different molecular weights to separate—exists in the homosphere, it is always counterbalanced by eddy diffusion—the tendency to perfect mixture, in the case of the principal gases. But in the case, for example, of methane and of molecular hydrogen, which are oxidized as is water vapour, their removal from the air cannot be compensated by an influx of molecules from the troposphere. Molecular diffusion and turbulent diffusion are not sufficient to compensate for the loss resulting from oxidation. At the level of the stratopause, methane begins to disappear from the atmosphere. Water vapour is still present, however, because of its rapid recombination in the stratosphere and in the mesosphere.

The examples given illustrate the importance of the mechanisms of horizontal and vertical transport of the air in the stratosphere and in the mesophere. Analysis of the homosphere requires that the dynamic aspect be taken fully into account; further, the presence of helium and hydrogen in the heterosphere depends upon the conditions of transport in the homosphere. The helium produced in the Earth's crust enters the atmosphere and makes its way through the homosphere by the process of molecular diffusion until it reaches the thermosphere, where it plays an important role that will be discussed elsewhere in this article; atomic hydrogen is the product of the oxidation of hydrogen compounds, which occurs as determined by the properties of the homosphere.

THE HETEROSPHERE

At the beginning of the lower part of the thermosphere the change of composition and the increase in temperature are evident. Atomic oxygen becomes a factor in determining the mean molecular weight at an altitude of about 100 kilometres (60 miles). In addition to the atomic weight, 32, of the oxygen molecule, O_2, and 28, of the nitrogen molecule, N_2, the weight, 16, of atomic oxygen, O, must be considered. The decrease of the mean molecular weight essentially results from the photo-dissociation of the oxygen molecule under the influence of solar ultraviolet radiation of wavelengths below 1750 angstroms. Dissociation also occurs between 2000 and 2400 angstroms.

Oxygen dissociation in the lower thermosphere. An examination of thermosphere conditions reveals that equilibrium conditions cannot exist at each level between dissociation and reconstitution of the oxygen molecule. In other words, equality between the number of reactions that result in dissociation of the oxygen molecule and the number that result in recombination of the oxygen atoms is not possible under the conditions imposed by the altitude. At 100 kilometres the molecule can exist for more than ten days without being photo-dissociated, and accordingly its vertical distribution depends much more on the transport conditions than upon conditions of formation or destruction.

Variance in equilibrium conditions

There is, in fact, a departure from the conditions of photo-dissociation equilibrium and an approach to conditions of diffusion equilibrium. As a result, the following mechanisms are observed in the upper thermosphere: (1) when a molecule of oxygen is photo-dissociated by solar radiation, it yields two atoms of oxygen which do not recombine at the altitude at which they were produced, but are subject to a diffusion current descending to the altitude at which the atmosphere is dense enough to cause their disappearance; (2) the dissociated molecule is replaced by a molecule arriving from below, because O_2 survives long enough in the field of solar radiation to be transported upward by molecular diffusion.

In short, the dissociation state of the oxygen in the lower thermosphere is not determined by the equilibrium of photo-dissociation; instead, heavy O_2 molecules are carried upward, whereas the light atoms of oxygen must descend before they can recombine.

Effects of vertical transport. In the region in which the oxygen is subject to conditions of vertical transport, the transport processes also apply to other constituents of the atmosphere. At the altitude between 100 and 120 kilometres, eddy diffusion begins to lose its superiority over molecular diffusion. The transition results from the fact that the coefficient of molecular diffusion is inversely proportional to the density. Between sea level and 100 kilometres the density has diminished by a factor of at least 1,000,000,000; accordingly, molecular diffusion has increased in intensity by the same factor. Eddy diffusion having, on the other hand, gained no special advantage at 100 kilometres, it follows that molecular diffusion has become predominant at 120 kilometres. As a result, there is time for all of the atmospheric constituents that are not exceptionally reactive to become distributed in the gravity field according to their individual masses.

Atmospheric distribution by mass

Distribution of oxygen and nitrogen. Nitrogen, N_2, which is the most abundant molecule at 100 kilometres (of the order of 10^{13} molecules per cubic centimetre) and has a mass of 28, follows practically the vertical distribution of normal air, of which the mean molecular weight is 29. Molecular oxygen, O_2, with a mass of 32, decreases more rapidly with altitude than does molecular nitrogen (Figure 3).

Atomic oxygen, O, of mass 16, shows a relative increase with altitude in comparison with the oxygen and nitrogen molecules; it becomes more abundant than molecular oxygen, O_2, above 125 kilometres and more abundant than nitrogen, N_2, above 250 kilometres. As a result, the heterosphere is characterized by a thick layer of atomic oxygen extending for several hundreds of kilometres.

Distribution of helium and hydrogen. When subject to the diffusion process, helium and atomic hydrogen, whose proportions at 100 kilometres are of the order of $1/1{,}000{,}000$, can become the predominant elements because of their low masses (helium, 4; hydrogen, 1). It can be

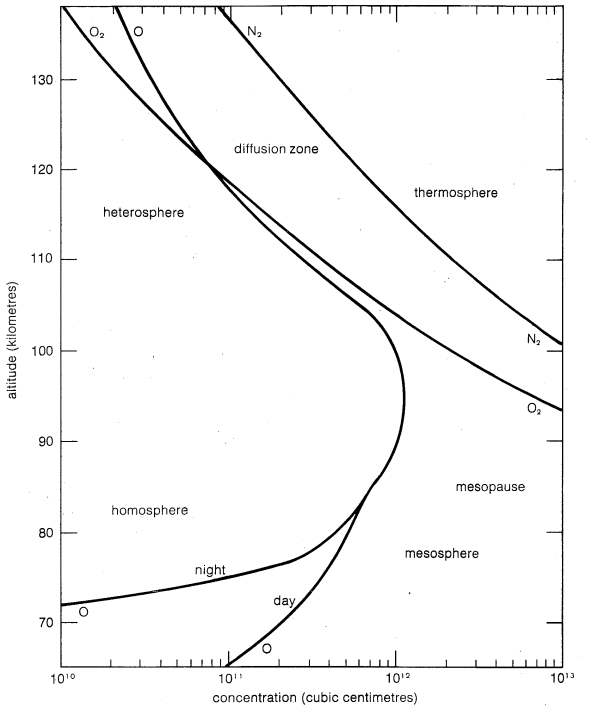

Figure 3: Concentration of oxygen and nitrogen in the atmosphere with respect to altitude.

shown that a belt of helium exists above the layer of atomic oxygen and also that atomic hydrogen forms the uppermost levels (corona) of the terrestrial atmosphere. The vertical distributions of atomic hydrogen, helium, atomic oxygen, molecular nitrogen, and molecular oxygen are presented in Figure 4, in which the density at a relatively low temperature of 600° K is given for each constituent.

Variations in atmospheric densities. Review of the data obtained from the drag on artificial satellites makes it evident that the density of the heterosphere is subject to considerable variations (Figure 5). Whereas at the maximum of solar activity that occurred in 1958 the density was extraordinarily high, it came down to a very low value during the 1964 minimum of solar activity. There is, thus, a close correlation with solar activity. It is the ultraviolet radiation, which penetrates into the heterosphere and is absorbed there, that exhibits variations closely linked to the Sun's activity. To the 11-year cycle of solar activity must be added the variation corresponding to the rotation of the Sun. Finally, it must be emphasized that above 200 kilometres there is a remarkable variation of density between day and night.

The rate of ultraviolet radiation

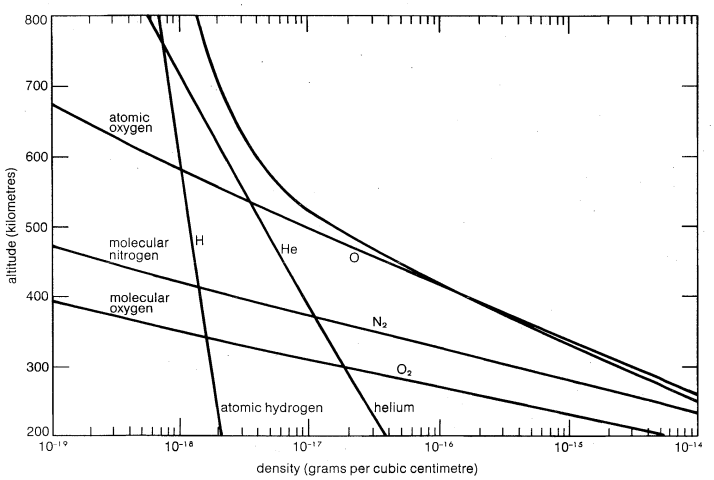

Figure 4: Density of atmospheric constituents in the heterosphere at a temperature of 600° K.

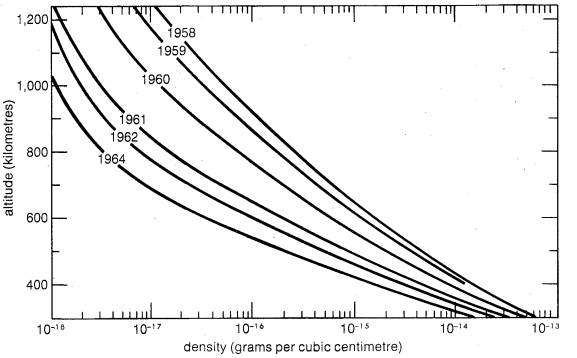

Figure 5: Relationship between mean atmospheric density and solar activity in the heterosphere.

Temperature fluctuations. To interpret the density variations in the thermosphere, it is important to consider that the thermospheric gas is subjected to strong variations of temperature. The thermal balance is evaluated using the assumption that an ultraviolet heating effect and a rapid recooling work against each other. Thermal conditions in the heterosphere evidently differ from those of the homosphere. In the lowest region of the homosphere, the troposphere, which is in contact with the ground, the source of heating is essentially the ground, which has absorbed the Sun's rays, and convection is an adequate means of transporting the heat. In the stratosphere and mesosphere, convection and infrared radiation from one direction meet ultraviolet heating from the other. But in the thermosphere the third means of heat transport—conduction—decisively outweighs the other means, radiation and convection. For that reason the thermal balance is such that very different conditions appear by day and by night.

During the day, the cooling by conduction is compensated by ultraviolet heating, whereas during the night the heat loss by vertical conduction is not compensated by horizontal transport. As a result, there is a very large daily variation of the temperature of the thermopause, which is manifest to the observer as a variation of the atmospheric density.

Cycles of solar activity. Furthermore, the fact that periods of 27 days can be detected in the variations of atmospheric density must be interpreted in terms of the rotation of the Sun. Ultraviolet emission does take place when the Sun is perfectly calm over the whole of its disk; but the brilliant regions visible as sunspots emit a greater ultraviolet radiation. An increase of solar activity in the hemisphere of the Sun that is visible from the Earth is an index of increased ultraviolet heating. Accordingly, the thermal balance in the thermosphere varies according to the amount of ultraviolet heating available to counter the conductive cooling.

Taking account of the variation in ultraviolet radiation during a cycle of solar activity, it is possible to predict the long-term variations of the thermospheric temperature. In Figure 6 the maximum variation of daytime temperature is shown; the mean temperature varies from a low of 750° K, with minimum solar activity, to a high of about 2,000° K.

Because the composition of the heterosphere varies as a function of temperature, the vertical distribution of the atmospheric constituents is variable (Figure 7). The proportion of helium is greatest at the highest temperatures and the proportion of hydrogen is greatest when the temperature is lowest.

The escape of helium and hydrogen. It must be remembered that the aeronomic problems regarding helium and atomic hydrogen are essentially different from those associated with the other elements. The continual introduction of helium into the atmosphere—at an average rate of about 1,000,000 atoms per square centimetre per second (as a result of its formation in the Earth's crust by the disintegration of thorium and uranium)—would lead in the course of some millions of years to a doubling of the total quantity of helium existing in the atmosphere.

Sources of airborne helium

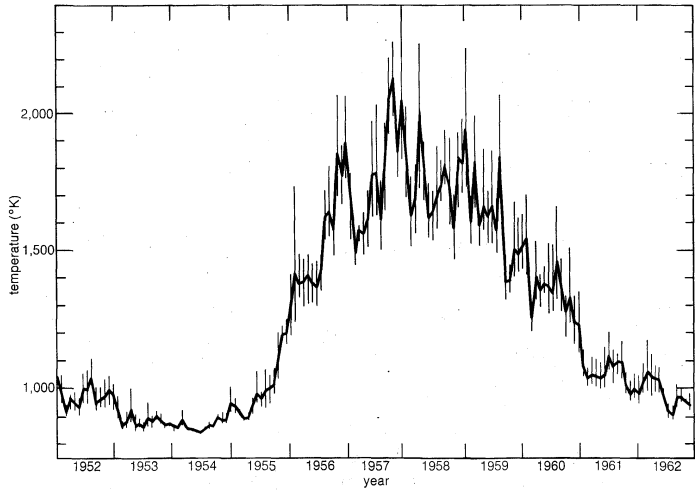

Figure 6: Mean temperatures at the thermopause for 27-day periods during 1952–1962 (see text).

Since the formation of the Earth about 4,600,000,000 years ago, an amount of helium equal to that introduced from the above sources must have escaped to avoid accumulation. Such escape can occur only at the top of the atmosphere by a transport process taking place in the homosphere and the heterosphere. The equations of diffusion reveal that the escape of 1,000,000 atoms of helium per square centimetre per second is perfectly possible, thus maintaining a helium distribution close to the equilibrium of diffusion in the heterosphere.

In the case of hydrogen, of which some 100,000,000 atoms escape, the limit of what diffusion will support is reached. For this reason, the vertical distribution of hydrogen is not that of a diffusion equilibrium but depends on a transport state in which the number of atoms moving toward the base of the heterosphere is equal to the number leaving it. It can be concluded that there are more atoms of hydrogen in the thermosphere at low temperature than at high temperature. The role of hydrogen in the thermosphere is therefore most evident at the minimum of solar activity. In the last analysis, the total mass of hydrogen atoms passing from the terrestrial atmosphere into interplanetary space is several hundred grams per second.

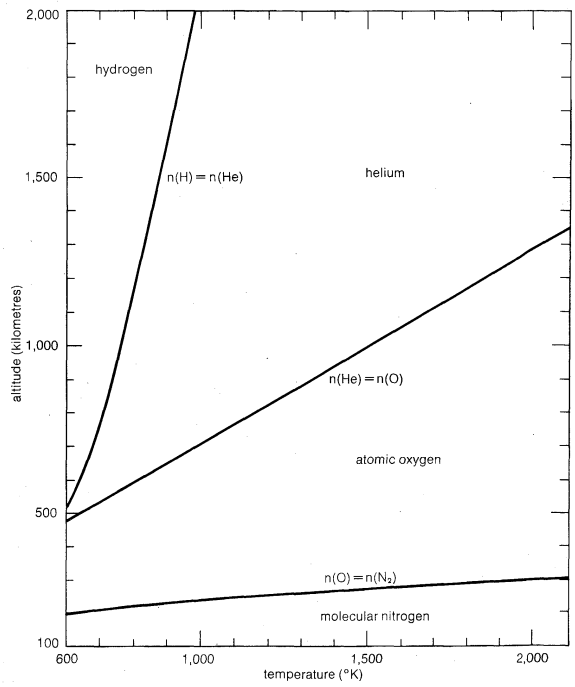

Figure 7: Atmospheric zones of common gases as a function of temperature and altitude.

It is possible to go further into the subject of the heterosphere with respect to perturbations such as the magnetic storms. It is clear that the contribution of energy due to certain particles can cause a general heating only if the energy is capable of penetrating across the lines of force of the terrestrial magnetic field. The heating can be local, as in the auroral oval, where there is direct precipitation of particles. It has been shown that the density of the thermospheric gas varies with the geomagnetic index, which can be explained by a variation of temperature. Such processes, however, require complicated explanations.

Ionization mechanisms. Because the aeronomic conditions of the ionization state depend simultaneously on the vertical distribution of the neutral elements nitrogen and oxygen and on the spectral distribution and the absorption of the solar radiation, it may be readily concluded that the amount of photo-ionization is closely related to the diurnal, seasonal, periodic, and 11-year variations in solar activity. In addition, account must be taken of the reactions occurring between the ions and the neutral particles and also of the processes that result in the disappearance of electrons and ions.

Ionization and solar activity

When an ionizing radiation causes the ejection of an electron from an atom or a particular molecule, a photoelectron appears, which possesses kinetic energy corresponding to the difference between the solar radiation energy and the energy required for the ionization. Such a photoelectron can give up part of its energy to ionize another atom if its energy is sufficiently high, as is the case with strongly energized electrons produced by X-rays. In general, any photoelectron loses part of its energy in exciting the most plentiful atoms and molecules; however, in the upper ionosphere, photoelectrons colliding particularly with the other electrons cause a general heating of the electronic gas.

The nitrogen ion. A photo-ion (atomic or molecular ion produced by photo-ionization) can collide with an electron, and it is possible that the two will reconstitute the neutral element. But it is more likely that the photo-ion will collide with an atom or molecule of another kind, exchange its charge, and return to the neutral state; for example, the nitrogen molecule—the element most plentiful below 200 kilometres—should furnish the most abundant ion. In reality, the photo-ion of molecular nitrogen very quickly comes into contact with a molecule of oxygen or with an atom of oxygen. The first case involves a transfer of charge; that is to say, the peripheral electron of the oxygen molecule, O_2, is transferred to the nitrogen ion, N_2^+, which reconstitutes the normal molecule, N_2, and forms the molecular ion, O_2^+: $N_2^+ + O_2 \rightarrow N_2 + O_2^+$.

The second case corresponds to a change of the atom and of the ion, in which the molecular nitrogen ion, N_2^+, colliding with the oxygen atom, O, dissociates to form an ion of nitric oxide, NO^+, and an atom of nitrogen, N: $N_2^+ + O \rightarrow NO^+ + N$. Thus, the second case results in an NO^+ ion that has been produced directly by the action of solar radiation. A molecule of nitric oxide appears in the heterosphere by way of the formation of the ion. In any case, the formation of the NO molecule in the thermosphere results in its descent toward the mesophere, where it is subject to the dissociation effect in that region.

Atomic-hydrogen ions. Although the hydrogen atom is photo-ionized by solar radiation, its ionization state is determined primarily by its reaction with atomic oxygen. There is an equilibrium of exchange of charges closely related to the neutral or ionized condition of the atmosphere. This equilibrium is written:

Equilibrium exchange of atomic charge

$$O^+ + H \leftrightharpoons H^+ + O,$$

in which an atomic oxygen ion, O^+, and a neutral atom of hydrogen, H, react to produce a neutral atom of oxygen, O, and a hydrogen ion, H^+, and vice versa. This equilibrium results from the fact that the two atoms have nearly equal ionization energies, and, if the concentrations are great enough, they will pass readily from one state to the other in accordance with the proportions of the two constituents, H and O, present in the neutral

state. But ionization equilibrium conditions between atomic oxygen and hydrogen cannot be maintained at the highest altitudes. The mechanism of exchange of charge depends on the frequency of the collisions of the ions with neutral atoms, whose concentration decreases with increasing altitude. Consequently, when the exchanges are infrequent the phenomenon of diffusion of the ions in the gravity field appears. The hydrogen ion, H^+, which is only $\frac{1}{16}$ as heavy as the oxygen ion, O^+, will have a tendency to distribute itself along a line of force of the magnetic field in accord with its particular weight and to escape reaction with the neutral oxygen atom. As a result, atomic-hydrogen ions become much more numerous than atomic-oxygen ions.

THE EXOSPHERE

When it is stated that the temperature is about 273° K at sea level or at 50 kilometres altitude or that it is about 1,500° K at 500 kilometres, the same physical basis of determination is used, and it is incorrect to suppose that a change of concept is involved. The thermometer currently used in meteorology is not sufficiently sensitive to measure the exact temperature of the air at high altitudes. Even at sea level, many precautions must be taken in order to obtain an exact measurement of the air temperature.

Division of molecular energies

The temperature of gases. The kinetic theory of gases states that the molecules are characterized by very rapid motions, with a distribution of velocities such that a mean velocity corresponding to a specific temperature can be determined. When the collisions are very numerous, there is an equal division of the energy among the various kinds of molecules, which defines a unique temperature. To state that the temperature is of the order of 273°K at a certain altitude means that the kinetic energies of the molecules are identical, because there are enough collisions to assure equal division of the energy. Consequently, perfect thermometers (which could attain equilibrium immediately) would give the same indication. No such thermometers can be made, however, and, accordingly, indirect procedures are used, based on the determination of pressure and on the law of perfect gases.

Reactions between particles. When the heterosphere is analyzed in terms of its physical constitution, in which electrons, ions, and neutral atoms are simultaneously involved, it is necessary to go into the details of various types of reactions and to determine their exact nature. First of all, it must be remembered that the interaction between two electrons is much more marked than that occurring between an ion and an electron. Also, the interaction between an electron and a neutral atom is much weaker than that between an ion and an electron. All these interactions can take various forms, ranging from elastic collisions to exchanges of charge or of energy. It follows that the electrons can have their own temperature when there are so many electrons relative to neutral particles that the interaction between electrons predominates over other interactions. Moreover, when the time required for exchanges of energy in interactions between ions and neutral particles is relatively long, it is possible for the ions and the neutral atoms to be maintained at different temperatures.

Collision frequency and temperature differences

Distribution of energy exchange. The problem of the temperature of a neutral gas, ions, or electrons can be described as follows: a photoelectron ejected, under the action of solar radiation, from a neutral atom of oxygen possesses a certain kinetic energy distinctly greater than that of the electrons already present at the same altitude. In the lower thermosphere (below 120 kilometres), the photoelectron will collide with the relatively numerous neutral molecules, rapidly lose its excess energy to them, and reach the temperature of the neutral gas. In the middle thermosphere (above 150 kilometres), the photoelectron will come into contact primarily with the electrons already present, and its excess energy will serve initially to increase their total energy; the result will be an increase of the temperature of the electrons as a group relative to the temperature of the ions and to that of the neutral atoms. In the upper strata, high-energy photoelectrons will come initially into contact with the other electrons that undergo collisions with the ions. Again, the photoelectrons will cause a rise in the electron temperature and indirectly in that of the ions, but, just as in the neutral atmosphere, it must be taken into account that heat conduction exists within an electronic gas exhibiting a temperature gradient. Consequently, there will be a tendency to isothermy at the highest altitudes by reason of the rapid heat transport. Thus, it is evident how greatly the physical state of the neutral atoms, the ions, and the electrons in the upper atmosphere differs from that created in the laboratory.

Atom velocities at the critical level

The gradation of particle collisions. Beginning at the critical level, temperature loses its ordinary meaning, because the particles follow their free-space trajectory and practically do not undergo collisions. Because of this it must be kept in mind that, although for a given temperature the atoms have the same energy, they do not have the same velocity; the latter depends on their mass. The light atoms move with greater velocities than the heavy ones; for a given energy, hydrogen has double the velocity of helium, which in turn has twice the velocity of atomic oxygen. Consequently, in the exosphere a light atom such as hydrogen can escape from the terrestrial atmosphere because of its velocity, four times that of atomic oxygen, which remains permanently subject to the gravity field.

Assuming that all the elementary physical processes can operate without restriction in the heterosphere, it is then clear that the changes of structure and composition can be explained within the usual framework of a hydrostatic equilibrium. The collisions are always sufficiently numerous to provide a complete distribution of particle velocities as defined in the kinetic theory of gases. This is what is called a Maxwell distribution, leading to a mean kinetic energy of the particles and a clear definition of the temperature. With increasing altitude above the thermopause, however, the mean free path of the atoms gradually increases. Beyond a certain altitude this mean free path is so great that collisions between the atoms are too few to maintain the uniformity of the atmospheric gas. The particles—atoms, ions, electrons—can traverse long distances under the influence only of the field of gravity in the case of the neutral particles, and only of gravity and the magnetic and electric fields in the case of the charged particles.

Thus, the heterosphere, in which the collisions must be taken into account, is separated from the exosphere, where the collisions can be neglected, by a critical zone in which transition occurs from the point, at its base, where the number of collisions is significant to the zone above it, where the number of collisions is negligible.

Determination of the critical zone. The most satisfactory means of determining the critical zone is to search for a level at which the aeronomic conditions can be defined for each element, neutral or ionized. It is possible, for example, to study the mean free path of each element. To specify the probability that, for example, in one out of two instances a particle arriving at a particular level will be able to escape without undergoing a collision is also to specify the mean free path characterizing a critical level corresponding to the base of the exosphere.

Neutral and ionic exosphere differences

Computation shows that, for the neutral atoms, the critical level for temperatures ranging from 750° to 2,000° K is located at altitudes ranging from 400 to 800 kilometres (250 to 500 miles), respectively. In other words, the neutral exosphere, considered as the region in which the collisions between neutral atoms are so infrequent as to permit the escape of atoms whose velocity is sufficient (11 kilometres per second), begins at 400 kilometres with minimum solar activity and can reach 800 kilometres with maximum solar activity. The ionic exosphere begins at an altitude 2,000 or 3,000 kilometres (1,000 or 2,000 miles) higher than that of the neutral exosphere, because collisions between charged particles are always more numerous. The ionic exosphere differs in another respect from the neutral ionosphere: although the gravity field influences the trajectory of the charged particles as it does in the neutral exosphere, the charged particles also are

controlled by the geomagnetic field and by the electrostatic field between heavy ions and electrons.

Particle trajectories in the exosphere. In any case, a given volume of the exosphere can contain a certain number of particles having a priori the following trajectories (see Figure 8): (1) particles coming from the critical level and returning there; (2) particles coming neither from the critical level nor from interplanetary space; (3) particles coming from the critical level and proceeding to interplanetary space or vice versa; (4) particles coming from and returning to interplanetary space. These four groups represent all the possibilities arising from a Maxwell distribution of velocities; it can accordingly be said that at any altitude the density, ρ, of a given element normalized to unity is composed of four densities:

$$\rho = \rho_{I} + \rho_{II} + \rho_{III} + \rho_{IV} = 1.$$

Particles with ballistic trajectories. The first group (see Figure 8) consists of particles with ballistic trajectories: those that leave the critical level at a certain angle with a certain velocity and return to it after having attained their limiting altitudes in the exosphere. The kinetic energy at departure from the critical level is less than that required for escape from terrestrial attraction. This is the case of the neutral particle the trajectory of which is regulated by the gravity field; but a charged particle is constrained to follow the lines of force of the geomagnetic field. A completely closed line of force does not permit the escape of an ion or an electron, whatever its velocity.

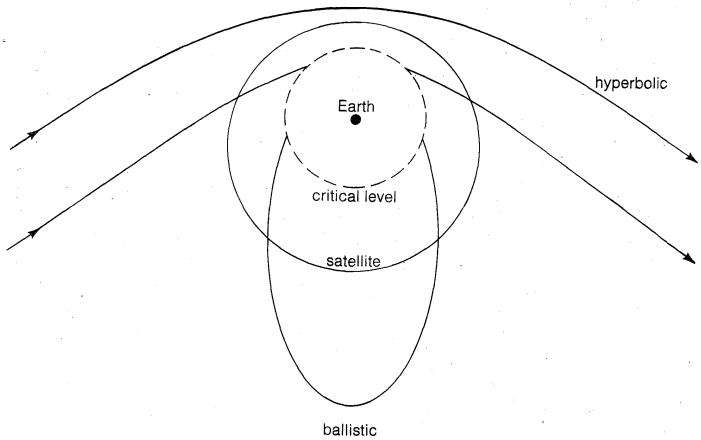

Figure 8: Trajectories of particles in the exosphere. In the vicinity of the critical level, 400 to 800 kilometres above the Earth, ballistic trajectories are most numerous, whereas at much greater distances, hyperbolic trajectories are evident.

Trapped particles. The second group of particles (Figure 8), not making contact with the critical level or with the exterior, corresponds to trapped particles. These are satellite neutral atoms or ions, subject to backward and forward movements along a line of force of the magnetic field. It can be shown that the conditions to be satisfied in order to maintain thermal particles in elliptic orbits are difficult to achieve. In general, the presence of satellite or entrapped particles in the exospheric distribution can be disregarded; the density ρ_{II} of exospheric particles following elliptical orbits in the presence of particles of density ρ_{I} following ballistic orbits is not significant.

Significant and insignificant exosphere constituents

Particles with escape velocities. The third group of particles must be subdivided according to whether they leave the critical level and escape to interplanetary space or arrive at the critical level from interplanetary space. In general, it is not necessary to consider particles with adequate velocities arriving from interplanetary space; the significant component of the third group consists of atoms at the critical level capable of attaining velocities above the escape velocity of 11 kilometres per second. This is the case with the hydrogen atom and sometimes the helium atom when the temperature of the heterosphere is sufficiently high. In the case of the ionic exosphere, escape is possible only where the particles follow open lines of force of the geomagnetic field into free space. In general, the escape of charged particles from the ionic exosphere is neglected, because a line of force of the geomagnetic field joins one hemisphere to the other except near the poles. Only through the channel of the polar cap, where the lines of force of the geomagnetic field are open toward the nocturnal magnetosphere, do charged particles have the possibility of escaping. Indeed, such is found to be the case for ions of hydrogen and helium, which escape easily from the polar ionic exosphere.

Extraterrestrial particles. Finally, it is possible to conceive of particles moving at high velocities that arrive from the exterior of the exosphere and return without touching the critical level. These would comprise the fourth group. Such particles are naturally neglected in the exospheric population, as they never attain sufficient concentration.

To sum up, the population of the neutral or the ionic exosphere is composed almost exclusively of particles coming from the critical level. In fact, the ballistic trajectories represent the practical conditions of vertical distribution for such elements as atomic oxygen. The concentration of neutral helium differs according to whether the temperature is high or low. In the case of neutral hydrogen, the trajectories representing permanent escape of this atom from the terrestrial atmosphere into interplanetary space are significant compared with the ballistic trajectories. As for the ions, it may equally be said that it is the elements that come to the critical level that constitute the population of the ionic exosphere. The oxygen ion, which is too heavy, does not escape, whereas the ions of hydrogen and helium escape into the polar exosphere. Thus, the atmosphere of the Earth, terminating in its neutral or ionic exosphere, is populated at its extreme limits by neutral and ionized atoms of hydrogen.

BIBLIOGRAPHY. During the last 20 years, available information on the atmosphere has been subject to a constant evolution. T.F. STICKLAND (1969), is a series that describes various aspects of the physics of the upper atmosphere after the Year of the Quiet Sun (1964–65).

(M.N.)

Atmosphere, Development of

The development of the Earth's atmosphere is a subject on which there is little direct evidence. Conjecture is limited only by geological consequences attributable to atmospheric evolution and by available theory. Among the important questions to which answers are sought are the origin of the gaseous components, the nature of the initial and early atmosphere, and the kinds of compositional changes that subsequently occurred in response to additions of some gases and losses of others. The answers to such questions must be sought within diverse areas of knowledge, because atmospheric evolution is related to

the general evolution of the planet Earth and, hence, to the development and interactions through time of the Earth's hydrosphere (waters), biosphere (life), and outer shell of rocks.

It would be helpful if a general theory of development of planetary atmospheres was available. The only planetary system known, however, is the solar system, and the question at once arises whether this system is a representative sample of the universe at large. The Sun appears to be a very ordinary star, and it seems likely that many millions of the stars in the visible universe are similar to it. Of still greater importance, it is likely that these visible stars have undergone or are undergoing similar evolutionary development.

If, then, our solar system does not depart drastically in attributes from the mean of all solar systems in the universe, it is probable that the existence, composition, and history of planetary atmospheres are related to the size, distance from parent star (or sun), and subsequent physical, chemical, and biological evolution of the planet concerned. Related variables include the temperature, electromagnetic and particle radiation, and previous history of the central sun; the presence or absence and the strength of a planetary magnetic field that would deflect the solar wind; the relative proportions of the elements; and the volatilities that different gases require to attain escape velocities from a planet of a given mass, size, and temperature. The origin of the chemical elements must also be considered. Their very regular periodic relationships signify that they have been put together from universally similar elementary particles. Hydrogen and helium are the basic building blocks involved in the processes and events usual in the course of stellar evolution. The abundances of the elements are (roughly) inversely proportional to their atomic weights, and the heavier elements are found only in stars that have undergone one or more novations or supernovations (explosions during which the outer shells of stars are blown off). The Earth's Sun, therefore, is a second- or third-generation star; and the Earth's composition of the heavy elements and radioactive isotopes and, thus, its internal differentiation, thermal history, and atmospheric evolution are different than would have been the case otherwise.

Distribution of elements

After the Sun's last novation (or supernovation), a solar nebula or plasma of luminous, incandescently hot, thinly dispersed matter presumably extended beyond the present orbit of Neptune and perhaps as far out as Pluto. If the Sun had simply condensed from such a state, the distribution of angular momentum in the solar system would be very different from what it is, however. Angular momentum is the product of the moment of inertia of a body (the distribution of mass about its rotational axis) and its speed of rotation, or angular velocity. If angular momentum is to be conserved then one of these quantities must increase as the other decreases. The Sun has more than 99.9 percent of the matter in the solar system, but less than 1 percent of the total angular momentum of the system. The great decrease in the moment of inertia was not accompanied by the much higher speed of rotation needed to compensate for this and to conserve angular momentum within the Sun. Instead, as several astronomers have suggested, there was apparently an outward transfer of angular momentum and of matter, in the form of hot ionized gases moving along, but not across, magnetic lines of force, such that the angular momentum of the entire solar system became concentrated in the outer planets, especially in Jupiter.

Planetary atmospheres

Outward transfer of matter was restrained gravitationally, however, so that the lighter components travelled preferentially to greater distances from the central Sun, leaving the heavier ones behind. Thus the planets closest to the Sun have relatively larger fractions of the heavier elements, and those more distant are composed mainly of hydrogen and helium, all of which bears on the question of what manner of atmosphere the Earth had when it first acquired its present mass and before it underwent subsequent evolution.

One approach to this question is to look at the atmospheres of the outer or Jovian planets (Jupiter, Saturn, Uranus, Neptune, and Pluto), which, having far greater mass and gravitational attraction than the terrestrial planets (Mercury, Venus, Earth, and Mars), would accumulate with and retain primitive planetary atmospheres. Such an approach can be taken to imply that the primary terrestrial atmosphere probably contained a lot of methane and ammonia, as well as hydrogen and helium. A difficulty with this method, as implied above, is that the atmospheres of the outer planets may be products of their location within the evolving solar nebula; hence, they would not be representative of initial planetary atmospheres.

A second approach, adopted here, is to seek a model that is consistent with what is known about the present chemistry, probable origin, and evolution of the solid Earth and its life forms. Such a search leads to the concept of a primary Earth without an atmosphere or with a very thin one. The present atmosphere, then, has probably evolved from primary components occluded within the Earth as a consequence of outgassing (emanation of gases from the Earth's interior, principally by volcanism), weathering, irradiation, biological processes, and selective escape and geochemical alternation and removal of components. Hydrogen and helium, however, are the only elements that now escape the Earth's gravity field.

This article treats the evidence sustaining this model of the Earth's original atmosphere and its subsequent development. A section on the effect of man's activities also is included. For relevant information on the evolution of the Earth's hydrosphere, see OCEANS, DEVELOPMENT OF; and for treatment of the development of the Earth and its life forms through time, see PRECAMBRIAN TIME; FOSSIL RECORD; and EARTH, GEOLOGICAL HISTORY OF. See ATMOSPHERE for a detailed account of modern properties and composition.

ORIGINAL ATMOSPHERE OF THE EARTH

Noble gases and theory of planetary origins. A number of investigators have commented on the great deficiencies of the noble gases, such as neon, argon, krypton, and xenon, in the terrestrial atmosphere as compared with their cosmic abundances. These gases are generally inert and relatively heavy. Helium is the only one having sufficiently high volatility and sufficiently low escape velocity (besides hydrogen) to be lost from the terrestrial atmosphere at existing temperatures. This can only mean that the Earth's present atmosphere has evolved from one deficient in the noble gases, either because the Earth's surface generally was exposed to very high temperatures (5,000° to 8,000° K) at some time in the geologic past or because the Earth accumulated without a primary atmosphere. (The Kelvin [K] temperature scale is an absolute Celsius scale; 0° K equals −273.15° C or −459.7° F, which is absolute zero.)

It is difficult to choose between such alternatives on the basis of direct evidence. Because life could not have survived the temperatures needed for the escape of the noble gases, no such thermal episode can have occurred during the continuous record of biological evolution, which began probably 3,200,000,000 years or more ago (3.2 aeons). There is a record of a possible major thermal event of global dimensions perhaps 3.6 aeons ago, however, that could account for such a loss of the primary atmosphere, and the only record so far available of Earth history prior to that time is the lead- and xenon-isotope data that imply birth of the planets from the Sun over a short interval about 4.6 to 4.8 aeons ago.

The nature of the initial atmosphere, if any, can only be deduced from the theory of planetary origins. Assuming that the Earth originated as a result either of the condensation of hot gases or the gravitational aggregation of cold particles, what kind of volatile envelope would it have had at the conclusion of this process? However it began, the final aggregation of the Earth had to be the result of the gravitational aggregation of solid particulate matter. When large enough, such a nucleus would be able to retain, by gravitational attraction, any gaseous components that had not previously radiated

away and whose escape velocities were low enough at temperatures then existing to prevent their loss. The ratios of present planetary masses, compared with their atmospheric compositions, strongly imply that the terrestrial planets are too small for the latter stage to have occurred. The great bulk of volatile gases in the solar system at that time was either within a then retracted solar disk or grouped around the outer, Jovian planets. The atmospheres of the terrestrial planets, including Earth, can have had only a trivial primary component, at most.

Even assuming the condensation of the atmosphere and hydrosphere from a completely molten Earth (a once popular model), without subsequent additions only about 10 percent of the water present as vapour and liquid could be accounted for. This would pose drastic problems of scale in explaining the present quantities and ratios of the atmospheric gases (see ATMOSPHERE).

Juvenile gases

Thus, the most probable explanation is that the Earth's atmosphere and the hydrosphere that condensed from it originally arose from within the Earth and thus most probably consisted of those gases that can reasonably be regarded as "juvenile." A gas is considered to be juvenile if it is found in gaseous inclusions in plutonic rocks (deep-seated crystalline rocks) or if it is a component of lavas or thermal waters. Because waters can recycle a significant fraction of such volcanic gases in the course of the hydrologic cycle, however, more work is needed to determine precisely the kinds and proportions of truly juvenile gases. Gases now thought to be juvenile and thus likely components of primitive atmosphere include, above all, water vapour. There is a difference of opinion as to whether the other main volatile elements were primarily in the form of methane (CH_4) and ammonia (NH_3), subsequently oxidized, with escape of hydrogen (H_2) to carbon monoxide (CO), carbon dioxide (CO_2), and nitrogen (N_2) or whether, in fact, the latter gases are juvenile, along with lesser quantities of H_2, hydrogen chloride (HCl), sulfur (S), Fluorine (F_2), Argon (Ar), helium (He), hydrogen sulfide (H_2S), ammonia (NH_3), and methane (CH_4).

Anoxic state of original atmosphere. There is no juvenile or primary source of gaseous oxygen (O_2) in the Earth, although combined oxygen is the most abundant element in the lithosphere and accounts for over 20 percent of the atmosphere. The free O_2 in Earth's atmosphere, therefore, must have a secondary source. Moreover, because of its striking chemical activity, it should be possible from geochemical evidence to deduce something both about when free O_2 began to accumulate in the terrestrial atmosphere and about prior and subsequent atmospheric evolution.

Whatever may have been the source and nature of the atmosphere before the beginning of the record of Earth history about 3.6 aeons ago, there is ample independent evidence that the atmosphere during the interval from 3.6 to about 1.9 aeons ago was essentially devoid of O_2; that is, it was anoxic, if not reducing (a reducing environment is one in which substances will not be oxidized by loss of electrons—*e.g.*, iron will not rust). This evidence is of four main kinds: (1) Prebiological evolution of the primary organic molecules and the origin of life could not occur in the presence of free O_2. (2) It is difficult to account for the transportation of the iron that formed the banded iron formations (BIF) unique to this part of geologic time except in the ferrous state, which could not persist in the presence of free O_2. (3) Fresh, worn, and rounded grains of pyrite (iron disulfide) and uraninite (a uranium-bearing mineral), obviously transported and shaped by traction in shallow waters, are abundant and widely distributed in some rocks older than about two eons. Such readily oxidizable minerals do not today appear as detrital (particulate) sediments except under local glacial regimes. (4) The fact that sedimentary carbon older than about two aeons is in the form of elemental carbon and kerogen and not ordinarily as carbonate rocks implies a scarcity of free O_2, as does the absence of other oxidized sediments (other than BIF) in the older rocks.

Evidence of the absence of O_2

Inasmuch as such evidence affords almost the only controls on speculation as to the nature of the original atmosphere other than that of a purely theoretical nature, it is worth examining in some detail.

1. Why, for instance, is it said that life and its precursor molecules could not have originated in the presence of free O_2? The evidence is partly experimental. Assuming an evolutionary origin, the large organic molecules of which proteins and the nucleic acids are constructed must exist before they can be assembled into an organism. Experiments utilizing various energizing mechanisms on different atmospheric models consistently fail to produce such molecules when O_2 is present. They do produce them, however, in plausible primitive-atmosphere models where free O_2 is absent and under a variety of temperatures. Ultraviolet (UV) irradiation of an atmosphere of likely juvenile gases characteristically yields hydrogen cyanide (HCN), formaldehyde (HCHO), and sometimes ammonia (NH_3), from which amino acids, polypeptides, sugars, lipids, and nucleotide bases can be synthesized, provided there is no free O_2 to degrade primary components or products. Even if such a mixture could originate in the presence of O_2, it could not survive but would oxidize back to H_2O, CO_2, and N_2 or NO_2 (nitrogen dioxide). And if it could persist long enough for living cells to arise from it, they could not survive in the absence of suitable oxygen-mediating enzymes, which represent a significant biochemical advance over the simple, anaerobic first organisms. The fundamental life processes are reducing processes, and free O_2 generally is lethal to all forms of life. The existence of living things, therefore, is in itself evidence that the original atmosphere was deficient in free O_2.

Banded iron formations

2. The banded iron formations (BIF) have long been a geochemical mystery. Occurrences of these distinctive, rhythmically banded, iron-rich rocks are accepted by all as chemical deposits precipitated from open water bodies as a result of some recurrent equilibration process. But what process will explain simultaneously how the vast quantities of iron involved could have been transported, presumably in the ferrous state, given the presence of free O_2 or, alternatively, how the iron-bearing minerals hematite (Fe_2O_3) and magnetite (Fe_3O_4), which are represented in the oxide facies of the iron formation, could have originated in the absence of free O_2? Some of the hematite, to be sure, is a recognizable alteration product, and it is barely possible that most of the O_2 is secondary; but whether the oxidation be secondary or primary, the presence of contemporaneous atmospheric O_2 would have inhibited the mobilization and transport of the source iron by causing its retention within the weathering profile (or near the source area) in the ferric state. Thus the existence of the BIF and its limitation in geologic time is best explained under a contemporaneous atmosphere without free O_2 but with a limited source of local O_2 that could combine with the ferrous oxide (FeO) in solution to bring about its precipitation (as hematite or magnetite). A biological source for such O_2, involving local anaerobic photosynthesis, with the ferrous ion as an O_2 acceptor, is a possibility to be considered below.

Detrital pyrite grains

3. The occurrence of readily oxidizable minerals as detrital grains in sedimentary rocks older than about two eons but not in younger sediments (except locally in glacially transported deposits) is the third item of concrete geological evidence opposed to appreciable oxygen in the original atmosphere. That such minerals do occur abundantly as detritally rounded grains in conglomerates and sandstones associated with middle pre-Paleozoic (older than 2,000,000,000 years) sequences of the Witwatersrand in South Africa, the Blind River area of Ontario, and other places is now well established. What is not established is whether they necessarily imply absence or scarcity of atmospheric oxygen. On the present surface of the Earth such minerals survive unaltered in detrital form only associated with glacial deposits in high latitude or alpine regions. A similar relation is possible for the pre-Paleozoic occurrences. Their former extent and abundance, compared with their absence from younger occurrences, however, favours a more general

explanation and is most consistent with the evidence cited above as indicative of an anoxic atmosphere for the first half of pre-Paleozoic time.

4. Carbonate rocks older than two aeons are uncommon, sedimentary carbon of this age being mainly in the form of graphite and kerogen. This implies an insufficiency of free O_2 to balance against the ultimate loss occasioned by conversion of CO_2 to CO_3^{2-} (carbonate ion).

There are, of course, uncertainties. In addition to the fact that detrital pyrite and uraninite do, in special circumstances, survive unaltered under the present highly oxidizing atmosphere, there is the painful incompleteness of the pre-Paleozoic stratigraphic record, with opportunity for the loss or nonrecording of intervals equivalent to eras of geological time. The possible range of geological, geochemical, and experimental error in the chronological resolution and correlation of pre-Paleozoic events is also considerable—in many instances as much as 10 percent or more of the total time involved.

A degree of confidence in the conclusion that the original atmosphere was anoxic and that the change to an oxygenous atmosphere began about 1.8 to 2 aeons ago is not provided by the force of any particular line of evidence, but by the convergence of many different lines of evidence toward this same conclusion.

EVOLUTION OF THE PRESENT TERRESTRIAL ATMOSPHERE

An initial atmosphere of any nature is bound to undergo change. Factors involved in atmospheric change include atmospheric growth through addition from juvenile sources and variation in composition as a result of removal of components or change in state due to physical, chemical, and biological processes. Foremost among additive mechanisms is outgassing of volatiles from the Earth's interior, accompanying plutonism and volcanism (including hot springs, and geysers and fumaroles [*q.v.*]). Of lesser effect is the production of helium and argon resulting from nuclear decay of naturally radioactive isotopes and implantation of hydrogen and other gases by the solar wind.

Changes in composition of the atmosphere have resulted from the photodissociation of water vapour, followed by escape of hydrogen from the Earth's gravity field, and from green-plant photosynthesis, followed by sedimentary removal of carbon. Other changes have been brought about by oxidation of formerly reduced gases in the atmosphere, ions in the hydrosphere, and minerals at the surface of the Earth. And still others have resulted from the removal of both oxidized and reduced substances, as well as of N_2 and CO_2 as a result of soil formation and chemical and biogenic rock-forming processes. Such mechanisms are considered below.

Escape of volatiles from the Earth's interior

Additions to the atmosphere. Escape of occluded volatiles from the Earth's interior is the primary mechanism of atmospheric origin and growth. Such escape, of course, cannot take place until the rocks in which the gases were originally sealed are raised to melting temperatures and moved to low-pressure environments at or near the surface of the Earth. Such melting could have occurred during or following the Earth's accumulation, as a result of the conversion of gravitational energy to heat or later in response to the release of energy during the nuclear decay of potassium-40, or still later as a result of tidal forces set up by near approach of the Moon to the Earth. A very early melting event or one that occurred as recently as about 3.6 aeons ago could account for a large initial outgassing that would start the atmosphere and hydrosphere of the Earth at substantial fractions of their present size. William W. Rubey, a U.S. scientist who is one of the leading investigators of atmospheric evolution, has shown that no more than about 10 percent of the water in the hydrosphere can remain in the gaseous state in equilibrium with an initially molten Earth, the rest being contained in solution in the melt. For this and other reasons of geochemical balance elaborated by Rubey, it is necessary to assume that the hydrosphere and, thus, the atmosphere grew to their present size as a result of continuous or recurrent additions over geologic time and, in fact, are still growing.

To obtain a reasonable geochemical balance the atmosphere and hydrosphere must be considered together, as different phases of the Earth's volatile envelope. Rubey showed that, omitting O_2, the volatiles that now make up the Earth's hydrosphere and atmosphere (H_2O, 92.8 percent; C as CO_2, 5.1 percent; Cl_2, 1.7 percent; S, 0.13 percent; N_2, 0.24 percent; H_2, 0.07 percent; and traces of Ar and F_2) are found in crudely similar proportions in lavas, hot springs, fumaroles, and geysers and that current rates of emission, continued over geologic time, are more than sufficient to account for all of the present atmosphere and hydrosphere. It would be a digression here to consider the many subtleties involving recycling of metric waters and gases, chemical reactions with previously deposited rocks, and variations in rate that may be involved.

A second source of addition to the atmosphere, trivial in quantity but important for other reasons, is the production of helium as a by-product of the nuclear decay of uranium and thorium to lead and of argon as a result of the similar decay of potassium-40 to argon-40 (and calcium-40). This suffices to account for most of the roughly 1 percent Ar and 0.0005 percent He in the atmosphere and for the fact that these are relatively more abundant than noble gases of exclusively cosmic source.

Thus, the atmosphere has grown by accretion over geologic time; but its composition has changed concurrently as a result of processes mentioned, and the juvenile gases on the primitive Earth may have appeared in different guise. Much or all of the carbon dioxide, for instance, may have started out as carbon monoxide or even methane; hydrogen may have been more abundant and perhaps mainly in the form of methane and ammonia. The nitrogen also may conceivably have been initially in the form of ammonia. The compositions of the initial gases vary in accord with the chemical processes an investigator visualizes as taking place within the primitive Earth, and how strongly reducing the initial atmosphere is estimated to have been. If it contained large amounts of H_2, for instance, this would react with any CO or CO_2 to produce CH_4 and other C–H compounds (plus H_2O), while N_2 and H_2 would react to form NH_3; if the oceans were relatively alkaline (ph about 8.2) NH_3 would appear there as NH_4^+ (ammonium ion).

Changes in composition. What are the processes that brought about changes in the composition of the atmosphere, including changes in the relative proportion of gases that were not physically split or chemically degraded? The most striking aspect of the Earth's present atmosphere is its highly oxidized state. Excluding essentially inert nitrogen and argon, it consists primarily of oxygen with a little carbon dioxide and water, the latter being the oxidized counterparts of carbon monoxide and hydrogen. Likewise, any primary methane or ammonia has been oxidized to carbon dioxide (CO_2), nitrogen dioxide (NO_2), nitrogen, and water. Above all, therefore, a source of oxygen unknown as a juvenile gas, must be sought to account for this remarkable situation.

Sources of free O_2

Two sources of free O_2 are known, both involving photolytic dissociation—the action of light in splitting the H_2O molecule. A strictly photolytic dissociation of H_2O takes place under the impact of light photons (bundles, or pulses, of electromagnetic radiation) of wavelength less than 2390 Å (one angstrom unit [Å] equals 10^{-8} centimetre) with maximum absorption at around 1650 Å and effective absorption between 1750 and 2030 Å: this dissociation can be expressed

$$H_2O + UV \rightarrow OH + H,$$

in which H_2O is water, UV is the incident ultraviolet radiation and OH and H are the hydroxyl and hydrogen released. Green-plant photosynthesis involves carbon dioxide assimilation under the energy derived from electrons acquired by splitting the water molecule. The removal of carbon and its compounds from the system can then lead to the accumulation of oxygen.

Photolytic dissociation of water vapour in the outer atmosphere, permitting escape of hydrogen atoms from the Earth's gravitational field, has been considered to be

an inadequate source of the Earth's atmospheric and combined O_2, because the process becomes self-limiting when the quantity of photons absorbed by O_2 and O_3 (ozone) exceeds that absorbed by H_2O. It has been stressed, however, that O_2 is a much more important absorber than O_3 and that photochemical limitations cannot rule out the possibility that a substantial number of hydrogen atoms are liberated by photolysis and do survive long enough to avoid recombination to H_2O; thus they would escape the Earth's gravity field. Given a relatively constant volume of atmospheric H_2O during geological time and a roughly constant density of solar radiation, it can be concluded that O_2 derived from photolytic dissociation of H_2O alone (that is, without green-plant photosynthesis) could have reached about one-fourth the present atmospheric level early in Earth history and would have remained above such a level for most of geological time.

This contradicts the conclusion, expressed above, that free O_2 did not appear in appreciable quantities in the Earth's atmosphere prior to about 1.8 to 2 aeons ago. What could explain the discrepancy? The most likely explanation is that removal of O_2 by recombination with atomic hydrogen and by combination with other reduced atmospheric components, solid substances, and ions in solution, equalled or exceeded its rate of photolytic generation through much or all of geological time. In considering this factor, it has been argued that most atmospheric oxidation involves the formation of hematite (Fe_2O_3) from FeO. As Rubey showed in 1951, however, even larger pools of O_2 are tied up with organic matter in sedimentary rocks, in sedimentary sulfates, with the sulfate ion in seawater, and with the carbon dioxide required by the amount of carbonate ion in carbonate rocks. It even has been estimated that the rate of release of juvenile CO alone is more than sufficient to use up all photolytic O_2 during oxidation to CO_2, although this is probably not true. Finally, the rates of escape of hydrogen from the Earth are not really known, and it is unlikely that the solar UV flux was as high during the first aeons after the aggregation of the planets as it is now. In view of all of these difficulties and the fact that Rubey's data strongly imply a geochemical balance between carbon and oxygen, it seems reasonable to believe the evidence in favour of an initial anoxic atmosphere.

Something in addition to photolytic O_2 was evidently needed not only to provide a source for the present, richly oxygenous atmosphere but even to account for the lesser levels of oxygen concentration required to explain the atmospheric oxidation of the oldest recorded terrestrial red beds (ferric-iron containing terrestrial sediments) about 1.8 to 1.9 aeons ago.

Production of O_2 by green-plant photosynthesis is the obvious mechanism but, like the O_2 resulting from UV dissociation of H_2O, it requires sequestering of products that otherwise would be reoxidized to their original states. That is why the suggestion that the reproductive rates of phytoplankton are sufficient to account for all the Earth's oxygen in a very short time, starting from a small population, is not to be taken seriously. Unless carbon is removed in some form (*e.g.*, as reduced carbon or hydrocarbons) photosynthetic O_2 cannot accumulate. And, because O_2 is itself lost as a result of a variety of processes, implied above, sequestering of accessory products must exceed loss of O_2 in order for the latter to accumulate. The counterparts of our heritage of photosynthetic O_2 are to be sought in the graphitic schists, carbonaceous shales, limestones, and coal beds of Phanerozoic and older geological time as well as in the carbon that has been recirculated along the Benioff zones (seismic and volcanic zones associated with drifting continental margins) of the past. Together with O_2 from outer atmosphere photolysis, this was sufficient to outweigh the many reactions that work against the accumulation of oxygen in the atmosphere. Just how the various interacting factors may have functioned to bring about that result is suggested in the accompanying table.

Hypothetical course of atmospheric evolution. When the aggregation of the planets from eddies within the former solar disk was completed about 4.6 to 4.8 aeons ago, the mass of the Earth was too small to retain a surrounding cloud of volatiles of primary cosmic origin. Instead, volatiles occluded within the aggregated rocks, and minerals were thermally released to form the proto-atmosphere as a result of postaggregational core-forming processes and radioactive heating. There are theoretical reasons for concluding that such an atmosphere in its earliest stages may have included substantial quantities of CH_4 and perhaps NH_3, as well as the components now identified as the dominant juvenile gases, but there is as yet no geological record of such an atmosphere.

Oldest sedimentary rocks

The first concrete evidence of a terrestrial atmosphere is provided by the oldest sedimentary rocks, those more than 3.2 aeons old in the Swaziland System of eastern South Africa and northern Swaziland. These rocks, which may be as old as 3.4 or more aeons, could not have originated except in the presence of an atmosphere to produce the needed weathering and erosion of pre-existing rocks and a hydrosphere in which they could acquire their structures, which indicate water transportation and sedimentation. The Swaziland succession of rocks is a fairly normal succession of geosynclinal sediments (those deposited in subsiding trenches), including island-arc types of volcanic rocks in the lower part, terminating above in a coarse nonmarine sequence (but without oxidized sediments), and containing abundant carbonaceous shale and black chert and very little limestone in the middle and lower parts. It implies formation under a hydrologic regime not greatly different from that now prevalent except with regard to the absence of free O_2 and SO_4^{2-}. Had there been much NH_3, given atmospheric and hydrospheric CO_2 no less than now, carbonate ion should have been abundant and limestone common instead of rare among rocks of this age. Had there been enough H_2 to account for much of the carbon in the atmosphere as CH_4, one would expect the nitrogen to have been present as NH_3. The oldest sediments thus suggest a contemporaneous hydrosphere having a pH (measure of acidity–alkalinity) similar to or slightly less than that of the present and an atmosphere composed of likely juvenile gases, primarily H_2O, CO, and CO_2 with lesser N_2 and perhaps small quantities of H_2, CH_4, and NH_3.

Earliest life

From such an atmosphere, energized by UV irradiation in the 2400 to 2900 Å wavelength range, chemical evolution could have brought about the synthesis of large organic molecules, which accumulated and underwent hydrolysis, polymerization, and other changes in the waters beneath, eventually becoming organized into living cells. The record of metamorphic ages in the oldest rocks from several continents combines with the evidence of lead isotopes to suggest that such an atmosphere may have originated (perhaps after loss at high temperatures of an antecedent atmosphere of unknown composition) as a result of outgassing accompanying a global thermal event about 3.6 aeons ago. If that is the case, life probably arose very soon after a substantial atmosphere and hydrosphere had accumulated, because the old sedimentary rocks of the Swaziland System contain what are reasonably (but not conclusively) interpreted as fossil microorganisms, as well as much carbon of probable biological origin.

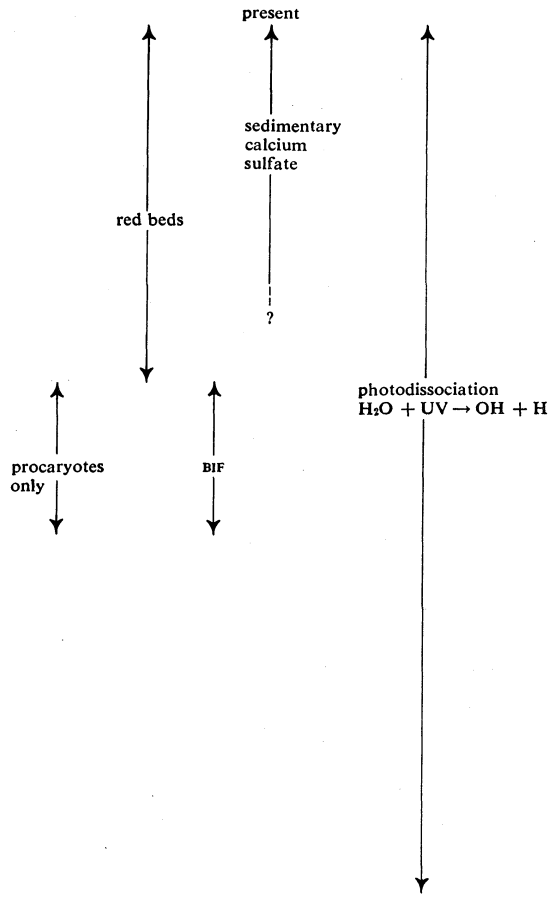
For reasons given earlier, it is not likely that the first cells were able to tolerate free O_2. Because of the biochemically advanced state of the processes involved in creating food from a mineral or gaseous substratum, it is also likely that they were dependent on a pre-existing nutrient source of abiotically evolved organic molecules. For these and other reasons, it is probable that the first cells were anaerobic, heterotrophic, and procaryotic (without nuclear membrane, organelles, or mitotic cell division).

Green-plant photosynthesis

The evolution of oxygen-releasing photosynthesis is probably signalled in the geologic record by the first appearance of BIF (banded iron formations), implying a local source of O_2 in the then generally anoxic hydrosphere. Such a signal is given by the BIF of the Swaziland System and by possibly near-contemporaneous deposits such as the Soudan BIF of northern Minnesota. Although

Content and Progress of Earth's Atmospheric Evolution

approximate years before present × 10^{-9} (not to scale)	
0.02	grasses appear, mammals diversify, atmosphere approaching present composition
0.07	more volcanism, more coal; carbon dioxide then oxygen increases
0.10	mammals, flowering plants, social insects appear
0.23	great volcanism (outgassing of carbon monoxide, carbon dioxide, water)
0.30	great coal formation, elaboration of land plants and insects
0.38	insects appear
0.40	land plants appear
0.64	oxygen reaches 3 percent of present atmospheric level (PAL); metazoa appear; glaciation; oxidative enrichment of banded iron formation (BIF); oxygen increasing; carbon dioxide decreasing; ozone accumulating as ultraviolet radiation shield; eucaryotes appear
1.8–2.0	begin evasion of oxygen from hydrosphere to atmosphere; advanced oxygen-mediating enzymes; biological production of oxygen in hydrosphere (plus photolytic oxygen) in fluctuating balance with ferrous oxide and other oxygen-sequestering systems: $4FeO + O_2 \rightleftarrows 2Fe_2O_3$; start of oxygen generating photosynthesis in hydrosphere in dependence on oxygen sink of ferrous ion
> 3.2	oldest terrestrial sediments; clear evidence of extant hydrosphere and atmosphere; origin of anaerobic, heterotrophic, procaryotic cells; abiogenic evolution of organic molecules under ultraviolet irradiation; major outgassing gives rise to primitive atmosphere of water, carbon monoxide, carbon dioxide, hydrogen, hydrogen chloride, nitrogen, etc; no free oxygen
3.5–3.6	oldest earth rocks; global melting event; moon approaches earth (?); no records available (possible time of core formation and origin of magnetic field)
4.6–4.8	age of meteorites and terrestrial lead; origin of solar system; no records available (possible time of core formation and origin of magnetic field)



it is an open question in biology whether the initiation of green-plant photosynthesis preceded, followed, or was accompanied by the evolution of oxygen-mediating enzymes, it is at least possible that FeO or the simple ferrous ion served as an immediate oxygen acceptor, and that the corresponding reduced biologic compounds were sequestered in other parts of the iron basins, perhaps in areas where the sulfide facies of the BIF were being formed. Some such mechanism could provide the episodic local sources of O_2 needed to account for the precipitation of the oxide facies of the BIF, while simultaneously accounting for its limitation in time and the ability of the first green-plant photosynthesizers to survive until suitable oxygen-mediating enzymes could arise. There is presumptive, although by no means compelling, evidence that photosynthetic procaryotes did exist in association with the oldest BIF and conclusive evidence that blue-green algae similar to modern forms were extant around 1.8 to two aeons ago. Thus the suggested mechanism is consistent with available evidence.

But the reduction of peroxides and of oxygen is universal among aerobic organisms, including modern blue-green algae. And the entry of oxygen-mediating enzymes capable of accomplishing these tasks was an event of such significance in biochemical and atmospheric evolution that it should be recognizable in the sedimentary records.

Oxidation of ferrous iron and appearance of red beds

Once advanced oxygen-mediating enzymes appeared, organisms possessing them would be freed from dependence on local oxygen acceptors such as ferrous iron. The photosynthetic population would then be able to exist independently and, given removal of carbon, would presumably bring about a depletion of iron in solution in the marine hydrosphere, followed by the general evasion of O_2 from hydrosphere to atmosphere. This would lead to a buildup of O_2 in the atmosphere and, consequently, oxidation of ferrous iron at the Earth's surface and its retention in the weathering profile. As a result, ferrous iron would no longer be transported to the sea in quantity in surface waters. No more BIF could form (except locally near volcanic sources of iron). Subsequent iron formation instead would be in local reducing environments (bog iron ores) and as earthy replacement deposits where iron transported in oxygen-depleted groundwaters moved into environments suitable for chemical replacement of calcium carbonates by ferrocarbonates and ferric oxides (minette ores). At the same time, the retention of iron in the weathering profile would lead to the coating of terrestrial detrital grains by ferric oxides and their deposition on land surfaces as red beds, consisting of such grains surrounded by a matrix rich in ferric oxides. Inasmuch as the oldest volumetrically significant red beds and the youngest volumetrically significant BIF both appear to be about 1.8 to two aeons old, it seems likely that this may have been the interval in geologic time during which free O_2 began to accumulate in the atmosphere, perhaps as a consequence of the evolution of the advanced oxygen-mediating enzymes among micro-organisms that were like modern blue-green algae except in their previous lack of such enzymes.

Thereafter there appears to have been a fairly progressive, though, no doubt, fluctuating accumulation of atmospheric O_2, accompanied by residual enrichment of N_2 and presumably by decrease of CO_2 as both it and O_2 were removed to form carbonate rocks and hydrocarbons. The eucaryotic cell, implying an appreciable level

of free O_2, appeared in the geologic record at least 1.2 to 1.4 aeons ago; and there was enough O_2 by the beginning of Phanerozoic time (about 0.68 aeon ago) to account for the massive formation of sedimentary sulfates and a widespread episode of oxidative enrichment of the BIF. A possibly related feature is the widespread glaciation attributed to younger pre-Paleozoic time. Such glaciation, if it proves to be real, could have been triggered by concomitant decrease in heat-retaining CO_2 and could have facilitated the concurrent oxidation of the BIF by bringing about a general lowering of continental water tables.

Attainment of present atmospheric levels of O_2

At the onset of Phanerozoic time, perhaps several percent of the present atmospheric level (PAL) of O_2 was already in existence. This follows from the fact that differentiated multicellular animal life (Metazoa) dependent on relatively high levels of free O_2 was then extant.

For the later records of Phanerozoic history, estimates of approximate O_2 level in the atmosphere may be wrung from such crumbs of evidence as the likely O_2 requirements of advanced life forms, episodes of volcanism, and probably from studies of sulfur isotopes, although it is not completely clear yet what variations in the latter signify. Among other things, they seem to imply little O_2 in the atmosphere before 0.8 aeon ago.

It has been suggested that the onset of terrestrial vegetation in Late Silurian or Early Devonian periods represented the attainment of ten percent of the present atmospheric level of O_2 and that the active Carboniferous insects might indicate something near present levels. Such estimates, bolstered by impressive mathematics, are still merely that; and there are other events that may equally well correlate with similar levels of O_2. The emergence or ascendancy of the social insects and the mammals or the formation of vast coal deposits during Carboniferous and Late Cretaceous periods are examples.

At the same time, great episodes of volcanism such as those of later Permian and Triassic and of Late Cretaceous periods may well have introduced sufficient CO into the atmosphere to lower the quantities of O_2 as a consequence of the oxidation of CO to CO_2. Or there may have been some causal linkage between increased CO and CO_2 from volcanism, enhanced plant growth, coal formation, and eventually increased O_2. The continuity of Metazoan evolution is sufficient proof that the atmosphere from about 0.68 aeon onward was never wholly depleted of O_2, yet there could have been wide excursions in abundance. Such excursions would certainly be reflected in and might be deciphered from the vagaries of biospheric, lithospheric, and chemospheric evolution. Although the possibility of such effects needs study, invoking sulfur and oxygen isotope ratios as indicators, it is too soon to go beyond the suggestion that such investigation offers hope of a more refined atmospheric history than is available at present, including both composition and temperature regime.

By processes such as those outlined above, dim though the details may be, the evolution of the Earth's present atmosphere can be accounted for from the outgassing and subsequent compositional changes of volatiles originally occluded within a waterless and airless primitive Earth. Although confidence in the broad validity of the model outlined is warranted by the fact that many lines of evidence are consistent with it, the model is still only a very rough approximation of reality, having many corollaries that remain to be investigated and many details to be added.

EFFECTS OF MAN'S ACTIVITIES

Nothing remains unchanged for very long, and the Earth's atmosphere also will continue to evolve with time. Volatile gases are constantly being added (though probably in decreasing quantity) by volcanic and hot-spring activity, and they come under the same chemical and biological influences that have acted on such additions from the beginning.

But industrial man has now become an agent of geological magnitude, acting to bring about changes in the composition of the atmosphere that may be to his own detriment. Conspicuous among the processes instituted by man is the burning of fossil fuels for industrial and other purposes, beginning early in the 18th century and attaining a particularly high rate of combustion since about 1938. Such combustion adds a variety of noxious gases such as sulfur dioxide (SO_2), nitrogen dioxide (NO_2), carbon monoxide (CO), and hydrogen chloride (HCl), as well as large quantities of CO_2 and particulate matter that may affect the heat balance of the Earth and the atmospheric ratio of CO_2 and O_2. The processes involved are so complexly interwoven that it is hard to be sure just what is happening other than that the atmosphere is becoming increasingly polluted (see URBAN CLIMATES). A diminution of, if not an end to, such pollution can be foreseen with the expected conversion to nuclear sources as the main energy supply. But there will be trade-offs. Although nuclear waste disposal itself is a manageable item, given sufficient funds and effort, some of the expected benefits of nuclear energy will pose problems of a different sort. Electrolysis of water to produce hydrogen for use as a reductant in extractive metallurgy could lead to oxygen increases that, on a large scale, might be as much of a problem in their own way as carbon dioxide increases. Or continuing or even increasing utilization of biocides to feed expected population increases may kill off enough of the world's phytoplankton to reduce oxygen levels. Without a great deal of new research it is impossible to predict the effects to expect. An examination of atmospheric history, however, clearly shows that there is a high level of interaction among the various threads of atmospheric, biospheric, hydrospheric, and lithospheric evolution. It would be well, therefore, to consider carefully the likely consequences of all actions for the future of the environment, including its atmosphere, lest the balance inadvertently be tipped against mankind.

BIBLIOGRAPHY. L.V. BERKNER and L.C. MARSHALL, "Limitation on Oxygen Concentration in a Primitive Planetary Atmosphere," *J. Atmos. Sci.*, 23:133–143 (1966), discusses factors that affect the concentration of oxygen and ozone in the atmosphere, with suggested correlations between atmospheric and biospheric evolution. P.J. BRANCAZIO and A.G.W. CAMERON (eds.), *The Origin and Evolution of Atmospheres and Oceans* (1964), a collection of papers dealing with the sources and history of volatiles in planets of the solar system, reprints W.W. RUBEY's classic paper on the origin of the Earth's volatiles by exhalation of juvenile gases from its interior. R.T. BRINKMANN, "Dissociation of Water Vapor and Evolution of Oxygen in the Terrestrial Atmosphere," *J. Geophys. Res.*, 74: 5355–68 (1969), challenges previous views holding photolytic dissociation of H_2O to be incapable of accounting for a large part of the free oxygen in the Earth's atmosphere. PRESTON CLOUD, "Pre-Metazoan Evolution and the Origins of the Metazoa," in E.T. DRAKE (ed.), *Evolution and Environment*, pp. 1–72 (1968), summarizes biochemical, geochemical, geological, and paleontological evidence and presents a model of atmospheric and biospheric evolution antecedent to that above. G.P. KUIPER (ed.), *The Earth As a Planet* (1954), is an important collection of facts and ideas about the nature and history of the Earth as it seemed in 1954. G.P. KUIPER, "Origin, Age, and Possible Ultimate Fate of the Earth," in D.R. BATES (ed.), *The Earth and Its Atmosphere*, pp. 12–30 (1958), is a good summary of facts and views about the origin and early atmospheric history of the Earth. W.M. LATIMER, "Astrochemical Problems in the Formation of the Earth," *Science*, 112:101–104 (1950), places thermodynamic limits on permissible conjecture. E.J. OPIK, "The Moon's Surface," *A. Rev. Astr. Astrophys.*, 7:473–526 (1969), discusses Earth–Moon relations and implications of the modern theory of planetary origins for the evolution of the Earth's atmosphere. H.C. UREY, "The Atmospheres of the Planets," *Handb. Phys.*, 52:363–418 (1959), examines the data and theory for the evolution of planetary atmospheres and discusses a self-limiting model for oxygen genesis from photolytic dissociation of water vapour. F.L. WHIPPLE, "The History of the Solar System," *Proc. Natn. Acad. Sci. U.S.A.*, 52:565–594 (1964), shows how the planets may have originated as a result of condensation of the solar nebula with magnetohydrodynamic outward transfer of angular momentum and segregation of planetary matter according to mass and volatility. I.P. WILLIAMS and A.W. CREMIN, "A Survey of Theories Relating to the Origin of the Solar System," *Q. Jl. R. Astr. Soc.*, 9:40–62 (1968), is a critique of theories proposed to date.

(P.C.)

Atmospheric Sciences

Scope and organization

The atmospheric sciences are concerned with understanding the composition, structure, and behaviour of the atmosphere. Their role can be described in terms of the natural phenomena to be understood: development of cumulus clouds, raindrops and ice crystals, middle-latitude storms, hurricanes, tornadoes, clear-air turbulence, fog, fair weather, monsoons, drought, the mechanisms of atmospheric tides, the trade winds, the intertropical convergence zone, changes of climate, formation of smog, dispersion of pollutants, radio "whistlers," the blueness of the sky, ultraviolet shielding, airglow, auroras, ionospheric storms, or the evolution of the atmosphere. This partial list suggests the scope of the atmospheric sciences; they provide understanding of a very wide range of natural phenomena, many of direct, intimate impact on life, some of more subtle significance.

The atmospheric sciences can also be described in terms of their relation to the basic scientific disciplines of physics and chemistry; the categories appropriate to this classification would be fluid dynamics, photochemistry, radiation, electromagnetism, optics, and thermodynamics. They may also be classified according to regions of the atmosphere or in terms of their application to weather modification, weather prediction, space exploration, communications, management of air quality, agriculture, and transportation. The atmospheric sciences are young and rapidly developing, so it is not surprising that they are approached in a variety of ways.

An important distinction exists between the basic disciplines of physics and chemistry and the atmospheric sciences. Physics and chemistry are concerned with understanding the fundamental properties of matter. Consequently, attention is focussed on matter in the small, and controlled laboratory experiments are crucial. The atmospheric sciences utilize the principles of physics and chemistry and are concerned with properties of matter in the large. They are addressed to understanding phenomena that are characteristic of extensive systems, phenomena that for the most part cannot be studied in the laboratory.

This article treats the disciplines of meteorology, climatology, and aeronomy and includes coverage of the study of planetary atmospheres and the applications and technology of the atmospheric sciences. The section on *Meteorology* is addressed to the physical state and the dominant phenomena associated with the portion of the atmosphere that is electrically neutral (that is, not ionized) and for which the molecules are in low energy states. Under *Meteorology* the following topics are discussed:

1. *Radiation:* transfer of energy by electromagnetic waves from the Sun to the Earth, from the Earth's surface to the atmosphere, within the atmosphere, and from the surface and atmosphere to the cosmos.
2. *Thermodynamics:* transfer of energy within the Earth–atmosphere system by the processes of heating, compression and expansion, condensation, evaporation, freezing, and melting.
3. *Cloud physics:* processes that lead to the formation, growth, and precipitation of droplets and ice crystals.
4. *Turbulence:* the unorganized chaotic motions, usually of small scale, that are responsible for transfer of heat, gases, particles, or other atmospheric constituents or properties, and for the dissipation of energy.
5. *Chemistry:* the chemical changes occurring in gases and particulate matter, especially those changes associated with air pollution near the ground and with the composition of the atmosphere up to a height of about 100 kilometres (60 miles).
6. *Analysis:* development of concepts and generalizations from observations, using graphical and statistical techniques primarily.
7. *Dynamics:* mathematical theory of atmospheric structure and flow based on the fundamental principles of physics.

In addition to these subjects, air–sea interaction constitutes an important special combination of dynamics and turbulence, which overlaps meteorology and oceanography. The fields of glaciology and hydrology constitute an analogous overlapping of meteorology and the geological sciences.

The section on *Climatology* is addressed to the study of stable or slowly changing statistical states of the atmosphere—past, present, and future. Under this section are included the classification of climate based on the equations of water balance or energy balance; the history of climate based on geological, botanical, and historical records; and the theory of climate, which explains (quite inexactly and tentatively at present) climate in terms of fundamental principles.

The discipline of *Aeronomy* is concerned with the physical state and dominant processes of the ionized and photodissociated upper atmosphere. The following topics are included:

1. Photochemistry: chemical changes resulting from absorption of electromagnetic radiation above a height of about 80 kilometres.
2. Airglow: processes of the upper atmosphere that give rise to the emission of light during both day and night.
3. Ionospheric physics: structure and behaviour of layers of electrons and positive ions in the upper atmosphere and their effects on the Earth's magnetic field and on radio waves.
4. Magnetosphere: structure and behaviour of the Earth's magnetic field and its interactions with charged particles.
5. Aurora: effects of energetic charged particles in the regions of the geomagnetic poles.

The short section on *Planetary atmospheres* is addressed to an understanding of the composition and structure of the atmosphere of the planets. It treats the observations made by space probes and by Earth-based spectroscopic observations.

The following applications of the atmospheric sciences to the needs of society are discussed in the next section:

1. Prediction of dangerous weather events and other changes in the atmosphere, which is the central objective of the atmospheric sciences.
2. Modification of weather and climate in order to reduce hazards and achieve economic benefits and to anticipate possible irreversible effects on climate.
3. Management of air quality to minimize dangerous effects on man, on the ecological balance of the Earth, and on property.
4. Informational services needed for the safety and economy of air and sea transportation, for public safety on lakes and on sea, for agriculture, lumbering operations, space operations, communications, and for military operations.

Finally, a short section is devoted to the technology of the atmospheric sciences: satellites, computers, instrumentation, and the data collection, transmission, and processing systems that make possible research and operational programs in the atmospheric sciences.

The total body of information associated with the foregoing topics is enormous, and detailed accounts are provided principally in the following related articles: CLIMATE; MICROCLIMATES; URBAN CLIMATES; CLIMATIC CHANGE; WINDS AND STORMS; CYCLONES AND ANTICYCLONES; THUNDERSTORMS; LIGHTNING; HURRICANES AND TYPHOONS; TORNADOES, WHIRLWINDS, AND WATERSPOUTS; MONSOONS; JET STREAMS; AURORAS; VAN ALLEN RADIATION BELTS; IONOSPHERE; ATMOSPHERE; ATMOSPHERE, DEVELOPMENT OF; CLOUDS; PRECIPITATION; SNOW AND SNOWFLAKES; WEATHER FORECASTING; WEATHER MODIFICATION; and WIND ACTION. See also HYDROLOGIC SCIENCES, which parallels this article, treating the nature, scope, and methods of hydrology, oceanography, limnology, and glaciology; EARTH SCIENCES, which treats the historical development of atmospheric sciences, and the interrelations between atmospheric, hydrologic, geologic, and other sciences; and METEOROLOGICAL MEASUREMENT, which covers some instrumentation.

METEOROLOGY

Understanding of the structure and behaviour of the atmosphere may be gained by viewing the Earth and its atmosphere from a satellite that circles the Earth while maintaining itself at a distance of 36,000 kilometres (22,000 miles) above the Equator. Such views have been published frequently in popular magazines and books, and they show that roughly half of the Earth's surface is covered with clouds, organized into a variety of forms on many different scales. Large storm systems thousands of

kilometres in horizontal extent are associated with much smaller cloud elements organized in complex ways; spiral bands, parallel bands, isolated clouds, and other forms. By viewing a sequence of pictures, the motion of the clouds and the airflow can be detected and measured.

Scale of atmospheric motions

A satellite picture showing the horizon just after sunset demonstrates, by the scattering of light from air molecules and dust particles, that the atmosphere is strongly concentrated close to the Earth's surface. Ninety-nine percent of the mass of the atmosphere is confined to a layer 30 kilometres (19 miles) in thickness, and clouds are confined for the most part to the lowest ten kilometres (six miles).

Some of the large-scale features of atmospheric motion are persistent and recurrent; it is possible to identify these features on any series of upper air charts or from any series of satellite pictures. This global scale of motion, or planetary circulation, is characterized in middle and high altitudes by slowly changing wavelike zonal flow from west to east; in low latitudes the flow is weaker and, near the Earth's surface, is directed from east to west.

Atmospheric phenomena occur on a very wide range of time and space scales in addition to the global or planetary scale. Turbulent eddies may be a few metres or less in size, thunderstorms have horizontal dimensions of a few kilometres, fronts may be thousands of kilometres in length and a hundred kilometres in width, an area of urban smog may be tens of kilometres in extent and last for days, drought may cover an area thousands of kilometres in width and may last for months or years. All of these phenomena and others are of scientific interest and practical importance.

The fundamental problem of meteorology is to account for the most important aspects of this range of phenomena in terms of physical principles, mathematically expressed. Here it is possible only to suggest the elements of the discipline of meteorology. Mathematical formulations are not included, and the more sophisticated concepts are beyond the reach of this article. Fuller exposition is provided in the references listed at the end of the article.

Radiation. Electromagnetic radiation emitted by the Sun provides nearly all the energy that, after transformations at the Earth's surface and in the atmosphere, is responsible for the generation of storms and air circulation on all scales. Changes in the intensity of solar energy undoubtedly occur, but they are smaller than the uncertainty of present measurement.

Absorption and reflection of solar radiation

In passing downward through the atmosphere some of the solar energy is absorbed by water vapour in the troposphere. Averaged over the globe, about 18 percent of the solar radiation is absorbed in the atmosphere, and about 35 percent is reflected to space by clouds, the Earth, and the atmosphere. The remaining 47 percent is absorbed at the Earth's surface.

Clouds, water surfaces, and solid Earth surfaces emit electromagnetic energy as infrared radiation, the intensity of which increases with temperature. Of the radiation emitted upward from the Earth's surface under clear skies, roughly 60 to 70 percent is absorbed by the carbon dioxide and water vapour in the troposphere. Thus, energy is trapped by the atmosphere, with the result that the Earth's average surface temperature is about 35° C (63° F) higher than it would be without an atmosphere. Cloud layers enhance this blanketing effect. Radiation absorbed and emitted by the Earth and atmosphere is in near balance when averaged over the whole Earth; otherwise large changes in climate would occur. In the tropics the radiation absorbed exceeds that emitted, whereas at higher latitudes radiation emitted exceeds that absorbed. These differences are balanced by the heat transported poleward by large-scale air and water currents.

The net radiational warming or cooling of the atmosphere can be studied and measured by sensors carried aloft in balloons or from Earth satellites. These measurements are inherently difficult to make accurately. Net radiational warming or cooling can also be calculated from knowledge of the scattering and absorption properties of the constituents of the atmosphere: gases, cloud particles, and aerosols. Research programs are directed at improving the accuracy of measured and calculated atmospheric radiation and at incorporating radiation processes in dynamical models of the atmosphere.

Thermodynamics. The electrically neutral atmosphere consists of a mixture of so-called permanent gases, whose concentrations are essentially constant, as well as several gases whose concentrations are variable, and various solid and liquid particles. The permanent gases are: nitrogen, 78 percent by volume; oxygen, 21 percent; argon, 1 percent; and other gases in much smaller concentrations. Because of turbulence they are mixed uniformly throughout the first 100 kilometres, or 60 miles (of altitude) of the atmosphere. The most important variable gases are: water vapour, 0 to 7 percent; carbon dioxide, 0.01 to 0.17 percent; ozone, 0 to 0.1 percent; sulfur dioxide, 0 to 0.0001 percent; nitrogen dioxide, 0 to 0.00002 percent.

The permanent gases can be treated as ideal gases; that is, an equation of state can express accurately the relation between gas pressure, density, and temperature over the whole range encountered in the atmosphere. The variable gases (especially water vapour) are treated separately.

Study of air and water vapour

For a static atmosphere the pressure (force per unit area) is equal to the weight of a column of air of unit cross-section extending to the top of the atmosphere. Because air is compressible, atmospheric pressure and density decrease with height exponentially, assuming uniform composition and temperature. One consequence is that pressure and density decrease much more rapidly with height near the Earth's surface than higher in the atmosphere. Therefore, the atmosphere extends hundreds of kilometres above the Earth's surface even though a column one square centimetre in cross-section contains only about one kilogram (two pounds) of air.

The first law of thermodynamics may be used to calculate that if a parcel of dry air is lifted adiabatically (without adding to or taking away heat), the temperature must decrease with height at the rate of 9.8° C per kilometre (28.3° F per mile), called the adiabatic lapse rate; that is, air lifted adiabatically cools 9.8° C for every kilometre it is lifted. Descending air warms at the same rate. In a region where temperature decreases with height more rapidly than the adiabatic rate, small vertical displacements will grow and active vertical convection occurs. The air is said to be statically unstable. In a region where temperature decreases with height at less than the adiabatic rate, vertical displacements are suppressed, and the air is said to be statically stable.

Temperature normally decreases with height within the lowest ten to 15 kilometres (six to nine miles) of the atmosphere (the troposphere) as a result of the dominant effect of vertical convection and mixing. Within the overlying stratosphere, as a result of absorption of radiation by the ozone layer, temperature increases gradually with height to a maximum at about 50 kilometres. In the mesosphere, between 50 and 80 kilometres (30 to 50 miles), temperature decreases on the average at about 3° C per kilometre, but over limited intervals of time and height at nearly the adiabatic rate, indicating that vertical mixing and convection are dominant processes. Above 80 kilometres (the thermosphere) temperature increases rapidly with height as a result of absorption of solar radiation by oxygen and nitrogen and possibly other processes. Above 150 kilometres (90 miles) temperatures exceed 1,000° K (absolute zero, −273° C, or −460° F, is taken as the zero point on the Kelvin temperature scale).

Effects of adiabatic cooling

Water vapour condenses and evaporates at atmospheric temperatures, so that water-vapour concentration varies in time and space. As a consequence of the adiabatic cooling that accompanies lifting, clouds normally form at some distance above the Earth's surface. Condensation of cloud droplets releases latent heat, which tends to warm the ascending air, thus creating a saturation–adiabatic lapse rate that is roughly half the adiabatic lapse rate. One consequence of this is that rising saturated air is more buoyant than unsaturated air, a phenomenon

that accounts for the development of cumulus clouds and the characteristic roughness of airplane flight in clouds, a subject of considerable interest and study.

Cloud physics. In order for cloud droplets to form in saturated (or even in supersaturated) air, there must be present solid or liquid particles on which condensation can occur. Natural air contains large numbers of very small particles on which condensation may occur when air is lifted. The resulting small droplets form clouds.

The initial formation of small ice crystals also occurs on minute particles called ice nuclei, which are much fewer in number than condensation nuclei. Ice nuclei are effective at a variety of temperatures depending upon the material of the nucleus. Most natural ice nuclei are effective only at temperatures below −10° C (14° F), so that cloud droplets normally remain in the liquid state at temperatures well below 0° C (32° F). Such supercooled clouds may be changed to ice-crystal clouds if ice crystals fall into them. They may also be converted to ice-crystal clouds by adding effective artificial nuclei. Silver iodide is effective at −5° C (23° F), the highest nucleating temperature of any known material other than ice crystals.

The vapour pressure of a liquid droplet exceeds the vapour pressure of ice at the same temperature. Consequently, in a mixture of ice crystals and liquid droplets, the ice crystals grow by evaporation of the droplets, diffusion of the vapour, and sublimation on the crystal surfaces. The difference in vapour pressure, hence the rate of growth, is greatest at about −12.5° C (9.5° F) where it amounts to 12.5 percent supersaturation. Understanding of the processes of ice nucleation and of the processes by which ice crystals multiply in clouds remains obscure, however. Laboratory and field research is directed at gaining a fuller understanding of the microphysics of clouds and of their interactions with the cloud environment.

Separation of electrical charge is intimately associated with the collision of ice crystals and supercooled droplets and also with collision of droplets; the mechanism or mechanisms have not yet been adequately explained.

When charge separation occurs in convective clouds, positive charges are carried on the small crystals to the upper part of the cloud, while negative charges are carried downward with the falling particles. In this way an active convective cell may generate electrical charge amounting to 1,000 coulombs in 20 minutes or so. A large electrical potential difference may develop between the cloud and ground leading to a lightning stroke, which carries negative charge to the Earth. At the top of the cloud positive charge is conducted upward to the conducting ionosphere. By this mechanism, thunderstorms maintain a potential difference between the Earth and ionosphere of several hundred thousand volts. The resulting normal vertical electrical field amounts to about 100 volts per metre near the ground; the associated electrical current of about 2,000 amperes distributed over the Earth's surface completes the electrical circuit for which the world's thunderstorms provide the generators.

Turbulence. In a fundamental sense the atmosphere is a turbulent fluid; there are few if any simple regularities. There are organized motion systems that can be described and understood in more or less complete detail, however; and there are other highly disorganized motions for which statistical analysis seems to be the only feasible approach to generalization. The latter are referred to as turbulence.

Atmospheric properties—for example, humidity, temperature, momentum, or aerosol concentrations—are transferred by turbulent air motions. Near the Earth's surface vertical flux of humidity and other conservative properties occurs entirely through turbulence. The latent heat supplied to the atmosphere by evaporation at the surface and vertical transfer by turbulence constitutes most of the energy that drives the atmosphere.

Inversions and clear-air turbulence

Above the surface layer, ten metres (30 feet) or so in thickness, vertical flux usually decreases with height. The extent of this flux is often limited by the height of an inversion layer in which temperature increases upward. An inversion often is present at a height of one or two kilometres. Inversions are statically stable in the sense that vertical displacements result in a damped periodic oscillation with periods of several minutes. When the surface layer is strongly heated, vertical convection currents develop that transport heat, water vapour, momentum, smoke, and other properties up into the middle troposphere or even higher.

A second important effect of turbulence is its role in the dissipation of energy. Thus, turbulence is essential both to the process that drives the atmosphere and to the final dissipation of the atmosphere's kinetic energy into heat.

Turbulence and dissipation occur not only near the Earth's surface but also in the atmosphere well above the planetary boundary layer. Turbulence is commonly associated with clouds, for reasons indicated earlier, and also occurs as clear-air turbulence in regions of strong shear (velocity gradients). Such turbulence may be generated by localized absorption of gravity wave energy that may have been introduced some distance away. It is estimated that the energy dissipated in clear-air turbulence is comparable to that dissipated in the boundary layer.

Chemistry. Chemical changes occurring in the atmosphere are often subtle and hard to measure, but they have important consequences. Chemical processes are important in the development of condensation nuclei and ice nuclei, in the changes in atmospheric composition that may influence climate, in the life histories of pollutant gases and particulates, and in their effects on visibility and on humans, animals, plants, and solid materials. Atmospheric aerosols are produced by many processes, in particular: condensation and sublimation of materials of low vapour pressures, reactions between gases of low concentration in the presence of sunlight or water, and dispersal of surface material, sea spray, mineral dust, or smoke. Chemical reaction rates vary with incident shortwave radiation, temperature, and humidity, as well as with concentration and the physical state of particles, so that changes in chemical state are occurring constantly, especially in urban areas. The sources of particles and of gases that form particles include: volcanoes, sea spray, agriculture, burning of fossil fuels, and evaporation of organic materials from forests.

Two processes in aerosol particle distribution

Two physical processes are important in determining the distribution of aerosol particles after they are injected into the atmosphere. Coagulation of particles smaller than 0.01 micron (one micron equals 0.001 millimetre) occurs rapidly as a result of Brownian motion (agitation of particles by molecular collision) so that smaller particles have a short lifetime. Particles of radius greater than 20 microns have an appreciable fall velocity relative to still air, so they are precipitated quickly. Under equilibrium conditions, the number density of aerosol particles is a maximum between 0.01 and 0.1 micron. Particles larger than one micron are most effective as condensation nuclei.

A worldwide layer of large aerosol particles exists in the stratosphere at a height of roughly 20 kilometres (12 miles). Sulfur is a dominant component of these particles, and it is inferred that they are formed by oxidation of sulfur dioxide, which diffuses upward from the Earth's surface.

Particulates are removed from the atmosphere by dry fallout and by attachment to cloud droplets and falling precipitation. Electrical effects undoubtedly play important parts in both processes. Gases are removed by rain and by chemical reactions with particles and with surfaces. Downwind from industrial areas, distinctly acidic rainfall is common.

Dissociation of molecular oxygen (O_2) to monatomic oxygen by absorption of ultraviolet radiation from the Sun has important effects on the composition of the atmosphere above a height of about 20 kilometres. In the region between about 20 and 50 kilometres (12 and 30 miles) the monatomic oxygen reacts with O_2 to form ozone (O_3). The resulting worldwide layer of ozone, although its relative concentration is less than 1/10,000, is sufficient to absorb ultraviolet radiation and thereby

serve as a vital protective shield for life on Earth. The equilibrium concentration of ozone depends strongly on air density, water vapour, and other variable gases, as well as on the intensities of various lines in the solar spectrum. At heights above about 80 kilometres (50 miles) where air density is about 2×10^{-8} gram per cubic centimetre, dissociated oxygen reacts slowly with O_3 and above 110 kilometres (70 miles) nearly all the oxygen is in monatomic form.

Analysis. Observations of atmospheric phenomena result in enormous numbers of data, which vary in three-space dimensions and in time. These data are reduced to tractable order by a number of analytical techniques. Graphical techniques have been important throughout development of the atmospheric sciences. In recent times, statistical techniques and objective numerical techniques have been developed, but the complexity of atmospheric behaviour is such that graphical techniques in the hands of well-trained, capable analysts remain essential aids to understanding and primary research tools.

Graphical techniques as primary research tools

Radiation charts have been devised to determine the net long-wave radiation absorbed or emitted in an atmosphere with arbitrary distribution of water vapour. From adiabatic charts both the thermodynamic energy that might be released in a specific situation and the vertical distribution of static stability can be determined.

In order to represent atmospheric structures and motions graphically, observations are plotted on vertical and horizontal cross-sections. Analysis of these charts requires that the analyst have in mind a generalized concept of the structures and fields under study. The analyst must fit constraints imposed by the dynamic equations and must make the analysis consistent with the sequence of analyses of which it is part. In many cases the objective is to depict a particular scale of phenomenon while filtering out the effects of other scales of motion. Experience, skill, and physical insight are all essential to good analysis. Many special techniques of graphical analysis are useful for determining the distributions of various scalar quantities: mean temperature of a layer, horizontal velocity divergence, vertical component of velocity, vertical component of vorticity, and others.

Objective numerical analysis can be carried out by fitting an arbitrary mathematical function to a particular set of data or by objectively smoothing the observations. These methods are particularly efficient and valuable for use with computers. In research on the structure and behaviour of complex phenomena, however, subjective analysis by an individual is indispensable.

Analysis of time series observations made at a fixed point—or in some instances from a moving ariplane, rocket, or balloon—is used widely in identifying features or phenomena that are heavily obscured by fluctuations of other origins and in determining phase relationships. Spectrum analysis of fluctuating data provides a powerful tool for investigating properties of turbulence. The power spectrum represents the variance or energy of the signal in relation to its frequency; the cospectrum of two time series represents the correlation of the two series with respect to frequency; and the quadrature spectrum determines the phase relation of the two series with respect to frequency. Aspects of greatest interest are the frequencies and magnitudes of the peaks of the spectrums, location of gaps, total "energy" or area under the curve, and the shape of the spectrum.

Dynamics. To understand and predict the structure and behaviour of the atmosphere, the fundamental physical principles of conservation of mass, momentum, and energy are expressed by appropriate mathematical equations. In the most general forms these include the effects of the physical processes discussed earlier in this article: radiation, thermodynamics, cloud physics, turbulence, and chemistry. The equations are partial differential equations in space and time, which are far too complex to be mathematically tractable. Atmospheric dynamics is concerned with development and analysis of mathematical models that are simple enough to be integrated but that contain the essential physics of the phenomena of interest. Thus, there are many kinds of models: of the general global circulation, of hurricanes, of cumulus clouds, of mountain gravity waves, and so on; for each model special simplified equations are developed from which predictions of the model behaviour can be made. Many interesting and useful results may be obtained neglecting turbulence and surface friction.

Mathematical models and atmospheric-waves

Atmospheric disturbances are of several types, which differ in their driving mechanism and in the fluid-mechanical response of the atmosphere. In order to understand these disturbances or the wave forms into which they can be resolved in a dynamical sense and to predict their behaviour, separate simplifications of the general equations are invoked. Upon linearizing the equations—that is, retaining only terms of the first power in the dependent variables—the relation between speed and wavelength, the phase relations, and criteria for instability can be determined for the following major types of atmospheric waves.

1. Acoustic. Waves that are formed by sudden shocks or impulses and travel by virtue of the compressibility of the atmosphere; sound waves are of insignificant meteorological interest and can be simply filtered from the dynamic equations.

2. Gravity. Waves that result from localized vertical displacements in the statically stable atmosphere; short gravity waves are unaffected by rotation of the Earth, but waves of several thousand kilometres length are increased in speed by the Earth's rotation, and their particle motions are inclined toward the horizontal plane. Such waves are referred to as inertia-gravity waves. The energy of gravity waves may propagate vertically as well as horizontally. In this way, gravity waves originating near the Earth's surface may transmit energy into the upper atmosphere. At such heights, where the density is small, the wave amplitudes and associated velocities are correspondingly large. It has been proposed but not yet thoroughly established that absorption of gravity-wave energy in the upper atmosphere constitutes an important source of thermal energy at these heights.

3. Barotropic. Gravity waves can be filtered from the dynamic equations by a mathematical approximation. Then, assuming that the mean air flow is zonal and unchanging with height, the existence of waves that move toward the west relative to the zonal flow can be demonstrated. These waves are manifestations of the conservation of absolute vorticity of vertical columns moving in a barotropic (surfaces of equal density parallel to surfaces of equal pressure) atmosphere.

4. Baroclinic analysis of atmospheric models in which there is a north–south gradient of mean density shows that small amplitude disturbances may be unstable and that greatest instability occurs for wavelengths in the range of 3,000 to 5,000 kilometres (2,000 to 3,000 miles), approximately. Consequently, waves of this length should grow most rapidly and ultimately dominate the global circulation in middle and high latitudes. The process can be understood as transformation of the potential energy associated with the normal meridional gradient of density to kinetic energy of middle-latitude storms. In this process the cold air sinks in flowing from polar to tropical regions, while the warm air rises in flowing from tropical to polar regions; this results in widespread cloudiness and precipitation in the poleward flowing air. These air currents transport most of the energy contributed by the net radiation absorbed by the tropical oceans.

Warm air flow from tropical to polar regions

5. Tropical. Close to the Equator both gravity and barotropic effects must be retained in the linear models. There arise waves of a mixed barotropic–gravity type that are strongly dependent on latitude and tend to be trapped in a region within 20° or so of the Equator. These tropical waves are probably driven by the energy released by condensation in the tropical troposphere.

6. Atmospheric tides. Internal gravity waves of planetary scale may result from the radiational heating and cooling of the atmosphere. Theory predicts semidiurnal and diurnal waves, which correspond closely to the observed atmospheric tides. At heights above about 30 kilometres tidal motions probably dominate the flow.

In the planetary boundary layer, the one- or two-kilometre layer just above the Earth's surface, surface friction and heat transfer by turbulence are important. Interaction of the boundary layer with the free atmosphere leads to reduction of the vorticity of the free atmosphere and dissipation of its energy. Secondary circulations develop within the boundary layer on a scale of several kilometres. These circulation systems may be recognized when they produce long parallel bands of clouds or other organized cloud forms near the top of the planetary boundary layer.

In order to make specific predictions of changes, the model equations (usually nonlinear) must be integrated over finite intervals of time, and this requires numerical methods using electronic computers of very large capacity and speed. Special numerical algorithms are utilized to avoid computational instability. Numerical models of the general circulation duplicate many features of the real atmosphere, and they permit quantitative analysis of the effects of surface influences, condensation, radiation, or other aspects of the model. They have revealed that growing baroclinic disturbances transfer momentum to the zonal current, thus generating the middle-latitude "jet stream" and maintaining it against frictional dissipation. These models contain the essential dynamical elements of a continuously operating general circulation and, therefore, permit an attack on long-range prediction and the theory of climate.

CLIMATOLOGY

Climatic classification. The climate of a region is defined by weather statistics over extended periods, usually 30 years or more. Description of the climate includes statistical analyses of a variety of weather elements: rainfall and snowfall, temperature, humidity, solar radiation, atmospheric radiation, wind velocity, aerosol content, soil heat transfer, evaporation, atmospheric heat transfer, and cloudiness. Among the statistical quantities considered are: annual, monthly, and daily mean values; mean annual and diurnal ranges; and the variances of individual values from the means. For special purposes more complicated statistics are compiled; for example, correlations of wind velocity with temperature or static stability with wind velocity and with aerosol content.

The energy balance and water balance

Climate changes so slowly that balance between incoming and outgoing energy can be assumed for suitable periods. Also, water balance can be assumed for corresponding periods. The two equations representing these balances provide a quantitative basis for classification of climates. The equation relating the incoming and outgoing energy for a portion of the Earth's surface is

$$S(1-a) + R_A + H_A = R_G + H_G + H_E,$$

in which S is incident solar flux, a is albedo of surface, R_A is long-wave radiation from the atmosphere, H_A is heat conduction from the atmosphere, R_G is long-wave radiation emitted by the surface, H_G is heat conduction into the Earth, and H_E is latent heat of evaporation or condensation on the surface. The corresponding equation of water balance, relating precipitation and condensation to losses by evaporation and drainage, is

$$P + C = E + D,$$

in which P is water mass added by precipitation, C is water mass added by condensation, E is water lost by evaporation, and D is water lost by drainage. The individual terms in these two equations vary with latitude, elevation above sea level, soil characteristics, and distance from a large body of water and also vary in relation to major features of the atmospheric and oceanic circulation systems. All these factors affect the climate.

Among the many indices of climate that can be defined on the basis of the water-balance equation are the runoff ratio, $(D-E)/P$; the evaporation ratio, E/P; and the potential evapotranspiration ratio, E_0/E, in which E_0 represents the evaporation that would occur from a wet surface. Some typical values of these indices are shown in the Table.

Climatic Indices

region	$(D-E)/P$	E/P	E_0/E
Tundra	>0.7	<0.3	<1.1
Forest	0.3–0.7	0.3–0.7	1.1–1.43
Steppe	0.1–0.3	0.7–0.9	1.43–2.22
Semidesert	0.03–0.1	0.9–0.97	2.22–3.09
Desert	<0.03	>0.97	>3.09

Source: W.D. Sellers, *Physical Climatology* (1965).

Climate classifications may be based on the energy balance. For example, the Bowen ratio, defined as H_A/H_E, varies from roughly unity over land, on the average, to 0.1 over the oceans and increases strongly with latitude.

Climatic change. The record provided by geologic and paleobotanical evidence proves that climates have changed substantially. For most of the past 500,000,000 years higher temperatures than at present prevailed, at least over the Earth north of 40° N. Major glaciations did occur, however; residual evidence of the most recent ice advance is found in the glaciated regions of Antarctica, Greenland, and high-latitude mountainous areas.

Evidence for the detailed climatic record of the past 10,000 years

For the past 10,000 years the record of climatic change is reasonably detailed, with evidence from such varied sources as lake levels, tree rings, pollen found in peat bogs, and anthropological and historical records. Among the climatic features that have probably influenced recent human history in important ways are the Little Climatic Optimum in northern Europe (1150–1300), the "Little Ice Age" (1500–1700), and recent worldwide warming (1900–50).

During periods of glaciation, global evaporation and precipitation were undoubtedly reduced somewhat from present values, but in regions on the Equator side of the ice sheets, considerably increased precipitation must have occurred as the middle-latitude storm track was shifted nearer the Equator. In this way substantial shifts of forests and deserts must have occurred.

Small sustained change in any one or more of the terms in the water-balance or energy-balance equations might account for change in climate. Among the mechanisms that may be of importance are the following: (1) interactive coupling of the ocean and atmosphere (two fluids with quite different response characteristics), along with the possible roles of glacial and sea ice in such coupling; (2) changes in solar radiation received by the Earth because of astronomical periodicities in the Earth's orbit about the Sun or to astrophysical changes in solar radiation; (3) effects of changed turbidity caused by volcanic eruptions and man-made pollution on the cloud cover and on absorption and scattering properties of the cloudless atmosphere; (4) effects of changed carbon dioxide content of the atmosphere from weathering of rocks, volcanic eruptions, decomposition of organic matter, combustion of fossil fuels, and the storage of carbon compounds in the ocean and in land plants; (5) changes in the albedo (reflectivity) of the Earth's surface accompanying development of agriculture or other changes in land-surface characteristics; and (6) changes in the distribution and elevation of land surfaces associated with continental drift and mountain building and erosion.

In addition to the changes that affect climate through the energy supplied to the atmospheric system, other statistical changes may be inherent in an atmosphere with fixed boundary conditions and fixed energy input. It is not known which of these mechanisms may account for past changes of climate; several or all of them may have operated simultaneously.

Numerical models operating for simulated times of one year to ten or 100 years have duplicated climatological statistics closely. Such results give some confidence that similar experiments in which the energy input or other features of the models were altered to simulate possible realistic processes might lead to an understanding of the mechanisms of climate change. The effect on temperature of doubling the carbon dioxide concentration in a model that considers some but not all the important atmospheric interactions has been computed to

be 2° C (4° F). Coupled ocean–atmosphere dynamical systems are beginning to be studied effectively. Many such experiments using more sophisticated models will be necessary to explain past climate changes with confidence and to predict future changes in climate.

AERONOMY

Prior to the 1960s knowledge of the atmosphere above about 30 kilometres (20 miles) was based largely on inferences from ground-based observations and was fragmentary and uncertain. The advent of Earth satellites and space probes made possible a decade of intensive exploratory research on the environment of the Earth in its relation to the Sun and interplanetary space. Description of this environment is now sufficiently complete and accurate that the mechanisms that control the interactions of the lower and the upper atmosphere and of the atmosphere with the Sun and with interplanetary space can now be examined effectively. To do this requires that electromagnetic forces be included in the fluid dynamical equations and that detailed observations of the state of the upper atmosphere and of its field of motion be made. Using the technique of incoherent scatter of radar waves, it is possible to measure many properties of atmospheric ions and electrons and to infer others in the region from 50 kilometres to 10,000 kilometres (30 to 6,000 miles). Included among the inferred properties are the temperature, density, and velocity of the neutral atmosphere.

In the region of the atmosphere above 50 to 80 kilometres (30 to 50 miles), corresponding to densities of 10^{16} to 10^{14} molecules per cubic centimetre, dissociation and ionization of air molecules by absorption of solar shortwave radiation are dominant physical processes. They are largely responsible for determining the composition of the upper atmosphere, its temperature distribution, and the distribution of charged particles. Interaction of ions and electrons driven by atmospheric tidal motions with the geomagnetic field gives rise to electrical currents in the upper atmosphere. Visible radiation is produced by recombination of ions with electrons and the recombination of neutral atoms. Interaction of ions and electrons streaming outward from the Sun with the Earth's magnetic field creates a boundary between the solar wind and the geomagnetic field at a distance of 14 or more Earth radii and strongly influences the behaviour of charged particles. These are a few of the dominant features of the upper atmosphere which aeronomy seeks to explain. The major subdivisions of aeronomy are those treating photochemistry, airglow, ionospheric physics, the magnetosphere, and the auroras.

The major subdivisions of aeronomy

Photochemistry. The most important photochemical processes in the upper atmosphere are those in which oxygen plays a part. Formation and maintenance of the ozone layer between heights of about 20 and 50 kilometres (ten and 30 miles) has already been discussed. At heights above 110 kilometres (70 miles) virtually all the oxygen is in monatomic form (that is, oxygen is present as O rather than the molecular O_2). In the exosphere, or region from which neutral molecules may escape from the Earth's gravitational field, dissociation of water vapour may provide a source for the hydrogen, which is a major component of this region. Dissociation of nitrogen, nitric oxide, and carbon dioxide are of lesser importance.

In the height range from about 20 to 80 kilometres (ten to 50 miles) dissociation is in approximate balance with recombination; the balance is determined by reaction rates that depend upon intensity of absorbed radiation, the concentrations of components, air density, and temperature. At heights of 100 kilometres (60 miles) or more, dissociated molecules remain dissociated for a day or more and during this long interval may be carried by air movements upward or downward to regions of greatly different photochemical equilibrium. Recombination releases energy in the form of visible light (chemiluminescence) or heat.

Airglow. Visible light is emitted at night in the upper atmosphere by chemiluminescence and by ion–electron recombination reactions. The night glow contributes radiation that is about equal to that from starlight. In the daytime, resonance scattering from sodium, atomic oxygen, nitric oxide, and nitrogen together with chemiluminescence contributes to the airglow. Charged-particle excitation of neutral atoms and molecules also contributes to airglow both day and night. Observations of the airglow have been made from the Earth's surface and also from rockets and satellites. Most of the airglow emanates from the region from 80 to 120 kilometres (50 to 75 miles) above the Earth. Airglow is, of course, difficult to observe during the day.

Ionospheric physics. At wavelengths of 0.1216 micron (Lyman α) or less, absorption of radiation may result in production of an ion–electron pair. The rate of production is proportional to radiation intensity and air density. Radiation intensity decreases at lower levels because of absorption, whereas air density increases downward. Therefore, the rate of ionization is small at very great heights in the atmosphere; it reaches a maximum at a characteristic height and decreases lower down where radiation intensity is low. In this way a layer of maximum concentration of ions or electrons is produced; in fact, separate layers can be produced corresponding to different constituents of the atmosphere. The layers overlap, however, so that there is only one distinct maximum (called the F layer), which occurs at a height of about 300 kilometres (200 miles). Inflections in the concentration curve occur at a height of roughly 150 kilometres or 90 miles (E layer) and 60 to 80 kilometres or 40 to 50 miles (D layer). The processes of photo-ionization and recombination are complex and are different for each of the layers. Ratios of ions or electrons to neutral particles during the day are roughly 10^{-4} for the F layer, 10^{-8} for the E layer, and 10^{-11} for the D layer. The D and E layers virtually disappear at night. The concentration of charged particles is sufficient to make the ionosphere an electrically conducting sphere. Conductivity is strongly influenced by the Earth's magnetic field, however, as well as by air density, ion or electron concentration, and mass of the charged particles. Conductivity consequently is directionally dependent; it is largest in the direction of the Earth's magnetic field and, in the normal directions, depends in complicated ways on frequency of collision, frequency of rotation of charges about magnetic lines of force, and the mobilities of the ions and electrons. Conductivity is largest in the E layer.

Atmospheric tides and electrical conductivity

The periodic motion of the atmospheric tides drives an electrical current in the ionosphere. For the diurnal tide, the total current amounts to about 62,000 amperes, most of it flowing on the sunlit side of the Earth where charge concentration is highest. Calculation of the electrical current for the E layer can be carried out using the equations of electrodynamics with appropriate values for the distribution of the conductivity tensor. The current for the equinoxes for each hemisphere can be visualized as a large vortex centred in middle latitudes with strong current from west to east along the Equator. The induced magnetic field is measurable at the surface of the Earth, providing a means for measuring the current. Current flow in the E layer must induce current flow in the F layer, but details are not known. When solar flares occur, greatly enhanced X-ray radiation results in increased ionization and unusually high concentrations in the D region. Sudden increases in concentration are also produced by meteor trails, which produce metallic ions, and by corpuscular radiation from the Sun.

Electrically conducting media tend to reflect electromagnetic waves. For a vertically directed radio signal, reflection occurs for particle concentration that is proportional to mass of the charged particle. Thus, electrons, by virtue of their small mass, are far more effective in reflecting radio waves than are ions. By varying the radio frequency and timing the transmit time for the reflected signal, the electron density can be scanned up to the height of maximum concentration (F layer). A similar observation made from an Earth-orbiting satellite can scan the electron density down to the F layer. In this way, changes in the ionosphere are observed at many

locations around the world. Above the F layer, concentration of charged particles decreases with height as air density decreases.

Magnetospheric studies. In the vast region far beyond the ionosphere, nearly all particles are electrically charged, and their paths are strongly bound to the geomagnetic field. The equations of electrodynamics require that moving charges spiral around the geomagnetic lines of force, following these lines from the Northern Hemisphere to the Southern as they loop far out into space. In an infinite and empty space the geomagnetic field would be visualized as doughnut-shaped with the Earth at the centre, the strength of the field falling off with the third power of distance. This was, in fact, the concept of the geomagnetic field that prevailed up to the era of space probes and satellites. This simple, symmetrical picture is now known to be changed drastically as a result of the solar wind, the flow of electrons, protons, and other ions outward from the Sun. Under more or less steady conditions, the solar wind flowing at 300 to 700 kilometres (200 to 400 miles) per second interacts with the geomagnetic field. On the side facing the solar wind the field is compressed and a frontal surface develops that is analogous to the bow wave produced by a ship anchored in a flowing stream. Behind this frontal surface is a transition region several Earth radii in thickness in which the solar-wind particles experience increase in energy and in which rapid magnetic fluctuations occur. Inside the transition zone, the boundary of the geomagnetic field, the magnetopause, is reached. The magnetopause forms an appropriate boundary to the atmosphere and an interface between the domains of solar and interplanetary physics and the atmospheric sciences. On the downstream side of the Earth the geomagnetic field is extended like a comet's tail in the solar wind, perhaps as far as 1,000 Earth radii. Thus, the magnetosphere is strongly influenced by the solar wind, and fluctuations in the solar wind produce distortions and pulsations of the geomagnetic field, which in turn affect the motions of charged particles throughout the magnetosphere.

The plasma sheet and magnetic shells of the Earth

Observations show that ions and electrons of a wide range of energies exist in the magnetosphere, but the source of the particles and the mechanism of their acceleration are not fully understood. High-energy particles exist in the plasma sheet, a region extending outward through the centre of the tail of the magnetosphere. In the plasma sheet, ion-pair density is about 0.5 pair per cubic centimetre; electron energy density is about 10^3 electron volts per cubic centimetre; and proton energy density 5×10^3 electron volts per cubic centimetre. Well to the north or south of the plasma sheet, ion-pair density is only about 0.01 pair per cubic centimetre, and energy density is 30 electron volts per cubic centimetre. Under quiet conditions, the plasma sheet extends inward to a distance of about ten Earth radii from the Earth, where it spreads out to join the Earth's magnetic field lines, which finally converge at low elevations in the polar regions. Under disturbed conditions the plasma sheet may extend in as close as five Earth radii.

Within the region extending out to about ten Earth radii, charges are constrained to the lines of force and, therefore, are trapped in the magnetosphere. They are influenced by magnetic effects induced by changes in solar wind and by hydromagnetic and electrostatic waves. Magnetospheric substorms having characteristic periods of about 2½ hours have been observed as gigantic pulsations affecting particles and fields everywhere from the Earth's surface through the magnetosphere far out in the tail. Coupling of the magnetosphere and ionosphere undoubtedly occurs, but the mechanisms are not clear.

The magnetic shells extending outward from the Earth's surface into the magnetosphere act as barriers to particulate radiation from space. The shell that is located at a height of four Earth radii above the geomagnetic equator may be considered as bounding an interior region to which solar particles do not penetrate under undisturbed conditions. Within this region ions and electrons are produced by photo-ionization; outside it they are produced by particulate radiation and by photo-ionization.

Auroral studies. The mechanism of the aurora, the most dramatic and one of the earliest sources of information about upper-atmosphere processes, remains unknown in important respects. Fundamental difficulties exist in understanding how the various auroral phenomena are produced. Present knowledge indicates that auroras are produced when high-energy electrons and protons excite atmospheric atoms and molecules, which then emit characteristic visible radiation. Most of the auroral light is emitted by oxygen and nitrogen. The electrons and protons, constrained by the Earth's magnetic field to spiral around lines of force, are guided down into the denser layers of the atmosphere in the vicinity of the geomagnetic poles. Normally they are reflected back and forth between the hemispheres along lines of force. This process occurs continuously; when the charged particles penetrate in the polar regions to within about 80 to several hundred kilometres above the Earth, sufficient collisions occur to produce visible effects. The normal auroral zone is an oval belt surrounding the geomagnetic poles at an angular radius of about 18°. The magnetic shell at four Earth radii is located at roughly the lower latitude limit of frequent auroral observation, and this also is the region of the often observed stable red arc. Auroras occur at all times of the day, with maximum frequency of occurrence during the first half of the night. This asymmetry of timing probably is related to the asymmetry of the magnetosphere. The plasma sheet provides a channel through which charges can enter the auroral zones, but the required acceleration has not yet been explained. Brilliant displays, which may be visible over large regions, may reflect major distortions of the magnetosphere, or they may result from acceleration of charges by mechanisms that are still obscure.

Occurrence of the auroras producing visible effects

Auroras occur in several forms, descriptively characterized as draperies, arcs, rays, and corona. Perhaps the most spectacular is the appearance of several parallel sheets or draperies extending east to west from horizon to horizon, changing over an interval of minutes in form, intensity, and colour. The draperies are formed of narrow rays parallel to the geomagnetic lines of force, typically visible between 90 and 250 kilometres (60 and 150 miles) above the Earth. In the auroral zone the rays have an angle of 10° to 15° to the vertical.

PLANETARY ATMOSPHERES

Comparison of the atmospheres of the planets of the solar system provides a unique guide to understanding the present state and the evolution of the solar system and of the Earth's atmosphere. Although the Earth's atmosphere is much more accessible to observation, certain atmospheric processes occurring on other planets may be simpler than those occurring on Earth. Direct measurements of the atmospheres of Venus and Mars have been carried out by Soviet space probes of the Venera and Mars series, while the Mariner vehicles launched by the United States have employed remote sensing techniques to obtain similar knowledge of these two planets and Mercury. The Pioneer probes of the United States have transmitted information about the atmosphere of Jupiter. Pioneer 11 revealed a polar icecap on Callisto, one of the satellites of Jupiter, as it passed by in late 1974; its path was expected to carry it close to Saturn in September 1979. Mercury appears to have no atmosphere. Jupiter, Saturn, Uranus, and Neptune have atmospheres of hydrogen, helium, methane, and ammonia, but the atmospheres of those planets are not clearly distinguished from the material of the underlying planets.

Carbon dioxide makes up more than 90 percent of the atmospheres of Mars and Venus; traces of other gases have been detected. Water vapour appears to amount to only about 0.01 percent on Mars and even less on Venus. Pressure of the Venus atmosphere at the surface is about 100 Earth atmospheres, whereas pressure of the Mars atmosphere is only 0.5 percent of that of the Earth atmosphere.

Magnetic fields around Mars and Venus are very weak, so that there are no magnetospheres shielding the planets from the solar wind. Ionospheres formed by ionization

of helium, however, provide shields much closer to the planet's surfaces than is the case on Earth. Each planet exhibits maximum ionization at heights of from 100 to 150 kilometres (60 to 90 miles).

Ultraviolet radiation, which is absorbed in the ozone layer of the Earth's atmosphere, penetrates to the Mars surface; consequently, terrestrial forms of life could not be expected to develop or to survive in that environment. The Venus clouds, which cover the planet at a height of 60 to 70 kilometres (40 to 45 miles), shield the surface from ultraviolet radiation. The composition of those clouds remains uncertain; ice and mercurous chloride have been proposed, but there are difficulties with either hypothesis.

The vertical temperature distributions for Venus and Mars are qualitatively similar to the distribution in the Earth's atmosphere, except that the Earth's warm ozone layer is absent from the atmospheres of Mars and Venus. In each case the thermosphere is evident above about 100 kilometres (60 miles) for Mars and 130 kilometres (80 miles) for Venus. The tropospheres are also evident, but there are no layers corresponding to the Earth's stratosphere or mesosphere.

Radiating temperatures and atmospheric circulation

The effective radiating temperature (based on the Stefan-Boltzmann relationship between emitted radiation and temperature) for Mars is 217° K (the zero point on the Kelvin temperature scale is absolute zero, or − 273° C, − 460° F), for Venus it is 243° K, and for Earth it is 250° K. The corresponding values for Mercury and Jupiter are, respectively, 443° K and 89° K. The diurnal range of surface temperature on the Martian equator is from 300° K in the daytime to 170° K at night, an enormous range in comparison to the diurnal range on Earth. The surface temperature on Venus cannot be determined from measurements of infrared radiation because of the obscuring clouds, but microwave observations indicate a surface temperature in the neighborhood of 700° K, and this is consistent with extrapolation of the Venera observations in the upper troposphere down to the surface.

The atmospheric circulations of Mars and Venus differ markedly because of the fact that Venus rotates only once in 243 days whereas Mars rotates at close to the rotation rate for the Earth. The Mariner 9 observations (1971 and 1972) have provided a wealth of information about the Mars atmosphere. Understanding of the circulation of Mars and Venus, however, is still largely derived from calculations using dynamic models rather than from direct observations; consequently, the following account must remain uncertain until direct observations are available. The dominant motion on Venus is thought to be that of a single cell with rising fluid at the subsolar point and sinking fluid at the antisolar point. This circulation creates the near adiabatic lapse rate in the Venus troposphere, and it provides an efficient mechanism for maintaining a horizontally uniform distribution of temperature. In the upper atmosphere, transport of ions and electrons by the circulation also accounts for the existence of the nighttime ionosphere. Circulation on Mars is much more like that on Earth because of similarities in the rotation rates and in the meridional gradients of solar heating. Because oceans are absent on Mars, the temperature gradients are larger, and the zonal wind velocity and the shear associated with baroclinic disturbances should be larger than on Earth. The large diurnal temperature change should result in an enhanced thermal tide. The extreme relief of the Martian topography must also affect circulation significantly.

APPLICATIONS

Much research effort in the atmospheric sciences is closely linked to applications of immediate importance. Research into the dynamics of storms is directed toward improving the ability to predict these events and thus to avoid damage and loss of life. Research in atmospheric chemistry is motivated by the need to understand and to specify the effectiveness of the atmosphere in dispersing and precipitating air pollution in a safe manner. And research in cloud physics is concerned with understanding processes in clouds so that they might be modified to produce more rainfall or to reduce the severity of storms. These examples illustrate that atmospheric research is often both basic, in the sense that it concerns the fundamental understanding of atmospheric processes, and applied, in the sense that it is directly useful. The distinction is more a reflection of individual interest and motivation than of the scientific nature of the problem or the mode of research.

Predictions and forecasts. The central function of the atmospheric sciences is to predict changes in the atmosphere within useful limits of accuracy. It would be most desirable to predict changes of the full range of scales which include tornadoes, middle latitude storms, droughts, and climate changes. Efforts to predict atmospheric changes, however, are for the most part concerned with forecast periods from about 12 hours to two or three days. The lower limit of 12 hours is a consequence of the fact that turbulence, vertical convection, and other microscale and mesoscale phenomena are strongly nonlinear and their physics so complex that simplifying approximations are invalid. The upper prediction limit is a consequence of lack of data covering large areas of the Earth and failure to represent the physics of atmospheric processes with sufficient accuracy. For periods of 12 hours to two or three days predictions are made routinely using the equations of large-scale atmospheric motions. These equations are transformed to finite-difference form and applied to a three-dimensional space grid. The model in current use by the National Meteorological Center (NMC) of the National Oceanic and Atmospheric Administration (NOAA) in the United States requires that initial values of the dependent variables be specified at grid points for six layers in the free atmosphere between the top of the atmosphere and the top of the boundary layer at a pressure of 950 millibars. An additional surface layer is introduced between 950 and 1,000 millibars (approximate sea level) in which the effects of turbulence are included. The grid is centred at the North Pole and is artificially bounded near the Equator, with the grid points approximately 380 kilometres apart. Other prediction models are in use in Australia, Canada, China, East Germany, France, Italy, Japan, Norway, Sweden, United Kingdom, Soviet Union, West Germany, and other countries.

Three-dimensional prediction grid

The initial data determine the values of all terms in the equations at each grid point, except the local derivatives with respect to time; therefore, changes in the dependent variables for small intervals of time (ten minutes in the current model) can be computed at each grid point. This provides a new set of data that serves to compute a new set of changes. By repeating this procedure, forecasts for the entire globe could be made in principle for as far in the future as desired. In fact, the forecast period is limited by (1) the existence of unavoidable errors in the initial data, (2) errors introduced by the finite-difference representation of continuous functions, and (3) features smaller than the grid intervals that cannot be represented by the model, as well as by lack of global data. These effects grow during the forecast period, and experiment has shown that they become as large as differences between randomly selected states of the system after about two weeks of forecast time. Thus, the limit for deterministic prediction is in the neighbourhood of two weeks; this result provides strong incentive and justification to the nations of the world to obtain complete global data. In response to a resolution of the United Nations General Assembly, the International Council of Scientific Unions and the World Meteorological Organization have undertaken to develop a system of global observations and to carry out a series of experiments to extend the range of forecasting as nearly as practicable to the theoretical limit.

Forecast models have become steadily more complex and more accurate as understanding of atmospheric dynamics has increased and computer speed and capacity has grown. The 36-hour NMC "skill score," which is a rough measure of the error of the wind forecast, has decreased over the past 15 years as each major model im-

provement has been introduced. The skill score for the current 500-millibar model is 30 percent below the skill score achieved prior to introduction of numerical prediction models in 1958. The model in use since 1966 represents, at least crudely, boundary layer and cloud processes; these steps have resulted in extension of routine forecasts since 1966 from 48 to 72 hours.

Decreasing error in wind forecasting

Operational weather forecasts have improved significantly and steadily over the past half century or more. The improvements are attributable to the effects of better basic data, improved communications, and more competent manpower, as well as to development of numerical models. Improvement in forecasts of one type of severe storm, the hurricane, has resulted in greatly reducing the loss of life in the United States from these storms since the early part of the 20th century. At the same time, however, property loss has increased because population and industries have grown along exposed coasts.

Forecasts for specific local areas utilize results of model calculations as a basis and add other considerations that must be treated more subjectively, terrain and surface effects or subgrid scale variability, for example. Roughly half of the variability of surface weather is contained in such subgrid scale features as thunderstorms, fronts, and sea breezes. This variability is superimposed on the variability of the numerical model prediction and therefore results in degrading the model forecasts for specific small areas and time periods. It is difficult to make valid comparisons of specific, local forecasts on a long-time basis. The limited data available indicate small but significant improvement in temperature and precipitation forecasts since numerical prediction has been used operationally.

For time periods longer than about two weeks, the mechanisms that produce changes in weather and climate are not understood well enough to make useful predictions, and, as noted earlier, numerical experiments indicate that the approach through deterministic prediction of specific weather states cannot be successful. There are many hypotheses of the causes of long-term variation of weather and climate, including: (1) some long-term variation in weather must be inherent in an atmosphere with fixed boundary conditions and composition, but how much is not known; (2) the atmosphere and the ocean have greatly different response times; as a result, when they are treated as a coupled fluid mechanical and thermal system, long-term fluctuations may occur; (3) it is plausible that changes in surface reflectivity accompanying the expansion of agriculture or other surface changes may have influenced climate to an important degree; and (4) past or future changes in atmospheric carbon dioxide concentration or in particulate concentration may change the radiation balance of the atmosphere and bring about changes in climate.

Statistics from models of the global atmosphere

After running models of the global atmosphere for simulated periods of several years, climatological statistics can be compiled from the sum of all the individual weather states. Although the separate daily predictions are not accurate, the statistics closely simulate present climate. This conformity gives a degree of confidence in the models and suggests that they might be used to identify the principal causes of climatic change. Experiments using arbitrary changes in carbon dioxide concentration have been conducted; these constitute the first early steps in predicting possible future climate. Other experiments can be carried out to test other hypotheses, but the physical subtleties are very great and the computer requirements severe.

Weather modification. The understanding of atmospheric processes, which is essential for successful prediction, also affords opportunities to modify weather deliberately for useful purposes and may make it possible to anticipate inadvertent, deleterious effects before it is too late to avoid them. Operational programs of weather modification have been carried out, but most of them have been exploratory in character. Weather modification so far has been in large part a research field, but it appears likely to become increasingly important as an applied field. It is pertinent to note also that as technical and scientific problems are solved, the associated public policy problems are looming larger. The most important question is not "Can precipitation be increased?" but "What programs of weather modification are in the public interest?"

Efforts to modify weather deliberately have been directed largely at cloud seeding to increase precipitation, mostly by introducing ice nuclei into supercooled clouds. Many programs have been poorly designed or executed, and only rarely have their effects been adequately observed or reported. Effects, even when observed carefully, are usually well within the natural variability of clouds. It is not surprising, therefore, that the results of cloud seeding have been regarded as controversial and uncertain. Sufficient reliable statistics have been accumulated to indicate that the results of individual cloud-seeding experiments vary depending upon weather situations and mode of seeding. Randomized experiments indicate that in some situations increases of precipitation of 10 to 30 percent have been achieved, whereas, in other situations, corresponding decreases have occurred. There is only limited understanding of the factors that distinguish positive from negative effects.

Role of latent heat in cloud seeding

The latent heat released when large numbers of ice crystals are formed and grow in a supercooled cloud may result in enhancing the updraft in a cumulus cloud. This may increase the height of the cloud, increase the total moist air flowing into the cloud, and therefore increase precipitation considerably. Numerical models have been developed to predict cloud growth and to aid in design of field experiments. In a series of experiments in Florida, it was found that three times as much rain fell to the ground from seeded single clouds as from unseeded clouds.

The dynamic effects of the release of latent heat by adding ice nuclei to supercooled clouds may also be useful in modifying the pressure field and in reducing the wind speed in hurricanes. This possibility has been examined by model calculations, indicating that significant results might result from seeding. A field test of Hurricane Debbie in August 1969 was followed by reductions of 15 to 30 percent in maximum wind speeds after silver-iodide seeding. This result suggests that it may be possible to reduce the damage inflicted by hurricanes and possibly to influence the path they follow, but further investigations are needed to establish this possibility and to determine how best to achieve the desired results.

Other examples of deliberate weather modification include hail suppression, which is carried on operationally at one site in the Soviet Union, and cold fog dissipation, which is an operational practice at several United States airports.

Inadvertent effects on weather and climate may in the long run be more important than deliberate effects. Research effort is just beginning to be directed toward long-range problems. Climate simulation models, which include a few of the interactive effects of the atmosphere and the underlying Earth and ocean, have indicated that the expected increase of 18 percent in atmospheric carbon dioxide concentration by the year 2000 might result in a surface temperature increase of ½ ° C. Because this is comparable to the natural variability of temperature over a period of 30 years, it appears that the climatic effects of increased carbon dioxide are not likely to be critical in the next few decades, but that over longer periods they may become very important.

Another example of a potentially important inadvertent effect is provided by major sources of air pollution. The acidity of rainfall in western Europe has increased markedly in recent decades because of the rising volume of effluents from industrial regions, largely sulfur dioxide. Adverse effects on the forests of Sweden have already been reported; and, as industrialization proceeds in many areas of the world, this example must be expected to be multiplied many times over.

Air pollution

Management of air quality. The problems posed by air pollution, already serious, are likely to become more so in the future; they can be managed only by the joint

efforts of chemists, biologists, engineers, medical doctors, and atmospheric scientists. The work of these professionals must be carried on within constraints of law, economics, traditional practice, and public acceptability. About 98 percent of world energy is produced by combustion of fossil fuels: coal, petroleum, and natural gas. Nuclear and hydroelectric sources account for only 2 percent of energy production. This ratio will remain the same until after 1980, even though world energy production is expected to nearly double by that time. Most of the waste products are injected into the atmosphere for ultimate disposal, and no alternative to this mode is feasible in the foreseeable future. In addition to the products of fossil fuels, radioactive gases and particles also may be introduced into the atmosphere. There are also natural pollutants that are of concern: aeroallergens, spores, fungi, agricultural and desert dust, and volcanic materials.

The specific fate of pollutants and their effects on man, animals, plants, and materials are strongly dependent on atmospheric processes; consequently, management of air quality must be based on the ability to predict the state of the atmosphere. The atmospheric scientist's responsibility, therefore, is to specify the capacity of the atmosphere to store, disperse, modify, and deposit pollutant materials.

Materials are emitted into the atmosphere as particles of various sizes and as gases. Particle size and chemical composition at the source can be controlled technologically to a limited extent, but the mass of effluent usually cannot be modified. Once the particulates and gases have been emitted into the atmosphere, they are transported horizontally by wind and mixed vertically by turbulence; chemical and photochemical changes occur; new particles are formed from gaseous pollutants; and rain or snow may wash out some of the particles and gases. These processes are seldom known in detail. The common pollutants sulfur dioxide and carbon monoxide evidently are transformed chemically within the atmosphere, but their histories are not understood, and efforts to identify how they are removed from the atmosphere have so far been unsuccessful. Understanding of the effects of solar radiation, humidity, and turbulent mixing in the chemical reactions that lead to urban smog are in a primitive state. So research on the chemistry of air pollution under various natural conditions is needed to make possible accurate specification of pollutant concentrations under the range of conditions for which they are needed.

The complexity of the problem requires the use of numerical models; the needed computers must be capable of storing large numbers of data and making many intricate calculations quickly. Beginnings have been made in constructing models that predict concentrations in certain urban areas, but they do not incorporate chemical changes or other sophisticated aspects of turbulence, cloud physics, radiation, and atmospheric dynamics.

In the United States urban pollution monitoring systems constitute an important part of the Air Pollution Control Meteorological Service under the Environmental Protection Agency. Together with data from the Basic Meteorological Service of the National Oceanic and Atmospheric Administration (NOAA) and, in some cases, from state agencies, these stations provide the data that determine safe limits for emission of air pollution by industry, homes, or motor vehicles. Dangerous levels of air pollution are especially likely to be encountered in valleys or in bowl-shaped topographic regions under conditions of low wind speed and strong surface temperature inversions. In such areas, where pollution is confined to the surface layer below the inversion, if emission continues, pollution concentrations may rise to lethal levels.

Information services. Atmospheric data serve a variety of additional specific uses. Sometimes the data alone are provided, or, in other cases, interpretation also is provided. In most of the developed countries, such services are available from governmental agencies or from private professionals employed for their specialized services; organizational details are unique to each country.

Specialized weather reports

Continuous, comprehensive weather information and forecasts are essential to airlines, private pilots, and terminal operators to ensure safe flying and to maintain schedules. This information is provided in the United States by the Aviation Meteorological Service of NOAA. Coastal and open-ocean shipping and small boat operators rely on weather reports and storm warnings issued by the Marine Meteorological Service. Specialized storm surge and tsunami (seismically generated sea waves) warnings are issued to the public in vulnerable low-lying coastal areas.

Decisions on what species of crops to plant and of when and where to plant are contingent on climatological information which is provided by the Agriculture Meteorological Service. The National Climate Center provides data useful for planning in many fields in addition to agriculture: architecture, highway construction and maintenance, truck operations, food distribution, and many others.

Radio communication over long distances on Earth is made possible by reflection of the radio signals from the underside of the ionosphere. Ionosphere monitoring stations are operated by many nations, and exchange of information occurs through World Data Centers in the United States, Soviet Union, and other countries. Scientific groups under the International Council of Scientific Unions (ICSU) sponsor joint research programs concerned with the ionosphere. In the United States ionospheric information is provided by the Aeronomy and Space Data Center of NOAA in order to make possible efficient, reliable radio communication. Safety in space operations depends on reliable radio communication and also in avoiding highly dangerous electromagnetic and particulate radiation, which may accompany solar flares or other eruptions on the surface of the Sun. These necessary data are provided by the Space Operations Meteorological Service. The Committee on Space Research of ICSU maintains an international roster of objects launched into space.

TECHNOLOGY OF THE ATMOSPHERIC SCIENCES

The atmospheric sciences are heavily dependent on sophisticated technology. Most of the scientific advances of the past three decades are directly related to developments in technology, and many of the critical problems facing atmospheric scientists will require further technological advances. Satellites have made possible for the first time observation of the entire Earth. The first experimental meteorological satellite was launched in 1960; it was capable of taking pictures of limited areas of clouds with low resolution. Present-day satellites provide far more data of better quality and greater usefulness. Stationary satellites situated above the Equator provide color pictures of cloud distribution at time intervals of 20 minutes each covering a circular area 5,500 kilometres (3,400 miles) in radius. Polar orbiting satellites scan the entire Earth each day, providing daytime and nighttime cloud images with high resolution. Even more important, infrared and microwave spectrometers flown on satellites can provide the vertical distributions of temperature and humidity for the entire globe.

Satellites and remote sensing

The vertical distributions of density and electrical charge can be measured by optical and radio occultation measurements. Other satellite instrumentation measures the incident and reflected solar and terrestrial radiation, the characteristics of the ionosphere, the airglow, the geomagnetic field, flux of ions and electrons, and other properties. Related instrumentation on space probes is used to observe planetary atmospheres and interplanetary space.

Other remote-sensing instruments have been developed for use on aircraft and on the ground. A review of remote-sensing technology for atmospheric measurements was published in 1969 by the National Academy of Sciences, Washington, D.C. Doppler radar is useful in examining the turbulent motions occurring in precipitation clouds. In clear air, small-scale temperature and humidity structure can be detected and tracked using highly sensitive microwave radar. With optical radar (lidar) equip-

ment the distribution of water vapour and aerosol can be measured; and acoustic echo-sounding may be applied to remote measurement of wind and turbulence by using natural small-scale temperature fluctuations as tracers. Spectrophotometric techniques can probably be used to detect and measure air pollution. Upper-atmosphere properties are measured by a variety of ground-based remote-sensing instruments; for example, radio waves are used to measure ionospheric properties and magnetospheric temperatures, and, by employing a correlation technique, wind velocity and turbulence in specified remote volumes can be measured. With incoherent scatter radar many properties of electrons, ions, and electrically neutral gas in the ionosphere and magnetosphere can be directly determined.

The great numbers of data provided by modern technology could not be put to profitable use if it were not for the development of high-speed, high-capacity computers. They are essential for processing raw data transmitted from satellite sensors, for organizing and analyzing data, and for carrying out numerical predictions. For operational use the computer time used in making a prediction must be considerably less than the forecast interval; this requirement limits the physical complexity of the operational models in current use. More sophisticated operational and research models require computers of the highest capacity and speed contemplated at this time.

Atmospheric data is exchanged internationally through the Global Telecommunications System, which utilizes satellite communications, radio, and land lines. World centres in Washington, Moscow, and Melbourne collect and store world data and provide two-way access to Regional Telecommunication Hubs in Tokyo, Brasília, Bracknell (London), Paris, Offenbach (Frankfurt am Main), Prague, Cairo, Nairobi, and New Delhi. The United States Automatic Picture Transmission (APT) satellites provide direct readout of cloud images to surface receiving stations all over the world. The World Meteorological Organization with headquarters in Geneva, Switzerland, provides an effective channel for exchange of data and multigovernmental agreements on matters concerning the atmosphere.

BIBLIOGRAPHY. General references on the varied topics that comprise the atmospheric sciences include the following works: M.I. Atomic Structure

The atom is defined as the smallest unit of a chemical element that retains its elemental identity. It consists, according to present knowledge, of a tiny but massive central core, called the nucleus, surrounded by a number of electrons. The arrangement and behaviour of these electrons determine the interaction of the atoms with one another and thus govern not only chemical processes but also most of the physical properties of bulk matter. Such arrangement and behaviour are what is meant by atomic structure, and they form the subject of this article.

The article follows this outline:

GENERAL CONSIDERATIONS

Nature of the atom. There exist a limited number of substances of a special class, called elements, that cannot be reduced or separated into chemically different components. A few examples would include the metals iron, aluminum, copper, and uranium; the gases oxygen, nitrogen, helium, and hydrogen; and the nonmetallic solids carbon, silicon, and sulfur. When elements are chemically bound together, they form compounds. Water, ammonia, and quartz are compounds of the elements; steel, brass, whiskey, and air are mixtures of elements and compounds. About 90 different elements occur in nature, and about 20 more have been produced artificially. The ultimate particles of these elements are the atoms, and thus there are as many basic kinds of atoms as there are elements.

Atoms are not indivisible but have a structure consisting of two kinds of particles, one with a positive electrical charge and the other with a negative. Some of the negatively charged particles are loosely bound in the atom and are easy to dislodge. Heating a wire, for example, releases negative particles. Regardless of what substance they come from or how they are set free, all are identical and have been given the name electrons.

An atom (and thus all matter) is mostly empty space. At the centre is a positively charged core, the nucleus,

which accounts for 99.95 percent of the mass of the atom, although it occupies only about 10^{-15} of the volume. The electrons are scattered through the remaining volume.

Atomic magnitudes. Because a molecule is a close association of atoms, the size of a molecule containing only a few atoms is not very much greater than that of an individual atom. The determination of molecular sizes is a useful step toward finding the sizes of individual atoms, and historically this was the way the problem was approached. The first quantitative estimates were obtained by the English scientist Thomas Young in the early 19th century and presented by him in the *Encyclopædia Britannica Supplement* of 1816. Young based his conclusions on a study of surface tension and tensile strength of liquids. Although his conception of the relation between these two effects was substantially correct, his ignorance of the intimate structure of liquids and vapours led him to false conclusions. The first truly significant values of molecular size came from the study of the diffusion, or mixing, of gases.

Early estimates of atomic size

One of the simplest and most direct deductions from the kinetic theory was that the molecules of gases must have high speeds, 1,000 feet per second more or less. Seemingly opposing this deduction, however, was the fact that if a flask of, say, gaseous carbon dioxide is opened to the air, no great amount of mixing of the two gases occurs over a period of hours. These results could be reconciled by ascribing to the molecules a diameter of such a size that any one molecule (at least in gas at normal atmospheric pressure) would travel only a very small distance before undergoing a collision with another molecule. In this way the movement or diffusion of the gas as a whole in a particular direction would be greatly discouraged. From the diffusive properties it is possible to estimate the average distance between successive molecular collisions. But this quantity, called the mean free path and denoted by the Greek letter λ, is determined from kinetic theory by the molecular diameter (d) and the number of molecules in a unit volume (n) according to the formula $\lambda = 1/(\sqrt{2}\pi nd^2)$. If, now, a volume V of gas or vapour, containing Vn molecules, condenses into liquid form so that the molecules are assumed to be densely packed, the volume v of condensed material cannot be less than $\pi Vnd^3/6$, because $\pi d^3/6$ is the volume of a spherical molecule of diameter d. A more realistic estimate would take simply Vnd^3, because the packing of equal spheres does not fill space completely. Multiplying v and λ together gives $v\lambda = Vd/\sqrt{2}\pi$, or $d = \sqrt{2}\pi\lambda(v/V)$. Experimental results show that for many gases v is equal to $0.005V$ approximately (*i.e.*, a given volume V of a gas at atmospheric pressure condenses to about $0.005V$ when converted to the liquid form of the substance) and that $\lambda = 2 \times 10^{-6}$ centimetre approximately. This would mean that the diameter, d, of a molecule is roughly equal to 5×10^{-8} centimetre.

Because of its extraordinary simplicity, a method of estimating molecular dimensions, developed in 1890 by physicists W.C. Röntgen of Germany and Lord Rayleigh of Great Britain, deserves mention. It consists of depositing a tiny drop of oil on a water surface; the assumption is that the oil can spread until it forms a layer only one molecule thick. The limits of the oil patch can be seen by first sprinkling the water surface with a fine powder, such as chalk dust or lycopodium powder. If the volume of the oil drop is V and the area of the resulting patch (*i.e.*, the film thickness) is A, then the molecular dimension is volume divided by the area, V/A.

Other methods give much the same results. Clearly, a convenient unit to use for lengths on the atomic scale is 10^{-8} centimetre—called the angstrom and abbreviated Å. It is a rather remarkable fact that all atoms have about the same diameter, roughly one angstrom.

Atomic Numbers (Z), Atomic Mass Numbers (A), and Masses (Atomic Weights) of Some Elements

	Z	A	mass		Z	A	mass
Neutron	0	1	1.00866522(6)	Tin	50	112	111.904834(8)
Hydrogen	1	1	1.00782522(4)			114	113.902776(7)
		2	2.01410222(7)			115	114.903353(7)
		3	3.01604972(16)			116	115.9017483(34)
Carbon	6	12	12.00000000			117	116.9029606(21)
		13	13.00335508(23)			118	117.9016126(21)
		14	14.00324202(30)			119	118.9033159(21)
Oxygen	8	16	15.99491502(20)			120	119.9022073(22)
		17	16.9991333(10)			122	121.9034511(33)
		18	17.9915996(29)			124	123.905283(4)

		58	57.9332745(27)			238	238.050816(11)
				Nobelium	102	257	257.096885(34)

The relative weights of different kinds of atoms, which lead to the concept of atomic weights, can be determined easily, provided chemical formulas are known. Thus, water has the formula H_2O, which means that two atoms of hydrogen (H) combine with one atom of oxygen (O) to form a molecule of water. When the water is decomposed, as by electrolysis (the passage of an electric current through an electrolyte, in this case water), the weight of the oxygen obtained is eight times that of the hydrogen. This difference means, there being twice as many atoms of hydrogen as of oxygen, that an atom of oxygen weighs 16 times as much as an atom of hydrogen. Similar observations for other compounds give the relative masses of most of the elements. (In addition, the requirement that all these experiments give self-consistent results provides a check on the assumed formulas.) It is then only necessary to choose one kind of atom as a standard. The choice currently accepted as standard by physicists is that of the most abundant isotope (atoms of an element having different mass are isotopes) of carbon, which is taken to have a mass value of exactly 12; some typical masses on this scale are given in the Table (see also ISOTOPES; ATOMIC WEIGHT).

Atomic weights

The quantity of an element having a mass in grams equal to its atomic weight is called a gram atom. The number of atoms in a gram atom is the same for all elements and is called Avogadro's number. This number can be determined in several ways and has the value 6.025×10^{23} per gram atom. With this number, it is possible to calculate the mass represented by one unit on the scale described above; it turns out to be 1.6604×10^{-24} gram. This figure is also, it will be noted, approximately the mass of a hydrogen atom; the heaviest atom yet produced, early in the 1970s, has a mass of 4.2×10^{-22} gram, still an unimaginably small number. The mass of the electron can be determined from the nature of its response to electric and magnetic forces and has a value a little more than 1/2,000 of the mass of the hydrogen atom; its precise value is 9.106×10^{-28} gram.

The electron's charge

The electric charge on an electron has been measured directly and can also be deduced, along with other constants, from several kinds of experiments. Its value is 1.6×10^{-19} coulomb. This value means that in a current of one ampere—roughly what a 100-watt light bulb uses in the ordinary 110-volt household circuit—about 6×10^{18} electrons pass through the wire every second. It turns out that the charge (e) carried by an electron is a natural unit of electric charge in atomic and nuclear physics. Every particle yet discovered, if it has a charge different from zero, has a charge that is a whole multiple of this unit, although sometimes positive rather than negative. (A class of subatomic particles called quarks, with charges $+\frac{2}{3}e$ and $-\frac{1}{3}e$, has been proposed on a theoretical basis, but their existence is still doubtful.) In these units the charge on the nucleus of an atom is equal to the atomic number, a number indicating the position of the element in the periodic table. Because the normal atom is electrically neutral, this positive charge must be just balanced by the negative charges of the electrons, so that the number of electrons in the normal atom is also given by the atomic number of the element. (If one or more electrons are added to or removed from the system, it acquires a net electric charge and is called an ion. Its elemental identity does not change, however.)

Energy is as important in the atomic realm as it is in everyday life. On the human scale, energy is often measured in kilowatt-hours. A kilowatt-hour is the energy consumed by a 100-watt light bulb in ten hours. It is also

the energy needed to lift a standard automobile, with a mass of about 1,500 kilograms (3,307 pounds), to a vertical height of about 200 metres—100 feet higher than 555-foot-high Washington Monument. On the atomic scale, energies are more conveniently expressed in electron volts. There are 2.26×10^{25} electron volts in one kilowatt-hour. To remove an electron from an atom requires an energy of the order of a few electron volts, the exact value depending on which atom is being dealt with. This value is also the typical amount of energy required or released in chemical reactions such as burning. Thus, because a gram of an element contains about 10^{23} atoms, the burning of that gram of matter yields roughly 10^{23} electron volts of energy, or roughly 1/200 of a kilowatt-hour.

Atomic structure and interactions. Because the atom is so much smaller than anything familiar to ordinary experience, it is not too surprising that physics on the atomic scale is different from the physics derived from experiments with larger objects. In the latter case, the laws of physics are an approximation that is more than adequate for objects on the everyday scale but that fails when atomic dimensions are involved; not only the laws of classical physics, however, but also some daily-life concepts are no longer valid on the atomic scale. This failure of classical physics has a peculiar consequence: if all the properties of atoms and their components as deduced from modern experimental investigations are considered, it is not possible to combine them into a pictorial representation of the atom. Nevertheless, pictures supposedly representing atoms are often seen. Probably the most familiar is one representing the atom as a sort of planetary system, with the nucleus at the centre and paths representing orbits of the surrounding electrons, as in the upper part of Figure 1. Another shows the electrons not in orbits but "smeared out" as clouds of various regular shapes that surround and hide the nucleus, as shown in the lower part of Figure 1. In fact, however, each of these pictures is only an approximation, even a caricature, because each picture overemphasizes some characteristics of the atom while suppressing others. The planetary picture stresses the properties of a single, isolated atom, especially its electrical and magnetic properties, but gives practically no clue to its interaction with other atoms. The cloud picture, on the other hand, can be used to advantage in helping to understand how atoms interact and form molecules but says little about other properties. Despite the fact that the structure of the atom is so hard to render pictorially, it is the basis of all differences as well as similarities in the properties of elements and ultimately of the behaviour of molecules and bulk matter.

Representations of atomic structure

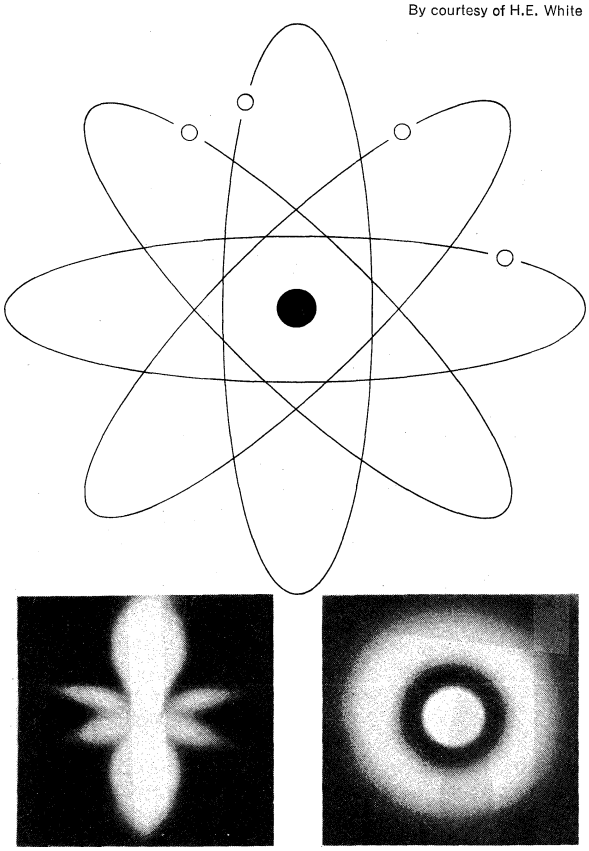

Figure 1: *Typical representations of atomic structure.*
(Top) The "planetary" or "orbital" model of atomic structure.
(Bottom) Electron "clouds" for two representative states; note the highly directional features on left, and their absence on right.

In the neutral atom, the electrons are held to the nucleus by the electrostatic forces of attraction resulting from the opposite charges they carry. Particles with similar charges—*e.g.*, the electrons—repel one another with the same electrostatic force. There are other kinds of forces acting on electrons; among other things, every electron behaves as if it were a tiny bar magnet. As far as electrical charge is concerned, a neutral atom should not have any effect on a passing electron, but, as a result of electrons behaving as magnets, some neutral atoms exhibit a positive affinity for the addition of an extra electron or even two. The measure of this tendency is the binding energy of the electron to be added. If it is larger than the binding energy of the electron when it is in a neighbouring atom, then it is likely that the electron will be transferred, thereby producing two ions, the former host atom being now positive and the new host being negative. These oppositely charged ions will then be attracted to one another, resulting in the formation of a molecule of a compound.

More generally, the electrons most loosely bound in an atom are the ones most likely to have their properties greatly modified by the proximity of other atoms. In some situations, the outer electrons of each of a group of atoms will be so strongly mutually influenced that they can no longer be characterized as "belonging to" one atom rather than another; as a result, they tend to draw the atoms together into a single entity, a molecule of some kind.

Thus, these loosely bound electrons have the essential role in what is called chemical behaviour; they also provide the key to understanding many of the properties of condensed matter, including the conduction of heat and electricity. The electron clouds have directional properties that are reflected in the geometrical characteristics of molecules and of crystals. Magnetic properties of matter depend on the overall electronic structure of atoms and molecules, as does much of its optical behaviour.

DEVELOPMENT OF ATOMIC CONCEPTS

Early philosophical speculations. The concept of an atom with structure is quite recent. The Greek word *atomos*, from which the English word atom is derived, means "undivided"; hence, structureless. An understanding of the atom, however, has grown through incorporation of developments in virtually every field of physics and many areas of chemistry. Thus, a tracing of the historical development of the concepts involved amounts almost to an outline of the history of the physical sciences.

The atomic hypothesis appears to have originated with a Greek philosopher of the 5th century BC, Leucippus. Although nothing is known of his life, and only a single line of his own work survives, his ideas were carried forward by his followers, notably the 5th-century-BC Greek philosopher Democritus of Abdera; in addition to atomism, they include a rigid mechanistic determinism and at least the foreshadowings of the modern principles of conservation of matter and energy. The theories expounded by Democritus were in turn taken over by the 4th- and 3rd-century-BC philosopher Epicurus and his school, who incorporated them into a materialistic philosophy of life; their fullest surviving description is that given by the Roman poet Lucretius in the 1st century BC, in his book *De rerum natura* ("On the Nature of Things"). The es-

sential features are these: (1) All matter is composed of ultimate, indivisible entities, the atoms; and all changes in matter are merely changes in the groupings of atoms. (2) There are many kinds of atoms, of different sizes and shapes, and the properties of bulk matter reflect in some way the properties of the atoms of which it is composed. Thus, for example, a white colour might be a manifestation of smooth atoms on the surface; a sour taste, a manifestation of needle-shaped atoms; and so on. (3) The only forces are those of collision between atoms, and the only causation is that produced by the atomic forces. (4) Apart from atoms, the only reality is infinite empty space, through which the atoms move. (5) An atom in its eternal "falling" through space may occasionally undergo a minute deviation of its path, which then enables it to collide with other atoms, leading ultimately through a succession of collisions to the formation of a whorl that develops into a material object. Of these principles, the first, third, and fourth still appear, with some modification or conceptual extension, as basic tenets of atomism today.

During the medieval period, atomism shared in the general decline of scientific thought in the Western world, as well as experiencing specific opposition to its highly deterministic approach. It seems to have attracted negligible attention in the Muslim world, where, however, significant advances were made in optics and chemistry, as well as substantial contributions to the advances in mathematical notation that were essential to the development of science in the quantitative form now known.

Beginning of modern science

The 17th century witnessed a veritable revolution in science, extending roughly from Galileo Galilei, at the end of the 16th century, to Sir Isaac Newton, one century later. It was characterized by a resurgence of careful, quantitative observation and, more especially, controlled experimentation and by a rise in synthesis and generalization. Out of it there emerged two results of importance to the atomic concept. One was an essentially completely developed science of mechanics, and particularly an emphasis on the role of the mass of a body as the property most important in determining the behaviour of the body in response to an external influence. The other was a dispute over whether light consists of a wave or of a stream of corpuscles. This dispute, won temporarily by the corpuscularists on the weight of Newton's authority, was resolved experimentally in favour of the wave theory a century later, only to be partially revived after still another century. A side development of the work in optics was Newton's discovery of the dispersion of white light into a spectrum by a refracting body such as a prism, which made possible the science of spectroscopy, which in turn has advanced knowledge of atomic structure, as will be seen later.

All the important scientific figures of the 17th century seem to have been more or less staunch atomists, including not only Galileo and Newton but also the English scientists Robert Boyle and Robert Hooke and the Dutch physicist Christiaan Huygens. Hooke even propounded a theory whereby the properties of matter, particularly gases, were to be understood in terms of the motion and collision of atoms, a concept later known as kinetic theory. His idea was considerably ahead of its time; unfortunately, he did not have enough mathematical ability to do it justice. Under the circumstances, it is somewhat surprising that the first work in which atoms were regarded not merely as tiny hard objects but rather as centres of force did not appear until after the middle of the 18th century. This work was published in Venice but was written largely in Vienna, by Ruggero Boscovich, a remarkable scientist-poet-diplomat-priest, born in what is now Yugoslavia and educated in Rome.

Origin of the atomic theory in chemistry. The rise of modern chemistry, too, came later than that of physics. Although Boyle had given effectively the modern definition of an element in 1661, significant progress appeared only when chemical studies became more quantitative, partly under the influence of Newton's emphasis on the importance of mass. Meanwhile, techniques had been developed for the isolation of gases, making possible a wider range of studies. Thus, it became possible to deduce the law of definite proportions, stating that, in a given compound, no matter where or how formed, the components always occur in the same proportions by weight. This law in turn led to tabulations of "equivalent weights," or simply "equivalents," of elements, defined as the weight that would combine with or replace in combination a unit weight of some reference element; *e.g.*, hydrogen.

Laws of proportions

Dalton's postulates. In this setting appeared the first attempt to relate atoms to chemistry: *A New System of Chemical Philosophy*, published in 1808 by an English chemist, John Dalton. Dalton had been led to believe in the atomic hypothesis because of the failure of mixtures of gases of different densities to stratify. He also knew of the law of definite proportions, and he himself had deduced the law of simple multiple proportions, which states that, when two elements combine in more than one proportion by weight, forming more than one compound, the weights of one that combine with a fixed weight of the other are in simple ratios to one another. Thus, for example, nitrogen and oxygen form five different compounds; the weights of oxygen combining with unit weight of nitrogen in each compound are in the ratio 1:2:3:4:5. Dalton was thus led to postulate that (1) all atoms of a given element are identical, and they are different from atoms of any other element; (2) chemical reactions are merely a rearrangement of atoms; and (3) the formation of a compound from its elements takes place by the formation of "compound atoms" from a fixed small number of atoms of the compound elements. These postulates alone were of no particular significance; they were not even essentially new. Dalton wanted to establish the relative weights of atoms, and to do so required at least one additional postulate. A natural preference for simplicity led him to a wrong guess—that (4) if two elements *A* and *B* form only one compound, it is formed by combination of one atom of *A* with one atom of *B;* in particular, the compound atom of water was assumed to consist of one atom of hydrogen and one atom of oxygen.

The law of combining volumes of gases. With this additional assumption, specific results were possible, and tables of relative atomic weights began to be published. The fallacy of the rule of greatest simplicity, however, led to some confusion; related to this was the tacit assumption that the "ultimate particles" of any element are single atoms. The resolution of the difficulty had as its basis a law enunciated in 1808 by a French scientist, Joseph-Louis Gay-Lussac: when gases combine chemically, the ratios of the combining volumes are ratios of simple integers. Thus, hydrogen and oxygen combine to form water in the ratio of two volumes of hydrogen to one of oxygen; carbon monoxide and oxygen combine to form carbon dioxide in the ratio of two volumes of carbon monoxide to one volume of oxygen, forming just two volumes of carbon dioxide; and so on.

Avogadro's hypothesis. These results led an Italian chemist, Amedeo Avogadro, to propose, in 1811, a two-part hypothesis: first, that the ultimate particles (in Dalton's terminology) of even elemental gases are not necessarily atoms but may be groups of atoms joined to form molecules; and, second, that equal volumes of gases contain equal numbers of molecules. Despite the fact that this proposal would have resulted in an entirely consistent scheme, it attracted little notice, because it flew in the face of the prejudices of outstanding chemists of the day. Rather, it was largely neglected until 1858, when another Italian chemist, Stanislao Cannizzaro, presented it, with further supporting evidence, to a chemists' congress at Karlsruhe, Germany. This presentation brought fairly widespread acceptance, but there was still considerable resistance until the early years of the 20th century.

Electrochemistry. In a slightly different vein, the rapid advances in electricity, especially the development of the voltaic cell in 1800, by an Italian physicist, Alessandro Volta, made possible a study of what is now known as electrochemistry, carried out in England by the scientist Michael Faraday. His work in this field is best remem-

The first study of electrochemistry

bered because of his deduction of the quantitative laws of electrolysis; but it is to be noted that these studies led him to recognize that the forces holding atoms together in chemical combination are electrical in origin and extremely strong.

The periodic law. One other development in chemistry was important not because it contributed to knowledge about atoms but because it provided a fundamental datum that a satisfactory atomic theory would have to explain. The existence of groups of elements with similar properties, such as lithium, sodium, potassium, rubidium, and cesium or iron, cobalt, and nickel, had long been known. Once reasonably accurate atomic weights began to be obtained, there appeared certain regularities in the atomic weights of the members of such groups. Often a group consisted of three elements; in many of those cases, either the atomic weights were close together, 56 for iron, 59 for both cobalt and nickel, with no known element having an intermediate value, or else they were widely but approximately equally spaced, 39 for potassium, 85.4 for rubidium, and 133 for cesium. In 1869 the Russian chemist Dmitry Mendeleyev found that, if the elements were listed in the order of increasing atomic weight, these groupings appeared as part of a much more striking and extensive regularity, involving the approximately periodic recurrence of similar sequences of elements. Thus, if hydrogen is skipped, it being somewhat anomalous, and if helium, which along with the other inert gases was unknown at the time, is also ignored, then the sequence lithium, beryllium, boron, carbon, nitrogen, oxygen, fluorine is obtained (see PERIODIC LAW). This sequence runs from a quite reactive element, lithium, which forms positive ions, through the relatively inert and ambivalent element carbon, to a highly active element, fluorine, which forms negative ions. The next seven elements are sodium, magnesium, aluminum, silicon, phosphorus, sulfur, and chlorine. Not only does this sequence display the same variation of properties as the first, but each member of it is chemically quite similar to the corresponding member of the preceding. Continuing in this way, Mendeleyev was led to form a tabular array similar in principle to the modern periodic table, as shown in the articles CHEMICAL ELEMENTS and PERIODIC LAW. It was, of course, not as complete as these, because many elements besides the inert gases were not yet known; in addition, there were some problems arising from the fact that some atomic weights were incorrect at the time (notably uranium, for which Mendeleyev used the value 118, and indium, for which he used 75). Actually, however, its very incompleteness turned out to be an advantage. Mendeleyev was sufficiently convinced of the essential correctness of his scheme that he predicted the existence and the approximate properties of several elements, notably those now known as gallium, scandium, and germanium. These were discovered in 1875, 1879, and 1886, respectively, leaving no doubt as to the validity of Mendeleyev's idea.

Mendeleyev's predictions verified

Spectroscopy and spectral regularities. As was mentioned earlier, Newton discovered that white light could be dispersed into a band of colours by a prism and that the colours were inherent in the light itself. Further work revealed that light from any incandescent solid or liquid gave a continuous band of colours. A luminous vapour, on the other hand, gave a set of isolated colours separated by darkness. These colours became known as spectrum lines, each colour of the spectrum being displayed as the image of a narrow slit. A crucial step was taken in 1859, when the German physicists Gustav R. Kirchhoff and R.W. Bunsen showed that the pattern of lines given off by a given chemical substance is characteristic of the substance.

A search then began for some sort of regularities in spectra, under the assumption that the spectra must originate in some sort of mechanical vibrations within the atom. This assumption led to the expectation of harmonic relations, which were not found.

What ultimately proved to be a major breakthrough was a relationship enunciated in 1885 by Johann Balmer, a Swiss schoolmaster who seems to have been led to his discovery by a love of numerology. By this time, the wave nature of light had been established, and spectroscopy had become the measurement of wavelengths. Balmer found that the wavelengths (symbolized by lambda, λ) of the four visible lines in the spectrum of hydrogen are given to high accuracy by the formula

$$\lambda = b\left(\frac{m^2}{m^2 - n^2}\right), \qquad (1)$$

in which b is a constant having the value 3645.6 angstroms, and m and n are integers; specifically, $n = 2$ and $m = 3,4,5,6$, according to the line involved. Before publication of his findings, he learned of the existence of several more lines, extending into the ultraviolet range of the spectrum; all had wavelengths in striking agreement with the values predicted by his formula with successively higher values of integer m.

In his paper announcing this formula, Balmer suggested that it might be a special case of a more general relationship applicable to other elements, but he carried the work no further. It was left to Johannes Rydberg, a Swedish physicist, to determine, in 1890, that for a large number of series of spectral lines for various elements the wave number (number of waves per unit length, or the reciprocal of the wavelength, symbolized by the Greek letter nu with a superior tilde, $\tilde{\nu}$) of a member of the series is given by an equation of the form

$$\tilde{\nu} = \tilde{\nu}_\infty - \left[\frac{R}{(m + \mu)^2}\right], \qquad (2)$$

in which the subscript ∞ (representing infinity) indicates a particular value of $\tilde{\nu}$, a value that varies from one series to another; m is an integer labelling the position of the line within the series; the Greek letter mu (μ) denotes another constant that depends on the series; and R is a constant that is nearly the same, $1.097 \times 10^5\ \mathrm{cm}^{-1}$, for all series and all elements; *i.e.*, the Rydberg constant.

It is important to note that Balmer's formula, equation (1), is a special case of equation (2). Written in terms of wave numbers instead of frequencies, equation (1) becomes

$$\tilde{\nu} = \frac{1}{\lambda} = \frac{n^2}{b}\left(\frac{1}{n^2} - \frac{1}{m^2}\right) = R\left(\frac{1}{n^2} - \frac{1}{m^2}\right). \qquad (3)$$

This equation is of the form of equation (2) with $\tilde{\nu}_\infty = R/n^2$ (n^2 was fixed at 4 in Balmer's formula) and $\mu = 0$. Other series in hydrogen were not known at the time of Rydberg's work; but in 1908 one was discovered in the infrared for which n in the last form of equation (3) is 3, and m is successively 4,5,6,. . . . Others have been found since.

These relationships and others recognized later finally led to a broad general principle, enunciated in 1908, that states: for any atom there exists a set of characteristic sequences of terms, numbers of the form $T_n = R/(n + \mu)^2$, with n taking on successive integer values and with μ varying from sequence to sequence; the wave number of any line in the spectrum of the atom is expressible as the difference between terms from two such sequences,

$$\tilde{\nu} = R\left[\frac{1}{(n + \mu_1)^2} - \frac{1}{(m + \mu_2)^2}\right] \qquad (4)$$

and a series of lines all having similar characteristics results from the combination of a fixed term of one sequence with all the terms in succession of another sequence; *i.e.*, keeping n fixed in equation (4) and varying m.

Light and related radiations. The 19th century saw an enormous growth in the understanding of light, only to close with a development that would lead to a thoroughgoing modification of the entire structure of that understanding. The century opened with the discovery that there are invisible radiations that have every characteristic of light except visibility: infrared radiation was discovered in 1800 and ultraviolet in 1801. Also in 1801, the English physicist Thomas Young pointed out that a wave theory of light implied the wave phenomenon called interference; and he proceeded to produce examples of it.

Proofs of the wave theory of light

The corpuscularists were not convinced. The dispute was not finally settled until 1850, when it was shown by direct measurement that light travels more slowly in water than in air, a result consistent with the wave description of refraction, whereas the corpuscular description requires the reverse. The phenomenon of polarization was discovered in 1809. This phenomenon implies that light waves are transverse; *i.e.*, whatever the vibration consists of, it takes place in a plane perpendicular to the direction of propagation of the wave.

In 1865 a Scottish physicist, James Clerk Maxwell, produced "A Dynamical Theory of the Electromagnetic Field," which encompassed all the previous laws of electricity and magnetism in unified form. Maxwell concluded from his theory that light is indeed an electromagnetic wave; and his conclusion gained support when in 1887 a German physicist, Heinrich Hertz, was able to generate waves, now known to have been actually radio waves, by purely electromagnetic means.

As the century ended, two pairs of workers at the Imperial Physical and Technological Institution in Berlin undertook experimental measurements of the radiation spectrum of a blackbody (defined as an ideal body that absorbs all radiation incident on it). They made use of the equivalence, established in 1884 by Ludwig Boltzmann, an Austrian physicist, between radiation from a blackbody and radiation emanating through a small hole in a wall of an oven held at uniform temperature. Their experimental findings were analyzed by a German physicist, Max Planck. Planck found that, in order to produce a consistent interpretation of the results, he had to assume that radiant energy is "quantized"; that is, is emitted or absorbed only in discrete amounts, proportional to the frequency that is symbolized by the Greek letter nu, ν. The factor of proportionality he denoted by the symbol h, so that quantized energy (E) is written $E = nh\nu$, in which n is an integer. The factor h had to be a universal constant. Planck calculated its value, and the presently accepted value, deduced from a variety of experiments analyzed simultaneously, is 6.624×10^{-34} joule second. The dimensions joule second—*i.e.*, energy times time, or momentum times distance—are those of a quantity in classical analytical dynamics called the action; thus h is often referred to as the quantum of action, and it plays an essential part in the description of atomic structure.

Planck's constant

Discovery of the electron. In 1858 a form of radiation was discovered emanating from the cathode, or negative plate, of a tube in which an electrical discharge was being passed through a gas; the radiation caused fluorescence when it struck the glass wall of the tube, and the position of the fluorescent spot was affected by a magnetic field in the vicinity. The radiation, called cathode rays, attracted much study. In 1879 an English physicist, Sir William Crookes, found strong indications that they consisted of negatively charged particles. This evidence was confirmed in 1897 by another English physicist, Sir J.J. Thomson, who also measured the ratio of the mass (m) to the charge (e) of the particles, m/e, obtaining a value of about 10^{-7} gram per electromagnetic unit of charge. This value was smaller by a factor of about 1,000 than the smallest value previously known for such a ratio, that of the hydrogen ion in electrolysis; moreover, it was independent of the nature of the gas in which the discharge was produced. Thomson proceeded to study the negative electrification discharged from metals by ultraviolet light and that produced by an incandescent filament in hydrogen gas. He concluded that these all represented a single kind of particle, which he called corpuscles but which soon became known as electrons. He also suggested that electrons were constituents of every kind of atom, which meant, in effect, that the atom could be subdivided.

Multiple independent discoveries of the photoelectric effect

In 1888 several workers independently discovered the photoelectric effect: light falling on a metal surface ejects negatively charged particles from the surface, provided the light includes wavelengths shorter than a critical value dependent on the metal used. As noted above, Thomson identified the particles as electrons. The existence of a threshold wavelength, together with the fact that the energy of the electrons is directly proportional to the difference between the stimulating frequency (ν) and the frequency (ν_0) corresponding to the threshold wavelength, could not be understood on the basis of Maxwell's theory of light. In 1905 Albert Einstein showed that these features followed from Planck's hypothesis of quanta, if it is assumed that each quantum of energy $h\nu$ interacts with just one electron and that an amount of energy $h\nu_0$ is needed just to free the electron from the metal; the remainder, $h\nu - h\nu_0$, is available to the electron as energy of motion. The conclusive experimental confirmation of this theory by a U.S. physicist, Robert A. Millikan, in 1914 established the fact that radiation exhibits some properties normally associated with particles.

Discovery of X-rays and radioactivity. In 1895 the German physicist Wilhelm Röntgen discovered X-rays. Their nature remained controversial for at least 20 years, though some wavelike behaviour was established as early as 1904. In that same year an English physicist, Charles Glover Barkla, showed that each element could be made to emit one or more characteristic groups of X-rays. These groups were labelled K, L, and M, in order of decreasing penetrating power, each group shifting to a more penetrating quality as the atomic weight increased. Barkla also established that the number of electrons in an atom is roughly half the atomic weight. Finally, in 1913 it was established that X-rays are indeed electromagnetic waves that can be made to display interference and diffraction patterns by the natural orderly arrays of atoms in crystals.

This property was adapted in 1913 by the English crystallographer Sir William H. Bragg and his son Sir William L. Bragg into a convenient method for measuring the wavelengths of X-rays.

In 1896 the French physicist Henri Becquerel discovered radioactivity in uranium; this discovery was quickly followed by the isolation of other radioactive elements by two French scientists, Pierre Curie and his wife, Marie. By 1900 it was shown by a British physicist, Ernest Rutherford, and a French physicist, Paul Villard, that there are three kinds of radiation of different penetrating power: alpha rays, the least penetrating, identical with helium nuclei; beta rays, identical with electrons; and gamma rays, the most penetrating, of the same nature as X-rays. The most striking result, however, was the discovery in 1902 by Rutherford and a coworker, Frederick Soddy, that radioactivity is associated with a natural transmutation of the elements. Thus, the atom had lost not only its indivisibility but also its immutability.

Discovery of the existence of isotopes. The study of electrical discharges in gases led to still another surprise. If the cathode of the discharge tube is perforated, a beam of radiation passes through the openings away from the anode and can cause visible fluorescence of the walls of the tube. It was found that these rays consist of positively charged particles, with a ratio of charge to mass that depends on the nature of the gas used. In 1912 Thomson devised a method of subjecting the beam of these rays to parallel and coextensive electric and magnetic fields. The deflections produced by the fields in that configuration are such that all particles of the same charge-to-mass ratio strike the wall of the tube (or a photographic plate used as a detector) along a single parabola-shaped curve; the detailed shape of the parabola can be used to evaluate the ratio of the mass (m) of each particle to its charge (c). He found that with neon as the discharge gas, two parabolas were obtained, which indicated singly charged particles of masses 20 and 22, instead of the expected single parabola of mass 20.2 (the atomic weight of neon). The relative intensities of the two were always the same regardless of the purity of the neon.

The conclusion was that there are two varieties (isotopes) of neon atoms of different masses, thereby dethroning still another hypothesis of the original atomic concept, namely, that all atoms of a given element are absolutely identical.

MODELS OF ATOMIC STRUCTURE

Early atomic models. Several models of the atom were proposed in the first few years of the 20th century. The earliest (1902) was originated by an English physicist, Lord Kelvin, but was supported so strongly by Thomson that it became known as the Thomson atom. According to this model, the atom consists of a sphere of uniformly distributed positive charge, about one angstrom in diameter, in which the electrons are embedded like raisins in a pudding. Lord Kelvin himself at least partly abandoned this model and in 1905 proposed another, in which the uniform positive sphere is replaced by alternate positive and negative spherical shells, with a net surplus of positive charge; the electrons are embedded in the positive charge. Another model, proposed in 1903, suggested that all atoms are composed of varying numbers of a single constituent, called dynamids. Each dynamid is conceived as consisting of an intimate association of an electron and a much more massive positive body, having a linear dimension (diameter) of the order of 10^{-4} angstrom with the dynamids held together by unspecified forces. Still another model, proposed in 1904 by a Japanese physicist, Hantaro Nagaoka, considered the positive charge as concentrated at the centre of the atom, with the electrons forming a ring similar to Saturn's rings.

The Thomson model

The Rutherford model. In 1910 two researchers working under Rutherford's direction were studying the scattering of alpha particles—that is, their deflection from straight-line paths—as they passed through thin foils. They noted that a small but significant number were scattered through quite large angles. Rutherford recognized that, if the Thomson model were valid, an alpha particle would interact with many atoms on the way through the foil; no single interaction could produce a large deflection, and the effects of the many interactions would tend to cancel rather than add up. On the other hand, if the positive charge and most of the mass were concentrated in a very small region at the centre, as Nagaoka had suggested, multiple interactions would be rare, but a single interaction could produce a large deviation. Rutherford worked out the theory in 1911 and showed that the scattering should be proportional to the foil thickness t for a nuclear atom but to the square root of the thickness, $\sqrt{t}$, for the Thomson atom; that it should decrease with increasing deflection angle for a nuclear atom but decrease much faster for the Thomson atom. With refined techniques, a complete verification was obtained of the results of the nuclear model.

The Bohr–Sommerfeld atom. Rutherford's nuclear model of the atom also had serious defects. A well-known theorem in electromagnetic theory states that a system of charged bodies cannot be in static (stationary) equilibrium under the action of their mutual electrostatic interactions alone. On the other hand, a dynamic equilibrium would mean that electrons are travelling in some sort of orbits, analogous to the planets in the solar system; then another, equally well-known result of electromagnetic theory would imply that, because of the centripetal acceleration needed to keep the electrons in their curved paths, they would radiate, lose energy, and spiral into the nucleus. This property would produce a continuous spectrum rather than the discrete (line) spectrum characteristic of noninteracting ions; moreover, the resulting lifetimes of atoms could be calculated straightforwardly and turned out to be ridiculously short.

Bohr's theory and the hydrogen spectrum. The difficulty with instability was resolved by a Danish physicist, Niels Bohr, in 1913, essentially by giving up the relationship between the motion of a charged particle and the radiation it emitted. Bohr's theory was based on four postulates, the first three of which are as follows: (1) An atom, consisting of a nucleus together with its system of electrons, possesses certain special dynamical states having the property that as long as the atom remains in one of these states it does not radiate. (2) The dynamical equilibrium of the special states can be treated by ordinary mechanics; but the transitions between them cannot be so treated and indeed are not subject to explicit description. (3) When an atom makes a transition from one state, of energy E_1, to another, of lower energy E_2, the excess energy is emitted as radiation of a single frequency, ν, related to the energy difference by Planck's relationship, $E_1 - E_2 = h\nu$. Bohr gave three forms for the fourth postulate; the simplest, and the one that became the basis for additional developments, was that (4) for a single electron moving in an orbit around the nucleus, the angular momentum, L, is an integer multiple of $h/2\pi$.

Bohr's postulates

These principles can easily be applied to circular orbits in a hydrogen atom—that is, an atom with a single electron of negative charge, $-e$, bound to a nucleus of positive charge, $+Ze$, Z being an integer, in this case equal to one. The total energy of the system consists of the sum of two parts: (1) the kinetic energy (energy of motion) of the electron, given by the formula $\frac{1}{2}mv^2$, in which m is the electron's mass and v its speed; and (2) the electrostatic potential energy, given by the formula $-(Ze)e/r$, in which r is the radius of the orbit. Thus, adding the two gives

$$E = \tfrac{1}{2}mv^2 - \frac{Ze^2}{r}. \tag{5}$$

To keep the electron in its orbit, there must be a centripetal force on it, which is equal to mv^2/r; this force is provided by the electrostatic attraction of the nucleus, $(Ze)e/r^2$, so that

$$\frac{Ze^2}{r^2} = \frac{mv^2}{r};$$

multiplying by r gives

$$\frac{Ze^2}{r} = mv^2, \tag{6}$$

so that equation (5) can be written

$$E = \tfrac{1}{2}\frac{Ze^2}{r} - \frac{Ze^2}{r},$$

$$E = -\tfrac{1}{2}\frac{Ze^2}{r}. \tag{7}$$

The next step is to apply the quantum condition on the angular momentum. For a circular orbit, the angular momentum is just mvr, so that the condition is

$$mvr = \frac{nh}{2\pi}.$$

Dividing this equation by mr gives

$$v = \frac{nh}{2\pi mr},$$

which can be substituted into equation (5) to give

$$\frac{Ze^2}{r} = \frac{n^2h^2}{4\pi^2m^2r^2}m = \frac{n^2h^2}{4\pi^2mr^2}.$$

This equation can be solved for $1/r$, giving

$$\frac{1}{r} = \frac{4\pi^2mZe^2}{n^2h^2};$$

this in turn can be substituted into equation (7) to give

$$E = -\tfrac{1}{2}Ze^2 \cdot \frac{4\pi^2mZe^2}{n^2h^2},$$

$$E = -\frac{2\pi^2mZ^2e^4}{n^2h^2}. \tag{8}$$

If now the atom makes a transition from a state with energy E_1, corresponding to a value n_1 of n, to another state of energy E_2, corresponding to n_2, the frequency of the radiation emitted is

$$\nu = \frac{1}{h}(E_1 - E_2)$$

$$= \frac{1}{h}\left(-\frac{2\pi^2m\,Z^2e^4}{h^2}\right)\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right)$$

$$\nu = \frac{2\pi^2m\,Z^2e^4}{h^3}\left(\frac{1}{n_2^2} - \frac{1}{n_1^2}\right). \tag{9}$$

This equation can be put in terms of the wave number $\tilde{\nu}$, which is related to frequency ν by $\nu = c\tilde{\nu}$, so that

$$\tilde{\nu} = \frac{2\pi^2 mZ^2e^4}{ch^3}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right).$$

This is exactly the form of Balmer's formula, equation (1), and of the formula for the infrared series, if Balmer's constant b (and Rydberg's constant R) satisfies

$$\frac{4}{b} = R = \frac{2\pi^2 me^4}{ch^3},$$

in which Z has been set equal to 1 because these series pertain to hydrogen (the nucleus of hydrogen has a single positive charge). At the time of Bohr's work, the accepted value of R was 1.1×10^5 cm^{-1}; the value of $2\pi^2me^4/ch^3$, as calculated from then known values of m, e, c, and h, was 1.03×10^5 cm^{-1}, in complete agreement, considering the uncertainties in the quantities involved.

Correspondence principle

Bohr, in deriving the Balmer formula, made use of the correspondence principle, according to which, for large quantum numbers, the results of classical theory are approximately valid. From this, Bohr asserted that, for large orbits, the wave frequency emitted by an electron in transition between two successive orbits equalled the frequency of revolution in either.

The theory had other successful applications. In 1896 a set of lines forming a series similar to the Balmer series was discovered in a stellar spectrum. The wavelengths were given by a variation of Balmer's formula in which the integer m was replaced by half an odd integer, and on that basis it was ascribed to hydrogen. Bohr noted that this series of lines (called the Pickering series for its discoverer, a U.S. astronomer, Edward C. Pickering) could be described as arising from ionized helium (the positive charge on the nucleus of helium, Z, equals 2), and proposed an experiment that was carried out in 1913, and that confirmed this conjecture. Bohr also pointed out that certain lines in stellar spectra not yet identified at the time appeared to be due to doubly ionized lithium (for which $Z = 3$). Slight discrepancies between the observed and calculated values in both these cases were shown to be removed by taking account of the motion of the nucleus. Also, he noted that the energy needed to remove the most tightly bound electron corresponds well to the energy needed to excite characteristic X-rays, and finally he was able to account for some of the features of what is called the Stark effect, the splitting of the lines of a spectrum into several components when the source of radiation is subjected to a strong electric field.

Within two years, two additional experimental results lent strong support to the theory. An English physicist, Henry G.J. Moseley, working initially under Rutherford and later with Thomson, made a systematic study of the variation of the frequencies of characteristic X-rays through the periodic table. He found that the atomic property that appeared to govern the wavelength was not the atomic weight (A) but the atomic number (Z). This discovery confirmed a proposal made earlier by a Dutch lawyer and amateur physicist, Antonius van der Broek, on the basis of an analysis of Geiger and Marsden's work on the scattering of alpha particles, and it resolved some discrepancies that had long existed with regard to the Mendeleyev periodic scheme. In particular, Moseley found that the frequency of the K X-ray series satisfied the equation

$$\sqrt{\nu} = \sqrt{(3/4)cR}\,(Z - 1),$$

in which R is Rydberg's constant and c is the speed of light. The significance of this equation (and of a similar equation for the L series) was recognized by Walther Kossel, a German physicist, in 1914. If both sides of the equation are squared,

$$\nu = (3/4)cR\,(Z - 1)^2,$$

and if the factor 3/4 is written as

$$1 - \frac{1}{4} = \frac{1}{1^2} - \frac{1}{2^2},$$

the resulting equation is just of the form of equation (9) above with $n_1 = 2$ and $n_2 = 1$, except for the replacement of Z by $Z - 1$, the explanation being that if there are normally two electrons in the innermost orbit, and the K series is produced by ejecting one of them, then one electron is left to shield the outer electrons from one unit of the nuclear charge.

The other development was a series of experiments by two German physicists, James Franck and Gustav Hertz, to measure ionization potentials; *i.e.*, the energy required to ionize an atom. When an atom was bombarded with electrons, the energy given to the atom by the electron was restricted to certain discrete values related to the frequencies of certain lines in the spectrum of the atom by Planck's law, $E = h\nu$. This corroborated Bohr's first postulate and provided an extension of the third.

Bohr's fourth postulate had introduced one integer, or quantum number, as it became known, into the description of atomic behaviour. This first one, n, was called the principal quantum number. In 1915 this postulate was generalized by the German physicist Arnold Sommerfeld and others, who noted that a similar condition should apply to any periodically changing variable. Sommerfeld treated the effects of relativity on an electron in an elliptical orbit and thereby partially accounted for the fine structure in the hydrogen spectrum—the fact that the lines of, say, the Balmer series actually consist of several components, resolvable by a sufficiently delicate instrument. This treatment involved introduction of a second integer, the orbital quantum number k, which could have the values 1, 2, ..., n and which presumably measured the angular momentum in units of $h/2\pi$ (symbolized $\hbar$). Still a third quantum number was associated with the frequency of precession of the plane of the orbit, if the atom were placed in a magnetic field, caused by the interaction of the field with the equivalent magnet produced by the motion of the electron in its orbit. Use of this magnetic quantum number, with values $-k$, $-k + 1$, $-k + 2$, . . ., $k - 1$, k, permitted understanding of the normal Zeeman effect, which is the splitting of a spectral line into three components under the influence of a magnetic field. With the addition of semiclassical considerations about the angular momentum carried by radiation, it was possible to formulate selection rules that accounted for the absence of certain spectral lines on purely energetic considerations. Experiments in 1922 confirmed the restrictions on spatial orientation of atomic magnets implied by the quantum numbers.

Quantum numbers

Even the extended Bohr theory, however, had serious flaws. The relativistic fine structure was completely unaccounted for; and the "normal" Zeeman effect is actually rarer than the anomalous Zeeman effect, in which the number of components of the split line is different from three. The theory was also incapable of dealing correctly with any system containing more than one electron.

Electron spin and the Pauli principle. The former difficulty was overcome first. Early in 1925 an Austrian physicist, Wolfgang Pauli, suggested that there should be a fourth quantum number, relating to "a characteristic, classically indescribable kind of double valuedness of the quantum-theoretical properties of the state of the electron." Within the year, the Dutch physicists George Uhlenbeck and Samuel Goudsmit pointed out that it was possible to avoid this "nonmechanical constraint" by ascribing to the electron an intrinsic angular momentum or "spin," of magnitude $\frac{1}{2}\hbar$, in contrast to the "orbital" angular momentum of Bohr's postulate, which was a whole multiple of $\hbar$. According to the quantum rules about angular momentum, the spin could be aligned only along or opposite to a specified direction, giving the required two values. If it had associated with it a magnetic moment of appropriate magnitude, an explanation of the hydrogen fine structure and of the anomalous Zeeman effect on a quantitative basis became possible.

Even before this explanation, Pauli made use of the additional quantum number. The Bohr–Sommerfeld theory implied the existence of shells, groups of orbits all partially similar in their spatial configurations and not too widely separated in energy; and, by a certain amount of

juggling with quantum numbers, it was possible to make the number of orbits in a shell agree, apart from a factor of two, with the number of electrons that the shell seemed to be able to accommodate. There was, however, no explanation for the apparent limitation on the number of electrons in a shell; in particular, there was nothing to prevent all the electrons from dropping into the state of lowest energy, that with $n = 1$. Pauli showed that the limitation on the number of electrons in a shell and, with it, at least a qualitative understanding of the periodic structure of Mendeleyev's table followed from a simple rule: no two electrons in an atom can have the same sets of values for the four quantum numbers. This rule, the Pauli exclusion principle, has subsequently been shown to apply to any particle having a spin that is an odd multiple of $\frac{1}{2}\hbar$.

Pauli exclusion principle

Contemporary atomic models. The key to the solution of the other difficulty with the Bohr–Sommerfeld theory came in two forms, almost simultaneously, one fairly simple in concept and the other rather abstract. The latter will be described only briefly here.

De Broglie's wave particle duality. Ever since Planck's theory of blackbody radiation in 1900, the idea that light has some particle-like aspects had been gaining currency. It had been given support by Millikan's verification of Einstein's theory of the photoelectric effect; and the conclusive result was the discovery in 1923 by a U.S. physicist, A.H. Compton, of the Compton effect, the shift in frequency of the X-rays scattered by an atom, and his explanation of it by treating the X-rays as a stream of particles. (It must be noted, however, that, as Compton himself acknowledged, the experiment itself depended on the use of wave properties of the X-rays.) The French physicist Louis-Victor de Broglie accordingly proposed in 1923 that, correspondingly, particles should possess wave properties. Specifically, he suggested that a particle of mass m_0 at rest and thus having (according to relativistic dynamics) an energy m_0c^2 has associated with it a periodic phenomenon of a specific frequency, $\nu_0 = E/h = m_0c^2/h$. If it moves relative to an observer with a certain velocity v, the observer will see the frequency shifted (by the relativistic time dilation defined by the theory of relativity) to a value $\nu = \nu_0(1 - v^2/c^2)^{1/2}$. On the other hand, the energy of the moving particle is such that it would correspond to a frequency $\nu_1 = \nu_0(1 - v^2/c^2)^{-1/2}$. De Broglie proved that these two waves moved so as to be always in phase: the former at the same speed as the particle and the second at a different speed V. Because according to simple mathematical calculations, V is greater than c (the speed of light), it cannot, according to the theory of relativity, represent a transport of energy, and de Broglie called it the phase wave. He recognized the analogy to a phenomenon of ordinary wave motion in a dispersive medium that, when a group of waves of slightly different frequencies travel at slightly different speeds, they produce by interference a group wave that travels at a speed significantly different from all of them, and it is the group velocity that represents the speed of transport of energy by the waves. Making use of this parallel, he deduced the wavelength of his matter waves: if the momentum of the particle is p, the wavelength λ is given by

Particles with wave properties

$$\lambda = \frac{h}{p}. \tag{10}$$

Just as Planck's equation $E = h\nu$ is the fundamental relationship for light quanta, so equation (10) is the fundamental equation for matter waves.

De Broglie's proposal was an act of sheer bold imagination, based on nothing more substantive than a belief in a symmetry of nature. Nevertheless, in four years it had acquired firm experimental support. Experiments showed that electrons could be diffracted by crystal lattices just as if they were waves of wavelength given by de Broglie's formula.

Schrödinger's equation. De Broglie's development had been influenced by the work of a 19th-century Irish mathematician, William Hamilton, who had produced a formulation of Newtonian mechanics completely parallel to the theory of geometrical optics. In 1926 Erwin Schrödinger, a German physicist, took up de Broglie's idea and exploited further the connection with Hamilton's formulation, thus obtaining the equation that must be satisfied by matter waves. This is a partial differential equation containing the energy of the particle as a parameter (a variable fixed as a constant), and acceptable solutions can be obtained only for certain values of the energy. The form of the equation appropriate to the electron in a hydrogen-type atom is particularly tractable, and Schrödinger found the values of the energy giving acceptable solutions: they were just the values given by Bohr's model, equation (8).

The nature of the solutions of Schrödinger's equation often pointed up the deficiencies in the orbital model that had been built up on the basis of the Bohr–Sommerfeld postulates. An outstanding example of this is the problem of angular momentum. It was noted above that the orbital quantum number k is supposed to give the measure of the orbital angular momentum of the electron in units of $\hbar$. It was on the basis of this interpretation, for example, that the value 0 was excluded: a classical orbit with zero angular momentum is a straight line segment, and an electron in such an orbit would collide with the nucleus. Already before 1925, many formulas involving angular momentum had had to be artificially manipulated in order to give quantitatively correct answers. In some cases k had to be replaced by $k + \frac{1}{2}$, in others by $\sqrt{k\,(k+1)}$, all purely ad hoc; in still others, no change was necessary. In the Schrödinger formulation, the situation is quite different. There is still a quantum number describing "orbital" angular momentum, now conventionally designated by l, but the word "orbital" is here put in quotation marks to emphasize that there is no longer an orbit. Moreover, it is not l itself that gives the magnitude of the angular momentum, but $\sqrt{l\,(l+1)}$. The allowed values of k were 1, 2, ..., n; those of l, instead, are 0, 1, ..., $n - 1$. It is now possible to have a state of zero angular momentum, but, because there is no orbit in the classical sense, this state no longer presents any difficulty.

Schrödinger's formulation also permits a mathematical expression of the Pauli exclusion principle in terms of the properties of the function obtained as a solution of the equation. This function, customarily denoted by the Greek letter psi (Ψ), depends on the coordinates of the electrons; in the calculation of observable quantities it always appears squared. Now, because all electrons are identical, no physical difference can result from the interchange of two of them. This statement implies that Ψ must either remain the same or change its sign (so that its square is unchanged) upon interchanging the values of the coordinates of any two electrons. If it is unchanged, it is called symmetric; if it changes sign, it is called antisymmetric. In 1926 a German physicist, Werner Heisenberg, and an English physicist, Paul A.M. Dirac, independently showed that the Pauli principle is equivalent to the requirement that electrons must be described by an antisymmetric Ψ. At the time and for many years thereafter, this principle in either form was an extra added postulate; only in the late 1950s was it found to follow from abstruse considerations of relativistic quantum theory.

Symmetry and antisymmetry of the electron wave function

With this tool at hand, the Schrödinger theory was able to score a clear triumph over the orbital model. The old model had failed completely on the simplest system beyond hydrogen, the neutral helium atom. It could not even provide an arrangement of orbits that was more than marginally stable, let alone account for the nature of the spectrum. The Schrödinger equation, on the other hand, with the inclusion of spin and the requirement of antisymmetry, gave a description that was completely satisfactory.

The difficulties with Schrödinger's equation are of a more philosophical character, having to do with the interpretation and significance of the function Ψ. One disturbing feature is that Ψ is a complex function—that is, it involves $\sqrt{-1}$—so that it cannot by itself represent an observable quantity. The conventional interpretation is

that Ψ is a probability amplitude. The measurable quantity is the corresponding intensity, $|\Psi|^2$, which is a probability density and describes the probability that the electron will be found in a given region of space. It is this probability density that is represented by the clouds mentioned earlier. It must be emphasized that the electron itself is *not* to be regarded as spread out into a cloud.

An entirely different approach to the difficulties of Bohr's theory was taken by Heisenberg and developed by Heisenberg and the German physicists Max Born and Pascual Jordan. Heisenberg insisted that the theory should deal only with observable quantities. Because the atom could be observed only by making it change from one stationary state to another, each quantity had to be represented in some fashion by an array of numbers, each number labelled by the initial and final states to which it pertained. The resulting rules of calculation were recognized by Born as just those of a branch of mathematics called matrix algebra, and together with Jordan, they were able to carry out the development.

Most physicists of the time knew very little about matrix algebra, and therefore this method as such was relatively unexploited—especially because Schrödinger proved in 1926 that it was completely equivalent to his wave mechanics. Nevertheless, one very important result came from it: Heisenberg's uncertainty principle, which states that it is inherently impossible to determine simultaneously and with unlimited accuracy the position and the momentum of a particle. This principle is of great significance on the atomic scale but plays no role in ordinary experience because of the very small value of Planck's constant, h, which is an integral part of the mathematical statement.

The uncertainty principle

At this point the stage was basically set for a complete understanding of "a large part of physics and the whole of chemistry," as Dirac expressed it; the fundamental nature of the new quantum theory was demonstrated in 1928, when the physicist George Gamow and, independently, physicists Edward Condon and R.W. Gurney used its principles to explain the relationship, known since 1911, between the half-life of a radioactive element that emits alpha particles and the energy with which the alpha particles are emitted.

Despite the recognized power of the theory, the details of the structure of any but the simplest atoms are not known exactly. The reason is that there are no techniques for solving any but the simplest partial differential equations. Schrödinger's equation for an atom containing just one electron can be solved exactly; but, even for the next simplest case, that of two electrons, approximation methods must be used. The situation with regard to molecules and aggregates of atoms in bulk matter is even worse. Some of the approximation methods, however, can give very accurate results; and in any case certain general features can be deduced.

Relativistic quantum theories. There remained some defects of principle in Schrödinger's theory. For one thing, the spin of the electron had to be included on an ad hoc basis; for another, the equation is not in harmony with the theory of relativity. Several people, including Schrödinger himself, attempted to remedy the second of these defects, but without success. The difficulty arises from the fact that the relativistic expression for the energy (E) of a free particle is

$$E = \pm[(cp)^2 + (mc^2)^2]^{1/2} \qquad (11)$$

in which m and p are the mass and momentum, respectively, of the free particle, and c is the velocity of light. This cannot be used directly, as the square root has no clear meaning once the transition is made to the operators (either Schrödinger's derivatives or Heisenberg's matrices) of quantum theory. Although it would be possible to use the square of the energy as the form to convert to operators, a probability density with the appropriate behaviour would be impossible to define.

The problem was solved by Dirac in 1928 by the expedient of setting

$$E = c(\alpha_x p_x + \alpha_y p_y + \alpha_z p_z) + \beta mc^2 \qquad (12)$$

in which p_x, p_y, and p_z are the three mutually perpendicular components of momentum, satisfying $p_x^2 + p_y^2 + p_z^2 = p^2$. Here α_x, α_y, α_z, and β are determined by the requirements that they be independent of position and time and that $E^2 = (cp)^2 + (mc^2)^2$, the same result that would be obtained by squaring both sides of Equation (11). The α's and β cannot be ordinary numbers, as the restrictions on them show; a typical one is $\alpha_x\beta + \beta\alpha_x = 0$. Rather, they turn out to be operators themselves. Moreover, whereas for a classical free particle the orbital angular momentum L is a constant of the motion, this is not true for a particle the energy of which is of the form of Equation (12); instead, to L must be added a combination of the α's and β. This combination must represent an angular momentum, which does not depend on the motion of the particle and is therefore an intrinsic angular momentum, or spin. When the effect of an electromagnetic field is included in the equation, the spin is found to have associated with it a magnetic moment of just the magnitude that had been proposed by Uhlenbeck and Goudsmit. Thus, Dirac's proposal solved the two difficulties at once. It also implied the existence of particles identical to the electron except for the sign of the electric charge; these particles, called positrons, were discovered in cosmic radiation in 1932 and are produced in some radioactive processes.

The theories of Schrödinger, Heisenberg, and Dirac all pertain to entities that were classically regarded as particles. The quantum of light, the photon, is in a different category, because the classical theory of light is cast in terms of a continuous quantity, a field. Even before his development of the relativistic theory of the electron, Dirac developed a method for bringing electrodynamics within the realm of quantum theory. The significant development of quantum electrodynamics, however, took place in the late 1940s, partly as a result of experimental revelations. According to the Dirac theory, the lowest level of the hydrogen atom is single; the next two levels should have identical energies. Already in the 1930s, there were some indications that this was not quite so, as well as some theoretical arguments why it should not be. In 1947 a delicate microwave experiment by the U.S. physicists Willis Lamb, Jr., and Robert Retherford proved that the two levels do indeed differ in energy, by an amount corresponding to a frequency of about 1,040 megacycles per second. The Dirac theory also ascribes to the electron a magnetic moment of a definite magnitude; but a careful measurement in 1941 by the U.S. physicist Polykarp Kusch showed that the value differs from the prediction by a little over a tenth of a percent. Results were obtained that led several researchers to develop, independently and almost simultaneously in 1949, a relativistic quantum electrodynamics that eliminated some of the difficulties encountered in earlier works.

The problem with photons

The story is far from complete. Relativistic quantum electrodynamics has its own shortcomings; they are primarily of a philosophical nature, but the fact remains that no one yet knows how to write down exactly, in compact form, an equation describing the complete interaction between a proton and an electron, let alone solve it. Fortunately, the approximations that have been discussed are more than adequate for most purposes.

THE ORIGIN OF ATOMIC SPECTRA

That the richest source of clues for the development of atomic structure theory was furnished by atomic spectra is not surprising. It had been recognized early that each chemical element when heated or electrically excited emits a very characteristic array of spectral lines. Elements occurring in stars and in the solar atmosphere had been identified by their spectra. Moreover, the wavelength of each spectral line could be measured with high precision: rather simple equipment could determine these values easily to one part in 10,000. Thus, any proposed atomic model faced the formidable requirement of explaining in minute quantitative detail the origin of the numerous spectral lines emitted by each element. The later extension of spectroscopy into the invisible regions of ultraviolet and infrared radiation added enormously

Usefulness of atomic spectra

to the wealth of data to be explained. From the mid-20th century, new techniques, such as optical pumping, the principle on which the laser works, opened the radio-frequency and microwave regions for atomic spectroscopy, and the precision of all measurements increased tremendously.

A great simplification was recognition that the sets of terms rather than the spectral lines constitute the characteristic property of the atoms. The Bohr model and the experiment of Franck and Hertz have shown that each of these terms represents a sharply defined excited state, or energy level, of the atom. Spectral lines result when the atom goes over from one discrete excited state into another. If the final state of excitation is of lower energy than the initial one, the energy difference between them is emitted as a spectral line. If, on the other hand, incident light "lifts" the atom into a state of higher excitation, a dark absorption line appears on the spectrum of the transmitted light. The most easily observed absorption lines are those in the solar spectrum; the gases in the atmosphere of the Sun absorb lines in the continuous spectrum emitted by its core (these lines were discovered in 1814 and show the presence of a number of elements in the Sun).

The heart of the problem is to relate the terms to the structure of the atom. For details of this process in complex atoms, see SPECTROSCOPY, PRINCIPLES OF.

ATOMIC STRUCTURE AND MOLECULES

The nature of forces between atoms. For full details of this subject see CHEMICAL BONDING. In order to understand the formation of aggregates of atoms—*i.e.*, molecules and bulk matter—it is necessary to examine in somewhat greater detail the nature of the forces between atoms and their relation to atomic structure. It has been pointed out that the details of the Rutherford–Bohr model, of electrons travelling in orbits like those of planets, cannot be taken literally. Nevertheless, some features of that model are still valid. One such feature is the clustering of the permitted orbits into groups, or shells, as described above. In addition to the spatial compactness described there, the shells have the property that there is a special stability associated with the occupancy of all the orbits in a shell by electrons, two to an orbit. The innermost shell contains just one orbit; thus, helium, with two electrons, represents a particularly stable configuration: it is difficult to remove an electron from a helium atom, and there is virtually no tendency for an extra electron to attach itself to a helium atom. Because forces between atoms result primarily from the transfer (at least partial or temporary) of electrons from one to another, the forces between a helium atom and any other atom are very weak. Consequently, helium does not normally form compounds, liquefies only at very low temperature, and solidifies only under the application of pressure.

Electrons in shells

The next shell contains four orbits and thus can accommodate eight electrons and so is filled when the total number of electrons is ten. This arrangement corresponds to neon, another inert gas. The third shell also contains four orbits, and its completion, at a total of 18 electrons, also corresponds to an inert gas, argon.

Formation of a molecular bond. *Van der Waals force.* There are forces even between such inert atoms. An atom composed of filled shells is spherically symmetric on the average, with the positive charge of the nucleus located at the centre of the sphere of negative charge of the electrons. Such a distribution appears electrically neutral from the outside. But the electrons are in continuous motion, and at some instants the negative charge distribution is not centred on the nucleus. At such instants the atom as seen from outside is equivalent to an electric dipole: two charges, one positive and one negative, at opposite ends of a tiny rod. If two of these dipoles approach each other oriented so that like charges are at adjacent ends, they repel each other; but, if the adjacent ends carry the unlike charges, there is a net attractive force between them. In addition, the interaction in that orientation tends to reinforce the formation of the dipoles. The net result is to give a coherent force between any two atoms, known as the van der Waals force. It is very weak, and in atoms without closed shells it is overwhelmed by other forces.

Electrostatic force. The next example is sodium and chlorine. The sodium atom has one electron more than the capacity of the two innermost shells; the chlorine atom, one fewer than needed to complete the third. Consequently, the sodium atom loses one electron very easily, while the chlorine atom holds an extra electron tightly. If a sodium atom and a chlorine atom encounter one another, the electron is readily transferred from the sodium to the chlorine, forming two ions, one positive and one negative, which then are attracted to each other by the electrostatic force between unlike charges, forming a molecule of sodium chloride, common salt. This is called ionic bonding.

Covalent bonding. Pure ionic bonding is relatively rare; it is almost completely limited to compounds between the alkali metals (each of which has just one electron outside a complete shell) and halogens— fluorine, chlorine, bromine, and iodine, each of which lacks one electron from having a complete shell. Other combinations of atoms rely instead, at least partially, on the sharing of electrons. Two or more atoms are likely to share electrons when each atom thereby attains a closed shell, with each shared electron being counted in both atoms. This is called covalent bonding.

Some understanding may be obtained of how this process operates by considering a special but important case, that of two hydrogen atoms. When the two atoms are very far apart, they have no significant effect on one another. The set of possible states is just the combination of the two sets of atomic states, and the total number of states is therefore twice the number of states for a single atom. Each energy value is represented by two states, one localized around each of the atoms; such an energy and its associated states are called (doubly) degenerate. As the atoms get closer together, however, they begin to influence one another, and the nature of the states changes. They lose the property of being localized around a specific atom, and they change their energies. In particular, the degeneracy is removed, each pair of degenerate states separating into one somewhat higher and one somewhat lower, in a fashion shown schematically in Figure 2A. The labels symmetric and antisymmetric refer to properties of the corresponding Schrödinger functions, Ψ. The

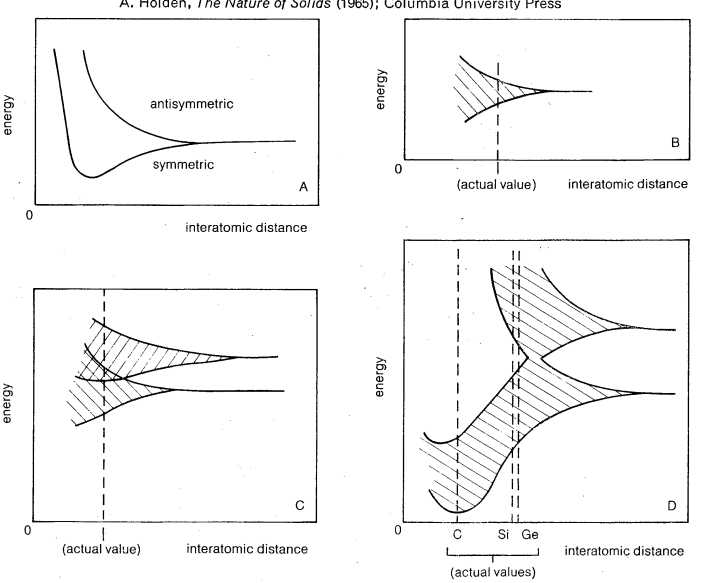

Figure 2: *Energy and distance relationships.*
(A) Variation in energy of the symmetric and antisymmetric states of two hydrogen atoms as the distance between the atoms is varied; (B) spreading of states of a very large number of atoms into a band as the interatomic distance is changed; (C) formation of overlapping bands in, say, zinc; (D) band structure of an insulator (diamond) and two semiconductors.

reason for the difference in behaviour is that an electron in the symmetric state has a high probability of being found between the two nuclei, where it exerts an attractive force on both of them and tends to hold them together. In the antisymmetric state, on the other hand, the electron has a very low probability of being found between the nuclei, so that the positive charges of the nuclei are more exposed to one another, and their electrostatic repulsion comes into play.

Effect of electron spin

These considerations have so far included only the spatial aspects of the states. The inclusion of spin means that each state can accommodate two electrons. In the case of two hydrogen atoms, there are just two electrons present, and so they can both be in the symmetric state, reinforcing the bonding. In the case of two helium atoms, with four electrons, two must go into the antisymmetric state; their effect is to draw the nuclei apart, and this action more than compensates for the binding effect of the two in the symmetric state. The helium molecule-ion, with two electrons in the symmetric state and one in the antisymmetric, is stable.

A basically similar process takes place between other combinations of atoms, although the details will naturally be different. Some examples are shown graphically in Figure 3. Just as purely ionic bonding is rare, however,

Adapted from A. Holden, *The Nature of Solids* (1965); Columbia University Press

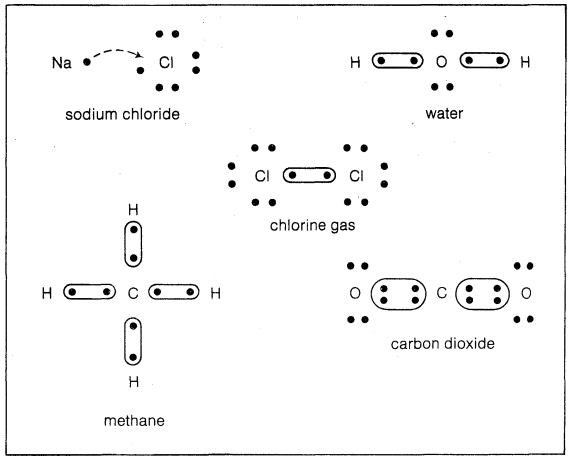

Figure 3: The formation of closed shells in molecules. The dots around each chemical symbol denote the electrons in the outermost incomplete shell. In the case of sodium chloride, the chlorine shell is completed by the transfer of the extra electron from sodium, as indicated by the arrow; in all other cases, the sharing of electrons is indicated by enclosing them together. The hydrogen shell is complete with only two electrons.

so does purely covalent bonding occur only in special cases. A bond between two identical atoms will be purely covalent; but, if the atoms are not identical, there is likely to be a tendency for the shared electrons to be closer on the average to one than to the other. This arrangement results in an average negative charge on the former, positive on the latter, and these average net charges provide some ionic character to the bond.

The origin of molecular spectra. The optical spectra of atoms are produced by transitions between various possible electronic configurations, or states, of the atoms. In molecules, too, the spectra are produced by transitions between different states; but there are two features by which the situation differs from that in atoms. First and most obvious is the fact that the outer electrons are no longer influenced by a single atom but by the whole molecule, so that the states of the molecule are not simply the states of the component atoms; an indication of this effect has been given in the preceding section. Second, it is not only the electrons that contribute to the energy of the molecule. The atoms can move within the molecule to some extent, in a variety of bendings and stretchings of the linkages between them; these motions are known as vibrational modes. Moreover, the molecule as a whole can rotate about various axes. Because the masses involved are those of atoms and molecules rather than electrons, the associated frequencies are much lower than those of purely electronic transitions, giving wavelengths well into the infrared and extending into the microwave range. Especially in large, complicated molecules such as those of organic compounds, many of these motions are characteristic not of the whole molecule but of subordinate parts, such as, say, the group defining an aldehyde, and are very useful for elucidating the structure of the molecule.

The vibrational and rotational modes also affect the spectra associated with the electronic transitions. The molecule may change both its electronic state and, say, its vibrational state simultaneously, and the frequency emitted is then determined by the total change in energy. Because the vibrational and rotational energies are so small, the effect is to associate each electronic transition with not one but a large number of very closely spaced spectrum lines, which under low resolution give the appearance of continuous bands.

ATOMIC STRUCTURE AND BULK MATTER

The nature of bonding in solids. For full details see SOLID STATE OF MATTER; PHASE CHANGES AND EQUILIBRIA. The preceding section described the types of forces that tend to bind atoms or molecules together. Opposing those forces is the motion of the atoms related to temperature: if a gas is at a temperature $T°$ K (kelvin), the atoms composing it are in motion and have an energy of motion (kinetic energy) of the order of kT, k being a constant called Boltzmann's constant and having the value 8.6×10^{-5} electron volt per °K. (At room temperature, about 300° K, this thermal energy is about 1/40 electron volt.) If the thermal energy is less than the energy that can be obtained from the coherent forces, the gas will condense into a liquid or a solid.

Just as there are different kinds of forces between atoms involved in the formation of molecules, so there are different kinds of forces involved in binding bulk matter. A great number of solids, including most organic (compounds of carbon) solids, the solid forms of the inert gases, and the solid forms of such elements as hydrogen and oxygen that are gaseous at ordinary temperatures, are bound by van der Waals forces between the molecules (atoms, in the case of inert gases). These forces are comparatively weak but are stronger for larger molecules, and, moreover, many molecules have permanent dipole moments so that many organic substances remain solid to moderately high temperatures.

Such substances as sodium chloride that form molecules bound by ionic bonding also form solids bound by the electrostatic forces between ions. Each ion tends to surround itself by four, six, or eight ions of the opposite charge, the number depending on the relative sizes of the ions and whether the ions of opposite charges occur in equal numbers in the compound (as sodium chloride, NaCl) of different numbers (as calcium fluoride, CaF_2).

Most inorganic compounds, having some covalent character to their bonds, form solids held together by essentially the same mechanism. Covalent bonds reflect the directional properties of the electron clouds, and solids of this type may have quite complicated structures, which are manifested in complex crystal forms.

Energy bands in the solid state. For full details see SEMICONDUCTORS AND INSULATORS, THEORY OF; ELECTRICITY. The influence of neighbouring atoms on each other's energy states occurs in solids, and the discussion of the covalent bond can easily by carried over. If the number of atoms is N, then the degeneracy of each state when the atoms are isolated is N-fold. Again the degeneracy is removed as the interatomic distance decreases; but the separation between the highest and the lowest energies coming from one originally degenerate level is not affected by the number of atoms. Consequently, if N is very large, as in a piece of bulk matter, the intermediate levels will be so closely spaced as to form an essentially continuous band of energies. Several properties of solids, especially electrical and optical behaviour, are governed by the existence and nature of these bands.

Mechanism of electrical conductivity

The details of the theory of electrical conduction are outside the scope of this article. Generally speaking, however, a substance is an electrical conductor if there is an energy band that contains some electrons but not as many as it could accommodate; it is an insulator if every nonempty band is filled to capacity, with certain exceptions discussed later. Evidently, the electrical properties of a substance depend on the arrangement of the energy bands and the number of electrons that must be accommodated in them. Three cases are shown in Figure 2B–D.

Figure 2B shows the case that applies to the alkali metals. Here the highest occupied band arises from a single set of states. Each of these states in the isolated atoms, however, contains only one electron, so that there are N electrons in a band that can hold $2N$. Thus, the alkali metals are good conductors.

Figure 2C shows another situation that gives rise to metallic conduction, this time the type appropriate to, say, zinc. Here the highest normally occupied atomic state contains two electrons; a band formed from it alone would therefore be filled to capacity. In this case, however, this band overlaps one formed from the next higher atomic state, so that the combined band is only partly filled, and zinc is a conductor.

Two other cases are combined in Figure 2D, which is actually a simplified summary of a much more complicated situation. Here again there is some tendency for the bands to overlap; but here an interaction between the bands causes them to separate again as the interatomic distance decreases still further. Such a picture applies to the elements in the centre of the periodic table; *e.g.*, carbon in the form of diamond, silicon, and germanium. In each case, the lower band is filled by the $4N$ outermost electrons of the N atoms. For diamond, the interatomic distance is well away from the crossover range, the gap between bands is much larger than kT, and diamond is an insulator. For silicon or germanium, however, the interatomic spacing is quite close to the crossover point—close enough so that the gap between the bands is about the same order of magnitude as the thermal energy at ordinary temperatures. Thus, some electrons can absorb enough thermal energy to be raised across the gap. This situation both leaves the lower band incompletely filled and provides some occupancy of the upper, both of which processes give the possibility of electrical conduction. The number of charge carriers, however, that can be made available in this way is several factors of 10 smaller than the number available in a typical metal, so that substances with this sort of band structure are semiconductors (see SEMICONDUCTORS AND INSULATORS, THEORY OF).

Semiconductors

Optical behaviour. Many interesting colour effects in solids have their origin in the structure of the atoms composing the solid. It was pointed out in the section *Origin of atomic spectra* that an atom can absorb radiation only when that radiation is of a frequency corresponding, by Planck's rule, to the energy needed to lift an atomic electron from its normal state to a higher state in the atom. This statement still is true if the atom is part of a solid; now, however, the energy states that must be considered are not those of the isolated atom but those of the atom as affected by its neighbours. Earlier sections have shown that the modification takes two forms: it spreads the originally sharp levels into bands, and it shifts their energies somewhat. The result of the first of these forms is that, whereas an isolated atom will absorb only a relatively few discrete frequencies, a solid will absorb a range of frequencies.

For many crystalline substances, the energy interval from the highest occupied band to the next higher band corresponds to frequencies outside the range of visible light. Such is the case, for example, for pure quartz, sodium chloride, and calcite. In others, however, the energy gap corresponds to visible light. Copper sulfate, for example, absorbs light in the red and yellow region of the spectrum and so has a blue colour.

An especially interesting case of the effect of surroundings occurs in cobaltous chloride. This substance has a tendency to incorporate water into its crystal structure. When it has all the water it can hold, its absorption range is such as to give it a pink colour. As the water is removed, however, the energies of the bands change, and the completely dehydrated form is blue. The water of crystallization can be gained or lost merely by exposure to moist or dry air, so that this substance can be used as a crude humidity indicator.

Luminescence. Every absorption process has corresponding to it an emission process, in which the electron returns from the excited state to its normal state. It would seem at first that these two processes should occur with identical wavelengths, but such is not always the case. An atom in an excited state will generally be different in some spatial respect, such as size, from one in the normal state, with the result that the equilibrium configuration of it and its surroundings may also be altered. When this is so, the crystal usually can readjust itself in a time short compared with the duration of the excited state, leading to changes in the energies of the atomic states involved, usually somewhat different for different states. The return of the electron to its normal state then gives rise to emission of a different (and always lower) frequency than that which was absorbed. This emission is one form of luminescence. Other forms occur when the electron does not return directly to its original state but goes by way of some intermediate state. In some cases, moreover, the excited electron may wander away from its parent atom before it de-excites; it may then spend a considerable time wandering through the crystal before it encounters a vacant lower level to drop into.

It should be noted that the electron may be raised to an excited state by a variety of mechanisms. Not only visible light but also ultraviolet or X-rays may be absorbed —fluorescent lamps use luminescence stimulated by ultraviolet light from a mercury discharge. Also the action of an electric field may be effective in some cases. Even a mechanical strain is sufficent for a few substances.

Stimulated emission. The operation of a laser depends on luminescence of the intermediate-state variety, together with the phenomenon of stimulated emission: an excited atom will be triggered to emit a photon when it is struck by an outside photon of just the energy it would naturally emit; moreover, the emitted photon forms a wave that is in phase—*i.e.*, exactly "in step"—with the triggering wave. In a laser, a large number of electrons are raised to an excited state by an external agency, the pumping light. They then give up some of their energy and drop into an intermediate state the average lifetime of which is typically a few thousandths of a second. (In a ruby laser, this excess energy is given to the crystal as heat; in a gas laser, it may be emitted as a photon of a fairly low frequency.) The laser emission begins when one of these intermediate states emits a photon parallel to the axis of the laser. This photon travels back and forth between the ends, which are silvered so as to act as mirrors, triggering other excited atoms as it passes them; the emission then builds up an avalanche effect.

Magnetism. For full details see MAGNETISM. All atoms possess some magnetic properties. It has already been noted that the orbital motions correspond to current loops that behave like magnets and that the electron spin has a magnetic moment associated with it. Different kinds of atoms, however, behave differently.

The one universal property is called diamagnetism. When the atom is subjected to a magnetic field, the electronic states are altered, and therefore so are the magnetic moments associated with them. The effect is such as to produce an atomic magnetic field opposing the applied field. A bar-shaped piece of material in which this is the only magnetic effect tends to align itself across a magnetic field. Bismuth is the outstanding example of such a substance. Usually, this effect is masked by others.

In most materials, including not only atoms (gases) but also molecules, liquids, and solids, the electronic magnetic fields do not exactly add to zero. This situation leaves a weak magnetic effect called paramagnetism.

In a very few substances, notably iron, cobalt, and nickel but including some special alloys, there are several electrons per atom the spins of which are all in the same

direction. (These are not the outermost, or valence, electrons but are farther in the interior of the atom.) This arrangement produces a large net effect, one that extends to neighbouring atoms, causing the atoms throughout large portions of the resulting solids to arrange themselves with their atomic magnetic moments aligned parallel to one another. These portions, called domains, interact strongly with applied magnetic fields and give the substances involved their characteristic magnetic properties, called ferromagnetism. While ferromagnetism has its ultimate origin in the properties of individual atoms, however, it is basically a phenomenon involving correlation of many atoms.

Atomic Weight

The term atomic weight is equivalent to "relative atomic mass," the ratio of the average mass of an element's atoms to some standard. Since 1961 the standard unit of atomic mass has been $\frac{1}{12}$ of the mass of an atom of the isotope carbon-12 (an isotope is one of two or more species of atoms of the same chemical element that have different atomic masses). The atomic weight of carbon is 12.011, the average that reflects the typical ratio of natural abundances of its isotopes.

The concept of atomic weight is basic to chemistry, because most chemical reactions take place in accordance with simple numerical relationships among atoms. Since it is almost always impossible to count the atoms directly, chemists measure reactants and products by weighing and reach their conclusions through calculations involving atomic weights.

The quest to determine the atomic weights of elements occupied the greatest chemists of the 19th and early 20th centuries. Their careful experimental work became the key to chemical science and technology.

Variations in atomic-weight values. At the turn of the 20th century, the simple concept of a true atomic weight characteristic of all specimens of any one element remained unchallenged. The idea was that, as precision measurement improved, true values would be increasingly more closely approached.

What followed is typical of the history of the science of measurement. Need for more accurate knowledge of a supposed constant of nature is recognized. Experimenters take up the challenge. As they obtain more precise values, it is suddenly realized that the desired number is not a universal constant. The discovery of isotopes disproved the idea that atomic weights were universal constants, yet the vast majority of changes that occur in the composition of matter are those in which neither the atoms themselves are altered nor significant isotope discrimination is involved. Today, all quantitative operations in chemical reactions, whether aimed at analysis or synthesis of materials, still pivot on atomic and molecular weights. (The molecular weight of a molecule is numerically equal to the sum of the atomic weights of all the atoms that comprise the molecule.)

Atomic masses of individual nuclides (specific isotopic species of one element) can be determined with great accuracy, but only 20 stable elements are limited to one stable nuclide. For all others, the chemist needs the average of the atomic masses appropriate for the mixture of nuclides as he finds them. Basic limitations on precision thus present themselves in the provision and use of atomic weights for the chemist: (1) Even the most precise methods of measurement presently available introduce uncertainties that limit knowledge. (2) There are significant differences in isotopic composition of elements and surprisingly sparse knowledge of the variabilities, especially for minor elemental constituents in rocks and minerals. (3) Modern technology changes the isotopic composition of processed materials. To a small extent, every chemical and every physical process and, to a large extent, every nuclear process differentiates among isotopes of the same element. (4) Extraterrestrial materials, the isotopic compositions of which have not yet been determined, will soon be more widely available.

Problems of measurement

Significance of atomic weights to chemistry. The general acceptance of the early-19th-century atomic theory of the constitution of matter—*i.e.*, as being composed of indivisible atoms, indestructible and merely rearranged by chemical reactions—developed by the English chemist John Dalton, was soon followed by the conclusion that atoms of different elements combine in simple numerical proportions and prepared the ground for a rapid growth of experimentation in chemistry. There were diverse objectives, among them the discovery of new elements, the analysis of rocks and minerals, the synthesis of new substances, and the study of the distribution of the elements in nature. Fundamental tools available for this task were the laboratory balance and volume-measuring devices. The latter served directly, with the aid of Avogadro's hypothesis (which states that equal volumes of gases, at the same pressure and temperature, contain equal numbers of molecules), to deduce the numerical proportions in which atoms of gaseous substances react. For solids and liquids, the primary measurable information was the proportion by weight that characterizes the reactions. On the basic assumption that atoms combine in integral numerical proportions, it could be concluded that relative combining weights were either identical with, or simple submultiples of, atomic weights.

In the early history of chemistry, chemists sought to measure the masses of atoms solely as a means of counting atoms, not out of interest in atomic mass as such. As long as the atom was considered immutable, its mass was of only secondary interest. The relative values of atomic masses, on a common scale, were of the greatest importance. Such ratios provided the means of deriving numerical relationships among reacting atoms, and, by simple calculations, the formulas of molecules could be derived.

Work toward continual improvement of atomic-weight values yielded important by-products. Since the end result of such efforts was considered to be a true constant of nature, variations in experimental results obviously revealed errors. Uncovering sources of errors and determining their magnitudes eventually resulted in significant advances in chemical knowledge. Areas of special interest were the purity and stoichiometric (combining proportions) composition of substances, prevention of loss of substance and contamination during chemical reactions, accurate weighing, and improved knowledge of the chemical reactions themselves. A marked advance in laboratory procedures resulted when fused-silica reaction vessels and electrically heated furnaces became available to the chemist. The use of these devices greatly decreased the likelihood of contamination of reactants and their product by container materials and products of combustion.

Key discoveries

As the accuracy of atomic-weight values increased, their significance to the understanding of the laws of chemistry increased also. Anomalies in the periodic classification of the elements (the periodic table), based on their atomic weights, were confirmed even if not immediately explained. It became clear that iodine should follow tellurium and that nickel should follow cobalt in the table, despite the fact that, according to their atomic weights, the order should be reversed.

The answer to these riddles had to await the discovery of isotopes, a discovery that was itself hastened by the

reluctant conclusion of T.W. Richards, an American chemist and Nobel Prize recipient for his researches on atomic weights, that a group of lead samples of differing geological origins were identical chemically but differed in atomic weight. Thus the way was prepared for the discovery, soon to follow, that most elements occur in nature as mixtures of atomic species to which the name isotopes was given.

Because the rationale of organic compounds depends so strongly on the atomic weight of carbon, much effort was expended on this element. An unusual number of difficulties was encountered. As late as 1937 an attempt to elucidate the structure of the hydrocarbon that constitutes natural rubber failed to yield meaningful results when the then accepted value for the atomic weight of carbon (12) was used in calculating the numerical ratio of carbon and hydrogen atoms. A year later, a new determination yielded the value 12.01, which was later further revised to 12.011.

Reliable values for atomic weights serve an important purpose, in a quite different way, when chemical commodities are bought and sold on the basis of the content of one or more specified constituents. Ores of costly metals such as chromium or tantalum and the industrial chemical soda ash are examples. Content of the specified constituent must be determined by quantitative analysis. The computed worth of the material depends on the atomic-weight values used in the calculations.

Atomic-weight scales. The original standard of atomic weight, established in the 19th century, was hydrogen, with a value of 1. From about 1900 until 1961, oxygen was used as the reference standard, with an assigned value of 16. The unit of atomic mass was thereby defined as 1/16 the mass of an oxygen atom. In 1929, it was discovered that natural oxygen contains small amounts of two isotopes slightly heavier than the most abundant one and that the number 16 represents a weighted average of the masses of the atoms of the three isotopic forms of oxygen as they occur in nature. This situation was considered undesirable for several reasons, and, since it is possible to determine the relative masses of the atoms of individual isotopic species, a second scale was soon established with 16 as the value of the principal isotope of oxygen rather than the value of the natural mixture. This second scale, preferred by physicists, came to be known as the physical scale, and the earlier scale continued in use as the chemical scale, favoured by chemists, who generally worked with the natural isotopic mixtures rather than the pure isotopes.

Although the two scales differed only slightly, the ratio between them could not be fixed exactly, because of the slight variations in the isotopic composition of natural oxygen from different sources. It was also considered undesirable to have two different but closely related scales dealing with the same quantities. For both of these reasons, chemists and physicists established a new scale in 1961. This scale, based on carbon-12, required only minimal changes in the values that had been used for chemical atomic weights.

Methods of determining atomic weights. *Chemical methods.* In the late 19th century, chemists differed among themselves on the merits of two scales of atomic weights, one based on hydrogen with the assigned relative mass of 1 and the other on oxygen with the assigned integral value of 16. Values on these two scales differed by nearly 1 percent, and much effort was directed toward fixing the relationship between the scales more exactly by determining the combining-weight ratio of the two elements. The first results on this ratio had been published in 1821, and other measurements had followed at intervals, until the American chemists E.W. Morley in 1895 and W.A. Noyes in 1907 published their elaborate and definitive studies. Their results did not quite agree with each other, but the mean of the two investigations agrees well with that derived from more recent physical determinations of the relative atomic masses of the two elements.

The oxygen–hydrogen ratio

A good example of the directly measured ratio of an element to oxygen is found in the work of two American chemists, G.P. Baxter and C.R. Hoover, who in 1912 reduced weighed amounts of carefully prepared ferric oxide in a current of hydrogen and weighed the residue of pure iron. Their investigation yielded 55.8456 as the atomic weight of iron, in excellent agreement with the currently accepted value, 55.847 ± 0.003.

The relative ease of preparing highly pure metallic silver, together with the stability of silver chloride and silver bromide, led many investigators to determine the equivalence ratios (relationship between quantities of combining chemical species) of various soluble chlorides and bromides with silver and the corresponding silver salts. The experimental procedures involved in such measurements were brought to a high degree of perfection in the laboratories of T.W. Richards and G.P. Baxter at Harvard University and of O. Hönigschmid at the University of Munich, and it can now be said that the observed ratios of silver to chlorine, bromine, and oxygen were in error by no more than 0.001 percent, 0.002 percent, and 0.003 percent, respectively. Such determinations made major contributions during the period up to 1940 to the reliability of the International Table of Atomic Weights.

Halide–silver ratios

It seems probable that a principal source of the errors now known to have affected the halide–silver ratios was the virtual impossibility of achieving true equilibrium between a precipitate of silver chloride or bromide and the solution in which it was formed (equilibrium: a state of balance between all reactants and products in a reversible chemical reaction, attained when two opposing reactions go on at equal rates). If the equivalence point (where each reaction has the same rate) can be determined for two substances that react in solution without forming a precipitate, attainment of equilibrium is more assured. An example is provided by combining the ratio of sodium carbonate to iodine pentoxide (which forms periodic acid when dissolved in water) with that resulting from the dissociation of iodine pentoxide to iodine and oxygen. Combining these ratios cancels an apparent minute deviation of the iodine pentoxide from its nominal proportionate composition, and values then derived for sodium, carbon, and iodine are consistent within 0.001 percent of presently accepted values.

Physical methods. Physical measurements are rapidly increasing in diversity and precision. Probably the gradual change from atomic-weight values based on chemical determinations to values based on physical measurements will run its course to completion, but it is difficult as yet to predict which physical methods will be the most accurate.

Types of physical measurement

Basically, two types of physical measurements should be distinguished. First, there are those in which the atomic weight of an element is determined directly as an average appropriate for the isotopic composition of that element. Historically the most important technique of this kind is that of gas-density ratios depending on Avogadro's rule. The most promising method of this first type is the X-ray-diffraction method in which, ideally, the macroscopic density of a pure, perfect crystal is compared with the density of the atomic-scale-pattern unit, dimensionally determined by X-ray diffraction.

In the second type of physical determinations the atomic masses of nuclides are first measured. This can now be done with great accuracy by mass spectroscopy, the technique in which charged particles are separated according to their atomic masses and from the energy changes in nuclear reactions. For elements composed of only one nuclide, extremely accurate atomic-weight values are thus directly available. The isotopic composition must be separately measured, however, for the great majority of the elements before their atomic weights can be calculated from the nuclidic masses.

To date, mass spectroscopy is the only technique used for measuring isotopic compositions quantitatively, but the technique of resonance spectroscopy (in which the character of atomic nuclei placed in a static magnetic field is observed through resonant response to a high-frequency magnetic field) may become competitive in the future. Mass spectroscopic measurements, calibrated by

Atomic Weights, 1971

(based on the assigned relative atomic mass of $^{12}C = 12$)

The values given here apply to elements as they exist in materials of terrestrial origin and to certain artificial elements. When used with due regard to the footnotes they are considered reliable to ± 1 in the last digit, or ± 3 if that digit is underscored. Atomic weights of elements with no stable isotope are given as mass numbers, in parentheses, of the most stable isotope.

*Mononuclidic element. †Element with one predominant isotope (about 99–100% abundance). ‡Element for which the atomic weight is based on calibrated measurements. §Element for which variation in isotopic abundance in terrestrial samples limits the precision of the atomic weight given. ‖In some geological specimens this element has a highly anomalous isotopic composition, corresponding to an atomic weight significantly different from that given. ¶Most commonly available long-lived isotope. ♀Element for which users are cautioned against the possibility of large variations in atomic weight due to inadvertent or undisclosed artificial isotopic separation in commercially available materials.

synthetic isotope mixtures, are generally superior to chemical and to other physical methods for elements with two or at most three isotopes. Thus for some time to come mass spectroscopy is likely to remain the technique on which a large number of atomic-weight values are based.

Summary. The atomic weight of a chemical element is the ratio of the mass of a large number of its atoms (randomly selected from naturally occurring material) to the mass of the same number of atoms of carbon with six neutrons in their nucleus; *i.e.*, the isotope carbon-12.

Atomic-weight tables. The table of atomic weights here reproduced, with minor editorial changes, is published and biennially revised by the Commission on Atomic Weights of the International Union of Pure and Applied Chemistry. The Table sets out values intended to be as accurate as possible, so accurate as not to discard reliable knowledge; however, atomic-weight values are not carried to more decimal places than are justified by the variability of isotopic composition and uncertainty in determination. The Table is also intended to warn of some kinds of processed materials that need to be more closely characterized before published atomic-weight values can be applied with confidence; *e.g.*, lithium, which may have been subjected to isotopic separation in commercially available materials.

BIBLIOGRAPHY. The basic concepts involved in atomic weight measurement and use are discussed in all elementary textbooks on chemistry. The historic development and detailed considerations during the last 70 years are best followed through commission reports. The responsible commission since 1923 has been that on Atomic Weights of the International Union of Pure and Applied Chemistry. Its reports are now published in *Pure and Applied Chemistry*. They are usually translated or reprinted in national chemical literatures. Of recent reports the most important are those of 1961 and 1969, for which the following are among the best references: A.E. CAMERON and E. WICHERS, "Report of the International Commission on Atomic Weights 1961," *J. Am. Chem. Soc.*, 84:4175–4179 (1962); and the INTERNATIONAL UNION OF PURE AND APPLIED CHEMISTRY, COMMISSION ON ATOMIC WEIGHTS, "The Atomic Weights of the Elements 1969," *Pure Appl. Chem.*, 21:95–108 (1970).

(H.S.P./E.Wi.)

Atomism

In the broadest sense the term Atomism refers to any doctrine that explains complex phenomena in terms of aggregates of fixed particles or units. This philosophy has found its most successful application in natural science: according to the atomistic view, the material universe is composed of minute particles, which are considered to be relatively simple and immutable and too small to be visible. The multiplicity of visible forms in nature, then, is based upon differences in these particles and in their configurations; hence any observable changes must be reduced to changes in these configurations.

THE BASIC NATURE OF ATOMISM

Atomism is in essence an analytical doctrine. It regards observable forms in nature not as intrinsic wholes but as aggregates. In contrast to holistic theories, which explain the parts in terms of qualities displayed by the whole, Atomism explains the observable properties of the whole by those of its components and of their configurations.

Core concepts

In order to understand the historical development of Atomism and, especially, its relation to modern atomic theory, it is necessary to distinguish between Atomism in the strict sense and other forms of Atomism. Atomism in the strict sense is characterized by three points: the atoms are absolutely indivisible, qualitatively identical (*i.e.*, distinct only in shape, size, and motion), and combinable with each other only by juxtaposition. Other forms of Atomism are less strict on these points.

Atomism is usually associated with a "realistic" and mechanistic view of the world. It is realistic in that atoms are not considered as subjective constructs of the mind employed for the sake of getting a better grip upon the phenomena to be explained; instead, atoms exist in actual reality. By the same token, the mechanistic view of things, which holds that all observable changes can be reduced to changes of configuration, is not merely a matter of employing a useful explanatory model; the mechanistic thesis holds, instead, that all observable changes are caused by motions of the atoms. Finally, as an analytic doctrine Atomism is opposed to organismic doctrines, which teach that the nature of a whole cannot be discovered by dividing it into its component parts and studying each part by itself.

VARIOUS SENSES OF ATOMISM

The term Atomism is derived from the Greek word *atoma*—"things that cannot be cut or divided."

Two basic types of Atomism. The history of Atomism can be divided into two more or less distinct periods, one philosophical and the other scientific, with a transition period between them (from the 17th to the 19th century). This historical fact justifies the distinction between philosophical and scientific Atomism.

Philosophical Atomism. In philosophical Atomism, which is as old as Greek philosophy, attention was focussed not on the detailed explanation of all kinds of concrete phenomena but on some basic general aspects of these phenomena and on the general lines according to which a rational explanation of these aspects was possible. These basic aspects were the existence in nature of a manifold of different forms and of continuous change.

Forces and change

In what way could these features be explained? Philosophical Atomism offered a general answer to that question. It did not, however, strictly confine itself to the general problem of explaining the possibility of change and multiplicity—not even in ancient Greek Atomism, for in Greek thought philosophy and science still formed a unity. Consequently, Atomists also tried to give more detailed explanations of concrete phenomena, such as evaporation, though these explanations were meant more to endorse the general doctrine of Atomism than to establish a physical theory in the modern sense of the word. Such a theory was not yet possible, because a physical theory must be based upon indirect or direct information about the concrete properties of the atoms involved, and such information was not then available.

Modern atomic theory. With the development of a scientific atomic theory, the general philosophical problems gradually disappear into the background. All attention is focussed on the explanation of concrete phenomena. The properties of the atoms are determined in direct relationship with the phenomena to be explained. For this reason the chemical atomic theory of the 19th century supposes that each identified chemical element has its own specific atoms and that each chemical compound has its own molecules (fixed combinations of atoms). What particles act as unchanged and undivided units depends upon what kind of process is involved. Some phenomena, such as evaporation, are explained by a process in which the molecules remain unchanged and identical. In chemical reactions, however, the molecules lose their identity. Their structures are broken up, and the composing atoms, while retaining their own identity, are rearranged into new molecules. With nuclear reactions a new level is reached, on which the atoms themselves are no longer considered as indivisible: more elementary particles than the atoms appear in the explanations of nuclear reactions.

Extensions to other fields. Whereas classical Atomism spoke mainly of material atoms (*i.e.*, of particles of matter), the success of the atomic doctrine encouraged the extension of the general principles of Atomism to other phenomena, more or less removed from the original field of application. Rather plausible, for example, was the extension of Atomism to the phenomena of electricity. There were reasons to suppose the existence of an elementary charge of electricity associated with an elementary material particle: the electron (19th century). A second fruitful extension concerned energetic processes (20th century). Some experimental data suggested the hypothesis that energy can exist only in amounts that are whole multiples of an elementary quantity of energy. Extensions of the idea of an atomic structure to amounts of gravitation and even to time have been attempted but have not been sufficiently confirmed.

Logical Atomism, monadology, associationism

More removed from the original field of application of Atomism is a theory known as Logical Atomism (developed by the eminent philosopher and logician Bertrand Russell and by the philosopher of language Ludwig Wittgenstein), which supposes that a perfect isomorphism exists between an "atom" of language (*i.e.*, an atomic proposition) and an atomic fact; *i.e.*, that for each atomic fact there is a corresponding atomic proposition. An atomic proposition is one that asserts that a certain thing has a certain quality; *e.g.*, "this is red." An atomic fact is the simplest kind of fact and consists in the possession of a quality by some individual thing.

Another application of Atomism (albeit in a moot sense) lies in the monadology of the philosopher-scientist G.W. Leibniz. According to Leibniz the atoms of Democritus, who provides the paradigm case of ancient Greek Atomism, were not true unities; possessing size and shape, they still were divisible in principle. The ultimate constituents of things must, therefore, be points, said Leibniz—not mathematical but metaphysical points, *i.e.*, points of real existence. They are indeed a kind of soul, which he came to call "monads."

In psychology, Atomism is a doctrine about perception. It holds that what man perceives is a mosaic of atomic sensations, each independent and unconnected with any other sensation. According to the early modern Empiricist David Hume and the pre-World War I father of experimental psychology Wilhelm Wundt, the fact that man nevertheless experiences an ordered whole formed from the unordered "atoms" of perception is caused by the mind's capacity to combine them by "association."

DIVERSE PHILOSOPHICAL CHARACTERIZATIONS OF ATOMISM

The intrinsic nature of the atoms. In 1927 the Belgian astronomer Georges Lemaître formulated the hypothesis that the present high degree of differentiation of matter in space and the complexity of forms displayed by the various astronomical objects must have resulted from a violent explosion and subsequent dispersal of an origi-

One being: Lemaître and Parmenides

nally highly compressed homogeneous material, a kind of "primitive atom," containing all of the matter that exists. From the philosophical viewpoint this hypothesis is interesting. By its attempt to reduce the manifold to unity it recalls the beginning of Greek philosophy, which was also inspired by a thesis of the unity of being, propounded by the Eleatic Parmenides. Even apart from their respective contexts, there is, of course, a great difference between Lemaître's and Parmenides' conceptions of the unity of being, for the latter combined the thesis of the unity of being with that of the immutability of being.

Although it would be wrong to classify Parmenides among the Atomists, it is nonetheless appropriate that in an introduction to the diverse forms of Atomism, his conception of reality as just one being should be mentioned. Parmenides' thesis is not only historically but also logically the cornerstone of atomistic thought. Any atomic theory can be interpreted as an attempt to reconcile the thesis of the unity and immutability of being with the fact that the senses observe multiplicity and change. The different ways in which the unity and immutability are understood characterize the different forms of Atomism.

Atoms as lumpish corpuscles. As corpuscles (minute particles), atoms can either be endowed with intrinsic qualities or be inherently qualityless.

Inherently qualitied atoms

The most striking basic differences in the material world, which lead to a first classification of substances in nature, are those between solids, liquids, gases, and fire. These differences are an observed datum that must be accounted for by every scientific theory of nature. It is, therefore, only natural that one of the first attempts to explain the phenomena of nature was based upon these differences and proclaimed that there are four qualitatively different primitive constituents of everything, namely, the four elements: earth, water, air, and fire (Empedocles, 5th century BC)—a theory that dominated physics and chemistry until the 17th century.

Although the theory of the four elements is not necessarily an atomistic theory, it obviously lends itself to interpretation in atomistic terms, namely, when the elements are conceived as smallest parts that are immutable. In this case, all observable changes are reduced to the separation and commingling of the primitive elementary substances. Thus Parmenides' thesis that being is immutable is maintained, whereas the absolute unity of being is abandoned. Yet, the fact that the infinite variety of forms and changes in nature is reduced to just one type of process between only four elementary kinds of atoms shows its affinity with the thesis of the unity of all being.

Notwithstanding the great disparity between the theory of the four elements and modern chemistry, it is clear that modern chemistry with its approximately 100 qualitatively different atoms falls into the same class of atomic theories as that of Empedocles. There are differences, of course, but these will be deferred for later discussion.

More removed from the original thesis of Parmenides was the theory of his contemporary Anaxagoras of Clazomenae, which assumed as many qualitatively different "atoms" as there are different qualitied substances in nature. Inasmuch as these atoms, which Anaxagoras called "seeds," were eternal and incorruptible, this theory still contains an idea borrowed from Parmenides. A special feature of Anaxagoras' theory was that every substance contains all possible kinds of seeds and is named after the kind of seed that predominates in it. Since the substance contains also other kinds of seed, it can change into something else by the separation of its seeds.

Another interesting form of Atomism with inherently qualitied atoms, also based on the doctrine of the four elements, was proposed by Plato. On mathematical grounds he determined the exact forms that the smallest parts of the elements must have. Fire has the form of a tetrahedron, air of an octahedron, water of an icosahedron, and earth of a cube. Inasmuch as he characterized the atoms of the four elements by different mathematical forms, Plato's conception can be considered as a transition between the qualitative and quantitative types of Atomism.

Qualityless atoms

The most significant system of Atomism in ancient philosophy was that of Democritus (5th century BC). Democritus agreed with Parmenides on the impossibility of qualitative change but did not agree with him on that of quantitative change. This type of change, he maintained, is subject to mathematical reasoning and therefore possible. By the same token, Democritus also denied the qualitative multiplicity of visible forms but accepted a multiplicity based on purely quantitative differences. In order to reduce the observable qualitative differences to quantitative differences, Democritus postulated the existence of invisible atoms, characterized only by quantitative properties: size, shape, and motion. Observed qualitative changes are based upon changes in the combination of the atoms, which themselves remain intrinsically unchanged. Thus Democritus arrived at a position that was defined above as Atomism in the strict sense. In order to make the motion of atoms possible, this Atomism had to accept the existence of the void (empty space) as a real entity in which the atoms could move and rearrange themselves. By accepting the void and by admitting a plurality of beings, even an infinite number of them, Democritus seemed to abandon—even more than Empedocles did—the unity of being. Nevertheless, there are sound reasons to maintain that, in spite of this doctrine of the void, Democritus' theory remained close to Parmenides' thesis of the unity of being. For Democritus' atoms were conceived in such a way that almost no differences can be assigned to them. First of all, there are no qualitative differences; the atoms differ only in shape and size. Secondly, the latter difference is characterized by *continuity;* there are no privileged shapes and no privileged sizes. All shapes and sizes exist, but they could be placed in a row in such a manner that there would be no observable difference between successive shapes and sizes. Thus not even the differences in shape and size seem to offer any ground explaining why atoms should be different. By accepting an infinite number of atoms, Democritus retained as much as possible the principle that being is *one.* With respect to the acceptance of the void, it must be stressed that the void in the eyes of Democritus is more nonbeing than being. Thus even this acceptance does not seriously contradict the unity of being.

Atoms as sheer extension. Democritus had declared quantitative differences to be intelligible, because they were subject to mathematical reasoning. Precisely this relationship between quantitative differences and mathematics made it impossible for Descartes (17th century) to think along the atomistic lines of Democritus. If the only thing that is clearly understandable in matter is mathematical proportions, then matter and spatial extension are the same—a conclusion that Descartes did not hesitate to draw. Consequently, he rejected not only the idea of indivisible atoms but also that of the void. In his eyes the concept "void" is a contradiction in terms. Where there is space, there is by definition extension and, therefore, matter.

Descartes's vortices

Yet, however strange it may seem in view of his identification of matter with extension, Descartes offered nonetheless a fully developed theory of smallest particles. To the questions that arise immediately as to how these particles are separated and distinct from each other, Descartes answered that a body or a piece of matter is all of that which moves together. In the beginning of the world all matter was divided into particles of equal size. These particles were in constant motion and filled all of space. As, however, there was no empty space for moving particles to move into, they could only move by taking the places vacated by other particles that, however, were themselves in motion. Thus the motion of a single particle involved the motion of an entire closed chain of particles, called a vortex. As a result of the original motion, some particles were gradually ground into a spherical form, and the resulting intermediary space became filled with the surplus splinters or "grindings." Ulti-

mately, three main types of particles were formed: (1) the splinter materials, which form the finest matter and possess the greatest velocity; (2) the spherical particles, which are less fine and have a smaller velocity; and (3) the biggest particles, which originated from those original particles that were not subject to grinding and became united into larger parts.

Thus Descartes could construct an atomic theory without atoms in the classical sense. Although this theory as such has not been of great value for the scientific atomic theory of modern times, its general tendency was not without importance. However arbitrarily and speculatively Descartes may have proceeded in the derivation of the different kind of corpuscles, he finally arrived at corpuscles characterized by differences in mass, velocity, amount of motion, etc.—properties that could be treated mathematically.

Boscovich's point-centres and Leibniz's monads

Atoms as centres of force: dynamic particles. Most systems of Atomism depict the action between atoms in terms of collision—*i.e.*, as actual contact. In Newton's theory of gravitation, however, action between bodies is supposed to be action at a distance—which means that the body in question acts everywhere in space. As its action is the expression of its existence, it is difficult to confine its existence to the limited space that it is supposed to occupy according to its precise shape and size. There is, therefore, no reason for a sharp distinction between occupied and empty space. Consequently, the mind finds it natural to consider the atoms not as extended particles but as point-centres of force. This conception was worked out by the Dalmatian scientist R.G. Boscovich (1711–87), who attempted to account for all known physical effects in terms of action at a distance between point-particles, dynamic centres of force.

Atoms as psychophysical monads. The idea of applying the atomistic conceptions not only to material but also to psychical phenomena is as old as Atomism itself. Democritus had spoken of the atoms of the soul. According to the principles of his doctrine these atoms could differ only quantitatively from those of the body: they were smoother, rounder, and finer. This made it easy for them to move into all parts of the body. Basically, however, the atoms of the soul were no less material than other atoms.

In Leibniz's monadology the situation was quite different. Leibniz did not first conceive of material atoms and then only later interpret the soul in terms of these atoms; from the beginning he conceived his "atoms," the monads, in terms of an analogy with the soul. A monad is much more a spiritual than a material substance. Monads have no extension; they are centres of action but not, first of all, in the physical sense. Each of the monads is gifted with some degree of perception; each mirrors the universe in its own way. Monads differ from each other, however, in the degree of perception of which they are capable.

The immutability of atoms. By their nature all atomic theories accept a certain degree of immutability of the atoms. For without any fixed units no rational analysis of complex phenomena is possible. At least with respect to the stable factors in the analysis involved, the atoms have to be considered as immutable. According to Atomism in the strict sense, this immutability had to be interpreted in an absolute way.

Absolute vs. relative

The same absolute interpretation appeared in classical chemistry, although its atomic theory deviated from Atomism in the strict sense by assuming qualitatively different atoms and by assuming molecules (rather stable aggregates of atoms). The decisive point, however, is that molecules were formed by mere juxtaposition of atoms without any intrinsic change of the qualities of the atoms. Modern atomic theory, in contrast, gives a less rigid interpretation of the immutability of elementary particles: the particles that build up an atom do not retain their identity in an absolute way.

In some philosophical atomistic theories, the immutability of the atoms has been understood in a highly relative sense. This interpretation arose mainly in the circles of those Aristotelian philosophers who tried to combine atomistic principles with the principle of Aristotle that elements changed their nature when entering a chemical compound. The combination of both principles led to the doctrine known as the *minima naturalia* theory, which holds that each kind of substance has its specific *minima naturalia*, or smallest entities in nature. *Minima naturalia* are not absolutely indivisible: they can be divided but then become *minima naturalia* of another substance; they change their nature. In a chemical reaction the *minima* of the reagents change into the *minima* of the substances that result from the reaction.

Other differences. Atomisms also differ regarding the number of atoms, whether they occupy a void, and how they relate to one another.

Number of atoms. As has already been mentioned, Democritus introduced the hypothesis that the atoms are infinite in number. Although one may question whether the term infinite has to be taken in its strict sense, there is no doubt that by using this term Democritus wanted not merely to express the triviality that, on account of their smallness, there had to be an enormous quantity of atoms. Democritus also had a strong rational argument for postulating a strictly infinite quantity of atoms: only thus could he exclude the existence of atoms that specifically differed from each other (see above *Qualityless atoms*).

When in modern science the problem of the number of atoms arises, the situation is quite different from that of the Greek Atomists. There is now much more detailed information about the properties of the atoms and of the elementary particles, and there is also in astrophysical cosmology some information about the universe as a whole. Consequently, the attempt to calculate the total number of atoms that exist is not entirely impossible, although it remains a highly speculative matter. In a time (around 1930) when all chemical atoms were supposed to be composed of electrons and protons, the pioneering joint-relativity-quantum astrophysicist A.S. Eddington calculated the number of these elementary particles to be $2 \times 136 \times 2^{256}$, or approximately 10^{79}, arguing that, since matter curves space, this is just the number of particles required barely to close the universe up into a hypersphere and to fill up all possible existence states.

Eddington's cosmical number

The existence of the void. To Democritus the existence of the void was a necessary element in atomistic theory. Without the void the atoms could not be separated from each other and they could not move. In the 17th century Descartes rejected the existence of the void, whereas Newton's conception of action at a distance was in perfect harmony with the acceptance of the void and the drawing of a sharp distinction between occupied and nonoccupied space.

The success of the Newtonian law of gravitation was one of the reasons that atomic theories came to prevail in the 18th century. Even with respect to the phenomena of light, the corpuscular and hence atomic theory of Newton, which held that light is made of tiny particles, was adopted almost universally, in spite of Huygens' brilliant development of the wave hypothesis (see LIGHT).

When in the beginning of the 19th century the corpuscular theory of light in its turn was abandoned in favour of the wave theory, the case for the existence of the void had to be reopened, for the proponents of the wave theory did not think in terms of action at a distance; the propagation of waves seemed to presuppose, instead, a medium with not only geometrical properties but with physical ones as well. At first the physical properties of the medium, the ether, were described in the language of mechanics; later they were described in that of the electromagnetic field theory of J.C. Maxwell. Yet, to a certain extent the old dichotomy between occupied and nonoccupied space continued to exist. For, according to the ether theory, the atoms moved without difficulty in the ether, whereas the ether pervaded all physical bodies.

In contemporary science this dichotomy has lost its sharpness, owing to the fact that the distinction between material phenomena, which were supposed to be discon-

tinuous, and the phenomena of light, which were supposed to be continuous, appears to be only a relative one. In conclusion it can be claimed that although modern theories still speak of space and even of "empty" space, this "emptiness" is not absolute: space has come to be regarded as the seat of the electromagnetic field, and it certainly is not the void in the sense in which the term was used by Democritus.

Atoms in external aggregation versus in internal relationship. In most forms of Atomism it is a matter of principle that any combination of atoms into a greater unity can only be an aggregate of these atoms. The atoms remain intrinsically unchanged and retain their identity. The classical atomic theory of chemistry was based upon the same principle: the union of the atoms into the molecules of a compound was conceived as a simple juxtaposition. Each chemical formula (*e.g.*, H_2O, H_2SO_4, NaCl, etc.) reflects this principle through the tacit implication that each atom is still an H, O, or S, etc., even when in combination to form a molecule.

Chemistry had a twofold reason for adopting this principle. One reason was an observational, the other a philosophical one. The fact that some of the properties of a chemical compound could, by simple juxtaposition, be derived from those of the elements (the molecular weight, for example, equals the simple sum of the respective atomic weights) was a strong factual argument in favour of the principle. Many properties of the components, however, could not be determined in this way. In fact, most chemical properties of compounds differed considerably from those of the composing elements. Consequently, the principle of juxtaposition could not be based on factual data alone. It was in need of a more general support. This support was offered by the philosophical idea that inspired all Atomism, viz., that if complex phenomena cannot be explained in terms of aggregates of more elementary factors, they cannot be explained at all.

Holistic tendencies

For the evaluation of this idea, the development of the scientific atomic theory is highly interesting, especially with respect to the interpretation of the concept of an aggregate. Is the only interpretation of this concept that of an assemblage in which the components preserve their individuality—like, for instance, a heap of stones?

Modern atomic theory offers an answer to this question. This theory still adheres to the basic principle that a complex structure has to be explained in terms of aggregates of more elementary factors, but it interprets the term "aggregate" in such a way that it is not limited to a mere juxtaposition of the components. In modern theories atomic and molecular structures are characterized as associations of many interacting entities that *lose* their own identity. The resulting aggregate originates from the converging contributions of all of its components. Yet, it forms a new entity, which in its turn controls the behaviour of its components. Instead of mere juxtaposition of components, there is an internal relationship between them. Or, expressed in another way: in order to know the properties of the components, one has to study not only the isolated components but also the structures into which they enter. To a certain extent modern atomic theory has bridged the gap between atomistic and holistic thought.

HISTORY AND MAJOR REPRESENTATIVES OF THE VARIOUS ATOMISMS

Philosophical Atomism. From the ancient Greeks through the 16th century, Atomism remained mainly philosophical.

Ancient Greek Atomism. It is characteristic of the importance of Greek philosophy that, already in the foregoing exposition of the different aspects of Atomism, several Greek philosophers had to be introduced. Not only the general idea of Atomism but also the whole spectrum of its different forms originated in ancient Greece. As early as the 5th century BC Atomism in the strict sense (Leucippus and Democritus) is found, along with various qualitative forms of Atomism: that of Empedocles, based on the doctrine of the four elements and that of Anaxagoras, with as many qualitatively different atoms as there are different substances.

Criticisms by Plato and Aristotle

Yet, in spite of its successful start, Atomism did not gain preeminence in Greek thought. This is mainly because Plato and Aristotle were not satisfied with the atomistic solution of the problems of change as a *general* solution. They refused to reduce the whole of reality, including man, to a system that knew nothing but moving atoms. Even with respect to the problems of the material world, Atomism seemed to offer no sufficient explanation. It did not explain the observable fact that, notwithstanding continual changes, a total order of specific forms continued to exist. For this reason Aristotle, with Plato, was more interested in the principle of order than in that of the material elements. In his own analysis of change, which resulted in the matter-form doctrine, Aristotle explicitly rejected the thesis of Democritus that in a chemical reaction the component parts retain their identity. According to Aristotle, the elements that entered into a composite with each other did not remain what they were but became a compound. Although there is some indication that in Aristotle's chemical theory smallest particles played a role, it was certainly not a very important one.

Meanwhile, atomistic ideas remained known in Greek thought. Their opponents paid much attention to them, and there were also a few adherents of Democritean Atomism in later times, such as the Greek hedonist Epicurus (*c.* 341–279 BC) and the Roman poet Lucretius Carus (*c.* 95–55 BC) who, through his famous didactic poem *De rerum natura* ("On the Nature of Things"), introduced Atomism into the Latin world.

The elachista of the early Aristotelian commentators. Empedocles had suggested an Atomism with qualitatively different atoms, based upon the doctrine of the four elements. Aristotle adopted the latter doctrine but without its atomistic suggestion. Certain Greek commentators on the works of Aristotle, however, viz., Alexander of Aphrodisias (2nd century AD), Themistius (4th century AD), and Philoponus (6th century AD), combined the Aristotelian theory of chemical reactions with atomistic conceptions. In their systems the atoms were called *elachista* ("very small" or "smallest"). The choice of this term is connected with the Aristotelian rejection of the infinite divisibility of matter. Each substance had its own minimum of magnitude below which it could not exist. If such a minimum particle were to be divided, then it would become a minimum of another substance.

The minima naturalia of the Averroists. The Latin commentators on Aristotle translated the term *elachista* into its Latin equivalent *minima* or also into *minima naturalia; i.e., minima* determined by the nature of each substance. In fact, for most medieval Aristotelians the *minima* acquired little more reality than the theoretical limit of divisibility of a substance; and in their descriptions of physical and chemical processes, they paid no attention to the *minima*. With the Averroists—followers of the Arab Aristotelian Averroës (1126–98)—an interesting development occurred. Agostino Nifo (1473–1538), for example, explicitly stated that in a substance the *minima naturalia* are present as *parts;* they are physical entities that actually play a role in certain physical and chemical processes. Because the *minima* had acquired more physical reality, it then became necessary to know how the properties of the *minima* could be connected with the sensible properties of a substance. Speculations in this direction were developed by the Italian physician, philosopher, and litterateur Julius Caesar Scaliger (1484–1558).

Modern scientific Atomism: Early pioneering work. Modern Atomism arose with the flowering of science in the present sense of the word.

The 17th century. In the history of Atomism the 17th century occupies a special place for two reasons: it saw the revival of Democritean Atomism and it saw the beginning of a *scientific* atomic theory.

The revival of Democritean Atomism was the work of the ambiguous Epicureo-Christian thinker Pierre Gas-

Gassendi, Sennert, and Boyle

sendi (1592–1655), who made his contemporaries not only better acquainted with Atomism but also succeeded in divesting it of the materialistic interpretation with which it was hereditarily infected. This reintroduction of Democritus was well timed. Because of its quantitative character Democritus' Atomism invited for its elucidation the application of mathematics and mechanics, which in the 17th century were sufficiently developed to answer this invitation. In point of fact, the 17th century was more interested in the possibilities that Atomism offered for a physical theory than it was in the philosophical differences between the different atomistic systems. For this reason it saw, for example, hardly any difference between the systems of Gassendi and Descartes, although the latter explicitly rejected some of the fundamentals of Democritus, such as the existence of the void and the indivisibility of the atoms, as noted above (see *Atoms as sheer extension*).

In the case of scientists mainly interested in the chemical aspects, the same shift of emphasis from philosophical to scientific considerations can be discerned. According to the physician and philosopher of nature Daniel Sennert (1572–1637), Democritus' Atomism and the *minima* theory really amounted to the same thing. As far as philosophy was concerned, Sennert was only interested in the general idea of Atomism; the precise content of an atomic doctrine in his view ought to be a matter of chemical experimentation. His own experience as a chemist taught him the specific differences existing between the atoms. In this respect Sennert continued the *minima* tradition. His own contribution to the chemical atomic theory lay in the clear distinction that he made between elementary atoms and the *prima mista*, or atoms of chemical compounds.

The early modern experimentalist Robert Boyle (1627–91) followed the same line of thought as Sennert, but he was much more aware of the discrepancy between Democritus' Atomism and an atomic theory suitable for chemical purposes. Boyle's solution to this problem was the thesis that the atoms of Democritus were normally associated into primary concretions, which did not easily dissociate and which acted as elementary atoms in the chemical sense. These primary concretions can combine to form compounds of a higher order, which may be compared to Sennert's *prima mista* and to the molecules of modern chemistry.

Founding of modern Atomism. The 17th century had laid the theoretical foundations for a scientific atomic theory. For its further development it was in need of better chemical insights, especially concerning the problem of what substances should be considered as chemical elements. Boyle had shown conclusively that the traditional four "elements" were certainly not elementary substances, but at the same time he confessed that he did not yet see any satisfactory method to determine which substances were true elements. This method was provided by another of the principal founders of modern chemistry A.-L. Lavoisier (1743–94): a chemical element is a substance that cannot be further analyzed by known chemical methods.

Lavoisier and Dalton

John Dalton (1766–1844), usually regarded as the father of modern atomic theory, applied the results of Lavoisier's chemical work to atomistic conceptions. When Dalton spoke of elementary atoms, he did not have a merely theoretical idea in mind but the chemical elements as determined by Lavoisier. Dalton held that there are as many different kinds of elementary atoms as there are chemical elements. The atoms of a certain element are perfectly alike in weight, figure, etc.; and the same point applies to the atoms of a certain compound. As weight was the decisive characteristic in Lavoisier's theory, Dalton stressed the importance of ascertaining the relative weights of atoms and the number of elementary atoms that constituted one compound "atom." As to the question of the way in which the atoms are combined in a compound, Dalton conceived this combination as a simple juxtaposition with each atom under the influence of Newtonian forces of attraction. The atoms retain their identity through a chemical reaction. In this one point the founder of the chemical atomic theory did not differ from Democritus.

Recent and contemporary scientific Atomism. Until its development in the third decade of the 20th century, the scientific atomic theory did not differ philosophically very much from that of Dalton, although at first sight the difference may appear large. Dalton's atoms were no longer considered to be immutable and indivisible; new elementary particles sometimes appeared on the scene; and molecules were no longer seen as a mere juxtaposition of atoms—when entering into a compound atoms became ions. Yet, these differences were only accidental; the atoms revealed themselves as composed of more elementary particles—protons, neutrons, and electrons—but these particles themselves were considered then as immutable. Thus the general picture remained the same. The material world was still thought to be composed of smallest particles, which differed in nature and which in certain definite ways could form relatively stable structures (atoms). These structures were able to form new combinations (molecules) by exchanging certain component parts (electrons). The whole process was ruled by well-known mechanical and electrodynamic laws.

In contemporary atomic theory the differences from Dalton are much more fundamental. The hypothesis of the existence of immutable elementary particles has been abandoned: elementary particles can be transformed into radiation and vice versa. And when they combine into greater units, the particles do not necessarily preserve their identity; they can be absorbed into a greater whole.

Atomism in the thought of India. It is interesting to note that atomistic conceptions are not restricted to Western philosophy and science. Examples of qualitative Atomism, based upon the doctrine of the four elements, are also found in Indian philosophy. In some Indian systems the atoms are not absolutely indivisible but only relatively so. In certain aspects Indian Atomism is, therefore, more related to the *minima* doctrine than to the Atomism of Democritus. Indian Atomism has, however, not developed into a scientific theory.

FOUNDATIONAL ISSUES POSED BY ATOMISM

Atomism as a metaphysical system. In discussing Atomism, one particular system, that of Democritus, has been here distinguished as Atomism in the strict sense because of the fact that in no other system have the foundational issues of Atomism been so clearly expressed. Atomism in the strict sense is not merely one of the historical forms of Atomism, one of the many possible scientific attempts at explaining certain physical phenomena; it is, first of all, a metaphysical system: it has been presented as the only possible explanation of change and multiplicity. And as a metaphysic it is rationalistic, mechanistic, and realistic.

Rationalistic, mechanistic, realistic

It is *rationalistic* because it has so much confidence in reason that, in order to explain observed phenomena, it does not hesitate to postulate the existence of unobservable atoms: *i.e.*, of things that are in principle unobservable by the human senses and can be known only by a process of reasoning. Atomists go even further, for they not only are convinced of the existence of atoms but they also think it possible to deduce in a rational way their fundamental properties. Moreover, the description of these properties in *mechanistic* terms is not just a matter of convenience; it is supposed to be the adequate expression of *reality*.

This rationalistic and mechanistic metaphysics is not only characteristic of Democritus' Atomism but also of the early forms of scientific Atomism. The clearest expression of this metaphysics is found in Descartes. For Democritus mechanistic concepts are clear and distinct ideas, so that any further experimental investigation is superfluous. It should be stressed that the atomistic assumption that the human mind, by mere reasoning, can know the properties of the atoms is a necessary consequence of the idea that atoms are not subject to internal change; for the changeless can never be a subject of ex-

perimentation. The great weakness of the mechanistic concept of immutable atoms was that it forced the analyzing experiments to stop at the atoms; but this weakness could reveal itself only after, in the course of the further development of science, the fundamentally experimental character of human knowledge had become evident.

This weakness, in fact, was precisely one of the reasons why Aristotle rejected the Atomism of Democritus, viz., that the latter had postulated atoms that were not subject to change. For Aristotle the very essence of matter was its being subject to change; hence to him the concept of immutable atoms was a contradiction in terms.

Kant's anti-realism and scientific models

Aristotle's criticism of Atomism was clearly directed against its mechanistic metaphysics, not against its realism. This latter characteristic was the target, however, of an attack launched by the incomparable 18th-century epistemologist Immanuel Kant. In a famous argument, known as the antinomy of the continuum, Kant tried to prove that the acceptance of the reality of spatial extension, the cornerstone of Atomism, led to contradictions. His argument can be summarized as follows: It is possible to prove that any compound must be composed of simple things (for if not, there would be nothing but composition). On the other hand, it also is possible to prove that no material thing can be simple, for the very reason that a part of an extended being is always extended and is thus open to division. Hence, every allegedly simple part is at once simple and nonsimple. Consequently, spatial extension cannot be real. Extension is therefore not a property of the material world itself; it is a form imposed upon reality by man's perception.

By his argument Kant did not intend to reject atomic theories as such; he rejected only their realistic pretensions. Kant was deeply convinced that man had to *think* of nature by way of analogy with a mechanism, but he denied that knowledge construed in such a fashion could reach reality itself.

In the 19th century, scientists were, as a rule, hardly impressed by Kant's attack on the realistic pretensions of human knowledge. Scientists had already learned to go their own way and no longer worried about philosophical considerations. Only when an internal crisis in science itself arose were they prepared to reflect upon their presuppositions. Such a crisis occurred in the 20th century when science was forced to accept the relativity of both classical models: the wave and the particle model.

To a certain extent, the problem of whether a scientific model is nothing but a subjective construct in which the scientist unites his experience is the same as the problem that Kant had in mind. One of the differences, however, is that in Kant's time science was still rather exclusively *theory*. Its close connection with praxis (practice, doing) had not yet been discovered. For this reason the Kantian epistemological (or human knowledge) problem could centre on such a question as: what guarantee does the *knowing* subject have that his "models" of reality reflect reality itself? Inasmuch as, in an exclusively theoretical science, the only contact that one has with reality is afforded by means of his knowledge, the problem seems to be insoluble.

The development of science from a theoretical to an experimental discipline forces philosophy to view the epistemological problem in a new way. For in an experimental science man is in a twofold contact with reality, viz., by his knowledge and by his experimental praxis. Modern atomic theory is one of the best examples to illustrate this point. It was this theory that was most directly confronted with the problem of the realistic value of its models. It could take up this challenge because of the theory's effectiveness for experimental praxis, which is the final judge of the realistic value of the theoretical models. It has confirmed the audacious rational speculations of ancient Atomism; but at the same time it has revealed that, in order to be really effective, reason is in need of experimental assistance.

Ancient Greek Atomism versus contemporary scientific Atomism. In comparing Greek Atomism and modern atomic theories, it should be recalled that in Greek thought philosophy and science still formed a unity. Greek Atomism was inspired as much by the desire to find a solution for the problems of mutability and plurality in nature as by the desire to provide scientific explanations for specific phenomena. While it is true that some of the Greek Atomists' ideas can rightly be considered as precursors of later physics, the main importance of the old atomistic doctrines for modern science does not lie in these primitive anticipations. Much more important is the attempt to take seriously the variety and mutability discerned by sense experience and yet to reconcile it with the thesis of Parmenides about the unity and the immutability of matter. In its search for universal and unchangeable laws, modern science is to a great extent inspired by the same idea as Parmenides, since universal laws presuppose a certain unity in the material world and unchangeable laws cannot be established without the presupposition that something unchangeable must be hidden behind all changes. By the same token, without this latter presupposition experiments would not make any sense at all. For if the diversity of reactions occurring under different conditions is to reveal anything, these reactions must be the expression of an immutable nature. The differences have to indicate something about that which remains the same. The great achievement of the Greek philosophers was, therefore, that they took a general view of nature as a whole that made a scientific attitude possible. To this, both the quantitative and the qualitative forms of Atomism contributed, the former drawing attention to the mathematical aspects of the problem, the latter to the observational.

Parmenides and the modern quest for laws

A comparison of ancient Greek Atomism with scientific Atomism merely on the basis of their respective scientific contents would therefore do a great injustice to Greek Atomism; it would in fact misjudge its main value. Such a comparison would, however, also take too narrow a view of modern scientific Atomism. It would imply the philosophical irrelevance of the latter. It has here been shown, however, that the later development of the scientific atomic theory has clarified many philosophical problems that, as basic issues, divided Atomism in the strict sense from other forms of Atomism. To mention only a few examples: the development of the scientific atomic theory has deepened man's insights into the relationship between a whole and its components, into the relative character of ultimate particles, and into certain fundamental epistemological problems.

Evaluation of Atomism. The success of the atomic theory shows the value of the general idea of Atomism: the explanation of the complex in terms of aggregates of fixed particles or units. Its history also shows, however, the inherent danger of this idea, viz., that of absolutism. History has corrected this absolutism: the unitary factors have to be conceived as ultimate only with respect to the complex under consideration, and their union into aggregates need not occur only by way of juxtaposition.

Atrophy

Atrophy is a decrease in size of a cell, organ, tissue, or of a part of the body such as a limb. The term implies that

the atrophied part was of a size normal for the individual, considering age and circumstance, prior to the diminution. In atrophy of an organ or body part, there may be a reduction in the number or in the size of the component cells, or in both.

NORMAL ATROPHY

Certain cells and organs normally undergo atrophy at certain ages or under certain physiologic circumstances. In the human embryo, for example, a number of structures are transient and at birth have already undergone atrophy. The adrenal glands become smaller shortly after birth because an inner layer of the cortex has shrunk. The thymus and other lymphoid tissues atrophy at adolescence. The pineal organ tends to atrophy about the time of puberty; usually calcium deposits, or concretions, form in the atrophic tissue. The widespread atrophy of many tissues that accompanies advanced age, although universal, is influenced by changes of nutrition and blood supply that occur during active mature life.

The normal cyclic changes of female reproductive organs are accompanied by physiologic atrophy of portions of these organs. During the menstrual cycle, the *corpus luteum* of the ovary atrophies if pregnancy has not occurred. The muscles of the uterus, which enlarge during pregnancy, rapidly atrophy after the delivery of the child; and after completion of lactation the milk-producing acinar structures of the breast diminish in size. After the menopause the ovaries, uterus, and breasts normally undergo a degree of atrophic change.

ABNORMAL ATROPHY

Whole body atrophy. Atrophy in general is related to changes in nutrition and metabolic activity of cells and tissues. A widespread or generalized atrophy of body tissues occurs under conditions of starvation, whether because food is unavailable or because it cannot be taken and absorbed due to the presence of disease. The unavailability of certain essential protein components and vitamins disturbs the metabolic processes and leads to atrophy of cells and tissues. Under conditions of protein starvation, the body protein is broken down into constituent amino acids, which serve to provide energy and help maintain the structure and cells of the most essential organs. The brain, heart, adrenals, thyroid, pituitary, gonads, and kidneys show less atrophy, relatively, than the body as a whole; whereas the fatty stores of the body, liver, spleen, and lymphoid tissues diminish relatively more than the body as a whole. The brain, heart, and kidneys, organs with abundant blood supply, appear to be the least subject to the wasting effects of starvation.

Associated with the widespread atrophy due to lack of protein is the atrophy of certain tissues that is due to deficiencies of specific vitamins. Atrophic changes of the skin increase because of the lack of vitamin A, and atrophy of muscle increases because of the unavailability of vitamin E.

Senile atrophy

After a growth period of human metabolism, there sets in a gradual decline: slow structural changes other than those due to preventable diseases or accidents occur. Aging eventually is characterized by marked atrophy of many tissues and organs, with both a decline in the number of cells and an alteration in their constitution. This is reflected eventually in the changed, diminished, or lost function characteristic of old age and eventuates in death. The changes in senescence are affected by both inherited constitution and environmental influences, including disease and accident.

Atrophic changes of aging affect almost all tissues and organs, but some changes are more obvious and important. Arteriosclerosis—the thickening and hardening of arterial walls—decreases the vascular supply and usually accentuates aging processes.

Atrophy in old age is especially noticeable in the skin, characteristically flat, glossy or satiny, and wrinkled. The atrophy is due to aging changes in the fibres of the true skin, or dermis, and in the cells and sweat glands of the outer skin.

Wasting of muscle accompanied by some loss of muscular strength and agility is common in the aged. In a somewhat irregular pattern, there is shrinkage of many individual muscle fibres as well as a decrease in their number. Other changes have been observed within the muscle cells.

Increase of the pigment lipofuscin is also characteristic in the muscle fibres of the heart in the aged in a condition known as brown atrophy of the heart. Wasting of the heart muscle in old age may be accompanied by increase of fibrous and fatty tissue in the walls of the right side of the heart and by increased replacement of elastic tissue with fibrous tissue in the lining and walls of coronary arteries within the heart muscle. Abnormal deposits of the protein substance amyloid also occur with greater frequency in the atrophic heart muscle in old age.

Atrophy of the liver in the aged is also accompanied by increased lipochrome pigment in the atrophied cells.

The bones become progressively lighter and more porous with aging, a process known as osteoporosis. The reduction of bone tissue is most marked in cancellous bone —the open-textured tissue in the ends of the long bones— and in the inner parts of the cortex of these bones. In addition to changes in and loss of osteocytes, or bone cells, there is decreasing mineralization, or calcium deposit, with enhanced fragility of the bones.

Atrophy of the brain

Atrophy of the brain in old age is shown by narrowing of the ridges, or gyri, on the surface of the brain and by increased fluid in the space beneath the arachnoid membrane, the middle layer of the brain covering. There is shrinkage of individual nerve cells, with an increase in their lipochrome pigment content, as well as a decrease in their number. Sometimes the nerve fibrils have degenerated, and deposits called senile plaques may be found between the nerve cells, particularly in the frontal cortex and hippocampus (a ridge in the wall of an extension, or horn, of the lateral ventricle, or cavity, of the brain). Similar atrophic changes are seen in the brain in Alzheimer's disease, a condition of unknown cause most likely to occur in older patients. The mental deterioration (senile dementia) of the aged is the clinical manifestation of these changes. Senile atrophy may be increased and complicated by the presence of arteriosclerosis.

Simmonds' disease is a chronic deficiency of function of the pituitary gland that leads to atrophy of many of the viscera including the heart, liver, spleen, kidneys, thyroid, adrenals, and gonads.

A destructive or atrophic lesion affecting the pituitary glands with loss of hormones leads to atrophy of the thyroid, adrenal glands, and gonads and in turn brings atrophic changes to their target organs and the viscera. The decrease in size of the endocrine glands may be extreme.

Atrophy of muscle or of muscle and bone. Local atrophy of muscle, bone, or other tissues results from disuse or diminished activity or function. Although the exact mechanisms may not be completely understood, decreased blood supply and diminished nutrition occur in inactive tissues. Disuse of muscle resulting from loss of motor nerve supply to the muscle (*e.g.*, as a result of poliomyelitis) leads to extreme inactivity and corresponding atrophy. Muscles become limp and paralyzed if there is destruction of the nerve cells in the spinal cord that normally activate them. The shrinkage of the paralyzed muscle fibres becomes evident within a few weeks. Eventually, after some months, fragmentation and disappearance of the muscle fibres occurs with some replacement by fat cells and a loose network of connective tissue. Some contracture may result.

The skeletal tissues forced to inactivity by paralysis (*e.g.*, of a limb as a result of poliomyelitis) also undergo disuse atrophy. If there is a tendency for bone to become lighter and more porous in some particular area, a condition known as local osteoporosis, this can be recognized by X-rays within a few weeks. The cortex of the long bones becomes considerably thinned or atrophic, with decreased mineral content. Disuse as a result of painfully diseased joints, as in rheumatoid arthritis, results in a

Rheumatoid arthritis

similar but lesser degree of atrophy of muscles concerned with movement of the involved joint; and local atrophy may also occur in the bone in the neighbourhood of the joint. A local osteoporosis of bone known as Sudeck's atrophy sometimes develops rapidly in the area of an injury to bone.

Severe or prolonged deficits of blood sugar deprive the nervous system of needed sources of energy and as a rare event result in degeneration of cells of the brain and peripheral nerves. The disuse atrophy of muscle or bone that may result is fundamentally similar to the other disuse atrophies of these tissues.

Persistent pressure will cause atrophy of a compressed cell, organ, or tissue, presumably because of interference with the nutrition and metabolic activity of the affected part. Cells in a local area (*e.g.*, in the liver) atrophy from the pressure of materials such as amyloid deposited around them. The pressure of an expanding benign tumour causes atrophy of adjacent normal structures. The pressure of a localized dilatation of an artery (aneurysm) will cause atrophy of tissues, even bone, on which it impinges.

Bulging of an intervertebral disk or growth of a tumour sometimes brings pressure on nerves near their point of exit from the spinal cord; if the pressure is prolonged, the muscles normally controlled by these nerves may atrophy. Most often the calf muscles are affected. Pressure as a result of involvement of the vertebrae at the level of the neck, or from compression of the network of nerves called the brachial plexus by the *scalenus anticus* muscle, produces similar effects in the upper chest and arms.

Simple disuse of muscle or bone, as, for example, from the immobilization produced when a limb is put in a cast or sling, results in atrophy of these tissues. In the case of muscle, the degree of atrophy is generally less severe than that caused by injury to a nerve, although the nature of the change is similar.

Localized atrophies of leg and arm muscles may result from hereditary or familial diseases in which the nerves of the spinal cord that supply them are inactivated or destroyed. In Charcot-Marie-Tooth disease, the atrophy involves mainly the peroneal muscles, at the outer side of the lower legs, and sometimes the muscles of the hand as well. It commonly begins in childhood or adolescence. Peroneal muscle atrophy is also seen in the hereditary spinal cord degenerative disease known as Friedreich's ataxia.

Atrophy due to injury

Atrophy of nerve tissue. Atrophy of brain or spinal cord tissue may be brought about by injuries that directly affect a localized area or that interfere with the blood supply to an area. When peripheral nerves are severed, degenerative and eventually atrophic changes ensue in the part beyond the injury. This type of atrophy is known as Wallerian degeneration. If conditions do not allow regeneration of nerve fibres from the proximal fragment of the cut nerve, atrophy is the eventual fate of the nerve tissue distal to the injury. Retrograde atrophy also occurs from disuse and affects the ganglion cells of the injured nerve.

Prolonged pressure brings about atrophy in the central nervous system as elsewhere. The pressure of an expanding tumour of the membranes covering the brain results in localized atrophy of the adjacent brain substance on which it impinges. In hydrocephalus more widespread atrophy of brain tissue results from the abnormal amounts of fluid confined within the rigid bony compartment of the skull. Increased pressure within the skull may force a portion of the brain through the *foramen magnum*, the bony opening at the base of the skull, and, if prolonged, results in a localized atrophy of cerebellar tissue pressed against the bony wall.

The late stages of chronic infections may be characterized by atrophy of the brain. A striking example of this is the variety of syphilitic infection of the nervous system known as general paresis in which the brain is shrunk and reduced in weight, the atrophy affecting mainly the cortex of the brain, particularly or most markedly in the frontal area. Occasionally the atrophy is local or affects only one side of the brain. The shrinkage of the brain tissue is mainly due to loss of many nerve cells of the cortex.

Atrophy of fatty tissue. Atrophy of adipose tissue of the body occurs as a part of the generalized atrophy of prolonged undernutrition. Localized atrophy of adipose tissue—lipodystrophy—may be the result of injury to the local area; *e.g.*, repeated insulin injections cause atrophy of fatty tissue at the site of the injections. Progressive lipodystrophy is a disease of unknown cause in which the fatty tissue atrophies only in certain regions of the body. It occurs mainly in women and often begins in childhood; the progressive wasting of adipose tissue affects mainly the face, arms, and trunk. In the affected areas, the specialized fat-holding cells of adipose tissue disappear.

Atrophy of skin. A widespread atrophic change in the skin has been noted as a prominent part of the aging process. Similar atrophic changes in the skin appear to be brought about or enhanced by excessive exposure to sunlight. While a number of abnormal conditions of the skin may include localized atrophic changes in the epidermis or dermis as a part of their lesions, certain generalized diseases of the skin are particularly characterized by such changes. The hardening of the skin known as scleroderma may occur in a localized, or circumscribed, form called morphea or as a more diffuse and severe disease. Advanced stages of scleroderma are characterized by marked atrophy of the tissue and appendages of the true skin. Atrophic thinning of the overlying epidermis also may occur, and the underlying fatty tissue and muscle may atrophy as well. The chronic form of the disease discoid lupus erythematosus also is characterized by atrophy. In advanced stages atrophy occurs particularly in the epidermis in focal areas. The thinned layer of epidermis may be a prominent feature of the microscopic appearance of the skin.

Atrophy of glands. Endocrine glandular tissues may undergo atrophy when an excess of their hormonal product is present as a result of disease. An example is seen in connection with a hormone-producing tumour of the cortical tissue of one adrenal gland, which may be accompanied by marked atrophy of the cortical tissue of the opposite adrenal gland. This probably results from disturbance of the delicate mechanism of hormonal stimulation via the pituitary gland.

Various endocrine organs (thyroid, adrenals, gonads) depend for their activity on endocrine stimulation by hormones of the pituitary gland. A severe general failure of production of the pituitary hormones results in the widespread endocrine atrophy of Simmonds' disease, as has been noted. Lesser degrees of pituitary functional disturbance may disturb a delicate balance, involving mainly one type of stimulating hormone of the pituitary, and may result in selective atrophy of the adrenal cortical tissue or of the gonads.

Glands that release their secretions through a duct (*e.g.*, salivary glands, pancreas) may become atrophic as a result of obstruction of the duct. In the case of the pancreas, a complete obstruction of its duct results in atrophy of the glandular tissue, except for the insulin-producing islets of Langerhans, the secretion of which is absorbed into the bloodstream. Factors of both disuse and increased pressure may be present in the atrophy resulting from obstruction of the outlet channel. Similarly, rapid and complete obstruction of a ureter is followed by atrophy of the corresponding kidney.

Chemical-induced atrophy. Atrophy brought about by chemical injury is not common. In chronic arsenic poisoning, degenerative changes occur in peripheral nerves, resulting in weakness and atrophy in the tissues (usually legs or arms) to which the nerves are distributed. Similar results may follow the peripheral neuropathy of chronic lead poisoning.

Attention

Aldous Huxley wrote in the opening chapters of his novel *Island:* ". . . you forget to pay attention to what's happening. And that's the same as not being here and now." If attention is awareness of here and now, how are we aware?

Sense organs and their associated brain structures obviously participate in consciousness, but one may be acutely aware of one's inner state apart from sensing the outer world. Indeed, internal aspects of attention are very rarely absent, since awareness of external events implies recognition, recall, and expectation derived from previous experience. The experience "now" is not instantaneous but includes traces of awareness of past and future. Similarly, the subjective "here," although it hinges on local stimulation on and in the body, involves the full range of the distance receptors of seeing and hearing as well.

The sensory implications of such words as gazing and listening accompany an element of conscious intention, selection, and direction. These features are less evident for other senses, although savouring is distinguished from tasting, and feeling from touching.

Problems of definition

In defining attention, the subjective, colloquial, scientific, and linguistic overtones and ambiguities tend to confound meaning.

Thus, in everyday waking life the feeling of being here and now is discontinuous, efforts to concentrate on immediate sensory data being obscured by periods of absentmindedness, reminiscence, and fantasy. Such states may merge into sleep and dreams in which attention is directed to experiences arising primarily from internal (endogenous) sources. Similarly, severely painful experience may divert attention from almost all else for long periods. Pain is likely to be regarded as a dominant here-and-now experience; recall the expression "I had to pinch myself" to validate a strange or incredible external (exogenous) event. Yet, even the dominance of pain can be overcome by more potent competition for attention; a seriously wounded soldier may not experience pain until the urgencies of battle are over. Such subjective aspects of attention as distraction and motivation are difficult to specify; the soldier himself may be hard put to say whether he was motivated by determination to survive, by political fanaticism, or what.

Definitions of attention as the state of "selective awareness" tend to be circular, as in William James's statement "*My experience is what I agree to attend to,*" implying a prior decision as to what is worthy of attention. Whatever the reasons, volitional or not, only a very small portion of external events that stimulate the sense organs are noticed. Also, the nerve signals generated in response to exogenous and endogenous events are corrupted or distorted by the physiologic mechanisms of the neural structures themselves. The eyes and ears, organs of touch, taste, smell, and limb position show specialized and limited response to changes, differences, and movement; steady or slowly changing states become less noticeable through adaptation in the sense organs, nerve fibres, and central nervous system. With such constraints on attention, verbal reports of external events are often untrustworthy guides to fact, however confidently made.

Early notions of attention. Although closely related to mind-body controversies, the term attention has been somewhat neglected by philosophers.

Gottfried Wilhelm Leibniz (1765) suggested that one's loss of awareness of the constant sound of a waterfall illustrates how events cease to be apperceived (represented in consciousness) without specific attention. He suggested that attention determines what will and will not be apperceived. Although the term is now little used, Immanuel Kant also considered apperception, and it found favour with Wilhelm Wundt, one of the founders of psychology in the 19th century. Wundt wrote of the wide field of awareness (the *Blickfeld*) within which lay the more limited focus of attention (the *Blickpunkt*). He suggested that the range of the *Blickpunkt* was about six items or groups and speculated that attention is a function of the frontal lobes of the brain. W.B. Pillsbury (1908) compared this notion with retinal activity in the eye, in which the central region of high definition is surrounded by a wide field of sensitive but coarse-grained vision.

Attention was equated with "sensible clearness" by Edward Bradford Titchener (1867–1927), while William James (1842–1910) conceived of attention as the active selection of events or stimuli. In combination, these views indicate a process of focalization or concentration of awareness leading to increased clarity of conscious content.

Introspective reports of attention can be supplemented by quantitative study of the effects of selected stimuli on bodily movement or on glandular secretion among laboratory animals and people. Thus, Ivan Petrovich Pavlov (1849–1936) found that secretion of such digestive juices as saliva in hungry dogs often was initiated by auditory signals that were routinely given to precede the ingestion of food. Copious salivary flow suggested that the animals attended to the signals as much as to the food itself. Similarly, movements of head, eyes, ears, and limbs were reliably produced by signals that repeatedly had been followed by such stimuli as electric shocks or bits of food. In such experiments the warning signal is called a conditional stimulus, and the punishment or reward an unconditional stimulus. That is, response to the warning, indicating the animal's attentiveness, is conditional on its past association with the punishment or reward that elicits the salivation or movements unconditionally (*i.e.*, without special training). Since such studies require that the dog be hungry beforehand or "dislike" or "like" the punishment or reward, effects of unconditional stimuli are inconsistent, in a real sense being conditional on the prior state of the animal, depending on what may be called its set, attitude, expectancy, or drive. Related difficulties in appraising attention are variations among individuals and the need to postulate a basic alertness, irrespective of specific drives.

Pavlov reported what is usually termed the orienting response today; in a dog this includes such signs of attention as pricked-up ears, movement of the head and eyes, increased muscular tension, and physiological changes detectable with instruments. The orienting response can be evoked by novel or unexpected events; subjectively identified in human beings with surprise, it is sometimes called the novelty response. In the main, this complex form of behaviour probably represents involuntary, automatic components of attention.

Incorporating the observations of Pavlov, John Broadus Watson (1878–1958) largely was concerned with stimulus-response relations; attention seemed an unnecessary concept in Watson's system (behaviourism), which rejected mentalistic notions such as volition, free will, introspection, and consciousness. Attention was operationally defined, if at all, in terms of discriminative responses to external stimuli. Explanations in terms of single-stimulus situations, however, were found inadequate. Further hypotheses were necessary to account for the effects of competing stimuli, leading to such notions as set, attitude, and expectancy and to renewed interest in attention.

Classification of attentive phenomena. Although attention has been treated here, thus far, as if it were a unitary phenomenon, the term already has been used in sev-

eral senses. Some of these relate to the background state of alertness and arousal rather than to the selective and immediate processes of attending to the here and now. Consider the word attention in everyday usage: familiar motor acts, for example, are performed in response to complex and changing patterns of stimulation with only fleeting attention. A man may be driving his automobile adequately while attending primarily to his own thoughts or his radio. At his destination he will be unable to give a full account of traffic conditions to which, at the time, he responded appropriately.

Pre-attentive processes

This effect suggests so-called preattentive processes similar to those involved in visual search, as in scanning a list for instances of a specific name. Such mechanisms are neither very accurate nor selective; the driver, for example, quickly must become selectively alert when confronted with an emergency. Preattentive processes pass to focal attention, leading to less routine response patterns that are more likely to produce learning. Thus, preattentive processes tend to be limited to the immediate present, whereas more permanent appreciation and storage of information is likely to require an act of well-focussed attention.

Responses tend to become preattentive with practice; once a skill is well learned, less attention is needed than while it was being acquired. Consider the painful degree of attention given to each act during a first driving lesson compared with the experienced driver's almost automatic performance. Clearly this transition is adaptive; in neural terms it seems to free parts of the brain for other demands, while retaining an emergency system that quickly will mobilize these brain centres as required. The mechanism seems to control the balance between width of field and detail of the incoming signals, like that of a zoom lens on a camera. As new, demanding stimuli enter the field, refocussing may be said to narrow the field of attention and sharpen the detail.

Attention in children

Jean Piaget has shown how children tend to anchor attention on dominant objects and distort the stimulus field. This effect (centration) prompts them to overestimate the size of objects, such as geometric figures, in the centre of the field. As a child grows up he learns to deploy attention in ways that compensate for these misperceptions and is able to improve his coordination.

Progressive accumulation of experience also acts to decrease the frequency with which attention is attracted to isolated events. The short attention span (distractibility) of young children is related to their lack of skill in discerning rare from commonplace events. To hold their attention it helps to isolate them in a classroom, even from events that are ordinary by adult standards.

Attention to two (or more) events that tend to occur together is related, within limits, to the improbability of any particular combination. The objective chances of association are reflected in signs of attention that imply a corresponding subjective estimate of probability. One general proposition is that brain mechanisms underlying attention constitute a computer of probabilities and contingencies. In young children and lower animals these mechanisms are held mainly to reconcile direct sensory experience with simple internal states to achieve survival. Among human adults, social influences such as language play a larger part in attracting attention. Thus, a speaker may preface a statement with an imperative ("Look!" or "Listen!") or use such rhetorical devices as irony and provocative questions. Attention to what is said implies that the brain of the listener already has set a high estimate on the probability that the speaker will say something that yields an appreciable reward. Attention will lapse or wander if what is said is too strange, excessively familiar, incoherent, or highly repetitive.

Apparently attention is determined not so much by the intensity or sense modality of signals as by their context, significance, and information content. In the limit, attention may be attracted by the absence, cessation, or omission of a signal or by a slight change in its character. A person may have become accustomed to the ticking of a clock but often is alerted at once should it stop.

In sustained periods between events, vigilance wanes and attention wanders intermittently. Thus an airport observer may fail to notice radar echoes that occur rarely, briefly, and unexpectedly toward the end of his watch and be quite unaware of his inattention. The shorter the signal, the more likely it is to be overlooked during one of these lapses.

Orientation reaction

Orientation reactions (mentioned before in relation to Pavlov) correspond in part to the concept of attention and mobilize action that may be required in a given situation. The pupils of the eyes dilate and allow in more light, hearing becomes more sensitive, ongoing muscular activity is arrested, and muscle tonus rises in readiness. Blood supply is increased to the heart, head, and muscles; respiration and heart rate accelerate; and there are changes in skin resistance to electrical flow. If they are brief, these effects are reported by people as "surprise"; if prolonged, as "excitement." Electroencephalographic (EEG) activity changes in the direction of increased arousal; *i.e.*, desynchronized brain waves of lower amplitude replace usually dominant rhythmic patterns.

Significantly, the orientation reaction becomes progressively weaker and eventually disappears in habituation to regularly repeated presentations of the same stimulus. From such evidence, the reaction seems to be concerned with attentive preparation for action in a novel situation, rather than with routine stimulation.

Determinants of attention. Great variations among individuals in attending to stimuli drove Pavlov to allow for temperament in his general theories of behaviour. A loud sound merely attracts the attention of one dog, while another (similarly reared) animal may scurry to the nearest cover. There is evidence that these differences may be constitutional rather than acquired; dog breeders are familiar with gun-shy strains, even among breeds originally selected for hunting. A noise that merely arouses the interest of one person may panic another, even if he be otherwise courageous or relaxed. These differences depend not only on a lifetime of past experiences but on inborn tendencies as well.

The organic condition of a person also may determine the stimulus to which he will most readily respond at any given moment. He is likely to attend selectively in terms of his immediate biological needs; in hunger he will be especially alert to stimuli related to food.

Social suggestion plays a strong part in determining attention. Two or three persons watching a hole being dug in the road have positively magnetic qualities in attracting a larger crowd. The particular social role played by a person strongly directs his attention. A mother will sleep through considerable noise, but may waken immediately at the slightest cry from her baby. A trained musician will rivet attention on one wrong note that may escape notice by most of the audience. An experienced soldier will duck only when the whistle of an enemy shell rises in pitch.

Novelty as an attractive property of a stimulus indicates the importance to attention of the statistical rarity of a new event. Similarly, it may be said that a complex stimulus tends to attract attention through its greater information content or improbability. Given the alternative, rats tend to choose a longer, complex path over a simple route in a maze. Chimpanzees spend the most time examining the most complex objects around them. Human infants viewing pairs of cards with patterns of different complexity seem to attend most to the more complex; adults also are observed to devote more time to viewing unusual shapes, arrangements, or sequences. Complexity can be defined in this context in terms of the improbability of association (incongruity) of the elements of the pattern or sequence of events. Again, subjective estimates of improbability are based on expectancies developed from past experience and personal temperament.

Personal factors that influence estimation of significance, and therefore thresholds of perception and degrees of attention, may be conscious and cultivated interests, unconscious prejudices, or repressed desires and fears. A person who knows Morse code may be very attentive

to a series of faint random buzzes on the chance that they may convey a coherent message; attention to this possibility even may distract him from other more important aspects of the situation. Another person having "forgotten" an attack by a swarm of bees in infancy may be equally distracted by faint buzzing sounds.

Unconscious factors

The importance of such unconscious influences is emphasized in psychoanalytic theories, particularly in relation to the anomalies of attention and behaviour found among persons with neurotic disturbances (see PSYCHONEUROSES). It is suggested that the subjective significance of commonplace events and objects may be amplified and distorted when they symbolize personal inadequacies or disturbing experiences in early life. These effects are seen in the clinic as compulsive washing rituals, obsessive fears of confinement or of open spaces, and depressive suicidal attempts. Reasons for these disturbances rarely can be elucidated by direct inquiry, but, it is claimed, sometimes they can be deduced from the content of dreams and free association during psychoanalysis.

Physiological mechanisms of attention. Twitchings of the tail or whiskers in a cat give evidence of attention, but there may be little outward indication of degree of attention in a person. With suitable techniques, however, an increase in a person's pulse rate, arrested respiration, increase in muscle tension, and a drop in skin resistance usually can be recorded following a novel or surprising stimulus, these effects varying widely among people. When the signals are familiar, peripheral signs of attention usually are diminished, and often the only signs of attention are in the brain itself.

Bioelectric aspects. Stimulation of any sense organ sets up nerve impulses that constitute the sensory messages relayed to various brain regions. For example, visual signals activate specific receiving areas of the cerebral cortex in the hindmost parts of the brain (occipital lobes), tactile signals reach strips of cortex in the lateral central regions, and auditory signals are relayed to patches on the brain surface just above each ear. There are also large areas of cortex in the frontal and temporal lobes (so-called silent areas) that receive signals from all sense organs. These are nonspecific and receive their information through relays branching from direct pathways in the brain stem and thalamus. The projection to the nonspecific cortex is a diffuse network called the ascending reticular activating system. Access to the nonspecific cortex is also provided by another widely dispersed system (arising in the thalamic relay centres) called the diffuse thalamic projection system.

Integrity of the reticular activating system is essential for wakefulness; reduced activity there (for example, by anesthesia or concussion) results in confusion, somnolence, or unconsciousness, even though exogenous sensory messages still pass to the brain over the direct pathways. The activating system appears to mediate rapid general arousal and attention to novel stimuli, while the diffuse thalamic projection system, which branches more directly from specific relay centres, may convey specific information about the details of signals to which attention has been attracted. The arrangement is more complex than this account would suggest. In human beings, diencephalic structures, particularly the hypothalamus, are involved in regulating states of sleep and wakefulness, and limbic structures, such as the hippocampus, take part in arousal reactions when reward or punishment are involved. Interactions among these systems and their relation to the extraction of information from memory remain obscure.

Brain waves

Responses of the cerebral cortex evoked by signals from the sense organs can be detected as very weak electric pulses through the scalp. This electroencephalographic (EEG) technique involves amplification of the neuroelectric signals, often followed by computer analysis and display. Types of evoked EEG response include: (1) those in the specific receiving areas, almost invariably found, even in sleep; (2) related responses in adjacent (association) zones that habituate with repetition and are maintained by attention to details of sensory events; and (3) responses in nonspecific cortex, mainly in the frontal lobes, that very closely reflect the degree of attention and engagement of the person.

Beyond these evoked responses, intrinsic brain rhythms often are modified by attention to external events and to thinking, imagining, and similar internal activity. The clearest effect of this kind is the inhibition (blocking) of so-called alpha rhythms, usually when the eyes are opened or when the person is thinking about a task, especially one involving visual imagery. Alpha rhythms are more or less regular electric oscillations at a frequency of about 10 Hz (cycles per second) and are most pronounced in the posterior (visual) brain regions. The amplitude and responsiveness of these rhythms vary considerably from person to person. While they tend to be maximized when a person is blank-minded and has his eyes closed, in some persons they persist even during visual activity; in others, there is no sign of alpha rhythms even with the eyes shut. Absence of rhythmic features in the EEG generally is regarded as evidence of arousal as long as there are signs of less rhythmic (asynchronous) activity; total lack of electric discharge is a serious sign of brain morbidity. Desynchronization of the EEG also is typical of sleep when dreams occur. Rapid eye movements at these times are controversially considered signs of attention to dream images (see DREAMS).

Nonspecific cortex responses to external signals are significantly related to overt signs of selective attention. When a person attends to such signals as clicks or flashes by counting them, by noticing changes of intensity, or by pressing a button when they occur, the nonspecific responses in the EEG are augmented in voltage and persist over hundreds of trials. If a subject attends to some other stimulus, the responses evoked by the clicks or flashes are attenuated and may disappear. The person's speed of reaction to the signals tends to increase when the amplitude and consistency of the nonspecific responses are enhanced by focussing attention on the signals; reaction speed is slower when evoked responses are diminished by distraction. Habituation, the decline in attention that results from regular, monotonous stimuli, is accompanied by a progressive decline in the voltage of the evoked brain potentials.

In tasks requiring vigilance, fluctuations in efficiency are accompanied by corresponding changes in evoked potentials. Signals that escape attention evoke lower amplitudes than do detected signals and sometimes show increased latencies (take longer to appear).

When paired stimuli (*e.g.*, two clicks) are presented, the subject's task may be complicated by having him respond to the second signal. In effect, the first signal becomes a warning or conditional stimulus (as in Pavlov's experiments) although the subject may not realize this for several trials. Since the response to the second stimulus is conditional on the instructions of the experimenter, that stimulus may be called imperative rather than unconditional. EEG responses from nonspecific cortex are evoked by both conditional and imperative stimuli in such cases. In addition, a slow cortical voltage change appears that links the responses evoked by the two stimuli. This slowly changing, electrically negative state of the surface of the brain (the contingent negative variation, or CNV) is contingent on the association of the two stimuli and the subject's intention to respond to the imperative second stimulus.

Contingent negative variation

The CNV is a most clear-cut objective correlate of attention. Its characteristic wave form rises slowly to a voltage peak at the moment the imperative signal is expected, dropping sharply to zero as the relevant response or decision is made. When the interval between the two stimuli is less than about half a second, the wave does not develop fully, and reaction time is shortened less than is usual when a longer period (say, up to ten seconds) intervenes. The CNV can be sustained over periods of about ten seconds when enough trials lead the subject to appreciate the association between stimuli. When the interval between conditional and imperative signals is longer, the CNV wave form often shows several peaks and

troughs before the subject's final response, probably a reflection of how attention wanders during the prolonged wait. In normal people the CNV emerges quite consistently and correlates very well with other measures of attention, subjective and objective; it appears regardless of the sense organ stimulated or the intensity of stimulation (*e.g.*, cessation or absence of stimuli, pictorial or verbal events, or situations selected by the subject).

The CNV may function to prime (increase the sensitivity of) the frontal cortex to expected stimuli. Indeed the responsiveness of the cortex to electrical stimulation does, in fact, peak when the CNV wave does. This suggests that direction of attention involves selective control of cortical excitability.

A similar effect (perhaps almost identical in origin) is seen when a person *intends* to perform some action. It is also a slow increase in the electronegativity of the frontal cortex and precedes a spontaneous voluntary act or decision by about one second. In German it has been called the *Bereitschaftspotential* (readiness potential or intention wave). This effect supports an interpretation of intention as a form of attention in which the active component is particularly explicit. Thus, an intention wave even can be produced when the person merely wills to perform an act but does not in fact do so.

Together with bioelectric changes, the rate of brain metabolism increases when a person attends to external events. When attention is drawn to sensory stimuli that require no action, brief rises in blood flow are detected in the appropriate cortical sensory receiving zones. When an act is performed, a more prolonged increase in energy exchange is observed that also involves the frontal lobe and brain parts that control bodily movement.

When attention is directed to a long sequence of related events, such as a conversation, a protracted negative variation in voltage often develops over the frontal cortex. This effect presumably is connected with the maintenance of attention to the transition probabilities and significance of the signals in the conversation.

If attention is concentrated on a given set of stimuli and the decision or action required by them, the CNV is at its highest voltage. Under distraction from a variety of competing stimuli, the wave is at its smallest amplitude. The distraction may come from an external source or from such inner experiences as stomach pain or ideational activities. Unlike the nonspecific evoked responses, the CNV does not appear to habituate. In a very long series of trials, however, it can be seen to weaken as attention begins to wander from the central task.

The distribution of the evoked responses, CNVs, and intention waves over the frontal cortex is very wide but patchy. The limited brain zones in which they arise are remarkably constant for the same person when a given situation recurs, but when attention is divided, each of several simultaneous electrical signals involves its distinctive mosaic of cortical precincts. In EEG recordings from the scalp, the separate potentials from the various patches summate to produce a larger potential than that seen when only a single signal draws attention. This suggests that the frontal cortex can carry on several simultaneous attentive operations with some adequacy. This capacity, however, is sharply limited and varies considerably from person to person. It is very difficult to attend to certain actions in combination. For example, most people must struggle to rotate an arm smoothly clockwise while a leg on the same side moves anticlockwise; attention seems to fluctuate from one to the other, the neglected limb tending to follow the one on which attention is concentrated.

Competition for attention

Microelectrodes implanted in the visual cortex of laboratory animals reveal cells that uniquely respond to spefic patterns of visual stimulation and others that respond to movement in a certain direction. Some groups of cells fire more impulses when the animal is alerted; in other groups the rate of firing is inhibited when there are signs of wakefulness and alertness. Some assemblies of cells in the auditory cortex respond as a unit only when the animal seems to attend to sound waves. Near these so-called attention units are other cell groupings that respond whether or not auditory stimuli appear to draw attention. Among humans, also, there are specific regions and cell groups fairly close together in the brain that respond quite differently to apparent attentional and distracting effects and to habituation. In the human thalamus, for example, some cells respond persistently to a touch on the skin, however frequently presented and whatever the distraction from other stimuli. In a nearby part of the thalamus, other cells seem to detect only novel, nonrepetitive stimuli.

Brain responses also relate attention to the conditional and semantic aspects of an event. Thus a television picture may be used as a conditional stimulus to precede an imperative signal. If the scene presented is especially interesting, however, the conditional effect may be impaired while the subject attends to the intriguing details. The appearance of the CNV is delayed, its amplitude is diminished, and reaction time to the imperative stimulus is prolonged.

Subliminal stimuli

Brain responses are of particular value in measuring the hearing acuity of small children or others who may not be able to communicate clearly. The stimulus intensity at which brain responses can be detected usually coincides with the subjective threshold (with properly adjusted EEG equipment). EEG responses sometimes can be detected below the level of subjective awareness when the signals are exciting or provocative. This relates to effects of so-called subliminal stimuli; *i.e.*, signals for which the subject reports no awareness but that sometimes can influence behaviour. As evidenced by brain responses, the threshold of perception is related not merely to stimulus intensity but to the subjective significance of the stimulus as derived from the unconscious effects of personal experience, temperament, and social factors.

Among patients suffering from chronic anxiety, brain responses to all stimuli generally are pronounced, widely distributed, and slow to habituate. Such patients have difficulty in initiating and in maintaining selective attention; they report most events as menacing and use such language as "Everything keeps coming in on me." Symptoms sometimes can be relieved by selective surgical interruption (leucotomy) of nerve tracts connecting the orbital frontal cortex (just above the eye sockets) with deeper brain structures called the thalamus and limbic system. That system seems to involve emotional components of attention (see EMOTION). When these components are exaggerated the person shows fear or even panic. In earlier versions of the leucotomy (lobotomy) operation, large lesions were made in the nerve tracts, and reduction of fear sometimes went so far as to interfere grossly with ability to sustain attention.

Interpersonal influences on attention are seen most clearly in hypnosis. Hypnotized deeply, a person (on the suggestion of the hypnotist) may show no signs of attending to a stimulus that normally produces excruciating pain, may report hallucinatory experiences of people and other objects, or deny seeing selected objects around him. Evoked brain responses during hypnosis are not distinctive, but the CNV can be controlled by suggesting to the subject that given stimuli are more (or less) important, regardless of the objective significance of such stimuli.

Biochemical aspects. Complex chemical changes underlie the electrical correlates of attention in the nervous system. In mediating attention, the brainstem reticular formation, hypothalamus, limbic system, and their respective projections all depend on the neurochemical called noradrenaline for transmission of impulses from one nerve cell to the next. The thalamic arousal system similarly functions through another chemical (acetylcholine), while cortical activity is associated with release of amino acids, particularly glutamic acid and aspartic acid during prolonged attentiveness (see NERVOUS SYSTEM, HUMAN).

The delicate balance of structures that serve the attentive process is easily disturbed by changes in body chemistry. A lowered level of sugar in the blood after fasting,

decreased carbon dioxide from excessive deep breathing, lack of oxygen in diseases of the heart or lungs, or from asphyxia may cloud consciousness, increase suggestibility, and even make the person hallucinate. Stimulants such as caffeine (in coffee, tea, cocoa, and some cola drinks) or amphetamine drugs enhance alertness, but at the same time may increase distractibility. Ethyl alcohol (as in whiskey and beer) in small doses sometimes seems to assist attention by relieving anxiety but in larger doses blunts sensory and motor selectivity. Most dramatic effects are seen with such hallucinogenic drugs as mescaline and lysergic acid diethylamide (LSD). Users of these drugs report spectacular intensification of visual experiences. Hallucinations of vivid colours and majestic scenery may so rivet attention that an LSD-intoxicated person may walk out of a high window or wander about in dangerous street traffic. The less dramatic effects of marijuana (*Cannabis sativa*) also may heighten attention to detail and shift the person's assessment of its importance; sometimes there is distortion of the time sense (see TIME PERCEPTION). As far as these drugs now are understood, they seem to be toxic, poisoning brain mechanisms involved in signal selection and evaluation; the word intoxicated literally means poisoned.

Information theory. Dependence of attention both on the unexpectedness of events and on their familiar association may seem paradoxical. This may be resolved, or at least redefined, by considering events (occurring as sequences in time, or as features of a spatial pattern) in relation to the information they may convey.

The formal approach called information theory suggests that the significance of any event only can be estimated in terms of what else might have happened. Its significance (and tendency to attract attention) is considered a function of its statistical improbability. Novelty, as estimated through the number of times an event has been experienced before (compared with all possible alternatives), provides a measure of so-called surprise value. Thus an event that never has been experienced before has a high surprise value and should attract attention, even without specific associations or consequences.

Research suggests that when sensory stimulation exceeds a given level (called the channel capacity) transmission becomes restricted. One perceptual channel may transmit at the expense of others, or there may be partial transmission of information from more than one source, with attendant error and uncertainty. (A listener may attend almost entirely to one of two simultaneous conversations or shift momentarily from one to the other.)

Investigators often use a unit of information called the bit (short for binary digit), reflecting a primitive choice between two alternatives; *i.e.*, yes or no. The limited success of efforts to apply such measures to human beings reflects the incalculable effect of past experience on the information carried by any objectively discernible bit.

Humans compared with computing devices

One view is that people can deal with data only from one source at a time. Stimulation arriving while a person is reacting to a previous signal theoretically has to wait until his so-called decision mechanism becomes free, as in a telephone line. This single-channel hypothesis arose when it was noticed that people do not track a moving target smoothly but make discrete corrections for misalignment spaced about half a second apart. They seemed to be performing as intermittent-correction servomechanisms (*e.g.*, thermostats in home heating systems). Some interpreted this to reflect a time lag in central (brain?) processes, in crude analogy to the refractory phase of a nerve.

The single-channel model accounts for evidence that only one of a set of signals that require different actions gets attention at a time. If the interval between successive signals is less than about 0.08 of a second, however, grouping seems to occur and movements can be coordinated, as in violin playing or typing.

D.E. Broadbent postulated some form of filter in the central nervous system that admits only selected data, deferring those that cannot receive immediate attention. Deferred information seems to be stored temporarily, being irrecoverable if barred from awareness too long. Simultaneous sensory messages are said to be processed in parallel initially and then to converge on a perceptual or decision channel of limited capacity. The information (in bits per second) carried by incoming messages is believed to be a critical element in the number of stimuli that can be perceived. It has been suggested that the filter serves to weaken rather than to eliminate signals, these still being detectable by appropriately attuned structures. Sleep is depicted as having a similar (presumably more general) attenuating effect on response to external stimuli.

Delays and intermittency of reaction

Another hypothesis posits an absolute refractory period following one signal during which others cannot be accepted. Others suggest that perceiving proceeds in discrete time units, incoming data having to wait until the next time sample begins. The exact length of the unit or refractory period variously has been estimated between 0.1 and 0.5 of a second (see TIME PERCEPTION). Still another account invokes the so-called temporal uncertainty effect. People take longer to react when a warning signal appears less than one-fifth of a second before the signal that requires the response. This is attributed to interference by the warning signal with the preparatory process; in single-channel theory the warning signal is said to capture the decision mechanism.

Reaction-time studies also reveal an intermittency effect. When pressing a switch in response to each of two auditory or visual stimuli, people become slower when the interval between signals is less than 0.25 of a second. This holds even when reaction is required only for the second signal of each pair. Perhaps the effect depends on attention to the first signal (rather than on preparation to respond), since people are not slowed in reacting to a single signal that follows one of their own spontaneous responses. The interval between signals can be varied from 0.05 to 0.5 of a second without significant effect of temporal uncertainty on the delays.

Intermittency has been attributed to control of data processing in the central nervous system by some kind of internal clock that "ticks" off about once every 0.05 of a second. Basically this is a time-sharing variation of single-channel and filter theories. Attention is held to be aligned with just one incoming channel, messages on unattended channels being delayed for the time required to switch attention. Additional lag, seen as the intermittency effect, is said to result from a need to wait for the next "tick." Some suggest that the frequency of EEG alpha waves might be an outward sign of the hypothetical clock. Attentional gating (control of the flow of incoming information, or input) might occur in phase with these brain waves.

In contrast to the view of input overloading is the suggestion that a person acts not through a limited, fixed-capacity channel but as a limited-capacity processor. Indeed, prolonged practice does abolish initial differences in reaction time involving two, four, and eight choices; little practice is needed if stimulus and response are highly compatible. There may be a central processor of limited capacity that calculates ways to serialize input.

Attention also may be explained simply in terms of selective output, placing no restrictions on perceptual processing at all. There is little evidence for a peripheral filter, and selection is more likely to occur in the central nervous system (brain and spinal cord). For example, the content of two competing messages seems to be taken into account before one of them is selected for transmission onward.

A number of so-called perceptual analyzers have been posited, each providing a set of mutually exclusive descriptions. Perhaps there are different levels of analyzers, lower levels dealing with primitive perceptual qualities and higher levels mediating recognition of complex percepts; *e.g.*, those of letters, faces, or words.

Despite all these theoretical uncertainties, there does seem to be evidence of specialized attentive functions for specific parts of the nervous system. Some brain regions are activated by all stimuli in a given sensory modality,

others respond only to novel stimuli, others to a shift from monotony to novelty, others when one stimulus is associated with another, still others when a motor response is intended. Some brain systems seem programmed for particular functions related to situational details. This would suggest continuous neural monitoring of experience in terms of novelty, familiarity, association, and significance. Since attention is subject to voluntary direction, there also must be processes for emphasizing some features and playing down others, as in balancing musical instruments in an orchestra. Although the diffusely interacting structures of the brain provide ample instrumentation, they give no evidence of a physical location for anything resembling a baton-wielding conductor.

Attila

King of the Huns from 434 to 453, Attila, known in western Europe as the "Scourge of God," was one of the greatest of the barbarian rulers who assailed the Roman Empire. The Huns, a nomadic people from north central Asia, had begun to conquer much of Europe in the 4th century AD. The empire that Attila and his elder brother Bleda inherited seems to have stretched from the Alps and the Baltic in the west to somewhere near the Caspian Sea in the east. Their first known action on becoming joint rulers was the negotiation of a peace treaty with the Eastern Roman Empire, which was concluded at the city of Margus (Požarevac). By the terms of the treaty the Romans undertook to double the subsidies they had been paying to the Huns and in future to pay 700 pounds (300 kilograms) of gold each year.

From 435 to 439 the activities of Attila are unknown, but he seems to have been engaged in subduing barbarian peoples to the north or east of his dominions. The Eastern Romans do not appear to have paid the sums stipulated in the treaty of Margus, and so in 441, when their forces were occupied in the west and on the eastern frontier, Attila launched a heavy assault on the Danubian frontier of the Eastern Empire. He captured and razed a number of important cities, including Singidunum (Belgrade). The Eastern Romans managed to arrange a truce for the year 442 and recalled their forces from the West. But in 443 Attila resumed his attack. He began by taking and destroying towns on the Danube and then drove into the interior of the empire toward Naissus (Niš) and Serdica (Sofia), both of which he destroyed. He next turned toward Constantinople, took Philippopolis, defeated the main Eastern Roman forces in a succession of battles, and so reached the sea both north and south of Constantinople. It was hopeless for the Hun archers to attack the great walls of the capital; so Attila turned on the remnants of the empire's forces, which had withdrawn into the peninsula of Gallipoli, and destroyed them. In the peace treaty that followed, he obliged the Eastern Empire to pay the arrears of tribute, which he calculated at 6,000 pounds (2,700 kilograms) of gold, and he trebled the annual tribute, henceforth extorting 2,100 pounds (950 kilograms) of gold each year.

Attacks on the Eastern Roman Empire

Attila's movements after the conclusion of peace in the autumn of 443 are unknown. About 445 he murdered his brother Bleda and thenceforth ruled the Huns as an autocrat. He made his second great attack on the Eastern Roman Empire in 447, but little is known of the details of the campaign. It was planned on an even bigger scale than that of 441–443, and its main weight was directed toward the provinces of Lower Scythia and Moesia in southeastern Europe—*i.e.*, farther to the east than the earlier assault. He engaged the Eastern Empire's forces on the Utus (Vid) River and defeated them, but he himself suffered serious losses. He then devastated the Balkan provinces and drove southward into Greece, where he was only stopped at Thermopylae. The three years following the invasion were filled with complicated negotiations between Attila and the diplomats of the Eastern Roman emperor Theodosius II. Much information about these diplomatic encounters has been preserved in the fragments of the *History* of Priscus of Panium, who visited Attila's headquarters in Walachia in company with a Roman embassy in 449. The treaty by which the war was terminated was harsher than that of 443; the Eastern Romans had to evacuate a wide belt of territory south of the Danube, and the tribute payable by them was continued, though the rate is not known.

Attila's next great campaign was the invasion of Gaul in 451. Hitherto, he appears to have been on friendly terms with the Roman general Aetius, the real ruler of the west at this time, and his motives for marching into Gaul have not been recorded. He announced that his objective in the west was the kingdom of the Visigoths (a Germanic people who had conquered parts of the two Roman empires) centred on Tolosa (Toulouse) and that he had no quarrel with the Western emperor, Valentinian III. But in the spring of 450, Honoria, the Emperor's sister, sent her ring to Attila, asking him to rescue her from a marriage that had been arranged for her. Attila thereupon claimed Honoria as his wife and demanded half the Western Empire as her dowry. When Attila had already entered Gaul, Aetius reached an agreement with the Visigothic king, Theodoric I, to combine their forces in resisting the Huns. Many legends surround the campaign that followed. It is certain, however, that Attila almost succeeded in occupying Aurelianum (Orléans) before the allies arrived. Indeed, the Huns had already gained a footing inside the city when Aetius and Theodoric forced them to withdraw. The decisive engagement was the Battle of the Catalaunian Plains, or, according to some authorities, of Maurica (both places are unidentified). After fierce fighting, in which the Visigothic king was killed, Attila withdrew and shortly afterward retired from Gaul. This was his first and only defeat.

Invasion of Gaul

In 452 the Huns invaded Italy and sacked several cities, including Aquileia, Patavium (Padua), Verona, Brixia (Brescia), Bergomum (Bergamo), and Mediolanum (Milan); Aetius could do nothing to halt them. But the famine and pestilence raging in Italy in that year compelled the Huns to leave without crossing the Apennines.

In 453 Attila was intending to attack the Eastern Empire, where the new emperor Marcian had refused to pay the subsidies agreed upon by his predecessor, Theodosius II. But during the night following his marriage, Attila died in his sleep. Those who buried him and his treasures were subsequently put to death by the Huns so that his grave might never be discovered. He was succeeded by his sons, who divided his empire among them.

Priscus, who saw Attila when he visited his camp in 448, described him as a short, squat man with a large head, deep-set eyes, flat nose, and a thin beard. According to the historians, Attila was, though of an irritable, blustering, and truculent disposition, a very persistent negotiator and by no means pitiless. When Priscus attended a banquet given by him, he noticed that Attila was served off wooden plates and ate only meat, whereas his chief lieutenants dined off silver platters loaded with dainties. No description of his qualities as a general survives, but his successes before the invasion of Gaul show him to have been an outstanding commander.

BIBLIOGRAPHY. The only comprehensive history of Attila in English is that of E.A. THOMPSON, *A History of Attila and the Huns* (1948); but the sources for his life and times are translated from the Latin and Greek by C.D. GORDON in *The Age of Attila* (1960). For what appear to be the archaeological remains of the Huns, see J. WERNER, *Beiträge zur Archäologie des Attila-Reiches*, 2 vol. (1956).

(E.A.T.)

Attitudes

Social psychologists of the 1920s focussed on attitudes as a central concept in seeking to develop their field as a scientific discipline. Indeed, attitudes seem so pervasive that their study might be said to cover the full range of human behaviour and experience. People tend to develop attitudes toward whatever they experience—toward other people, toward political and religious institutions, toward moral and philosophical systems, apparently toward everything. Yet often enough, attitudes fail to stand the test of logical scrutiny; each person seems to be (as the essayist Charles Lamb, 1775–1834, said of himself) a bundle of prejudice.

DEFINITIONS

The concept of attitude arises from attempts to account for observed regularities in the behaviour of individual persons. One tends to group others around him into common classes; he may assign people of a given skin colour to a single class and behave similarly toward all of them. In such case he is said to hold an attitude specific to that ethnic or racial group. He may lump together the rich or the pious or the lame and so is assumed to bear a particular attitude toward each group. Individuals also classify such objects as paintings or such events as battles and therefore may be considered to have distinctive attitudes toward nonobjective art or toward war.

The quality of one's attitudes is judged from the observable, evaluative responses he tends to make. He might react to everyone of the same ethnic background with expressions of dislike, with derogatory comments about their honesty or intelligence, or he may advocate repressive, exclusionary public policies against them. On the evidence of such negative responses he is said to have an unfavourable attitude toward that ethnic group. Someone who uniformly praises nonobjective paintings, who frequently attends museums that exhibit them, and who hangs their reproductions on his walls is judged to hold a favourable attitude toward nonobjective art.

Inferred attitudes

Attitudes held by others are not directly observable; they must be inferred from behaviour. While one might consult his inner experiences as evidence of his own attitudes, only his public behaviour can receive objective study. Thus, investigators heavily depend on behavioural indices of attitudes—*e.g.*, on what people say, on how they respond to questionnaires, or on such physiological signs as changes in heart rate.

By way of definition, then, attitudes are predispositions to classify sets of objects or events and to react to them with some degree of evaluative consistency. While attitudes logically are hypothetical constructs (*i.e.*, they are inferred but not objectively observable), they are manifested in conscious experience, verbal reports, gross behaviour, and physiological symptoms.

Distinctions. Some authorities see the critical distinction between attitudes and a number of other terms to reside in their relative inclusiveness. All are predispositions to group objects and respond to them in a similar evaluative way. They can be arranged in a hierarchy based on their degree of specificity or exclusiveness. "Values" are said to represent very broad tendencies of this type, "interests" being slightly less inclusive and "sentiments" narrower still; "attitudes" are viewed as still more narrow predispositions, with "beliefs" and "opinions" being progressively the most specific members of this hierarchy. According to this terminology the difference is one of degree rather than of kind.

Other investigators consider one's attitude toward any class to be the intensity with which he expects that group to serve his own values. For example, he may be asked to rate the extent to which he prizes given values (such as health, safety, independence, justice). Then he estimates the degree to which that class (say, politicians) tends to facilitate or impede each value. The sum of the products of these two ratings provides a measure of the individual's attitude toward the group. Thus, if he highly prizes justice and judges that politicians severely interfere with it, his attitude toward that class is taken to be negative.

Attitudes sometimes are regarded as underlying predispositions, and opinions as their overt manifestations. A rarer distinction equates attitudes with unconscious and irrational tendencies and opinions with conscious and rational activities. Others refer to attitudes as meaningful and central and to opinions as more peripheral and inconsequential. A still more popular distinction refers attitudes to matters of taste (*e.g.*, liking a certain country or type of music) and opinions to questions of fact (*e.g.*, whether Zeus exists).

Some apply the term knowledge to what are held to be certainties and attitudes to what is uncertain, even using them to mean "true" and "false" beliefs, respectively. Another suggestion is that attitudes refer to beliefs that impel action and that knowledge is more intellectual and passive.

There are many confusing alternative conventions for distinguishing attitudes from such related concepts as values, opinions, and knowledge. This tends to generate unnecessary dispute and mere proliferation of language. Generally accepted terminology is lacking, and investigators often accept or discard distinctions as they judge them to be useful.

COMPONENTS

The most common analysis invests attitudes with perceptual, emotional, and motivational attributes. These three dimensions or components of human activity were suggested at least as early as Plato and have been applied in a variety of psychological contexts ever since. Traditionally the three aspects are called cognitive (having to do with perceiving, knowing, believing); affective (emotional); and conative (motivational, striving, acting).

Cognitive, affective, and conative attributes

Thus the informational content of any attitude is cognitive. For example, in one's attitude toward an ethnic group the cognitive aspect embraces the stereotyped beliefs (valid or misinformed) he may hold about the group's ability, appearance, habits, and so on.

His feeling of like or dislike for the ethnic group represents the affective aspect of the attitude. The affective component most epitomizes the evaluative nature of attitudes. Such gross physiological signs as accelerated heart rate (sometimes taken as indices of attitudes) reflect affective activity in terms of intensity (either positive or negative). Physiological distinctions between positive and negative attitudes are more difficult to measure (see EMOTION).

One's tendency to exhibit overt behaviour toward the object of an attitude is conative. Depending on the direc-

tion of his attitude, one would be motivated to seek members of a given ethnic group as congenial companions or as targets for his hostility, or he might strive to avoid them (see MOTIVATION).

As a rule, favourable attitudes are characterized by positive directions for all three attributes; unfavourable attitudes tend to involve the reverse. Nevertheless, one may experience hearty dislike without the usual cognitive basis (*i.e.*, without knowing why). Or he may behave aggressively (conative) without feeling hostile (affective). Such unbalanced attitudes often are said to be symptomatic of psychiatric difficulties; frequently they are seen to reflect one's own inner conflicts rather than his objective experiences. So-called prejudices are often attitudes of this sort.

FUNCTIONS OF ATTITUDES

Instrumental functions: attitudes as means to other ends. In seeking social acceptance one may make a show of hostile attitude toward some religious minority held in low esteem by his neighbours; or he may go through the motions of dancing as instrumental to entering desired social groups. Attitudes thus function to facilitate the achievement of goals, retrospectively on the basis of past pleasant experiences or in prospective anticipation of future reward.

Goal facilitation

To the extent that one's attitude serves as a means to an end, the instrumental function, it derives intensity from its perceived effectiveness in goal facilitation. A person who first only acts as if he shares a popular antiminority attitude to facilitate his acceptance in the community may experience no animosity against the minority; should this community prejudice change, he readily could exhibit favourable behaviour without embarrassment. If his overt hostility continued for an extended period, however, he might begin (through learning) to experience the subjective attributes of full-blown prejudice (*e.g.*, a feeling of hate with cognitive beliefs to justify it).

Noetic functions: attitudes as ways of thinking and understanding. Attitudes function in one's daily life in the way theories serve the work of science. One develops attitudes by teasing out regularities in his experience, by learning appropriate reactions in a systematic way, and by stating these relationships as generalizations. As theories, attitudes can be judged true or false, uplifting or degrading, provocative or banal.

Attitudes have the same cognitive role in everyday life that theories have in one's broader philosophical or scientific understanding. One's experiences are so diverse and the range of available responses is so extensive that the simplifications inherent in attitudes are urgent if one is to avoid chaos. If one did not systematically associate classes of objects and events with consistent sets of responses, his life would be an uninterrupted sequence of strange, new problems. To generalize is to simplify and abstract by selectively ignoring many aspects of concrete experience. Nevertheless, despite potential errors, generalizations such as those embodied in attitudes permit the only approach to rational activity.

Expressive functions: attitudes as means for emotional release. Some theorists view human beings as energy systems in which excessive tension can build up (crudely analogous to steam boilers). Thus, the expressive aspect of attitudes is held to relieve psychological pressure as if it were some sort of safety valve. Expressive theorists stress conative-affective attributes of attitudes (noetic theorists emphasize the cognitive) and consider attitudes as useful tension reducers in their own right. People seem to enjoy their attitudes as some are said to enjoy their infirmities. Gratifying feelings of tension release through expressive attitudes are epitomized in such phrases as "It is lovely to be in love" or "The man you love to hate. . . ."

In their expressive function, attitudes provide a number of alternatives to overt action. It is held that, if a person can release hostile tensions through relatively safe attitudinal activity (*e.g.*, fantasy or daydreaming), he doesn't have to act them out with aggressive behaviour. The posited role of attitudes as substitutes for action is reminiscent of the Aristotelian theory of tragedy. According to Aristotle, one can vicariously experience emotional release or purgation (catharsis) of his pity and fear by witnessing a theatrical production of a tragedy.

Ego-defensive functions: attitudes as symptoms of psychiatric disturbance. According to Freudian theorists, one's conscience, his primitive drives, and the demands of the environment all may come into conflict. People are said to adapt to these conflicts by repressing (putting out of awareness) unwelcome urges. One is held to adopt those attitudes that serve to bolster repression; ego functions (those concerned with environmental "realities") thus are thought to be defended against anxiety.

For example, according to one theory, one's prejudice toward groups of nonconformists (*e.g.*, those with a bohemian life style) can be traced to occasions early in his life when he was punished for manifesting any hostility toward his father. Theoretically, he learns to repress angry feelings toward his father and, by extension, toward any figures of authority (*e.g.*, police, politicians, military leaders). To bolster this repression, he is said to cultivate a directly contrasting attitude ("reaction formation") tending to idealize all authorities. He has become an "authoritarian personality" who despises atypical social groups that threaten orthodox social institutions on which his precarious psychiatric adjustment depends. It is held that changes in such ego-defensive attitudes depend on the individual's gaining insight into his own personality difficulties.

DETERMINANTS OF ATTITUDES

Hereditary factors. One has attitudes toward many objects or events that were unknown to his ancestors, and so they could hardly have derived from biological inheritance. The notion that anyone genetically can transmit his learned attitudes to his children seems particularly untenable. Nevertheless, genetic factors do represent the biological potential for all human activities, including the development of attitudes.

Thus, hereditary factors do seem to play some role in determining the general intensity with which attitudes are held or expressed. In dogs, aggressive or hostile predispositions evidently are transmitted genetically. The statistical correspondence is incomplete, however; individual littermates produced by vicious dogs have been observed to be gentler than some bred from more benign animals.

The Swiss psychiatrist Carl Jung (1875–1961) even argued that significant ancestral experiences are communicated genetically as attitudes universal to the human race ("racial unconscious"). While his formulation may have poetic or metaphoric appeal, its literal validity remains very much in doubt.

Bodily states. A host of drugs (including alcoholic beverages) can make one's attitude generally more euphoric, more aggressive, less concerned with others, or whatever. Comparable general alterations in attitude appear when such anesthetic drugs as nitrous oxide (laughing gas) are used; or even when one breathes deeply (hyperventilates) for a few minutes. Transient but spectacular effects on very specific (sexual) attitudes are induced with such aphrodisiac substances as cantharis (obtained from dried beetles). Direct electrical stimulation of the brain as well as its surgical manipulation (lobotomy) can have attitudinal effects.

Role of the brain

Relatively spontaneous physiological changes as in hunger or thirst can sharply alter attitudes toward food or water. Abruptly heightened sexual appetites during adolescence seem to represent a maturational change in the physiological basis for attitudes. Attitudinal disturbances are observed among aged people with hardening of the arteries and during the course of such disorders as tuberculosis, epilepsy, anemia, and encephalitis at any age. Suspicious (paranoid) attitudes toward others are classical long-term symptoms among sufferers of brain syphilis (paresis).

Direct experience. Attitudes are also affected by direct experience. This obvious determinant seems so reason-

able and objective that its importance may tend to be exaggerated.

Effects of frequent interaction with objects of attitudes have been observed in studies of racial integration in the U.S. The evidence suggests that interaction between groups of people initially intensifies pre-existing attitudes; amiably disposed people become even friendlier, while those with negative feelings grow more hostile. With increased familiarity, however, hostility tends to yield to more favourable attitudes in the long run. Amelioration seems most likely when integrated groups share equal social and economic status, when they mutually facilitate their attainment of goals, and when they are able to discover that they share beliefs on many issues.

A single salient encounter also may play a role in determining one's attitude toward an object. Such dramatic confrontations include cases of so-called love at first sight; unreasonable fears (phobias) attributable to single terrifying experiences (*e.g.*, being locked in a closet); and apparently sudden religious conversion after some strikingly moving event (*e.g.*, St. Paul on the road to Damascus).

Most people spend at least part of their lives under the substantial control of others. A nearly universal and usually benign example is one's home environment during the early years of childhood; usually somewhat briefer (and less happy) are adult experiences in such highly controlled environments as hospitals, military installations, jails, schools, and concentration camps.

These so-called total institutions obviously have an important effect on individual attitudes. Typically one undergoes what variously is called rehabilitation, re-education, or brainwashing. Even when institutional concern is only with overt behaviour rather than beliefs, it almost inevitably shapes attitudes to accord with the induced behaviour.

Communication. The major determinant of most of the individual's attitudes is communication from other people. While face-to-face experience is limited to a narrow range of objects, indirect experience with objects through communication from other people is virtually unlimited. There is growing evidence that one's attitudes are affected by nonverbal communication; for example, it has been shown that parents (sometimes unconsciously) can communicate their fears, likes, and dislikes to children through bodily movements and facial expression. But language constitutes the dominant factor in determining attitudes toward objects and events both in direct discussion with others and through mass media (*e.g.*, television). Determination of attitudes through verbal communication constitutes the process of persuasion (*q.v.*).

MEASUREMENT OF ATTITUDES

As a problem in psychological measurement, attitude assessment is subject to the usual question of validity, or in this case, the degree to which any measure accurately reflects an underlying attitude.

Instruments for measuring attitudes differ in terms of the degree to which their purpose is disguised. Surreptitious methods include the use of indices of a person's physiological arousal, for example, dilation of the pupils of his eyes may be photographed while he is viewing pictures of members of different ethnic groups. Or he may be asked to learn different attitudinal statements, the inference being that he will most readily learn those statements that agree with his own attitudes. Undisguised instruments include questionnaires that ask one explicitly to state his own attitudes toward specific issues.

Psychological measurement

Attitude-measuring instruments (disguised or undisguised) also vary in terms of the response options they allow. In a highly constrained format one may be asked to state his attitude by responding to specific questions (or statements) with only one of two alternatives: agree or disagree. Or he may be asked to communicate an attitude under relatively little constraint by writing a paragraph or essay outlining his position.

By far the most commonly used instrument is the undisguised, highly constrained questionnaire. In printed form it is usually called an opinionnaire and consists of a series of evaluative statements to which the person is asked to respond by indicating his position along some scale of agreement or disagreement. It is considered good practice to use several different items for measuring any specific attitude. Wording should be objective, subdued, and moderate; the language of social desirability should be avoided: (*e.g.*, "Chairman Mao says . . . ," "The Queen believes . . . ," "All good Americans prefer . . ."). Items should be so constructed that some demand agreement while others require disagreement if the respondent is to show a consistent attitude. Otherwise the instrument may measure the individual's acquiescent or negativistic tendencies rather than his specific attitudes.

Special care needs to be taken when attitudes are to be measured through interviews. The evidence is that respondents tend to show "interviewer bias" by stating attitudes they perceive to be in agreement with the interviewer's own. A relatively cooperative, compliant person may respond to even the most subtle cues from an interviewer. Careful training of interviewers may reduce such biases; more indirect techniques (*e.g.*, telephone interviews) also may be helpful. Or the person may be asked to fill out a written questionnaire without the interviewer watching.

When assessing attitudes among a relatively large group of people (as in measuring public opinion) it may not be feasible to consult each member of the population under study. A relatively small sample of people, however, if well chosen, can give an accurate estimate of the whole population's attitude. The sample commonly is constituted by randomly selecting people or, better still, by systematically selecting from representative subgroups in the population (*e.g.*, by age, sex, and income). Increasing the size of a random sample tends to increase accuracy, but it may be economically prohibitive. For example, according to statistical estimates, to double the accuracy of the estimate requires quadrupling the size of the sample.

Sampling

In using a highly constrained instrument such as an opinionnaire, final scoring of responses is a clear-cut (if sometimes complex) mathematical procedure. In the simplest case (such as agree or disagree) the respondent may be given one unit of score for each item through which he responds favourably toward a given object, the simple sum being taken as an index of favourable attitude. When response scales permit degrees of agreement or disagreement to be recorded, each item might be assigned a different weight in proportion to the intensity of attitude exhibited. More elaborate statistical analyses may be performed on the full set of responses to yield an understanding of specific opinions that comprise the general attitude.

Less constrained instruments (*e.g.*, "open-ended" questions requiring an essay or paragraph) may need to be scored by one or more people serving as judges. In such a preliminary procedure (called content analysis) judges read the responses, attempt to break them down into components, and may score each in terms of favourable quality. While unconstrained instruments are held to allow more freedom and subtlety of expression to respondents, they have the disadvantage of being difficult to score; results depend on the judgments of investigators, just as they do in the construction of opinionnaires. Despite careful attention to technical details attitude measurement remains an intricate and imperfect process.

BIBLIOGRAPHY. A succinct overview of this subject is found in W.J. MCGUIRE, "The Nature of Attitudes and Attitude Change," in G. LINDZEY and E. ARONSON (eds.), *Handbook of Social Psychology*, 2nd ed., vol. 3 (1969). A fuller discussion of the nature of attitudes and their effects on human behaviour and conscious experience may be found in M.J. ROKEACH, *Beliefs, Attitudes and Values* (1968); and in D.T. CAMPBELL, "Social Attitudes and Other Acquired Behavioral Dispositions," in S. KOCH (ed.), *Psychology: A Study of a Science*, vol. 6 (1963). Techniques for measuring attitudes are reviewed extensively in A.N. OPPENHEIM, *Questionnaire Design and Attitude Measurement* (1966); while a wide variety of standardized scales for measuring specific attitudes are pre-

sented in M.E. SHAW and J.M. WRIGHT, *Scales for the Measurement of Attitudes* (1967). A discussion of more covert behavioral measures is contained in E.J. WEBB *et al.*, *Unobtrusive Measures* (1966). J. HARDING *et al.*, "Prejudice and Ethnic Relations," in *Handbook of Social Psychology*, vol. 5 (1969), reviews attitude research concerning interracial relations; R.P. ABELSON *et al.*, (eds.), *Theories of Cognitive Consistency: A Sourcebook* (1968), deals with the role of attitudes in maintaining consistent inter- and intrapersonal relations; C.W. and M. SHERIF (eds.), *Attitude, Ego-Involvement, and Change* (1967), relates attitudinal and perceptual processes.

(W.J.McG.)

Auden, W.H.

In the early 1930s W.H. Auden was acclaimed prematurely by some as the foremost poet then writing in English, on the disputable ground that his poetry was more relevant to contemporary social and political realities than that of T.S. Eliot and William Butler Yeats, who previously had shared the summit. By the time of Eliot's death in 1965, however, a convincing case could be made for the assertion that Auden was indeed Eliot's successor, as Eliot had inherited sole claim to supremacy when Yeats died in 1939.

Horst Tappe

Auden, 1965.

Auden was a counterpart to Eliot not only in transatlantic migration (Auden assuming United States citizenship as Eliot had British) but in his long and controversial career as critic and man of letters as well as poet. He was, as poet, far more copious and varied than Eliot and far more uneven. He tried to interpret the times, to diagnose the ills of society and deal with intellectual and moral problems of public concern. But the need to express the inner world of fantasy and dream was equally apparent, and, hence, the poetry is sometimes bewildering. If the poems, taken individually, are often obscure—especially the earlier ones—they create, when taken together, a meaningful poetic cosmos with symbolic landscapes and mythical characters and situations. In his later years Auden ordered the world of his poetry and made it easier of access; he collected his poems, revised them, and presented them chronologically in two volumes: *Collected Shorter Poems 1927–57* (1966) and *Collected Longer Poems* (1968). A religious poet who is also a clown, a virtuoso who is incorrigibly didactic, a satirist who is also a supreme lyricist is a problem for critics; and most useful criticism of Auden is recent.

Influences and early fame. Wystan Hugh Auden was born in York, England, February 21, 1907. In the next year the family moved to Birmingham, where his father became medical officer and professor in the university. Since the father was a distinguished physician of broad scientific interests and the mother had been a nurse, the atmosphere of the home was more scientific than literary. It was also devoutly Anglo-Catholic, and Auden's first religious memories were of "exciting magical rites." The family name, spelled Audun, appears in the Icelandic sagas, and Auden inherited from his father a fascination with Iceland.

Education and early influences

His education followed the standard pattern for children of the middle and upper classes. At eight he was sent away to St. Edmund's preparatory school, in Surrey, and at 13 to a public (private) school: Gresham's, at Holt, in Norfolk. Auden intended to be a mining engineer and was interested primarily in science; he specialized in biology. By 1922 he had discovered his vocation as a poet, and two years later his first poem was published in *Public School Verse*. In 1925 he entered Oxford (Christ Church), where he established a formidable reputation as poet and sage, having a strong influence on such other literary intellectuals as C. Day Lewis (named poet laureate in 1968), Louis MacNeice, and Stephen Spender, who printed by hand the first collection of Auden's poems in 1928. Though their names were often linked with his as poets of the so-called Auden generation, the notion of an "Auden Group" dedicated to revolutionary politics was largely a journalistic invention. Upon graduating from Oxford in 1928, Auden, offered a year abroad by his parents, chose Berlin rather than the Paris by which the previous literary generation had been fascinated. He fell in love with the German language and was influenced by its poetry, cabaret songs, and plays, especially those by Bertolt Brecht. He returned to become a schoolmaster in Scotland and England for the next five years.

In his *Collected Shorter Poems* Auden divides his career into four periods. The first extends from 1927, when he was still an undergraduate, through *The Orators* of 1932. The "charade" *Paid on Both Sides*, which along with *Poems* established Auden's reputation in 1930, best reveals the imperfectly fused but fascinating amalgam of material from the Icelandic sagas, Old English poetry, public-school stories, Karl Marx, Sigmund Freud and other psychologists, and schoolboy humour that enters into all these works. The poems are uneven and often obscure, pulled in contrary directions by the subjective impulse to fantasy, the mythic and unconscious, and the objective impulse to a diagnosis of the ills of society and the psychological and moral defects of the individuals who constitute it. Though the social and political implications of the poetry attracted most attention, the psychological aspect is primary. The notion of poetry as a kind of therapy, performing a function somehow analagous to the psychoanalytical, remains fundamental in Auden.

Political views in the 1930s

The second period, 1933–38, is that in which Auden was the hero of the left. Continuing the analysis of the evils of capitalist society, Auden also warned of the rise of totalitarianism. In *On This Island* (1937; in Britain, *Look, Stranger!*, 1936) his verse became more open in texture and accessible to a larger public. For the Group Theatre, a society that put on experimental and noncommercial plays in London, he wrote first *The Dance of Death* (a musical propaganda play) and then three plays in collaboration with Christopher Isherwood, Auden's friend since preparatory school: *The Dog Beneath the Skin* (1935), *The Ascent of F 6* (1936), and *On the Frontier* (1938). He also wrote commentaries for documentary films, including a classic of that genre, *Night Mail* (1936); numerous essays and book reviews; and reportage, most notably on a trip to Iceland with MacNeice, described in *Letters from Iceland* (1937), and a trip to China with Isherwood that was the basis of *Journey to a War* (1939). He visited Spain briefly in 1937, his poem *Spain* (1937) being the only immediate result; but the visit, according to his later recollections, marked the beginning both of his disillusion with the left and of his return to Christianity. In 1936 he married Erika Mann, the daughter of the German novelist Thomas Mann, in order to provide her with a British passport. When he and Isherwood went to China, they crossed the United States both ways, and on the return journey they both decided to settle there. In January 1939, both did so.

Change of citizenship

Reorientation of thought and faith. That move begins the third period, 1939–46, during which Auden became a U.S. citizen and underwent decisive changes in religious

and intellectual perspective. *Another Time* (1940) contains some of his best songs and topical verse, and *The Double Man* (containing "New Year Letter," which provided the title of the British edition; 1941) embodies his position on the verge of commitment to Christianity. The beliefs and attitudes that are basic to all of Auden's work after 1940 are defined in three long poems: religious in the Christmas oratorio *For the Time Being* (1944); aesthetic in the same volume's *Sea and the Mirror* (a quasi-dramatic "commentary" on Shakespeare's *Tempest*); and social–psychological in *The Age of Anxiety* (1947), the "baroque eclogue" that won Auden the Pulitzer Prize in 1948. Auden wrote no long poems after that, perhaps because these three together make a kind of triptych.

The fourth period began in 1948, when Auden established the pattern of leaving New York each year to spend the months from April to October in Europe. From 1948 to 1957 his summer residence was the Italian island of Ischia; in the latter year he bought a farmhouse in Kirchstetten, Austria, where he then spent his summers. In *The Shield of Achilles* (1955), *Homage to Clio* (1960), *About the House* (1965), and *City Without Walls* (1969), Auden's only longer works, are sequences of poems arranged according to an external pattern (canonical hours, types of landscape, rooms of a house). With Chester Kallman, a U.S. poet and close friend, he rehabilitated the art of the opera libretto. Their best known are *The Rake's Progress* (1951), with Igor Stravinsky, and *Elegy for Young Lovers* (1961) and *The Bassarids* (1966), with Hans Werner Henze. In 1962 Auden published a volume of criticism, *The Dyer's Hand,* and in 1970 a commonplace book, *A Certain World.* He spent much time on editing and translating, tasks that he performed with unfailing intelligence and zest. Of the numerous honours conferred on Auden in this last period, the Bollingen Prize (1953), the National Book Award (1956), and the professorship of poetry at Oxford (1956–61) may be mentioned.

Assessment

While some hostile critics regarded his migration as a betrayal and his whole development after the 1930s as a decline, most critics and innumerable readers were grateful for the long presence on the literary scene of one so entertaining, gifted, variously instructive, and wise. Robert Lowell, a leading U.S. poet of a younger generation, wrote:

> Auden's work and career are like no one else's, and have helped us all. He has been very responsible and ambitious . . ., constantly writing deeply on the big subjects, and yet keeping something wayward, eccentric, idiosyncratic, charming, and his own. . . . I am most grateful for three or four supreme things: the sad Anglo-Saxon alliteration of his beginnings, his prophecies that seemed the closest voice to our disaster, then the marvellous crackle of his light verse and broadside forms, . . . and finally for a kind of formal poem that combines a breezy baroque grandeur with a sophisticated Horatian simplicity.

In 1972 Auden transferred his winter residence from New York to Oxford, where he was an honorary fellow at Christ Church College. He died in Vienna on September 29, 1973.

MAJOR WORKS

POETICAL WORKS: *Poems* (1928, privately printed by Stephen Spender); *Poems* (1930), including the verse play *Paid on Both Sides,* subtitled "A Charade"; *The Orators* (1932); *Look, Stranger!* (1936; U.S. title, *On this Island,* 1937); *Spain* (1937); *Another Time* (1940); *New Year Letter* (U.S. title, *The Double Man;* includes sonnet sequence "The Quest," 1941); *For the Time Being* (1944), containing *The Sea and the Mirror,* subtitled "A Commentary on Shakespeare's The Tempest" and *For the Time Being,* subtitled "A Christmas Oratorio"; *The Age of Anxiety,* subtitled "A Baroque Eclogue" (1947); *Nones* (1951); *The Shield of Achilles* (1955); *Homage to Clio* (1960); *About the House* (1965); *City Without Walls and Other Poems* (1969).

PLAYS: *The Dance of Death* (1933); written in collaboration with Christopher Isherwood: *The Dog Beneath the Skin* (1935); *The Ascent of F 6* (1936); and *On the Frontier* (1938).

LIBRETTI (in collaboration with Chester Kallman): Igor Stravinsky's *Rake's Progress* (1951); Hans Werner Henze's *Elegy for Young Lovers* (1961) and *The Bassarids* (1966).

TRAVEL BOOKS AND CRITICISM (in collaboration with Louis MacNeice): *Letters from Iceland* (1937), contains the long piece of light verse "Letter to Lord Byron"; with Christopher Isherwood: *Journey to a War* (1939), includes the sonnet sequence "In Time of War," later called "Sonnets from China"; *The Enchafèd Flood,* subtitled "The Romantic Iconography of the Sea" (1950); *The Dyer's Hand and Other Essays* (1962); *Secondary Worlds* (T.S. Eliot Memorial Lectures) (1968); *A Certain World: A Commonplace Book* (1970).

BIBLIOGRAPHY. Full information about criticism of Auden (as well as about the publication of Auden's own works) may be found in B.C. BLOOMFIELD, *W.H. Auden: A Bibliography* (1964); and a selection, with introduction, in M.K. SPEARS (ed.), *Auden: A Collection of Critical Essays* (1964). The most useful recent books are JOHN FULLER, *A Reader's Guide to W.H. Auden* (1970); the interpretations by HERBERT GREENBERG, *Quest for the Necessary* (1968); and JOHN G. BLAIR, *The Poetic Art of W.H. Auden* (1965). M.K. SPEARS, *The Poetry of W.H. Auden* (1963, in paperback with added preface, 1968), remains the most comprehensive account. Earlier books still worth consulting are RICHARD HOGGART, *Auden: An Introductory Essay* (1951), the first full-length study (together with the same author's pamphlet of 1957, "W.H. Auden"); and JOSEPH W. BEACH, *The Making of the Auden Canon* (1957), an analysis of Auden's procedure in compiling his *Collected Poetry* (1945) and *Collected Shorter Poems* (1950).

(M.K.Sp.)

Augustine of Hippo, Saint

St. Augustine, bishop of Hippo in Roman Africa from 396 to 430, and the dominant personality of the Western Church of his time, is generally recognized as having been the greatest thinker of Christian antiquity. His mind was the crucible in which the religion of the New Testament was most completely fused with the Platonic tradition of Greek philosophy; and it was also the means by which the product of this fusion was transmitted to the Christendoms of medieval Roman Catholicism and Renaissance Protestantism.

Alinari—Art Reference Bureau

St. Augustine, fresco by Sandro Botticelli, 1480.
In the Church of Ognissanti, Florence.

This unique significance would have belonged to Augustine had he never written the famous *Confessions,* in which at the age of about 45 he told the story of his own restless youth and of the stormy voyage that had ended, as he believed, 12 years before he put it in writing, in the haven of the Catholic Church. It is easy to forget that the real work of Augustine's life did not begin until the last scene of the *Confessions* was already receding for him into a remembered past. Moreover, the *Confessions* themselves are not so much autobiography as they are devotional outpourings of penitence and thanksgiving.

Augustine's conscientious memory generally can be trusted for the facts: his reflections upon them are those of the bishop on his knees. This is not to say that, in any attempt to understand or appreciate the mind of the bishop, the *Confessions* can be neglected. The picture must, however, be drawn in proper proportion; it is essential to avoid giving undue prominence to what should be no more than its background.

Youth and conversion. Hippo Regius is the modern Annaba on the Algerian coast, in what was then the Roman province of Numidia. Augustine, named Aurelius Augustinus, was born on November 13, 354, of middle class parents at Tagaste (modern Souk-Ahras), a small town about 45 miles (72 kilometres) to the south. His father, Patricius, was and remained until late in life a pagan; his mother, Monica, was a Christian of intense but simple piety, from whose early teaching Augustine retained a reverence for the "name of Christ" that never left him. But he was not baptized in infancy. He went through primary and secondary schooling and soon displayed such intellectual promise that the modest family funds were banked upon securing him an academic career that would qualify him for government service. As a 19-year-old student at Carthage he was stirred by the reading of a treatise of Cicero—the now lost *Hortensius*—and was filled with an enthusiasm for "philosophy," which meant not only a devotion to the pursuit of truth but a conviction of the superiority of a life devoted to that pursuit (the *vita contemplativa*) over any aims of secular ambition. The faith of the Catholic Church seemed to him too hopelessly unphilosophical for any man of culture to entertain; and he was easily carried away by the discovery in Manichaeism of a religion that professed to appeal to reason rather than authority.

Enthusiasm for philosophy

Influence of Manichaeism. The Manichaean system as propagated in the Western Roman Empire was a materialistic dualism that accounted for the creation of the world as the product of a conflict between light and dark substances and for the soul of man as an element of the light entangled in the dark. Manichaeism claimed to be the true Christianity, preaching Christ as the Redeemer who enables the imprisoned particles of light to escape and return to their own region. In the Manichaean Church the higher order of "elect" were strictly ascetic and celibate, all physical generation being held to serve the realm of darkness. After an adolescence that probably was no more licentious than was common in his time and country, Augustine had formed a liaison with a woman of low birth by whom he had a son and to whom he remained loyally attached throughout the nine years of his association with the Manichaeans, and he was therefore allowed to join that sect's lower order as one of the "hearers," to whom marriage was permitted as a concession to human weakness.

His first zeal for this "religion of enlightenment" did not last long, however, for the Manichaean experts were intellectually second rate and proved incapable of dealing with the questions he put to them. He became increasingly disillusioned and was already falling into a general agnosticism when, at the age of about 28, he left Carthage, where he had worked as a free-lance teacher of rhetoric, and went to Rome in search of more satisfactory pupils. There he made connections that led to an official professorship at Milan, where the Western emperor then resided. The bishop of Milan was Ambrose, the most eminent Christian churchman of the day. Augustine was introduced to Ambrose but never came to know him well. He went to hear him preach, however, and this, his first contact with the mind of a Christian intellectual, was enough to shake Augustine's prejudice against Catholic teaching. Although he had abandoned the doctrines of Manichaeism, he retained its materialistic presuppositions, which left him still a skeptic with no satisfying alternative to Manichaean notions of ultimate reality. The being of God and the nature and origin of evil remained for him problems as insoluble as they had ever been.

Contact with St. Ambrose

Influence of Neoplatonism. The solution of both problems was given to him by a chance introduction to Neoplatonic writings, for which he may well have been prepared by Ambrose's use of them in some of his sermons. Neoplatonism, in the work of the 3rd-century philosopher and mystic Plotinus, its greatest exponent, is a spiritual monism—a philosophical doctrine holding that there is only one reality—according to which the universe exists as a series of emanations or degenerations from absolute unity. From the transcendent One arises self-conscious mind or spirit; from mind comes soul or life; and soul is the intermediary between the spheres of spirit and of sense. Matter is the lowest and last product of the supreme unity; and since the One is also the real and the good, the potentiality of evil is identified with unformed matter as the point of maximum departure from the One. Evil itself is thus the least real of all things, being simply the privation or absence of good. Neoplatonic mysticism relies on the principle that the inward is superior to the outward: to reach the good, which is the real, one must "return into" oneself; for it is the spirit at the heart of man's inmost self that links him to the ultimate unity.

In the seventh book of the *Confessions*, Augustine tells how in such an act of introspection he found God—the "changeless light," at once immanent and transcendent, which is the source of every intuitive recognition of truth and goodness. This discovery of God was more than the conclusion of a process of reasoning: it was a mystical experience, a vision or touch that came and went. But it left behind it the answer to Augustine's unsatisfied questionings. God is light, and evil is darkness, as the Manichaeans said. But neither is a material substance: the changeless light of God is pure spiritual being, and the evil is nonentity, as darkness is but the absence of light.

Conversion to Christianity. Augustine's mystical experience, his awareness of God, had been momentary and fleeting. He believed that this could be only because he had not made for himself the necessary total identification of supreme value with spirit; he was still himself entangled with the flesh. In fact, Neoplatonism had reinforced the Manichaean principle that the way of return to God must be through escape from the body; and for Augustine this meant primarily and immediately escape from the ties of sexuality. The immortal story of his conversion in the eighth book of the *Confessions* tells of his coming to learn of the heroic achievements of Christian asceticism in East and West, of the self-contempt induced in him by the contrast of his own weakness, and of the final breakdown of resistance in a Milan garden, when, at the sound of a child's voice calling *"tolle, lege: tolle, lege"* ("take up and read"), he opened the New Testament Letters and read in Letter of Paul to the Romans the words, ". . . put on the Lord Jesus Christ, and make no provision for the flesh, to gratify its desires" (Rom. 13:14).

Moral struggle

This was in the late summer of the year 386. Vacation was near, and Augustine resigned his teaching chair and went with some young pupils, his son Adeodatus, and his mother Monica to a reading party at a country house lent by a friend. Out of their literary study and philosophical discussions there came the earliest of Augustine's surviving works—the dialogues, which display so little of the storm and stress of a religious conversion and so little concern with specifically Christian themes that critics have been led to question the accuracy of the *Confessions* story written many years later. It is true that Augustine's struggle against the domination of his sexual nature can be regarded as the final phase in that fluctuating pursuit of the "philosophic life" first presented to him by Cicero's *Hortensius*. But there is no sufficient reason for doubting that he was a Catholic Christian in intention when he received Baptism at the hands of Ambrose in the spring of 387. It is certain that three or four years later, when he wrote his treatise *De vera religione* (*Of True Religion*), he was still thinking of Christianity in Neoplatonic terms. In this treatise, the divine Word (Logos) in Christ is the mind or spirit of Plotinus, illuminating the reason, through whom the human soul has access to the transcendent Godhead. Christ's human life is man's example of the ascetic victory over the pains and pleasures of the flesh; Christian morals serve only to

purify the soul for the life of contemplation; and Christian faith is the necessary acceptance of the church's authority in this preliminary stage of training.

Bishop and Christian philosopher. Shortly after his Baptism, Augustine left Milan, with his mother and a small party of friends, to return to Africa. At Rome's port city of Ostia, his mother died; and Augustine recorded his last talk with her, in which son led mother, through a discourse formed on the pattern of the Neoplatonic "ascent" from this world to the other, to share with him a momentary experience of the life eternal. Home again at Tagaste, the friends formed a little community devoted to the religious life of contemplation and study. But its peace was soon broken when, on a visit to Hippo in 391, Augustine was forced to accept ordination as assistant priest to its old bishop, Valerius. Five years later Valerius died, and Augustine entered the episcopate in which he was to labour until his death. The bishop in Roman Africa was not only the pastor of a parish, the busy teacher and preacher, but the presiding judge in a much-frequented court of summary jurisdiction in civil cases. Augustine never enjoyed robust health, and the vast extent of his literary output was made possible only by the constant services of stenographers and by an extraordinary capacity for the extempore formulation of ordered thought, of which at least 400 sermons remain as proof. He was not a systematic theologian. Much of his writing was in response to the appeals that his growing reputation in the Christian world brought to him for the solution of the most diverse problems. Over 200 of his letters have been preserved, many of them having the scale of minor treatises. He was tireless in controversy with heretics—Manichaeans, Donatists, and Pelagians. But his deepest thought, the real Augustinianism, is to be found in his scripture commentaries and homilies, especially his expositions of the Psalms and his writings on the Gospel and First Letter of John. The characteristic pattern he imposed upon Christian theology was not the outcome of controversy.

Pastor, teacher, and judge in Hippo

The decisive turn was given to his thinking by his ordination to the priesthood, which dragged him against his will from the *vita comtemplativa* into the world and at the same time diverted his studies from philosophy to Scripture. The realities of pastoral experience among the very imperfectly Christianized people of an African seaport, together with the rapid impregnation of his mind with the categories of biblical religion, made it impossible for him to overlook the differences between Neoplatonism and Pauline Christianity. The knowledge of God and of the soul always remained from the time of his Baptism the one and only knowledge that he desired; and Plotinus had not been mistaken in bidding him look within himself if he would find God, for the Bible also tells of a likeness to God imprinted on the soul. But although for the Neoplatonist the soul's likeness to God is that of a, so to speak, reduced divinity, for the Christian it is that of a temporal and mutable image of the "eternal and changeless." Augustine was assured that it is the task of a Christian philosophy, guided by the scriptural revelation, to seek to know God through his image in the soul; and this was the path he followed in his great treatise *De Trinitate* (*On the Trinity*). He insisted that a true knowledge of the soul's nature can be based only on the immediate awareness of self-consciousness; and the soul's awareness of itself is of a trinity in unity that reflects "as in a glass darkly" the being of its Maker. He claimed that knowledge of one's own being, of one's own thinking, of one's own willing is not open to doubt; there is an ego that exists, knows, and wills. But in none of these aspects is the ego self-sufficient or independent: it cannot maintain its own being, produce its own knowledge, or satisfy its own desires. Augustine believed that he had learned from the Platonists to find in God "the author of all existences, the illuminator of all truth, the bestower of all beatitude" (*De civitate Dei* viii, 4). But his theories of the universe, of knowledge, and of ethics were his own. The following three paragraphs summarize these theories.

Biblical and philosophical theologian

Theory of the universe. Creation in Plotinus is motiveless and purposeless, the automatic by-product of the divine self-contemplation; in Augustine its source is "the will of a good God that good things should be" (*De civitate Dei* xi, 21). The outgoing energy of creative love forms the basic principle of his entire theology. Since nothing can come into being or continue in it but by this divine will to create, all that exists is good "in so far as it has being"; and because there are evidently degrees of goodness, there must also be degrees of being. But even the formless matter that is nearest to "not being" is essentially good because God made it; the origin of evil is not to be sought in material existence. Augustine persistently refused to unload upon the material conditions of human life the responsibility for human wickedness.

Theory of knowledge. Following Plato, Augustine argued that the ability to make true judgments never can be inserted into the mind from outside. The human teacher never can do more than help his pupil to see for himself what he already knew without being aware of it. Augustine's favourite examples of these intuitive judgments are the propositions of mathematics and the appreciation of moral values; they are not the construction of the individual mind, because when properly formulated they are accepted by all minds alike. The individual thinker does not make the truth, he finds it; and he is able to do so because Christ, the revealing Word of God, is the *magister interior*, the "inward teacher," who enables him to see the truth for himself when he listens to him.

Ethics. Augustine accepts the basic assumption of ancient ethical theory that conduct is properly directed to the achievement of *eudaimonia*—the happiness or well-being that is taken to be the one universal desire of humanity. Augustine's cosmos is an ordered structure in which the degrees of being are at the same time degrees of value. This universal order requires the subordination of what is lower in the scale of being to what is higher: body is to be subject to spirit, and spirit to God. Man must know his place in the order of the universe and, knowing it, must voluntarily accept it; that is, he must set upon himself and upon everything else the relative value that is properly due. Augustine's word for the ethical valuation that influences conduct is *amor* ("love"). *Amor* is the moral dynamic that impels man to action. If it is rightly directed man will never set a higher value on what is lower in the scale. All lesser goods are to be "used" as means or aids toward the higher; only the highest is to be "enjoyed" as the ultimate end on which the heart is set. The supreme good in whose fruition alone man reaches his perfection is for Augustine the God whose nature is *agapē*, love in the New Testament sense of the word. If, then, man's love, his *amor*, can rise to the enjoyment of God, it will become a participation in the divine *agapē*, love itself. God will have given himself to men, and by sharing in his love men will love one another as he loves them, drawing from him the power to give themselves to others.

Struggle with the Donatist schism. The energies of Augustine, both pastoral and literary, were for the first 15 years of his episcopate distracted by the wearisome struggle to end the schism in the African Church that had persisted for nearly a century. The Donatists, a Christian sect (named after Donatus, one of its leaders) the members of which outnumbered the Catholics in the country districts and in many towns, claimed to be the only true church on the ground that their ministry was the only one the succession of which had not been stained by apostasy in the great persecution of the years 303–313, which had begun under the emperor Diocletian. Imperial attempts to suppress the schism had stimulated the martyr spirit that had always marked African Christianity and gained Donatism the support of strong elements in the native population whose grievances were social and economic rather than ecclesiastical. The schism maintained itself by fanatical violence, and Augustine's persevering attempts to settle the questions at issue by peaceful discussion were fruitless. In the end, the imperial government became convinced that the Donatists were a danger to the security of Africa. The Donatist bishops were compelled to meet their Catholic rivals at a formal conference held

under an official arbitrator at Carthage in 411, the foregone conclusion of which was a Catholic victory.

Answer to the Donatists

Donatists and Catholics were agreed that the power of the Holy Spirit is conveyed to the believer through the sacraments, which are administered by the church through the clergy. The Donatists alleged, however, that the sacraments require for their validity a ministry undefiled by serious sin; for the Spirit departs from the sinner, who cannot therefore "confer what he does not possess." Augustine replied that the sacraments convey the Spirit in virtue of Christ's ordinance alone and that this validity cannot be affected by the worthiness or unworthiness of the human minister. The unity of the church depends on the Spirit's supreme gift of charity, of which schism is the denial. Unfortunately, Augustine, who had for long stood out against the use of any means but persuasion to bring the schism to an end, eventually was induced to approve the enforcement of legal penalties upon the schismatics, in the interest, as he believed, of the many whose fear of Donatist violence had kept them from returning to the church. His famous saying, "Love, and do what thou wilt," was in fact a defense of compulsion in the service of charity.

Struggle with the Pelagian heresy. As the Donatist controversy was ending, the Pelagians were already beginning to threaten the traditional doctrines of sin and redemption in the Western Church. Pelagius had set himself to resist the slackening of Christian moral standards. Against those who pleaded human frailty in excuse for their failings, he insisted that God has made every man alike free to choose and to perform the good; that it is the essence of sin to be a voluntary act that God's law forbids and that the sinner was free to avoid; and that, were not this freedom real, there could be no justice in God's punishments and rewards. This reduction of Christianity to a bleak moralism could not avoid conflict with the plain implications of the church's sacramental and liturgical practice. Baptism had always been "for the remission of sins," and infants were held to need it because they inherit the guilt of Adam's transgression, which, as St. Paul taught, brought death upon the whole race of men. The doctrine of original sin was firmly established in the Western Church before Augustine's time; and when it was openly rejected by Pelagius' disciple Celestius, there was no escape for Pelagianism from being branded as a heresy. The prevarications of Pelagius were able to persuade Pope Zosimus (417–418) to reverse the condemnation pronounced by his predecessor, Innocent I. But in the spring of 418 the African bishops obtained from the emperor Honorius an edict banishing the heretics; and Zosimus was obliged to come into line.

Augustine was the soul of the Church's resistance. He had seen Pelagianism at once as not merely a denial of the virtue of Christian Baptism but also as a fatal misconception of the relationship between God and man. For to assert that man can achieve righteousness by his own effort is to contradict the fundamental truth that God is the giver of all good.

Original sin and its propagation

Before the controversy began, Augustine had worked out his own rationalizations of the doctrines of original sin and divine grace—rationalizations that the church was to prove unwilling to accept fully. He accepted the traditional belief in the fact and in the penal consequences of Adam's transgression, defining the fact as man's refusal to accept his place in the created order, and the consequences as a dislocation of the order of man's own nature—the revolt of flesh against spirit. He argued that not only are all men involved in Adam's guilt and punishment but also that this involvement takes effect through the dependence of human procreation on the sexual passion, in which the spirit's inability to control flesh is evident. It was this linking of original sin with human sexuality that exposed Augustine in his old age to the most damaging criticisms of the Pelagian bishop Julian, who boldly asserted the moral neutrality of the instincts that belong to man's created nature and charged Augustine with relapsing into Manichaeism in his argument that an impulse that a man is bound to fight and conquer must therefore be evil.

For Augustine the fall of man means that in all men the true order of love has been violated. Departing from the love of God above him, man has followed the love of self and become subject to what is below him. Man has fallen by the act of his own will. He cannot by a similar exercise of will reverse the consequences of that fall. The subjection of spirit to flesh is a slavery from which the perverted will has no power to deliver itself, just because it cannot will the deliverance. What is needed is a kind of reversal of gravity—the substitution of an uplifting for a down-dragging love. And Augustine believed that this could happen only by that gracious descent of the divine love to dwell within the sinner: the gospel of the incarnation and of Pentecost.

Pelagius, on the other hand, argued that all men have been created free to do what is right when they see it, and that Christians have received the needed moral enlightenment in Christ's teaching and example. Augustine knew the unreality of the Pelagian conception of freedom as an innate and absolute power of choice, unaffected by circumstances. He pointed to the inescapable conditioning of all moral activity by the situation of the agent—outside whose control are in general not only the presentation of an object but also the kind of feeling that the presentation excites. Moreover, the act of will is dependent on feeling as well as on cognition. In Augustine's words:

> Men will not do what is right, either because the right is hidden from them or because they find no delight in it. But that what was hidden may become clear, what delighted not may become sweet—this belongs to the grace of God" (*De peccatorum meritis et remissione*).

Augustine insisted that without this delight in righteousness there can be no true freedom in well-doing, but only a servile obedience to law. The love of God, which is the motive of the Christian life, must be free. Yet love of God, as St. Paul said, enters man's heart by the gift of the Holy Spirit; and Augustine found it increasingly difficult to leave room in his doctrine of grace for a genuinely free response on man's part to the Spirit's gift. The unexamined assumption that everything in human life must be ascribed either to God's or to man's working compelled him to hold that God alone is the cause of every human movement toward good. In the first year of his episcopate, the study of St. Paul's argument in Rom. 9–11 had convinced him that no event in time can alter the eternal setting of God's will toward any human soul: his elect are chosen before the foundations of the world. God knows—not before, but apart from, the time process—how each individual in the course of time will respond to the particular form in which grace is offered to him; and the elect alone receive the grace that will win their acceptance.

The City of God

The rigour of this doctrine did not soften in face of the Pelagian challenge. In *De civitate Dei* (*The City of God*), the masterpiece on which Augustine was working throughout the Pelagian controversy, he drew a picture, as majestic as it is appalling, of the "beginnings, course and destined ends" of the two invisible societies of the elect and the damned. The work seems to have been in his mind before the capture of Rome by the Visigoths in 410 had shaken the empire; but it took the form of a Christian apologetic against the pagan claim that the disaster was consequence and punishment of Rome's apostasy from its ancestral religion. Augustine's two cities are not to be identified with the Christian Church and the pagan or secular state. They are symbolic embodiments of the two spiritual powers that have contended for allegiance in God's creation ever since the fall of the angels—faith and unbelief, "the love of self extending to contempt for God, and the love of God extending to contempt of self." Neither power is embodied in its purity in any earthly institution; in this world the heavenly and earthly cities are inextricably intermingled. If there is a philosophy of history in the *De civitate Dei*, it is the religious philosophy of predestination.

Augustine found it difficult in his old age to reassure some of his own disciples, to whom his doctrine seemed to make moral effort futile and praise and blame alike

groundless. But he would retract nothing. His last completed treatises drew out the logic of predestination to its most ruthless conclusions. Though his doctrine in its final form was never accepted by the church, it reappeared virtually unmodified in the writings of both St. Thomas Aquinas and John Calvin, the most acute thinkers, respectively, of Scholasticism and Reform. It may indeed be regarded as product of the too audacious attempt of the time-bound human mind to contemplate existence with the eye of the eternal God.

The influence of Augustine. The end of Roman civilization in Africa was near and the Vandal armies were besieging Hippo when Augustine died there on August 28, 430. Not many years later, Vincent of Lérins defined Catholic orthodoxy in the famous phrase, *Quod ubique quod semper quod ab omnibus creditum est* ("What is everywhere, what is always, what is by all people believed"). He dared not call Augustine a heretic in so many words, but it was against the extravagances that he rightly detected in Augustinian doctrine that his definition was aimed. That these extravagances have been a noxious legacy to theology because of their author's authority cannot be denied. But that should not prevent the grateful acknowledgment of the debt that Christian thinking has owed through the centuries to Augustine's influence, which has spanned and may one day reconcile the divisions of Western Christendom. The secret of that influence is to be found not so much in the brilliance and profundity of his intellect, the magic of his style, or the validity of his constructions as in the unique power of his religious genius. St. Anselm of Canterbury, St. Bernard of Clairvaux, the makers of *The Book of Common Prayer*, St. Francis de Sales, Blaise Pascal, Jacques-Bénigne Bossuet, Joseph Butler, Jacques Maritain, Reinhold Niebuhr, and Paul Tillich—all these have in their different ways drawn inspiration from one in whom they have been compelled to recognize "the heart of the matter." *Verus philosophus est amator Dei* ("The true philosopher is the lover of God"). In those words from the *De civitate Dei*, Augustine has left at once the best portrait of himself and the fullest justification of his life's work.

St. Augustine has been revered as a doctor of the church since the early Middle Ages. His feast is celebrated on August 28.

MAJOR WORKS

TEXTS AND TRANSLATIONS: Modern critical editions of St. Augustine's works in the original Latin are in process of publication in the *Corpus Scriptorum Ecclesiasticorum Latinorum* and in the *Corpus Christianorum;* but the only available edition complete except for the Sermons is still that of the Benedictines of Saint-Maur (1670–1700), reprinted in Migne's *Patrologia Latina.* There are no complete English translations of all St. Augustine's works. The largest separate collection is in the series "Nicene and Post-Nicene Fathers of the Christian Church" (N.P.N.F.). Translations of most of the Major Works listed below can be found either in this collection or in one or other of the following more recent series: "Ancient Christian Writers" (A.C.W.); "The Fathers of the Church" (F.C.); "The Library of Christian Classics" (L.C.C.).

GENERAL: *Confessiones* (*c.* 400; *The Confessions,* L.C.C.); *De doctrina Christiana* (397–428; *Christian Instruction,* F.C.); *De Trinitate* (400–416; *On the Trinity,* N.P.N.F.); *De civitate Dei* (413–426; *The City of God,* F.C.); *Enchiridion ad Laurentium de fide, spe, et caritate* (421; *Enchiridion to Laurentius on Faith, Hope, and Love,* L.C.C.); *Sermones* (from 391; *Selected Sermons,* ed. by *Quincy Howe,* 1966); *Epistolae* (from 386; *Letters,* F.C.).

EXEGETICAL: *De Genesi ad litteram* (401–415), a commentary on the first three chapters of Genesis; *De sermone Domini in monte* (393–394; *Commentary on the Lord's Sermon on the Mount,* F.C.); *Enarrationes in Psalmos* (391–420; *Expositions on the Book of Psalms,* 1847–57; A.C.W. incomplete); *Tractatus in Joannis Evangelium* (407–418; *Homilies on the Gospel of John,* N.P.N.F.); *Tractatus in Epistolam Joannis ad Parthos* (*c.* 415; *Homilies on St. John's Epistle,* L.C.C.).

CONTROVERSIAL: (ANTI-MANICHAEAN): *De vera religione* (*c.* 390; *Of True Religion,* L.C.C.); *De libero arbitrio* (389–395; *On Free Will,* L.C.C.). (ANTI-DONATIST): *De Baptismo, contra Donatistas* (400–401; *On Baptism, Against the Donatists,* N.P.N.F.); *Contra litteras Petiliani* (400–403; *Answers to Letters of Petilian,* N.P.N.F.). (ANTI-PELAGIAN): *De spiritu et littera* (412; *The Spirit and the Letter,* L.C.C.); *De natura et gratia* (415; *On Nature and Grace,* N.P.N.F.); *De gratia Christi et de peccato originali* (418; *On the Grace of Christ, and on Original Sin,* N.P.N.F.); *De gratia et libero arbitrio* (426 or 427; *On Grace and Free Will,* N.P.N.F.).

BIBLIOGRAPHY. A fairly recent comprehensive bibliography of works dealing with St. Augustine is CARL ANDRESEN (ed.), *Bibliographia Augustiniana* (1962); T.J. VAN BAVEL and F. VAN DER ZANDE, *Répertoire bibliographique de Saint Augustin* (1963), covers material that appeared between 1950 and 1960. Annual bibliographies are provided in *L'Année philologique* (1924–), ed. by J. MAROUZEAU, in the *Revue des études augustiniennes* (quarterly), and in *Recherches augustiniennes* (1958–).

Biography: The best modern biography, both scholarly and readable, is PETER BROWN, *Augustine of Hippo* (1967). GERALD BONNER, *St. Augustine of Hippo: Life and Controversies* (1963), is also valuable. Of literary interest is REBECCA WEST, *St. Augustine* (1933). See also K. ADAM, *Die geistige Entwicklung des heiligen Augustinus* (1931; Eng. trans., *St. Augustine: The Odyssey of His Soul,* 1932); and HUGH POPE, *Saint Augustine of Hippo,* 2nd ed. (1949). The problems concerning the chronology and nature of Augustine's conversion, especially as related in his *Confessions,* are dealt with in P. AUBIN, *Le Problème de la "Conversion"* (1963); J.M. LE BLOND, *Les Conversions de Saint Augustin* (1950); A.M. LA BONNARDIERE, *Recherches de chronologie Augustinienne* (1965); P. COURCELLE, *Recherches sur les Confessions de Saint Augustin,* new ed. (1968); J.J. O'MEARA, *The Young Augustine* (1954); M. PELLEGRINO, *Les Confessions de Saint Augustin* (1961). Augustine's maturity is described in F. VAN DER MEER, *Augustine de Zielzorger* (1947; Eng. trans., *Augustine the Bishop,* 1961).

Thought: A general outline of Augustine's thought is provided in P. ALFARIC, *L'Évolution intellectuelle de Saint Augustin* (1918); H.I. MARROU, *Saint Augustine et l'augustinisme* (1956; Eng. trans., *St. Augustine and His Influence Through the Ages,* 1957), *Saint Augustin et la fin de la culture antique,* 4th ed. (1958); E. PORTALIE, *A Guide to the Thought of Saint Augustine* (1960). His philosophy is considered in J. BARION, *Plotin und Augustinus* (1935); ETIENNE GILSON, *Introduction à l'étude de Saint Augustin,* 2nd ed. rev. (1943; Eng. trans., *The Christian Philosophy of St. Augustine,* 1960). His political theory and view of history, especially as propounded in the *De civitate Dei,* is the subject of R.H. BARROW, *Introduction to St. Augustine: The City of God* (1950); J.H.S. BURLEIGH, *The City of God* (1949); H.A. DEANE, *The Political and Social Ideas of St. Augustine* (1963); G.L. KEYES, *Christian Faith and the Interpretation of History: A Study of St. Augustine's Philosophy of History* (1966).

Theology: For general accounts of Augustine's theology, see J. BURNABY, *Amor Dei: A Study of the Religion of St. Augustine* (1938, reprinted 1960); H. DE LUBAC, *Augustinisme et théologie moderne* (1965); E.A. TESELLE, *Augustine the Theologian* (1970).

Special topics: For Christology, see T.J. VAN BAVEL, *Recherches sur la Christologie de Saint Augustin* (1954); for the Eucharist, G. LECORDIER, *La Doctrine de l'eucharistie chez S. Augustin* (1930); for biblical exegesis, M. PONTET, *L'Exégèse de S. Augustin, prédicateur* (1946); for predestination and grace, H. RONDET, *Essais sur la théologie de la grâce* (1964).

(Jo.Bu.)

Augustus

Gaius Octavius, subsequently known as Gaius Julius Caesar and still later as Augustus or Caesar Augustus, was the first Roman emperor, following the republic, which had been finally destroyed by the dictatorship of Julius Caesar, his great-uncle and adoptive father. His autocratic regime is known as the principate because he was the *princeps,* the first citizen, at the head of that array of outwardly revived republican institutions that alone made his autocracy palatable. With unlimited patience, skill, and efficiency, he overhauled every aspect of Roman life and brought durable peace and prosperity to the Greco-Roman world.

Gaius Octavius was born on September 23, 63 BC, of a prosperous family that had long been settled at Velitrae (Velletri), southeast of Rome. His father, who died in 59 BC, had been the first of the family to become a Roman senator and was elected to the high annual office of the praetorship, which ranked second in the political hierarchy to the consulship. Gaius Octavius' mother Atia was the daughter of Julia, the sister of Julius Caesar; and it

was Caesar who launched the young Octavius in Roman public life. At the age of 12 he made his debut by delivering the funeral speech for his grandmother Julia. Three or four years later he received the coveted membership of the board of priests (*pontifices*). In 46 he accompanied Caesar, now dictator, in his triumphal procession after his victory in Africa over his opponents in the Civil War; and in the following year, in spite of ill health, he joined the dictator in Spain. He was at Apollonia (now in Albania), completing his academic and military studies when, in 44 BC, he learned that Julius Caesar had been murdered.

Augustus, bronze sculpture from Meroe, Sudan, 1st century AD. In the British Museum.

Rise to power. Returning to Italy, he was told that in his will Caesar had adopted him as his son and had made him his chief personal heir. He was only 18 when, against the advice of his stepfather and others, he decided to take up this perilous inheritance and proceeded to Rome. Mark Antony (Marcus Antonius), Caesar's chief lieutenant, who had taken possession of his papers and assets and had expected that he himself would be the principal heir, refused to hand over any of Caesar's funds, forcing Octavius to pay the late dictator's bequests to the Roman populace from such resources as he could raise. Caesar's assassins, Brutus and Cassius, ignored him and withdrew to the east. Cicero, the famous orator who was one of Rome's principal elder statesmen, hoped to make use of him but underestimated his abilities.

Celebrating public games, instituted by Caesar, to ingratiate himself with the city populace, Octavius succeeded in winning considerable numbers of the dictator's troops to his own allegiance. The Senate, encouraged by Cicero, broke with Antony, called upon Octavius for aid (granting him the rank of senator in spite of his youth), and joined in the campaign of Mutina (Modena) against Antony, who was compelled to withdraw to Gaul. When the consuls who were in command of the Senate's forces lost their lives, Octavius' soldiers compelled the unwilling Senate to confer one of the vacant consulships on him. Under the name of Gaius Julius Caesar he next secured official recognition as Caesar's adoptive son. Although it would have been normal for him to add "Octavianus" (with reference to his original family name), he preferred not to do so. Today, however, he is habitually described as Octavian (until the later date when he assumed the designation of Augustus).

The Second Triumvirate

Octavian soon reached an agreement with Antony, as well as with another of Caesar's principal supporters, Lepidus, who had succeeded him as chief priest. On November 27, 43 BC, the three men were formally given a five-year dictatorial appointment as triumvirs for the reconstitution of the state (the Second Triumvirate—the first having been the informal compact between Pompey, Crassus, and Julius Caesar). The east was occupied by Brutus and Cassius, but the triumvirs divided the west among themselves. They also drew up a list of "proscribed" political enemies, and the consequent executions included 300 senators (one of whom was Antony's enemy Cicero) and 2,000 members of the class immediately below the senators, the equites or knights. Julius Caesar's recognition as a god of the Roman state in January 42 BC enhanced Octavian's prestige as son of a god.

He and Antony crossed the Adriatic and under Antony's leadership (Octavian being ill) won the two battles of Philippi against Brutus and Cassius, both of whom committed suicide. Antony, the senior partner, was allotted the east (and Gaul); and Octavian returned to Italy, where difficulties caused by the settlement of his veterans involved him in the Perusine War (decided in his favour at Perusia, the modern Perugia) against Antony's brother and wife. In order to appease another potential enemy, Sextus Pompeius (Pompey the Great's son), who had seized Sicily and the sea routes, Octavian married Sextus' relative Scribonia (though before long he divorced her for personal incompatibility). These ties of kinship did not deter Sextus, after the Perusine War, from making overtures to Antony; but Antony rejected them and reached a fresh understanding with Octavian at the treaty of Brundisium, under the terms of which Octavian was to have the whole west (except for Africa, which Lepidus was allowed to keep) and Italy, which, though supposedly neutral ground, was in fact controlled by Octavian. The east was again to go to Antony, and it was arranged that Antony, who had spent the previous winter with Queen Cleopatra in Egypt, should marry Octavian's sister Octavia. The peoples of the empire were overjoyed by the treaty, which seemed to promise an end to so many years of civil war. In 38 BC Octavian formed a significant new link with the aristocracy by his marriage to Livia Drusilla.

But a reconciliation with Sextus Pompeius proved abortive, and Octavian was soon plunged into serious warfare against him. When his first operations against Sextus' Sicilian bases proved disastrous, he felt obliged to make a new compact with Antony at Tarentum (Taranto) in 37 BC. Antony was to provide Octavian with ships, in return for troops Antony needed for his forthcoming war against the empire's eastern neighbour Parthia and its Median allies. Antony handed over the ships, but Octavian never sent the troops. The treaty also provided for renewal of the Second Triumvirate for five years, until the end of 33 BC.

Military successes. In the following year the balance of power began to change: whereas Antony's eastern expedition failed, Octavian's fleet, commanded by his former schoolmate, Marcus Agrippa, who, although unpopular with the influential nobles, was an admiral of genius, totally defeated Sextus Pompeius off Cape Naulochus (Venetico) in Sicily. At this point the third triumvir, Lepidus, seeking to contest Octavian's supremacy in the west by force, was disarmed by Octavian, deprived of his triumviral office, and forced into retirement. Ignoring Antony's right to settle his own veterans in Italy and recruit fresh troops, Octavian discharged many legionaries and founded settlements for them. His deliberate rivalry with Antony for the eventual mastership of the Roman world became increasingly apparent. Octavian's marriage two years earlier had begun to win over some of the nobles who had previously been Antony's supporters. Octavian also launched elaborate religious and patriotic publicity, centring on the classical god of order, Apollo, in contrast to Antony's more un-Roman patron, Dionysus (Bacchus). In addition, Octavian had started to prefix his name with the designation "Imperator," to suggest that he was the commander *par excellence;* and now, although he continued to use his triumviral powers, he omitted all reference to them from his coins, gradually concentrating on the plain, emotive name "Caesar Son of a God."

But if Octavian was to compete with Antony's military

seniority, successes in a foreign war were necessary; and so Octavian between 35 and 33 BC fought three successive campaigns in Illyricum and Dalmatia (parts of the modern Yugoslavia) in order to protect the northeastern approaches of Italy. With the help of Agrippa, he also lavished large sums on the adornment of Rome. When Octavian fomented public clamour against Antony's territorial gifts to Cleopatra, it was clear that a clash between the two men was imminent.

In 32 BC the triumvirate had officially ended, and Octavian, unlike Antony, professed no longer to be employing its powers. Amid a virulent exchange of propaganda, Antony divorced Octavia, whereupon her brother Octavian seized Antony's will and claimed to find in it damaging proofs of Cleopatra's power over him. Each leader induced the populations under his control to swear formal oaths of allegiance to his own cause. Then, in spite of grave discontent aroused by his exactions in Italy, Octavian declared war—not against Antony but against Cleopatra.

Defeat of Antony and Cleopatra

Accompanied by her, Antony had brought up his fleet and army to guard strongpoints along the coast of western Greece; but in 31 BC Octavian dispatched Agrippa very early in the year to capture Methone, at the country's southwestern tip. His enemies were taken by surprise; and after Octavian himself arrived—leaving his Etruscan friend and adviser Maecenas in charge of Italy—he and Agrippa soon shut Antony's fleet inside the Gulf of Ambracia (Arta). At the Battle of Actium Antony tried to extricate his ships in the hope of continuing the fight elsewhere. Though Cleopatra and then Antony succeeded in getting away, only a quarter of their fleet was able to follow them. She and Antony fled to Egypt and committed suicide when Octavian captured the country in the following year. Executing Cleopatra's son Ptolemy XV Caesar (Caesarion)—whose father she had claimed was Caesar—he annexed Egypt and retained it under his direct control.

The seizure of Cleopatra's treasure enabled him to pay off his veterans and made him finally master of the entire Greco-Roman world. From this point on, by a long and gradual series of tentative, patient measures, he established the Roman principate, a system of government that enabled him to maintain, in all essentials, absolute control. Gradually reducing his 60 legions to 28, he retained approximately 150,000 legionaries, mostly Italian, and supplemented them by about the same number of auxiliaries drawn from the provinces. A permanent bodyguard (the Praetorians), based on the bodyguards maintained by earlier generals, was stationed partly in Rome and partly in other Italian towns. A superb network of roads was created to maintain internal order and facilitate trade; and an efficient fleet was organized to police the Mediterranean. In 28 BC Octavian and Agrippa held a census of the civil population, the first of three during the reign. They also reduced the Senate from about 1,000 to 800 (later 600) compliant members; and Octavian was appointed its president.

Master of the Greco-Roman world

Government and administration. Remembering, however, that Caesar had been assassinated because of his resort to naked power, Octavian realized that the governing class would welcome him as the terminator of civil war only if he concealed his autocracy beneath provisions avowedly harking back to republican traditions. From 31 until 23 BC the constitutional basis of his power remained a continuous succession of consulships, but in January 27 BC he ostensibly "transferred the State to the free disposal of the Senate and people," earning the misleading, though outwardly plausible, tribute that he had restored the republic. At the same time he was granted a ten-year tenure of an area of government (*provincia*) comprising Spain, Gaul, and Syria, the three regions containing the bulk of the army. The remaining provinces were to be governed by proconsuls appointed by the Senate in the old republican fashion. Octavian, however, believed that his supreme prestige—crystallized in the meaningful term *auctoritas*—safeguarded him against any defiance by these personages; and he was indeed able, more or less indirectly, to influence their appointments, just as he was able (on the rare occasions when he regarded it as desirable) to influence the appointments to the consulships and other metropolitan offices that continued to exist in "republican" fashion.

Autocracy in republican guise

Four days after these measures, his name Caesar, acquired through adoption in Julius' will, was supplemented by "Augustus," an appellation with an antique religious ring, believed to be linked etymologically with *auctoritas* and with the ancient practice of augury. The word *augustus* was often contrasted with *humanus;* its adoption as the title representing the new order cleverly indicated, in an extraconstitutional fashion, his superiority over the rest of mankind. With the aid of writers such as Virgil, Livy, and Horace, all of whom in their different ways shared the same ideas, he showed his patriotic veneration of the old Italian faith by reviving many of its ceremonials and repairing numerous temples.

Military operations continued in many frontier areas. In 25, recalcitrant Alpine tribes were reduced, and Galatia (central Asia Minor) was annexed. Mauretania, on the other hand, was transferred from Roman provincial status to that of a client-kingdom, for such dependent monarchies, as in the later republic, bore a considerable part of the burden of imperial defence. Augustus himself visited Gaul and directed part of a campaign in Spain until his health gave out; in 23 he fell ill again and seemed on the point of death. Feeling, amid reports of conspiracies, that new constitutional steps were necessary, he proceeded to terminate his series of consulships in favour of a power (*imperium majus*) which was separated altogether from office and its practical inconveniences. This power raised him above the proconsuls; it was never referred to on the official coinage or in Augustus' political testament but was intended to be exercised mainly in emergencies and on personal visits. He was also awarded the power of a tribune (*tribunicia potestas*) for life. Earlier, he had accepted certain privileges of a tribune. The full power he now assumed carried with it practical advantages, notably the right to convene the Senate. But, more particularly, the office of a tribune, because of the ancient character of the annually elected tribunes of the people as defenders of the *plebs,* surrounded him with a "democratic" aura, one which, perhaps, was needed all the more because Augustus himself —while admittedly supporting the interests of poorer people by a great extension of the right of judicial appeal —tended to back the established classes as the keystone of his system.

Agrippa, too, was granted superiority over proconsuls, presumably in order to ensure that the armies would be in safe hands in case one of Augustus' recurrent illnesses proved fatal. The next to die, however, was the emperor's young nephew Marcellus, who had been married to his daughter Julia and might eventually have been envisaged as his successor. In the same year, 23 BC, Agrippa was sent out to the east as deputy *princeps;* two years later he became Julia's second husband. Meanwhile Augustus himself travelled in Sicily, Greece, and Asia (22–19). Important reorganizations were put into effect wherever he went; and immense satisfaction was caused by an agreement in 20 BC with Parthia, under which the Parthians recognized Rome's protectorate over Armenia and returned the legionary standards captured from Crassus 33 years earlier. In 19 Agrippa completed the subjugation of Spain. In this year there was some adjustment of Octavian's powers to allow him to exercise them more freely in Italy, and the two following years witnessed social legislation attempting to encourage marriage, regulate penalties for adultery, and reduce extravagance. In 17 there were resplendent celebrations of ancient ritual, known as the Secular Games, to purify the Roman people of their past sins and provide full religious inauguration of the new age.

Although the principate was not an office which could be automatically handed on, Augustus seemed to be indicating his views regarding his ultimate successor when he adopted the two sons of his daughter Julia, boys aged three and one who were henceforward known as Gaius Caesar and Lucius Caesar. Their father Agrippa, whose

powers had been renewed along with his master's, returned to the east. But now Augustus also gave important employment to his stepsons—his wife Livia's sons by her former marriage—Tiberius and Drusus the elder. Proceeding across the Alps, they annexed Noricum and Raetia, comprising large parts of what are now Switzerland, Austria, and Bavaria, and extended the imperial frontier from Italy to the upper Danube (16–15).

Reform of the administration

It was probably during these years that an executive, or drafting, committee (*consilium*) of the Senate was established in order to help Augustus to prepare senatorial business. His administrative burden was also lightened by the expansion of his own staff (knights, who could also now rise to a number of key posts, and freedmen) to form the beginnings of a civil service, which had never existed before but was destined to become an essential feature of the imperial system. Gradually, too, a completely reformed administrative structure of Rome, Italy, and the whole empire was evolved. The financial system that made this possible was evidently far more effective than anything the empire had ever seen until then. The system was based on the central treasury (*aerarium*), but the details of its relationship with the treasuries of the provinces, and particularly the *provincia* of Augustus, are still imperfectly understood, partly because, although the emperor proudly recorded his gifts to the central treasury, he did not report what funds passed in the opposite direction.

The taxation providing these resources apparently included two main direct taxes: a poll tax (*tributum capitis*), paid in some provinces by all adults and in others by adult males only, and a land tax (*tributum soli*). There were also indirect taxes, which (as in the past) were farmed out to contractors because their yield was unpredictable and the embryonic civil service lacked the resources to handle them. The republican customs dues continued; but its rates were low enough not to hamper trade, which, in the peaceful conditions created by Augustus, flourished in wholly unprecedented fashion. Industries did not exist on a very large scale, but commerce was greatly stimulated by a sweeping reform and expansion of the Roman coinage. Gold and silver pieces, their designs reflecting many facets of imperial publicity, were issued in great quantities at a number of widely distributed mints; and from about 19 (or perhaps 23) BC onward the absence of bronze token coinage, which had been sparse for many decades, was remedied by the creation of abundant mintages in two bright new metals, yellow brass and red copper. In the West, the principal mint for these pieces, besides Rome, was Lugdunum (Lyon), whose coins displayed a view of the Altar of Rome and Augustus that formed a model for other provincial capitals. The Roman citizen colonies of the West, many of them established by Augustus to settle his veterans, supplemented this output by their own local coinages, and in the East, particularly Asia Minor and Syria, numerous Greek cities were also allowed to issue small change.

Expansion of the empire. The death in 12 BC of Lepidus, who had lived on in retirement for 24 years, enabled Augustus finally to succeed him as the official head of the Roman religion, the chief priest (*pontifex maximus*). In the same year, however, another death came as a severe blow to him, for Agrippa, too, died. Augustus compelled his widow Julia to marry Tiberius against the wishes of both of them. During the next three years, however, Tiberius was away in the field, reducing Pannonia (Yugoslavia and Hungary) up to the middle Danube, while his brother Drusus crossed the Rhine frontier and invaded Germany as far as the Elbe, where he died in 9 BC. In the following year Augustus lost another of his intimates, Maecenas, who had been the adviser of his early days and was an outstanding patron of letters.

Tiberius, who replaced Drusus in Germany, was elevated in 6 BC to a share in his stepfather's tribunician power. But shortly afterward he went into retirement on the island of Rhodes. This was attributed to jealousy of his stepnephew Gaius Caesar, who was introduced to public life with a great fanfare in the following year; and the same compliments were paid to his brother Lucius in 2 BC, the year in which Augustus received his climactic title "father of the country" (*pater patriae*). Gaius was sent to the East and Lucius to the West. Both, however, soon died, Lucius in AD 2 and Gaius in 4. Tiberius returned home in 2, and in 4 Augustus realized that he had to make him his heir. He adopted Tiberius as his son, who in turn was required to adopt Germanicus, the son of his brother Drusus. The powers conferred upon Tiberius made him almost Augustus' own equal in everything except prestige.

Tiberius named heir

Tiberius' next task was to consolidate the invasion and provincial organization of Germany (4–5); and now that the Elbe was the frontier instead of the Danube, Augustus instructed him to establish a shorter frontier line incorporating Bohemia, which had become the nucleus of a German (Marcomannic) empire ruled by King Maroboduus. An invasion of Bohemia, therefore, was planned, and had already been launched, from two directions, when news came in 6 that Pannonia and Illyricum had revolted. It took three years for the rebellion to be put down; and this had only just been completed when Arminius raised the Germans against their Roman governor Varus and destroyed him and his three legions. As Augustus could not readily replace the troops, the annexation of western Germany and Bohemia was postponed indefinitely; Tiberius and Germanicus were sent to consolidate the Rhine frontier.

Although Augustus was now feeling his age, these years in association with Tiberius were marked by administrative innovations: the annexation of Judaea in AD 6 (its client king Herod the Great had died ten years previously); the establishment at Rome (in the same year) of a fire brigade with police duties—supplemented seven years later by a regular police force (*cohortes urbanae*); the creation of a military treasury (*aerarium militare*) to defray soldiers' retirement bounties from taxes; and the conversion of the hitherto occasional appointment of prefect of the city (*praefectus urbi*) into a permanent office (AD 13). When, in the same year, the powers of Augustus were renewed for ten years—such renewals had been granted at intervals throughout the reign—Tiberius was made his equal in every constitutional respect. In April, Augustus deposited his will at the House of the Vestals in Rome. It included a summary of the military and financial resources of the empire (*breviarium totius imperii*) and his ingenious political testament known as the "Res Gestae Divi Augusti" ("Acts of the Divine Augustus"). The best preserved copy of the latter document is still to be seen on the walls of the Temple of Rome and Augustus at Ankara, Turkey. In 14 Tiberius was due to leave for Illyricum but was recalled by the news that Augustus was gravely ill. He died on August 19, and on September 17 the Senate enrolled him among the gods of the Roman state. By that time Tiberius had succeeded him as the second Roman emperor, though the formalities involved in the succession proved embarrassing both to himself and to the Senate because the "principate" of Augustus had not, constitutionally speaking, been heritable or continuous. Like other emperors, Tiberius assumed the designation "Augustus" as an additional title of his own. Agrippa Postumus, who had been named his co-heir but was later banished, was put to death. The order to kill him may already have been given by Augustus, but this is not certain.

Personality and achievement. Augustus was one of the great administrative geniuses of history. The gigantic work of reorganization that he carried out in every field of Roman life and throughout the entire empire not only transformed the decaying republic into a new, monarchic regime with many centuries of life ahead of it but created a durable Roman peace, based on easy communications and flourishing trade. It was this Pax Romana that ensured the survival and eventual transmission of the classical heritage, Greek and Roman alike, and provided the means for the diffusion of Judaism and Christianity (Jesus Christ was born during Augustus' reign). Although his regime was an autocracy, Augustus, being a tactful and imaginative master of propaganda of many kinds, knew how to cloak that autocracy in traditionalist

forms that would satisfy a warworn generation—perhaps, most of all, the upper bourgeoisie immediately below the leading nobility, since it was they who benefitted from the new order more than anyone. He was also able to win the approbation, through the patronage of Maecenas, of some of the greatest writers the world has ever known, including Virgil, Horace, and Livy.

Their enthusiasm was partly due to Augustus' conviction that the Roman peace must be under occidental, Italian control. This was in contrast to the views of Antony and Cleopatra, who had envisaged some sort of Greco-Roman partnership such as only began to prevail three or four centuries later. Augustus' narrower view, although modified by an informed admiration of Greek civilization, was based on his small-town Italian origins. These were also partly responsible for his patriotic, antiquarian attachment to the ancient religion and for his puritanical social policy.

Augustus was a cultured man, the author of a number of works (all lost): a pamphlet against Brutus, an exhortation to philosophy, an account of his own early life, a biography of Drusus, poems, and epigrams. The conventional view of his character distinguishes between his cruelty in early years and his mildness in later life. But there was not so much need for cruelty later on, and when it was needed (notably in the suppression of alleged plots), he was still ready to apply it. It is probable that nothing short of this degree of political ruthlessness could have achieved such enormous results. His domestic life, however, was simple and homespun. Within his family, the successive deaths of those he had earmarked as his successors or helpers caused him much sadness and disappointment. His devotion to his wife Livia Drusilla remained constant, though, like other Romans, he was unfaithful. His surviving letters show kindliness to his relations. Yet he exiled his daughter Julia for offending against his public moral attitudes, and he exiled her daughter by Agrippa for the same reason; he also exiled the son of Agrippa and Julia, Agrippa Postumus, though the suspicion that he later had him killed is unproved. As for Augustus' male relatives who were his helpers, he was loyal to them but drove them as hard as he drove himself. He needed them because the burden was so heavy, and he especially needed them in the military sphere because he was not a great commander. In Agrippa and Tiberius and a number of others he had men who supplied this deficiency, and although, on his deathbed, he is said to have advised against the further expansion of the empire, he himself, with their assistance, had expanded its frontiers in many directions.

His physical condition was subject to a host of ills and weaknesses, many of them recurrent. Indeed, in his early life, particularly, it was only his indomitable will that enabled him to survive—a strange preliminary to an unprecedented and unequalled life's work. His appearance is described by the biographer Suetonius.

> He was unusually handsome and exceedingly graceful at all periods of his life, though he cared nothing for personal adornment. His expression, whether in conversation or when he was silent, was calm and mild . . . He had clear, bright eyes, in which he liked to have it thought that there was a kind of divine power, and it greatly pleased him, whenever he looked keenly at anyone, if he let his face fall as if before the radiance of the sun. His teeth were wide apart, small and ill-kept; his hair was slightly curly and inclining to golden; his eybrows met . . . His complexion was between dark and fair. He was short of stature, but this was concealed by the fine proportion and symmetry of his figure, and was noticeable only by comparison with some taller person standing beside him.

Augustus' countenance proved a godsend to the Greeks and Hellenized easterners who were the best sculptors of the time, for they elevated his features into a moving, never to be forgotten imperial type, which Napoleon's artists, among others, keenly emulated. The contemporary portrait busts of Augustus, echoed on his coins, formed part of a significant renaissance of the arts in which Italic and Hellenic styles were discreetly and brilliantly blended. Still extant at Rome are the severe yet delicate reliefs of the Ara Pacis ("Altar of Peace"), depicting a religious procession in which the national leaders are taking part; there are also scenes from the Roman mythology. The altar was dedicated by the Senate and people of Rome in 13 BC to commemorate the pacification of Gaul and Spain.

Cultural heritage

The architectural masterpieces of the time were also numerous; and something of their monumental grandeur and classical purity can be seen today in the remains of the Theatre of Marcellus at Rome and of the massive Forum of Augustus, flanked by colonnades and culminating in the Temple of Mars the Avenger—the Avenger of Julius Caesar. Outside Rome, too, there are abundant memorials of the Augustan age; on either side of the Alps, for example, there are monuments to celebrate the submission and loyalty of the local tribes, an elegant arch at Segusio (Susa) and a square stone trophy, topped by a cylindrical drum, at La Turbie. From Livia's mansion on the outskirts of Rome, at Prima Porta, comes a reminder that not all the art of the day was formal and grand. For one of the rooms is adorned with wall paintings representing an enchanted garden; beyond a trellis are orchards and flower beds, in which birds and insects perch among the foliage. Augustus himself had no interest in personal luxury. Yet if ever he or his associates had any spare time, such were the rooms in which they spent it.

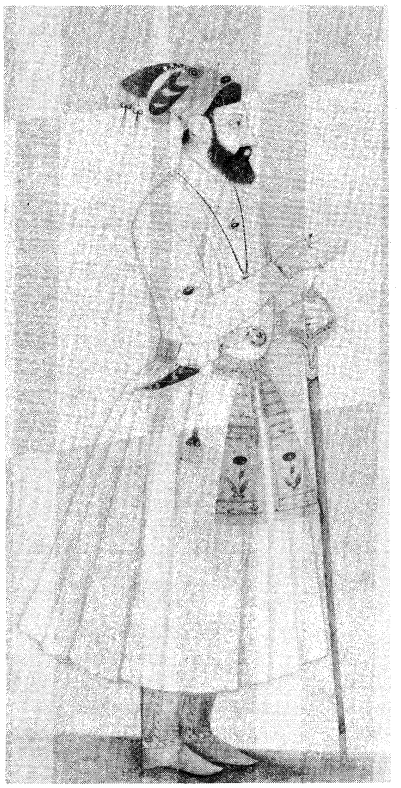
Aurangzeb

Aurangzeb, the last of the great Mughal emperors of India, was a zealous Muslim during whose reign (1659–1707) the empire reached its vastest extent, though at the cost of serious depletion of economic resources and administrative stability. His kingly title was ʿĀlamgīr ("World Holder"), but in Europe he became best known by his princely title, Aurangzeb ("Ornament of the Throne"), because of the war of succession that brought him to the throne. Aurangzeb is important in Indian history because his policies toward the Hindus, the Deccan kingdoms, and the Marāthās of western India gave rise to tensions that were to lead to the dissolution of the empire in the 18th century. His conception of his role as that of an orthodox ruler of an Islāmic state rather than as that of the Muslim ruler of an Indian empire was vital to these issues.

Aurangzeb was born on October 24, 1618 (old style), the third son of the emperor Shāh Jahān and Mumtāz Maḥal (for whom the Tāj Mahal was built). Given the name Muḥī-ud-Dīn Muḥammad, he grew up as a serious-minded and devout youth, wedded to the Muslim orthodoxy of the day and free from the royal Mughal traits of sensuality and drunkenness. He early showed signs of military and administrative ability; and these qualities, combined with a taste for power, brought him into rivalry with his eldest brother, the brilliant and volatile Dārā Shukōh, who was designated by their father as his successor to the throne. From 1636 he held a number



Aurangzeb, Mughal miniature, 17th century. In the Metropolitan Museum of Art, New York.

of important appointments, in all of which he distinguished himself. He commanded troops against the Uzbeks and the Persians with distinction (1646–47) and, as viceroy of the Deccan provinces in two terms (1636–44, 1654–58), reduced the two Muslim Deccan kingdoms to near-subjection.

When Shāh Jahān fell seriously ill in 1657, the tension between the two brothers made a war of succession seem inevitable. By the time of Shāh Jahān's unexpected recovery, matters had gone too far for either son to retreat. In the struggle for power (1657–59), Aurangzeb showed tactical and strategic military skill, great powers of dissimulation, and ruthless determination. Decisively defeating Dārā at Samugarh in May 1658, he confined his father in his own palace at Agra. In consolidating his power he caused one brother's death and had two other brothers, a son, and a nephew executed. The war became a legend and found its way to Europe.

Aurangzeb's reign falls into two almost equal parts. In the first, which lasted until about 1680, he was a capable Muslim monarch of a mixed Hindu–Muslim empire and as such was generally disliked for his ruthlessness but feared and respected for his vigour and skill. During this period he was much occupied with safeguarding the northwest from Persians and Central Asian Turks and less so with the Marāthā chief Śivajī, who twice plundered the great port of Surat (1664, 1670). He applied his great-grandfather Akbar's recipe for conquest: defeat one's enemies, reconcile them, and place them in imperial service. Thus Śivajī was defeated, called to Āgra for reconciliation (1666), and given an imperial rank. The plan broke down, however; then Śivajī fled to the Deccan and died, in 1680, as the ruler of an independent Marāthā kingdom.

Second phase of his rule

After about 1680, Aurangzeb's reign underwent a change of both attitude and policy. The pious ruler of an Islāmic state replaced the seasoned statesman of a mixed kingdom; Hindus became subordinates, not colleagues, and the Marāthās, like the southern Muslim kingdoms, were marked for annexation rather than containment. The overt sign of the first change was the reimposition of the *jizya*, or poll tax, on non-Muslims in 1679 (a tax that had been abolished by Akbar). This in turn was followed by a Rajput revolt in 1680–81, supported by Aurangzeb's third son, Akbar. Hindus still served the empire, but no longer with enthusiasm. The Deccan kingdoms of Bijāpur and Golconda were conquered in 1686–87, but the insecurity that followed precipitated a long and incipient economic crisis, which in turn was deepened by the Marāthā war. Śivajī's son Sambhājī was captured and executed in 1689 and his kingdom broken up. The Marāthās, however, then adopted guerrilla tactics, spreading all over South India amid a sympathetic population. The rest of Aurangzeb's life was spent in laborious and fruitless sieges of forts in the Marāthā hill country.

Aurangzeb's absence in the south prevented him from maintaining his former firm hold on the north. The administration weakened, and the process was hastened by pressure on the land by Mughal grantees who were paid by assignments on the land revenue. Agrarian discontent often took the form of religious movements, as in the case of the Satnamis and the Sikhs in the Punjab. In 1675 Aurangzeb arrested and executed the Sikh Gurū (spiritual leader) Tegh Bahādur, who had refused to embrace Islām; and the succeeding Gurū was in open rebellion for the rest of the reign. This was the real beginning of the still-existing Sikh–Muslim feud. Other agrarian revolts, such as those of the Jāṭs, were largely secular.

In general, Aurangzeb ruled as a militant orthodox Sunnī Muslim, who put through increasingly puritanical ordinances that were vigorously enforced by *muḥtasib*s, or censors of morals. The Muslim confession of faith, for instance, was removed from all coins lest it be defiled by unbelievers; courtiers were forbidden to salute in the Hindu fashion. In addition, Hindu idols, temples, and shrines were often destroyed.

Aurangzeb maintained the empire for nearly half a century and in fact extended it in the south as far as Tanjore and Trichinopoly. Behind this imposing facade, however, were serious weaknesses. The Marāthā campaign continually drained the imperial resources. The militancy of the Sikhs and the Jāṭs boded ill for the empire in the north. The new Islāmic policy alienated Hindu sentiment and undermined Rājput support. The financial pressure on the land strained the whole administrative framework. When Aurangzeb died on February 20, 1707 (O.S.), after a reign of nearly 49 years, he left an empire not moribund but confronted with a number of menacing problems. The failure of his son's successors to cope with them led to the collapse of the empire in the mid-18th century.

Auroras

The aurora, a familiar and often beautiful display of light in the upper air of both the Arctic and Antarctic regions, is caused by light emitted from the upper atmosphere in a form resembling the light of an electrical discharge. It was once erroneously thought to be sunlight reflected from polar snow and ice, or refracted light, like that of the rainbow. The name aurora is derived from the Latin name for the mythological personification of dawn. In the Northern Hemisphere it is called the Aurora Borealis, or the northern lights, and in the Southern Hemisphere, the Aurora Australis, or the southern lights; together they are called the Aurora Polaris or Polar Aurora.

The aurora commonly appears as a distinct, greenish, curtain-shaped light. Another type of aurora appears as an extensive dark-red glow in the poleward sky. The light is caused by the glow of atoms in the thin upper atmosphere as they are hit by fast-moving electrons and

protons, here called auroral electrons and protons, respectively.

It was once thought that auroral particles were thrown into interplanetary space from sunspots and solar flares, and that some of them reached the polar upper atmosphere after being deflected by the Earth's geomagnetic field. Although there is no doubt that the ultimate source of the energy of auroral particles originates in the Sun, it is now recognized that the origin and acceleration processes of auroral particles are very complex. The problem is closely related to the electromagnetic environment in space around the Earth.

The Earth's magnetic field is confined to a cylindrical cavity with a blunt nose, formed by the solar wind, a hot gas streaming Earthward from the sun. This cavity, called the magnetosphere, contains the Van Allen radiation belts. The magnetosphere acts like a gigantic cathode ray or television tube, generating and acting upon electron beams that in effect produce the image (the aurora) on the gigantic screen that is the polar upper atmosphere. Because the source of energy of the aurora comes from the Sun, auroral activity is closely associated with solar activity. In particular, a stormy solar wind that is generated by solar flares activates this gigantic cathode-ray tube and causes intense auroral display.

During the last ten years, a large number of artificial satellites have been made to traverse the magnetosphere to survey and map the distribution of auroral particles and the magnetic field, and rockets have been shot into the polar upper atmosphere to gain data about the characteristics of the auroral particle precipitation. An extensive international network of auroral and magnetic observatories has operated in the polar wilderness during and after the 1957–58 International Geophysical Year. These efforts have greatly enhanced comprehension of auroral phenomena in terms of magnetospheric processes.

This article deals with the cause, occurrence, and general distribution of the auroras. For further information on the charged particles in the Earth's atmosphere and their generation, see IONOSPHERE; VAN ALLEN RADIATION BELTS; see also EARTH, MAGNETIC FIELD OF for relevant information on the precise location, intensity, and effect of the Earth's magnetic field.

THE OCCURRENCE AND DISTRIBUTION OF THE AURORA

The two auroral ovals

The aurora is a common feature of the planet Earth and appears along two oval belts called the auroral ovals. There is one oval in each hemisphere, surrounding the geomagnetic poles; these are not coincident with the Earth's geographic poles. The northern geomagnetic pole is located near the northwestern tip of Greenland and the southern pole near Vostok, a Soviet station in the Antarctic. Each oval has an approximate radius of 2,000 kilometres (1,200 miles). It is eccentric with respect to the geomagnetic pole; that is, its centre is shifted towards the dark hemisphere a few degrees from the geomagnetic pole. Thus, the midnight portion is at about geomagnetic latitude 67° and the midday portion at about geomagnetic latitude 76°.

Each oval is more or less fixed in space with respect to the sun, and the Earth rotates beneath it once a day. The locus of the midnight portion of the Earth is called the auroral zone. It lies along the curve connecting the northern tip of Scandinavia, Iceland, the southern tip of Greenland, the southern part of Hudson Bay, Central Alaska, and the Siberian coast. Figure 1 shows the location of the oval at 10 o'clock Universal Time (UT) or Greenwich Mean Time (GMT). An observer in the auroral zone will come directly under the oval once a day during local midnight hours; daily occurrence of the aurora for such an observer will therefore have a single peak around midnight. On the other hand, an observer located between geomagnetic latitude 67° and 74° comes under the oval twice a day, once in the evening hours and once in the morning hours, and the daily occurrence of the aurora in this case will have a double peak. An observer located at geomagnetic latitude 76° will see the aurora most frequently at noon, if his location is in darkness. In the Northern Hemisphere, however, the midday aurora can be observed visually only over the Arctic Ocean around the December solstice (the shortest day of the year in the Northern Hemisphere); it can be observed for a few months at the South Pole (Amundsen-Scott Base) during southern winter months.

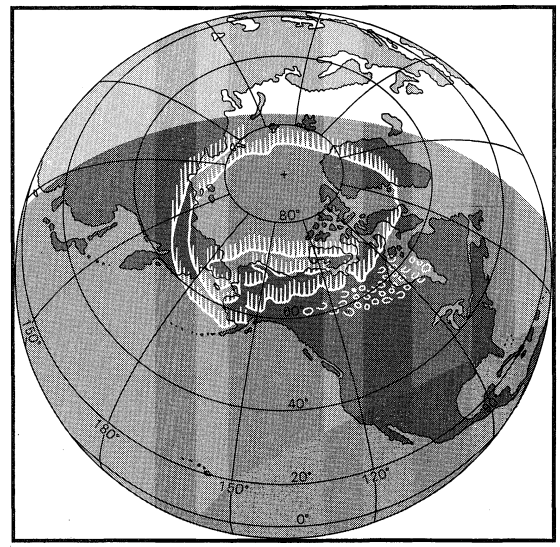

Figure 1: Distribution of the auroras in the Northern Hemisphere at 10:00 AM Greenwich Mean Time.

Changes in size of the ovals

The radius of the auroral oval varies with the intensity of solar activity. When there is little solar activity, the oval shrinks towards the geomagnetic pole; the midnight portion shifts polewards to about geomagnetic latitude 71°. The oval in Figure 1 approximately represents the size during moderate solar activity.

Conversely, during periods of great solar activity, about two days after an intense solar flare, the radius of the auroral oval increases considerably. On the evening of February 10, 1958, for example, the oval descended down as far as geographic latitude 40° in the United States (see Figure 1). The period of such an unusual expansion of the oval coincides with the period of an intense geomagnetic storm indicating the arrival of solar gas (consisting mainly of protons and electrons), which is ejected from the Sun during solar flares. The time lapse of two days after the flare is a result of the travel time of the solar gas from the Sun to the Earth at its average speed of about 880 kilometres per second.

In the polar cap region encircled by the auroral oval there sometimes appear very faint arcs called polar cap auroras, a unique feature of which is a tendency to align across the polar cap from the dayside to the nightside, approximately along the Sun–Earth line. These arcs differ spectroscopically from the auroral oval proper.

FORMS OF THE AURORA

One of the fundamental forms of the aurora has the appearance of a curtain and is greenish-white in colour. The lower border, generally fairly sharply defined, is located at a height of about 100 kilometres (60 miles). The upper border is much less clearly defined and extends to heights of several hundred kilometres; it may be as high as 1,000 kilometres for the aurora that appears in the twilight sky.

Arcs, bands, and patches

The curtain-like form lies along the auroral oval, extending roughly in the east–west direction with a length of more than several thousand kilometres, whereas its north–south extent (or the thickness of the curtain) is only about a few hundred metres. When this form is seen at a certain distance, particularly in the poleward sky, it appears as an arch rising from the horizon and is called an arc. If the brightness is nearly the same along its horizontal extent, it is called a homogeneous arc and appears to be motionless or relatively quiet. Multiple homogeneous arcs are often seen, and it is not uncommon for as

many as ten to stretch across the sky in the auroral zone (Figure 2). When the aurora becomes active, the arc develops five pleats that appear as vertical striations called rays; an arc with rays is called a rayed arc. In a more active form, called the band, the arc becomes wavy or folded. An active band with ray structure is called a rayed band, and a rayed band with a well-developed fold is often referred to as a drapery or horseshoe-type aurora. An active rayed band often moves with a speed of about 100 metres (300 feet) per second; a crimson-red colour often is added near the lower border of the greenish-white curtain. When a rayed band is seen from relatively nearby, the rays appear to converge towards a small region, resulting in an apparent fan-shaped form called a corona. Not a distinct form of the aurora, the corona results from the perspective effect of a great length of rays.

V.P. Hessler

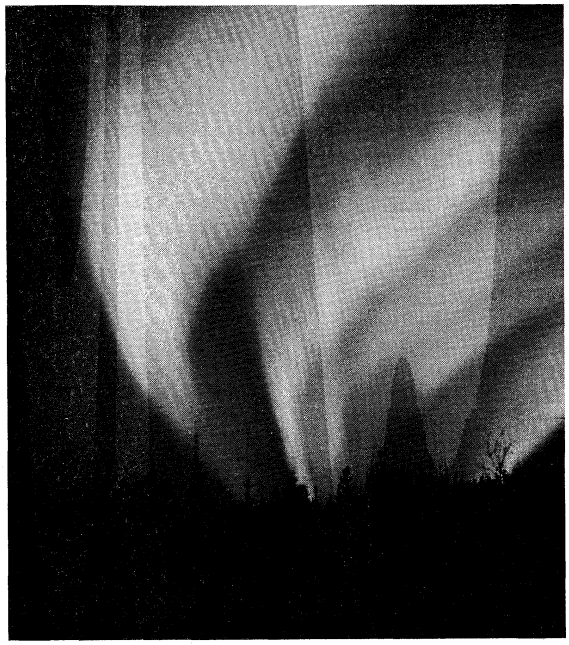

Figure 2: *Aurora borealis.*
Multiple auroral arcs photographed in Alaska.

After an intense auroral display, rayed bands often appear to break up into a number of isolated rays scattered over the whole sky. When the rays are not clearly seen, this broken-up form looks like a group of cumulus clouds; it is most commonly seen after midnight and is referred to as auroral patches. The brightness of most changes irregularly in a phenomenon called pulsation.

Auroral arcs, bands, and patches are quite common and occur practically daily in the auroral zone. Their frequency of occurrence decreases rapidly toward the Equator, and in the northern United States these forms may be seen an average of only five times a year, indicating that expansion of the oval is a rare event.

Another important form of the aurora is the veil, an extensive glow over a large region of the sky. The veil is commonly dark red and is seen well away from the oval, toward the Equator, during great geomagnetic storms. Indeed, many historic auroras seen as far away from the polar area as Samoa (May 13, 1921) and Mexico (September 13, 1957; February 11, 1958) were of this type. The frequency of occurrence of the veil in the southern United States is, on the average, once a year.

SPECTRAL CHARACTERISTICS OF THE AURORA

The curtain-shaped aurora is caused primarily by an intense sheet beam of energetic electrons (with energies of about 1,000 to 10,000 electron volts) that spiral down into the polar upper atmosphere. There the electrons collide with such particles as molecular nitrogen and oxygen and atomic oxygen, leading to such processes as ionization, excitation, or dissociation, or all three. Ionized nitrogen molecules emit radiation (emission lines) in several series of wavelengths, called bands. The first negative band extends from 3914 angstroms (one angstrom equals 10^{-7} millimetres) to 4700 angstroms. Some other emissions are in the infrared range. When the ionized nitrogen molecules recombine with electrons, some of the resulting molecules are in excited states and also emit several bands. The first positive band extends from 5800 to 6800 angstroms. There are some bands in the ultraviolet range that have been detected by rocket-borne instruments (see also ATMOSPHERE; IONOSPHERE).

Each ionization process by a high-energy electron produces a low-energy electron, called a secondary electron. The reaction itself is often sufficiently energetic to ionize or excite other atoms and molecules. The most common light of the aurora, the greenish-yellow emission at 5577 angstroms, is initiated in part by the excitation of oxygen atoms by these secondary (low energy) electrons.

Oxygen molecules also are ionized by incoming energetic electrons. The first negative band (5800 to 6800 angstroms) of O_2^+ is partly responsible for the crimson-red colour. When an ionized oxygen molecule recombines with an electron, it usually splits into two oxygen atoms, one of which is in an excited state; some of the excited oxygen atoms thus produced are another source of the aurora's greenish-yellow colour. After emitting radiation at 5577 angstroms (greenish-yellow light), the oxygen atom must emit additional radiation at 6300 angstroms before it returns to the ground (original, unexcited) state. This emission (dark-red colour) can be seen in the upper part of the curtain-like form when it is very intense.

The radiation at 6300 angstroms is mainly responsible for the extensive dark-red glow (the veil) in middle and low latitudes during great magnetic storms. The excitation mechanism for this particular type of aurora is, however, not well understood, and energetic electrons (approximately 10,000 electron volts) are not thought likely to be responsible for it. In mid-latitude regions during a great magnetic storm, there also occurs a subvisual belt of 6300 angstroms emission called the mid-latitude red arc. Its excitation mechanism is not well understood.

Collisions and emission shifts

Protons with energies of 200,000 electron volts also spiral down into the polar upper atmosphere. During descent, they collide with oxygen atoms, which are the major constituent of the atmosphere at heights between 500 and 1,000 kilometres (300 and 600 miles). The collision results in a charge exchange in which the proton becomes an energetic, neutral, hydrogen atom and the oxygen atom becomes ionized. Some of the neutral hydrogen atoms thus produced are in excited states, emitting fundamental radiation series that can be observed on the ground by optical instruments, such as a spectrometer and photometer, with appropriate filters. Being neutral and energetic, the atoms move in a straight line unhindered by the geomagnetic field, so that the observed emission lines are shifted from their normal positions.

The ultraviolet radiation from the neutral, excited hydrogen atoms is absorbed before reaching the ground, so that rocket-borne instruments are needed to detect it. When the hydrogen atom collides with an ionized oxygen atom, it exchanges charge and creates an energetic proton and a neutral oxygen atom. The energetic proton may exchange charge again by colliding with an oxygen atom, repeating this process more than 1,000 times before the proton is brought to rest. Eventually, the proton recombines with an electron to become a neutral atom.

The aurora containing this emitted radiation from the excited, neutral hydrogen atoms is called the proton aurora. It appears as a diffuse belt, a few hundred kilometres in width, that is displaced toward the Equator from the auroral oval. Because hydrogen atoms, in both neutral and ionized states, are energetic enough to ionize nitrogen and oxygen molecules during their descent, many of the emissions contained in curtain-shape auroras are also present in the glow; indeed, the glow seen by unaided eyes is mostly from such emissions, rather than from the hydrogen emissions.

A glow of similar spectral characteristics also appears in the polar cap several hours after an intense flare. It is called the polar-cap glow and is caused by the bombardment of solar cosmic rays, which consist mainly of very energetic protons (more than 1,000,000 electron volts).

THE AURORAL SUBSTORM AND AURORAL STORM

If one looked down on the Earth to observe the behaviour (or activity) of the aurora in the auroral oval, he could see homogeneous arcs, or relatively quiet forms, all along the auroral oval during a quiet period. Such a quiet period is often disrupted suddenly. The first indication of disruption occurs near the boundary between the auroral oval and the proton aurora in the midnight sector. There, a homogeneous arc becomes bright in a matter of minutes and begins to move toward the pole with a speed of several hundred metres per second. This motion produces a large "bulge" in the oval in the midnight sector. Along the boundary of the bulge closest to the pole lies a very bright rayed band with a crimson-red lower border. It is not uncommon to observe the bulge reaching geomagnetic latitude 75°.

Auroral activation

Subsequently, a surging motion of the aurora is generated on the evening side of the bulge. The surge is propagated westward along the oval with a speed of a few kilometres per second, and it may reach as far as the early afternoon sector of the oval. In the morning part of the oval, homogeneous arcs appear to disintegrate into isolated rays or patches. The resulting patches as a group drift eastward with a speed of about several hundred metres per second.

In this way, auroras are activated all along the auroral oval in about 30 to 60 minutes. Figure 1 shows the distribution of such activated auroras. After the boundary of the bulge closest to the pole reaches the highest latitude, it begins to shrink back toward the Equator. Rayed bands in the bulge start to move toward the Equator with a speed of about 50 metres (150 feet) per second; many of them fade away during the motion. Gradually, in one to two hours or so, homogeneous or other relatively quiet forms are restored at about the location where they were seen just before the onset of activity. The surges and drifting patches may still be seen at this time in the evening and morning twilight skies, respectively. Eventually, however, a quiet condition is restored all along the oval. The whole activity typically lasts for about three hours, although the period can be less than one hour.

Sequential activity

This sequence of activities, from a quiet to an active, and then back to a quiet condition, is called the auroral substorm, and it has two characteristic phases: the expansive phase and the recovery phase. The expansive phase is manifested most clearly by the expanding bulge of the auroral oval and the recovery phase by the shrinking bulge. The term breakup, often used in scientific literature, expresses only vaguely the overall auroral activity in the dark side of the oval during the auroral substorm.

As has been pointed out, the radius of the oval increases during intense geomagnetic storms. The increase takes about ten hours, during which as many as ten auroral substorms may occur, so that the oval undergoes a repeated expansion and subsequent contraction of the width, as well as an increase of radius. During this ten-hour period a geomagnetic storm develops, but after it the geomagnetic storm begins to subside, and the occurrence of substorms becomes much less frequent. Thus, it is possible to define the term auroral storm so as to describe overall auroral activity during the period of a geomagnetic storm. Clearly, the auroral storm consists of several to a dozen auroral substorms.

Both the geomagnetic storm and the auroral storm are different manifestations of a single stormy phenomenon in the magnetosphere, called the magnetospheric storm. There are a number of other manifestations of the magnetospheric storm; furthermore, the magnetospheric storm consists of about a dozen magnetospheric substorms. A large amount of energy is liberated in the magnetosphere during a magnetospheric substorm. A significant part streams into the polar region in the form of the kinetic energy of auroral particles.

RELATED PHENOMENA

The auroral substorm is not the only manifestation of the magnetospheric substorm. Greenish-yellow, curtain-shape auroras for the most part are caused by sheetlike electron beams with energy ranges from one to 10,000 electron volts. During magnetospheric storms, more-energetic electrons are also produced in the magnetosphere and precipitate in the vicinity of visible auroras. Electrons with energies of about 20,000 electron volts are responsible for exciting the crimson-red colour near the lower border of the curtain. Because they are more energetic, they can penetrate deeper into the upper atmosphere than the 10,000-electron-volt electrons, and they ionize oxygen molecules, which greatly increase in number below heights of 100 kilometres. Electrons with still greater energy penetrate even deeper.

X-rays and whistlers

Energetic electrons also generate strong X-rays (radiation produced by sudden retardation of the particle) when they collide with upper atmospheric particles. Since 1960 a great number of balloon-borne X-ray detectors have been sent up to observe the X-ray flux at the 30-kilometre (20-mile) level. Studies of the X-rays have been useful in observing fine time variations (as short as a few milliseconds) of the electron fluxes. It also has been found that intense bursts of X-rays occur during the auroral substorm along the morning half of the auroral zone, as well as in the region of active auroras. These energetic electrons are known to interact strongly with very low frequency radio waves called whistlers, which are generated by lightning and are then propagated through the magnetosphere. Some of the electrons are scattered out of the Van Allen radiation belts by such waves and are precipitated into the upper atmosphere. Under certain conditions, a cloud of the energetic electrons can generate very low frequency waves by itself. Indeed, it has been shown that this mechanism is so efficient as to limit the maximum flux of electrons to be trapped in the Van Allen belt.

Such energetic electrons also produce an appreciable amount of ionization in the lower ionosphere where short (radio) waves are most effectively absorbed. Thus, intense auroral activity may seriously disrupt transpolar short-wave communication. This phenomenon has been used to monitor the precipitation of the energetic electrons by a device called a riometer, which continuously monitors the intensity of cosmic radio waves (short-wavelength waves from interstellar sources) with frequencies of about 30 megahertz. When a layer of ionization is produced by the precipitation of the energetic electrons, the ionosphere becomes quite opaque to the radio waves, so that the intensity received by a riometer decreases.

Effect of auroras on communications transmission

On the other hand, such an ionization may be capable of reflecting (or scattering) radio waves of much higher frequencies. An unusual long-distance radio communication or television transmission may occur during great auroral displays. Using such a reflection of very high frequency waves, radars have been extensively used to study the aurora. A strong echo returns from the aurora when the radio beam strikes the auroral curtain perpendicularly.

During the auroral substorm, some auroras move with a speed exceeding that of sound in the upper atmosphere. It recently has been demonstrated that such a supersonic motion of the aurora is associated with infrasonic (below the audibility range of the human ear) shock waves.

Another important characteristic of the magnetospheric substorm is the worldwide extent of magnetic disturbance. Because it is most intense in the polar region, this particular magnetic disturbance is called the polar magnetic substorm. The distribution of the magnitude and orientation of magnetic disturbances over the Earth's surface has been studied by the analyzing of records from a large number of magnetic observatories. The main feature of the distribution is as follows: very intense magnetic disturbances, oriented toward the Equa-

Magnetic disturbances

tor, occur under the midnight part of the auroral oval, whereas less intense disturbances are oriented toward the poles along the auroral zone in the afternoon and evening sectors; in middle and low latitudes the orientation is toward the Equator in the afternoon and evening sectors and toward the poles in the midnight and morning sectors; and eastward and westward in the evening and morning sectors, respectively, in middle latitudes. It has long been known that the intense magnetic disturbances under the auroral oval are produced by a strongly concentrated (about 1,000,000 amperes) electric current flowing westward along the oval at about the level where the auroral curtain is brightest (110 kilometres [70 miles]); this current is called the auroral electrojet. The origin and distribution of the electrojet is not fully understood. Satellite observations are of great help in understanding the cause of magnetospheric substorms. A number of studies have yielded knowledge of the existence of drastic changes of the distribution of electrons and the magnetic field in the Van Allen belt and in the "tail" region of the magnetosphere during the substorm. It also has been reported that an extensive "sheet" of low energy, ionized gases, called plasma sheet, in the tail region of the magnetosphere undergoes a considerable change. Indirect observations show that a large-scale convective motion of the plasma in the sheet is generated during the substorm and that it plays a fundamental role in auroral processes. Theoretical and observational evidence shows that the direction of interplanetary magnetic fields is related to the occurrence of the substorm.

Magnetospheric processes

The magnetospheric substorm is also associated with the growth of an intense Van Allen radiation belt that consists mainly of protons with energies of about 20,000 electron volts and contains an electric current of about 1,000,000 amperes; they are partially responsible for the magnetic disturbance oriented toward the Equator in middle and low latitudes in the afternoon and evening sectors. The magnitude is much less than that produced by the auroral electrojet, simply because the belt is much farther from the Earth's surface than the electrojet. The radiation belt does not encircle the Earth completely.

When intense magnetospheric substorms occur very frequently, the radiation belt grows abnormally intense because a large number of protons are accumulated in the radiation belt. Such a belt, known as the equatorial ring current, causes a large decrease in the strength of the Earth's magnetic field in low latitudes, which is one of the major features of the geomagnetic storm field. It has been suggested that the proton aurora is caused by protons that leak out from the ring current and impinge into the polar upper atmosphere, just toward the Equator from the auroral oval.

Analogy with television

The magnetosphere might be considered to be a gigantic television tube (Figure 3). The polar upper atmosphere would correspond to the screen of a television tube that has a diameter of about 4,000 kilometres (2,500 miles) instead of 16 or 18 inches (41 or 46 centimetres), so that a person would be able to watch only about $\frac{1}{50}$ of the screen at a time. The aurora would then correspond to an image on the screen in the television tube. A television screen is coated by fluorescent material that emits light when it is hit by an electron beam. When an electron beam hits the polar upper atmosphere, one can observe auroras. In a television tube, the electron beam is acted upon (modulated) by a pair of electric plates and an electromagnet that create and produce a moving image. The movement of the aurora during the auroral storm is also caused by the modulation of the beam by changing electric and magnetic fields in the magnetosphere during the magnetospheric substorm.

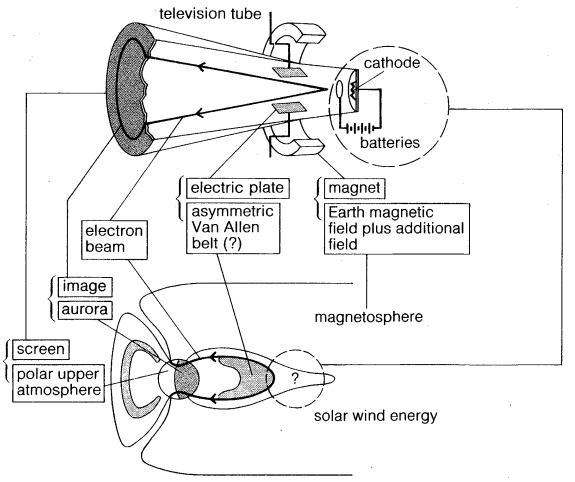

Figure 3: Analogy between the mechanisms of auroral displays and a television tube.

Auroral activity is, indeed, always associated with geomagnetic disturbances. For example, an intense ring current is known to deform considerably the Earth's dipole-like field in the outer magnetosphere. It has been found that the intensity of the ring current is closely related to the expansion toward the Equator of the auroral oval during an intense geomagnetic storm; that is to say, the ring-current field modulates the auroral-particle beam in such a way that it is shifted toward the Equator.

Recently there have been great efforts to measure, directly or indirectly, the electric fields in the magnetosphere and the aurora. Various types of electric probes have been devised to measure this field, but the most extensively used method has been to observe the drift velocity of a barium cloud released by a rocket or satellite and then ionized by solar radiation. An electric field of the order of 100 millivolts per metre that is directed toward the Equator has been detected in the vicinity of the auroral electrojet.

Several fundamental questions still puzzle scientists concerning the comparison of the aurora to a television tube. It is unclear what processes play the roles of the tube's cathode and anode in the magnetosphere, or what processes play the roles of the electric plate and electromagnet during the auroral substorm. It is not known how the energy carried by the solar wind is transformed into the energy of the aurora. It has been demonstrated that the southward directed interplanetary magnetic field is an essential ingredient in causing auroral substorms, so that the energy transfer appears to occur through interactions between the interplanetary and geomagnetic fields. A chain of processes leading to a substorm has not yet been unfolded, however. Current research efforts may unveil the secret of the aurora. It is not impossible that one day "magnetospheric weather" will be observed by watching auroral activity on the gigantic screen—the polar upper atmosphere.

BIBLIOGRAPHY. The literature on the aurora is vast and because of extremely rapid progress in this particular field during the last decade, no updated text dealing with all aspects of auroral studies is available. S.I. AKASOFU, S. CHAPMAN, and A.B. MEINEL, "The Aurora," in *Handbuch der Physik*, vol. 49/1 (1966); S.I. AKASOFU, *Polar and Magnetospheric Substorms* (1968); S. CHAPMAN, *Solar Plasma, Geomagnetism and Aurora* (1964); and S. MATSUSHITA and W.H. CAMPBELL (eds.), *Physics of Geomagnetic Phenomena*, 2 vol. (1967), provide reviews of morphological studies of the aurora and associated phenomena in the polar upper atmosphere. J.W. CHAMBERLAIN, *Physics of the Aurora and Airglow* (1961), is the most comprehensive text dealing with auroral and airglow spectra; new studies after its publication must, however, be supplemented by recent literature, such as B.M. MCCORMAC (ed.), *Aurora and Airglow* (1967), and *Atmospheric Emissions* (1969). W.N. HESS, *The Radiation Belt and Magnetosphere* (1968), is a comprehensive text on the electromagnetic environment surrounding the Earth which has an important relation to auroral phenomena. S. CHAPMAN and J. BARTELS, *Geomagnetism*, 2 vol. (1940); C. STORMER, *The Polar Aurora* (1955); and L. HARANG, *The Aurorae* (1951), are classic treatises on auroral phenomena.

(S.-I.A.)

Austen, Jane

While the birth of the English novel is to be seen in the first half of the 18th century in the work of Daniel Defoe, Samuel Richardson, and Henry Fielding, it is with Jane Austen that the novel takes on its distinctively modern

character in the realistic treatment of unremarkable people in the unremarkable situations of everyday life. In her six novels, published between 1811 and 1817—*Sense and Sensibility*, *Pride and Prejudice*, *Mansfield Park*, *Emma*, *Northanger Abbey*, and *Persuasion*—she created the comedy of manners of middle-class life in the England of her time, revealing the possibilities of "domestic" literature. Her repeated fable of a young woman's voyage to self-discovery on the passage through love to marriage focuses upon easily recognizable aspects of life. It is this concentration upon character and personality (second only to Shakespeare's, some critics say) and upon the tensions between her heroines and their society that relates her novels more closely to the modern world than to the traditions of the 18th century. The "daughter" of Dr. Samuel Johnson she is also the "parent" of Henry James. It is this modernity, together with the wit, realism, and timelessness of her prose style; her shrewd, amused sympathy; and the satisfaction to be found in stories so skillfully told, in novels so beautifully constructed, that helps to explain her continuing appeal for readers of all kinds. In her hands, the novel of entertainment becomes a work of art.

Steventon: early life and education

Family and upbringing. Jane Austen was born on December 16, 1775, in the Hampshire village of Steventon, where her father, the Rev. George Austen, was rector. She was the second daughter and seventh child in a family of eight: six boys and two girls. Her closest companion was her elder sister, Cassandra, who also remained a spinster: the young clergyman to whom she was engaged died in 1797. Of the relationship between the sisters, the niece who had known them longest was to write: "They alone fully understood what each had suffered and felt and thought."

Her formal education began in about 1782, when the sisters were sent to be tutored by a Mrs. Cawley at Oxford; and, in 1783 or 1784, they moved to the Abbey School, Reading, where they remained until about 1787. Thereafter, their education continued at home. This was no deprivation, as the household at the rectory was unusually gifted; and it is difficult to imagine circumstances in which Jane Austen's genius could have been better developed.

Her father was a scholar who, before entering the church, had been a fellow of St. John's College, Oxford; and he encouraged the love of learning in his children. His wife, Cassandra (*née* Leigh), was a woman of ready wit, famed for her impromptu verses and stories. Together they created a home decidedly, although not forbiddingly, bookish. Reading and writing were enjoyed as family activities, and their reading was by no means confined to "polite" literature or to the accepted English classics. Samuel Richardson and Henry Fielding were favourite novelists; and even Mr. Austen kept up with the latest fiction, including the Gothic romances or thrillers by such popular writers as Mrs. Ann Radcliffe, whose supernatural horrors Jane Austen was to make fun of in *Northanger Abbey*. The great family amusement was acting. A Steventon dramatic company was recruited from the Austens and their neighbours; and the rectory barn was converted into a little theatre for productions in the summer holidays, while at Christmas, plays were performed in the house. Again, the repertoire was not restricted and included even the broader kind of 18th-century comedy.

So the fact that Jane Austen's early years were spent in an actively Christian household in a remote country village does not mean that her life was intellectually or socially limited. The family circle was large and changing and constantly supplied with news. Two of her four elder brothers, James and Henry, went to Oxford and there edited a literary periodical, *The Loiterer* (running to 60 issues between 1789 and 1790). It was undoubtedly planned and discussed in their sister's presence when they were at home. The younger brothers, Francis (Frank) and Charles, joined the navy and wrote home about their adventures during the Napoleonic Wars. The Steventon household included young men whom Mr. Austen was preparing for the university. And there was a wide circle of relatives and friends to visit (sometimes for months at a stretch) and to be visited by, particularly on Mrs. Austen's side, for she was a member of a large and well-connected family. George Austen belonged to the poorer branch of an ancient Kentish family and had, through family patronage, become clergyman in charge of two small parishes—Steventon and its neighbour, Deane—which brought in a modest but adequate income.

Thus, although Jane Austen's early life was unmomentous and at a distance from the social and political upheavals of the time, a lively and affectionate family circle provided a stimulating context for her writing. Moreover, her experience was carried far beyond Steventon rectory by an extensive network of relationships by blood and friendship. It was this world—of the minor landed gentry and the country clergy, in the village, the neighbourhood, and the country town, with occasional visits to Bath and to London—that she was to use in the settings, characters, and subject matter of her novels. She wrote in a letter of 1814, "3 or 4 Families in a Country Village is the very thing to work on."

Literary development. Her earliest known writings date from about 1787, and between then and 1795 she wrote a large body of material that has survived in fair copy in three manuscript notebooks: *Volume the First*, *Volume the Second*, and *Volume the Third*. In all, these contain 21 items: plays, verses, short novels, and other prose. They are the product of an analytical mind engaged in parody of existing literary forms, notably sentimental fiction (remorselessly burlesqued in *Love and Friendship*, in *Volume the Second*). In this early writing can be traced her development toward a more humane interest in the portrayal of realistic characters in realistic situations; and in many of these pieces the antecedents of the mature novels can be recognized.

Jane Austen's literary development also reflects the outlines of her emotional and intellectual growth between the ages of 12 and 17; and her passage to a more serious view of life from the exuberant high spirits and extravagances of her earliest writings is announced finally in *Lady Susan*, a short novel-in-letters written about 1793–94. This, the portrait of a woman bent on the exercise of her own powerful mind and personality to the point of social self-destruction, is, in effect, a study of frustration and of woman's fate in a society that has no use for woman's stronger, more "masculine," talents. How far can this be read as the young Jane Austen's own self-admonitory fable? In a letter written in 1815, the essayist and dramatist Mary Russell Mitford, who had never known Jane Austen personally, repeats a description of her as "a poker of whom everyone is afraid." Her

Lady Susan

source was a member of a family on bad terms with the Austens. But if a malicious statement can contain a measure of truth, the reference was probably to Jane Austen's silent, watchful presence—the young novelist making her mental notes of this one's stupidity and that one's folly. The evidence of *Lady Susan* suggests that to encounter Jane Austen as a girl of 17 could have been a formidable experience. Somewhere within this notion may stand a solution to the problem of her spinsterhood.

Relations with men

The question can only be put forward speculatively, for the record of Jane Austen's life is tantalizingly incomplete on the subject of her relationships with men. From January 1796 onward some of her letters survive, to tell of her enjoyment of local parties and dances in Hampshire, of visits to London, Bath, Southampton, Kent, and to seaside resorts in Devon and Dorset. A gossipy recollection of Miss Mitford's mother (who had left the Steventon neighbourhood when Jane Austen was seven) describes her as "the prettiest, silliest, most affected, husband-hunting butterfly [she] ever remembers." (Only a remnant of "prettiness" can be glimpsed in the one authentic portrait, Cassandra's sketch of about 1810: here the dark eyes, dark ringlets, and round cheeks attend an expression of slightly soured resignation.)

A number of the intimate family letters that have been preserved, especially two to her niece, Fanny Knight, of November 1814, provide remarkable confirmation that the severe, yet sensible and humane, morality of the novels was wholly at one with the practicing morality of her own life and with the morality she advocated for others. Fanny, then aged 19, was uncertain about her affection for a 21-year-old suitor. Jane Austen's letters of advice are a model—analytical rather than persuasive—requiring the girl, gently and sympathetically, to search her own heart, to discover for herself whether what she feels is really love and of what nature and quality. But she is emphatic on one point: "Anything is to be preferred or endured rather than marrying without Affection"; "nothing can be compared to the misery of being bound *without* Love." She sketches the one man "in a Thousand" who could be thought "perfection": "Where Grace & Spirit are united to Worth, where the Manners are equal to the Heart & Understanding. . . ." Perhaps it is these letters, rather than *Lady Susan* or the tittle-tattle of gossips, that tell us the truth about Jane Austen's single life and the moral urgency of the novels, in their preoccupation with the appraisal of human relationships, the precise quality of feeling between one person and another.

Jane's first recorded romantic association was a flirtation early in 1796 with Tom Lefroy, a handsome young Irishman, nephew of the rector of a village near Steventon. In 1798 or 1799 she may have refused Samuel Blackall, a fellow of Emmanuel College, Cambridge, who was then staying with the Lefroys. In November 1802 it seems likely that she agreed to marry Harris Bigg-Wither, the 21-year-old heir of a Hampshire family: but next morning she changed her mind. Then there are a number of mutually contradictory stories connecting her with someone (sometimes a naval officer, sometimes an army officer, sometimes a clergyman) with whom she fell in love but who died very soon after.

Since Jane Austen's novels are so deeply concerned with love and marriage, there is some point in attempting to establish the facts of these relationships. Unfortunately, the evidence is unsatisfactory and incomplete. Cassandra was a jealous guardian of her sister's private life, and after Jane's death she (and other members of the family) censored the surviving letters, destroying many and cutting up others. Stories in the family memoirs and documents are confused; and Jane Austen's own references in her letters are always ironic and evasive. The novels, however, provide indisputable evidence that their author understood the experience of love and of love disappointed.

This observation relates most obviously to her last novel, *Persuasion*. Yet it has some relevance, too, to the earlier novels, on which she was working during the period of the recorded romances. The earliest, *Sense and Sensibility*, was begun about 1795 as a novel-in-letters called "Elinor and Marianne," after its heroines. Between October 1796 and August 1797 she completed the first version of *Pride and Prejudice*, then called "First Impressions." In November 1797 her father wrote to inquire from the London publisher Thomas Cadell about the possibilities for its publication, but there was no answer. *Northanger Abbey*, the last of the early novels, was written about 1798 or 1799, probably as "Susan."

Up to this time the tenor of life at Steventon rectory had been propitious for Jane Austen's growth as a novelist. The family provided an appreciative audience. There was all the variety of the neighbourhood society, with a much-loved home to return to after long visits to friends, relatives, and married brothers (Edward, the Austens' third son, adopted as heir by wealthy cousins, opened his home at Godmersham, Kent, to his sisters and later provided them with 11 motherless nieces and nephews to console and entertain; and Henry, living in London, often claimed their company). This stable pattern ended in 1801, when George Austen, then aged 70, handed on his parish duties to his eldest son, James, and retired to Bath with his wife and daughters. For eight years Jane Austen had to put up with a succession of temporary lodgings or visits to relatives, in Bath, London, Clifton, Warwickshire, and, finally, Southampton, where the Austens lived from 1805 to 1809.

Meanwhile, in 1803, the manuscript of "Susan" had been sold to the publisher Richard Crosby for £10. He took it for immediate publication, but although it was advertised, unaccountably it never appeared. In 1804 she began *The Watsons* but soon abandoned it. It is an unhappy work. Its social picture is one of unrelieved bleakness; its central character is the most assailed of her heroines in distress. Its satire is sharp to the point of cruelty. It signals a failing of generosity, a loss of creative power, perhaps the consequence of disappointment in love and other sorrows. In December 1804 her dearest friend, Mrs. Anne Lefroy, died suddenly; on January 21, 1805, her father died in Bath.

Critical acclaim. Eventually, in 1809, Edward provided his mother and sisters with a large cottage in the village of Chawton, his Hampshire property, not far from Steventon, where they were joined by a close friend who had lived with them in Southampton. The prospect of settling at Chawton had already given Jane Austen a renewed sense of purpose. In April she wrote to Crosby to sound his intentions about "Susan," and, once installed at the cottage, she began to prepare *Sense and Sensibility* and *Pride and Prejudice* for publication. Two years later Thomas Egerton agreed to publish *Sense and Sensibility*, with the author's guarantee against loss. It came out, anonymously, in November 1811. Both of the leading reviews, the *Critical Review* and the *Quarterly Review*, welcomed its blend of instruction and amusement. Meanwhile, in February 1811, she had begun *Mansfield Park*, finished in the summer of 1813 and published in 1814. By then she was an established (though anonymous) author; Egerton had published *Pride and Prejudice* in January 1813; in November there were second editions of *Pride and Prejudice* and *Sense and Sensibility*. Between January 1814 and March 1815 she wrote *Emma*, which appeared in December 1815. In February 1816 there was a second edition of *Mansfield Park*, published, like *Emma*, by Byron's publisher, John Murray ("a rogue, of course, but a civil one," Jane Austen commented). *Persuasion* (written August 1815–August 1816) was published posthumously, with *Northanger Abbey*, in December 1817.

The years after 1811 seem to have been the most rewarding of her life. She had the satisfaction of seeing her work in print and well reviewed and of knowing that the novels were widely read. They were so much enjoyed by the Prince Regent (later George IV) that he had a set in each of his residences; and *Emma*, at a discreet royal command, was "respectfully dedicated" to him. The reviewers praised the novels for their moral entertainment, admired the character drawing, and welcomed the homely realism as a refreshing change from the romantic melodrama then in vogue. Although she was at pains to pre-

serve her anonymity and avoided literary circles, Jane Austen was nonetheless concerned about the reception of the novels, not least because they earned her money as well as praise. At Chawton, she remained a housekeeper and an affectionate and dutiful attendant upon her mother. To an ever-growing band of nephews and nieces she was the favourite "Aunt Jane," a prized confidante and adviser on literature and affairs of the heart.

For the last 18 months of her life, she was busy writing. Early in 1816 she set down the burlesque *Plan of a Novel, According to Hints from Various Quarters* (first published in 1871). Until August 1816 she was occupied with *Persuasion*. She looked again at the manuscript of "Susan" (*Northanger Abbey;* to which she was now referring as "Miss Catherine"). Then, in January 1817, she began her last work, *Sanditon* (so named by the family), writing and revising more than 24,000 words in less than eight weeks. It was finally put aside on March 18. This may have been a race against time, for her health had been in decline since early 1816. She supposed that she was suffering from bile. But the symptoms (reported, wryly and unself-pityingly, in her letters) make possible a modern clinical assessment that she was suffering from Addison's disease of the suprarenal capsules. Her condition fluctuated. A final burst of energy seems to have gone into *Sanditon*, with its robust and self-mocking satire on health resorts and invalidism. In April she made her will. In May she was taken to Winchester to be under the care of an expert surgeon. On the morning of July 18, at 4:30 AM, she died. Six days later she was buried in Winchester Cathedral.

Her authorship was announced to the world at large by her brother Henry, who supervised the publication of *Northanger Abbey* and *Persuasion* and contributed a "Biographical Notice of the Author," paying tribute to his sister's qualities of mind and character and recording her final words: in answer to a question about her last wants, she replied, with characteristic decorum and economy, "I want nothing but death."

Reputation

There was no recognition at the time that regency England had lost its keenest observer and sharpest analyst; no understanding that a miniaturist (as she maintained that she was and as she was then seen), a "merely domestic" novelist, could be seriously concerned with the nature of society and the quality of its culture; no grasp of the fact that Jane Austen was a historian of the emergence of regency society into the modern world. During her lifetime there had been a solitary response in any way adequate to the nature of her achievement: Sir Walter Scott's review of *Emma* in the *Quarterly Review* for March 1816, where he hailed this "nameless author" as a masterful exponent of "the modern novel" in the new Realist tradition. Commenting on this to her publisher, Jane Austen was cool. She had, she said, "no reason . . . to complain of the review, except at the (anonymous) critic's failure to mention *Mansfield Park*." After her death, there was for long only one significant essay, the review of *Northanger Abbey* and *Persuasion* in the *Quarterly* for January 1821 by Richard Whately, the eccentric but far-sighted theologian, logician, and political economist, later archbishop of Dublin. Together, Scott's and Whately's essays provided the foundation for serious criticism of Jane Austen: their insights were appropriated by critics throughout the 19th century. Modern critics remain fascinated by the commanding structure and organization of the novels, by the triumphs of technique that enable the writer to lay bare the tragicomedy of existence in stories of which the events and settings are apparently so ordinary and so circumscribed.

MAJOR WORKS

NOVELS: *Sense and Sensibility* (1811); *Pride and Prejudice* (1813); *Mansfield Park* (1814); *Emma* (published December 1815, dated 1816); *Northanger Abbey* and *Persuasion* (published together, posthumously, December 1817, dated 1818).

UNFINISHED WORKS AND JUVENILIA: The early novel-in-letters, *Lady Susan* and *The Watsons* (unfinished), were first published in the 1871 edition of J.E. Austen-Leigh's *Memoir of Jane Austen. Lady Susan* was republished from the original autograph by R.W. Chapman (1925), and *The Watsons*, also by R.W. Chapman (1927). *Sanditon* (left unfinished; extracts published in the 1871 *Memoir*) was first published in full from the original autograph by R.W. Chapman (1925). Three manuscript notebooks, *Volume the First, Volume the Second,* and *Volume the Third,* containing juvenilia written *c.* 1787–95, were first published in full by R.W. Chapman (*Volume the First,* 1933; *Volume the Third,* 1951) and B.C. Southam (*Volume the Second,* 1963). *Volume the Second* contains *Love and Friendship* (first published 1922).

BIBLIOGRAPHY

Bibliographies: GEOFFREY L. KEYNES, *Jane Austen: A Bibliography* (1929), places emphasis on the early editions. R.W. CHAPMAN, *Jane Austen: A Critical Bibliography,* 2nd ed. (1969), lists critical works as well as original and early editions. B.C. SOUTHAM, "Jane Austen," in the *New Cambridge Bibliography of English Literature,* vol. 3 (1969), lists collections, editions, letters, and critical and biographical books and articles, 1812–1967.

Manuscripts: Only eight literary manuscripts are known to have survived: two are privately owned, two are in the Pierpont Morgan Library, New York; two are in the British Museum, London; one is in the Bodleian Library, Oxford; and one in the library of King's College, Cambridge. B.C. SOUTHAM, *Jane Austen's Literary Manuscripts* (1964), provides a full bibliographical, historical, and critical account of the manuscript material. Of many thousands of letters written by Jane Austen, only 154 are known to have survived; the principal collections are in the Pierpont Morgan Library and the British Museum. The Jane Austen Memorial Trust maintains Chawton Cottage, Hampshire (her last home), as a place of literary pilgrimage; and holds the only collection of Jane Austen's personal possessions, and of other items belonging to the period and to the Austen family. The Jane Austen Society (Alton, Hampshire, England) is an association of those interested in her and her work.

Editions: The Oxford Illustrated Jane Austen, ed. by R.W. CHAPMAN, 6 vol. (1923–54; vol. 6 rev. by B.C. SOUTHAM, 1968), is the definitive, standard edition of the works. Vol. 5 contains *Persuasion* and *Northanger Abbey;* vol. 6, the minor works. The Everyman's Library edition of the 6 novels, by MARY LASCELLES, 5 vol. (1962–64; vol. 5 containing *Persuasion* and *Northanger Abbey*), provides a sound working text. The only complete edition of Jane Austen's surviving *Letters* is that by R.W. CHAPMAN, 2 vol. (1932; 2nd ed., with corrections and additional indexes, 1952). The World's Classics *Selected Letters of Jane Austen* (1955), also ed. by Chapman, is useful.

Biography and criticism: HENRY AUSTEN's brief "Biographical Notice of the Author," written as a preface to *Northanger Abbey* and *Persuasion* (1818), was the first public acknowledgement of the identity of the author of the novels. J.E. AUSTEN-LEIGH, *A Memoir of Jane Austen* (1870; enlarged in 1871; later reprinted), written in old age by her favourite nephew, draws on family letters and personal recollections: the 1871 edition includes extracts from Jane Austen's letters. It should be supplemented by W. and R.A. AUSTEN LEIGH, *Jane Austen: Her Life and Letters* (1913), which provides a more complete account of her life and, although not a full edition of the letters, quotes almost all of those known. LORD BRABOURNE, *Letters of Jane Austen,* 2 vol. (1884), provides an edition of letters, mainly to her sister, Cassandra, with a biographical introduction based on recollections. CONSTANCE HILL, *Jane Austen: Her Homes and Her Friends* (1902), is an informal but knowledgeable account, drawing on family papers now unlocatable. R.W. CHAPMAN, *Jane Austen: Facts and Problems* (1948), is not a full biography, but provides the first scholarly and authoritative examination and evaluation of the evidence. MARGHANITA LASKI, *Jane Austen and Her World* (1969), in appearance a popular, illustrated biography, is the best introductory life. MARY LASCELLES, *Jane Austen and Her Art* (1939; corrected 1941, 1954), remains the best account of the novelist's art, and contains an introductory biographical chapter. Other modern critical works include W. LITZ, *Jane Austen: A Study of Her Artistic Development* (1965); M. MUDRICK, *Jane Austen: Irony As Defense and Discovery* (1952), a brilliant and contentious interpretation; N. SHERRY, *Jane Austen* (1969); and A.H. WRIGHT, *Jane Austen's Novels: A Study in Structure,* 2nd ed. (1962). B.C. SOUTHAM in *Jane Austen: The Critical Heritage* (1968), collects and discusses the contemporary reviews and criticism, 1811–70; his *Critical Essays on Jane Austen* (1968), is a collection of newly written modern critical approaches. I.P. WATT, *Jane Austen: A Collection of Critical Essays* (1963), collects the best essays from 1870 onward.

(B.C.So.)

Austin, John

The most distinguished English writer on the philosophy of law after Jeremy Bentham, John Austin exerted a pro-

found influence on English jurisprudence and legal education. During the 20th century much of his work has been subjected to valid criticism, yet the lucidity and precision of his analysis of law and legal terminology have made a permanent contribution to our understanding of the basic concepts of jurisprudence. Austin was born March 3, 1790, at Creeting Mill, Suffolk. He began to study law in 1812 after five years in the army and from 1818 to 1825 practiced unsuccessfully at the chancery bar. His powers of rigorous analysis and his uncompromising intellectual honesty deeply impressed his contemporaries, and in 1826 when University College, London, was founded, he was appointed its first professor of jurisprudence, a subject that had previously occupied an unimportant place in legal studies. He spent the next two years in Germany studying Roman law and the work of German experts on modern civil law whose ideas of classification and systematic analysis exerted an influence on him second only to that of Bentham. Both Austin and his wife, Sarah, were ardent Utilitarians, intimate friends of Bentham and of James and John Stuart Mill, and much concerned with legal reform. Austin's first lectures, in 1828, were attended by many distinguished men, but he failed to attract students and resigned his chair in 1832. In 1834, after delivering a shorter but equally unsuccessful version of his lectures, he abandoned the teaching of jurisprudence. He was appointed to the Criminal Law Commission in 1833 but, finding little support for his opinions, resigned in frustration after signing its first two reports. In 1836 he was appointed a commissioner on the affairs of Malta. The Austins then lived abroad, chiefly in Paris, until 1848 when they settled in Weybridge, Surrey, where Austin died in December 1859.

Best known work

Austin's best-known work, a version of part of his lectures, is *The Province of Jurisprudence Determined,* published in 1832. Here, in order to clarify the distinction between law and morality, which he considered to be blurred by doctrines of Natural Law, he elaborated his definition of law as a species of command. According to Austin, commands are expressions of desire that another shall do or forbear from some act and are accompanied by a threat of punishment (the "sanction") for disobedience. Commands are laws "simply and properly so-called" when they prescribe courses of conduct, not specific acts, and are "set" by the "sovereign" (*i.e.*, the person or persons to whom a society renders habitual obedience and who render no such obedience to others). This is the mark distinguishing "positive law" both from the fundamental principles of morality, which are the "law of God," and from "positive morality," or man-made rules of conduct, such as etiquette, conventional morality, and international law, which do not emanate from a sovereign. *The Province* also contains a version of Utilitarianism in which "utility" is regarded as the index of God's commands and the test of the moral quality of general rules of conduct rather than of particular actions.

Austin viewed the doctrines in *The Province* as "merely prefatory" to the study that he termed "general jurisprudence": the exposition and analysis of the fundamental notions forming the framework of all mature legal systems. He devoted the main part of his lectures (published in 1863) to an analysis of such "pervading notions" as those of right, duty, persons, status, delict, and sources of law. Austin distinguished this general, or analytical, jurisprudence from the criticism of legal institutions, which he called the "science of legislation"; he thought both were important parts of legal education.

Bouts of nervous illness and self-distrust prevented Austin from fully utilizing his great powers; his life, as his widow wrote, was one of "unbroken disappointment and failure," in ironic contrast with his posthumous fame and influence. A long succession of English writers have echoed or elaborated his doctrines or, when opposing them, have accepted his conception of the analysis of legal concepts as the central concern of jurisprudence. In the United States jurists such as J.C. Gray and Oliver Wendell Holmes welcomed his bold distinction between law and morality as a major clarification.

The reaction to Austin's work at the turn of the century was severe. His command theory was condemned as a misidentification of all law with the product of legislation and a distortion of many types of legal rule. The severance of a purely analytical jurisprudence from moral criticism of law was criticized as sterile verbalism obscuring the social function of law and the judicial process. Some critics consider that Austin's doctrine of sovereignty confuses the ideas of legal authority and political power; others hold "legal positivism" responsible for subservience to state tyranny or absolutism.

Some of these criticisms are well founded, but even so Austin's work is of permanent value. The rigour and clarity of his analysis have demonstrated the complexity of many important legal and political concepts and the perennial need for just such an analytical study as he proposed; and repeated efforts to show precisely where his simple distinctions between law and morality are wrong have increased the understanding of both.

BIBLIOGRAPHY. JOHN STUART MILL, "Austin on Jurisprudence," in *Dissertations and Discussions,* vol. 4, pp. 157–226 (1874); R.A. EASTWOOD and G.W. KEETON, *The Austinian Theories of Law and Sovereignty* (1929); E.M. CAMPBELL, *John Austin and Jurisprudence in Nineteenth Century England* (1959).

Australia

The most striking characteristics of the continent of Australia, a vast, 3,000,000-square-mile (8,000,000-square-kilometre) landmass in the Southern Hemisphere, are its isolation, its low relief, and the aridity of much of its surface. Its isolation from other continents explains much of the strangeness of Australian plant and animal life; its low relief results from the long and extensive erosive action of the forces of wind, rain, and the heat of the sun during the great periods of geological time when the continental mass was elevated well above sea level.

This article describes the geological history of the development of Australia as a continent; its current physical geography; its plant and animal life; and the natural resources available for exploitation by man. The article AUSTRALIA, COMMONWEALTH OF, describes the contemporary aspects of the life of man on the continent; the people and their relationship to the landscape; the national economy; and political and cultural life. The related article AUSTRALIA, HISTORY OF, describes the historical associations of man with the continent.

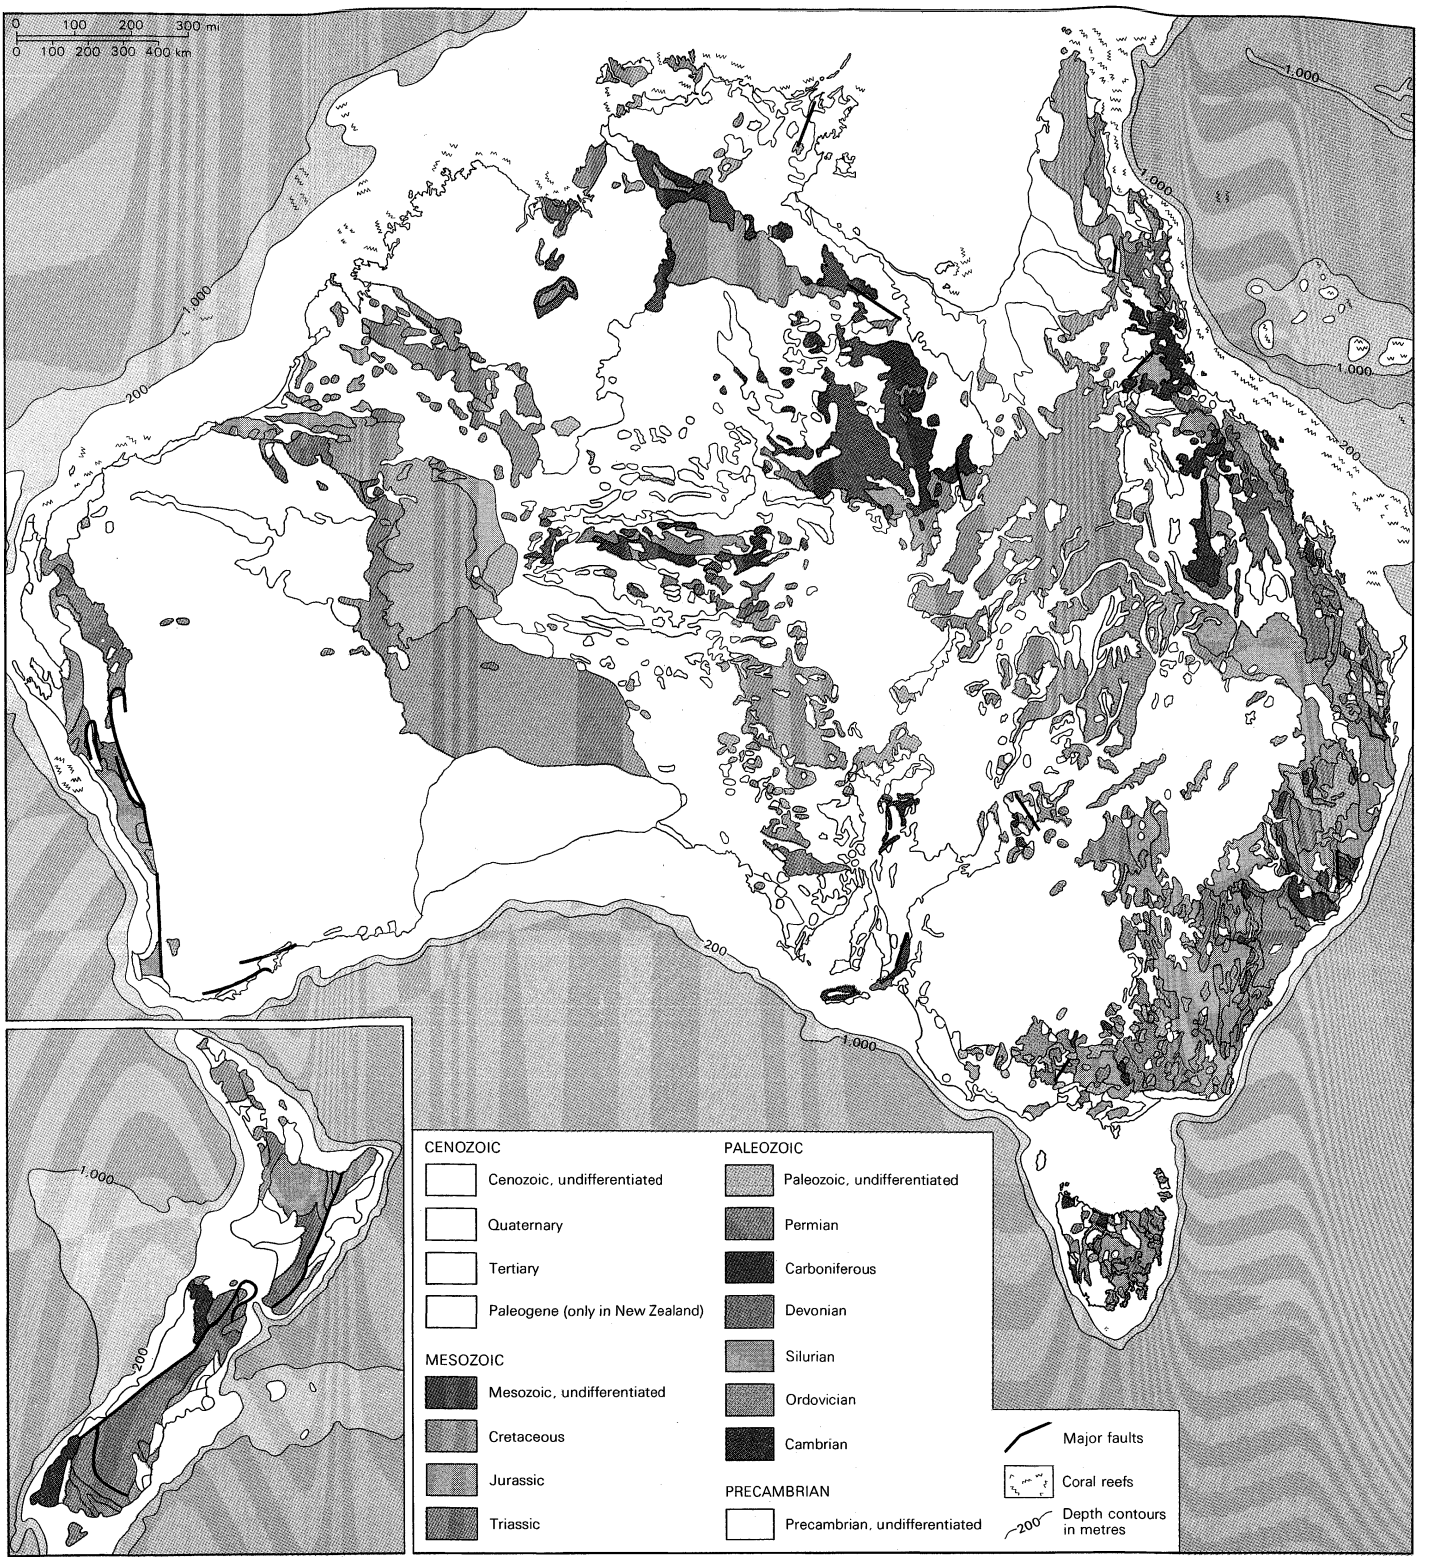
GEOLOGICAL HISTORY

A popular misconception about the observed peculiarities of Australia is that it is the oldest of continents. The statement is, in fact, unjustified: the cores of all of the continents are of approximately the same age, and rocks of all geological ages, of sedimentary as well as volcanic origin, are found in Australia. The misconception about its age stems partly from its relative paucity of surface relief, the result of relative stability and the absence of recent strong movements of the Earth's crust, rather than the old age of its rocks. The geologically young mountain-building forces, such as those that formed the Himalayas in Asia, the Alps in Europe, the Rocky Mountains in North America, and the Andes in South America, have bypassed Australia.

Comparison with other continents

Australia, like Eurasia and Africa, is strikingly different from the landmass of North America, which consists basically of an old core, the Canadian Shield, surrounded by mountain zones formed from belts of folded rocks of varying ages, all younger than the central core. Australia is strikingly asymmetric, with a folded belt of rocks bordering its east coast only and extending westward to no more than one quarter of the continent's width.

Like the other continental masses, Australia is built of three types of structural units. In the west is the West Australian Craton, a comparatively stable and resistant block consisting mainly of ancient rocks that have not been folded during at least the last 1,000,000,000 years. In the east is an ancient fold mountain belt, greatly eroded but relatively uplifted again. Between these two



Geological structure of Australia and (inset) New Zealand.

lies the platform-like area occupied by the central plains, a region where crystalline or folded rocks are overlain by relatively thin sequences of flat-lying or only gently deformed sediments. Each of these major units is complex. The West Australian Craton, for example, includes, in addition to extensive outcrops of crystalline rocks in the core area itself, many blocks of sedimentary strata deposited in troughs and basins within this structural unit. The platform consists of three major, and numerous minor, basin structures. The Eastern Uplands include upfaulted and depressed structural blocks, many large, exposed, formerly molten intrusions (batholiths) of granite, and extensive lava flows of the Cenozoic Era.

The continental outline

The outline of the Australian continent, unlike those of South America and Africa, and the Indian subcontinent, is not roughly triangular with an apex pointing southward, though some resemblance to this distinctive configuration of the other continents and subcontinents can be seen in the shape and position of Tasmania. This island is part of the continent if the base of the shallow peripheral submarine area known as the continental shelf is taken as its outer boundary. The continental shelf and the

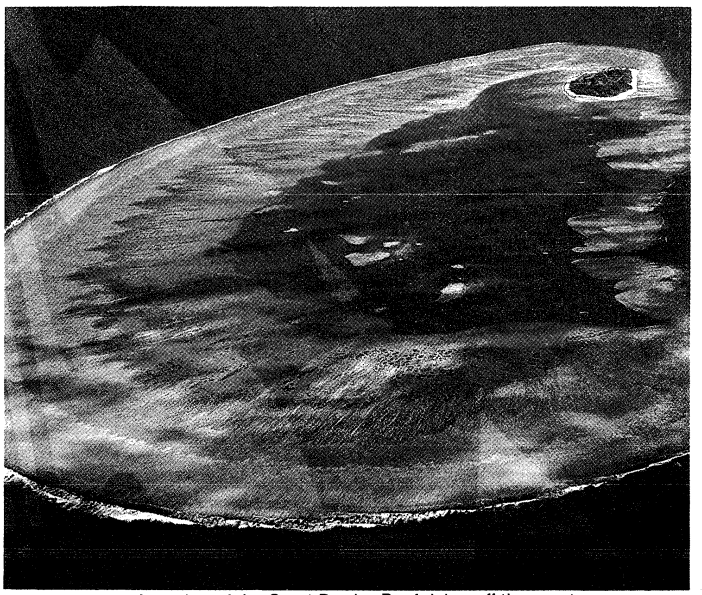
slope separating it from the ocean depths are moderately wide in the south and southwest and spectacularly wide in the northwest from Exmouth Gulf to the Timor Sea, where the distance of the slope base from the shore exceeds 300 miles, and the line marking depths of over 650 feet is over 250 miles from the shore. To the north of Australia, the continental shelf extends to the island of New Guinea. The shelf is narrow along the east coast, where the Great Barrier Reef (*q.v.*) marks its edge. A trough, with depths of about 3,000 feet, separates the Great Barrier Reef from the largely submerged Queensland Plateau, where only a few small islands and reef tops reach sea level. Off Brisbane and Sydney, the continental shelf is only some 30 miles wide, and the slope plunges steeply to the floor of the Tasman Sea.

Douglass Baglin



A portion of the Great Barrier Reef, lying off the coast of northeast Australia and forming the largest coral structure in the world.

The discovery of vast and varied mineral deposits in Australia stimulated intensive studies of its geological history and structure. At the same time, new developments in general geological theory, including the concepts of continental drift and ocean floor spreading, have led to renewed speculation regarding possible former land connections between Australia and other continents, particularly Antarctica. As a result, the answer to the problem of how the history of the Australian continent fits into the picture of the development of the Earth's crust as a whole will have to come from a deeper understanding not only of the geology of the continent but also of that of the ocean surrounding it.

The oldest rocks: the Precambrian. The oldest rocks of the continent occur in the southwest, where they form part of the Western Australian Shield, an area underlain by rocks that have not been folded since early Precambrian (Archaean) time. These oldest rocks are now thought to be about 3,000,000,000 years old. The Yilgarn nucleus of the Western Australian Shield extends over 230,000 square miles (600,000 square kilometres) and consists mostly of granite, with belts of altered sedimentary rocks (metasediments) and greenstones, the latter including ancient rocks rich in economic mineral deposits, as well as basic intrusions of formerly molten rocks. Similar to metal-bearing greenstone rock belts occurring in the nuclei of the ancient shield areas of other continents, these are being studied in the hope that the origin of these rock belts and their ore bodies will be explained in terms of the state of the Earth's crust and mantle at the beginning of geological time. The conditions under which the continental crust was formed and then reworked are not yet known, but geologists believe that some of the peculiarities of ancient rocks, their structure, and their composition can be explained only by assuming that the crust of the Earth was originally much thinner than it is today.

Formation of the continental crust

The Yilgarn nucleus does not reach the west and south coasts of Western Australia, where younger Precambrian rocks occur. Those on the west coast are separated by the Darling Fault, which forms the western margin of the shield near Perth, and by the Perth Basin. The Frazer Fault apparently marks the boundary between rocks of the main shield area that were metamorphosed by heat and pressure more than 2,500,000,000 years ago and others to the southeast that were similarly affected less than 2,000,000,000 years ago. Each of these major fault lines is about 600 miles long and is considered as a major lineament in the continental structure. The older rocks appear again in the Pilbara nucleus in the northwest, where some granites are more than 3,000,000,000 years old and where altered volcanic, greenstone, and sedimentary rocks also occur.

Large platforms and basins separate the Yilgarn and Pilbara nuclei of the Western Australian Shield from other occurrences of ancient rocks in the northwest and north of the continent and in central Australia. It is not yet known whether a major part of these rocks are as old as those that have been dated as Archaean in the west. Therefore, the earliest geographic configuration of the Australian continent cannot be reliably reconstructed; it could have extended northward and eastward far beyond the limits of the present Western Australian Shield.

Old (Archaean) rocks on the margins of the Kimberley Block form its basement; they occur also in the Katherine–Darwin area of the Northern Territory, in the Rum Jungle Complex. No definite datings of rocks in the east indicate ages as great as those of the oldest shield rocks, although part of the Arunta Complex, north of Alice Springs in the centre of Australia may be approximately 2,250,000,000 years old.

The post-Archaean geological history of Australia can be seen in a clearer framework; the general terms Early, Middle, and Late Proterozoic, or the regional terms Nullaginian, Carpentarian, and Adelaidean, are used to identify intervals in the time scale of this period and are documented by sedimentary rock sequences.

The Nullaginian System comprises platform cover south of the Pilbara nucleus, including the vast banded iron ore formations of the Hamersley Ranges (notably the Mt. Bruce supergroup, which also contains volcanic rocks dated at 1,950,000,000 to 2,200,000,000 years ago) and the rocks in the east Kimberley area. The Carpentarian System comprises a belt of sedimentary rocks—the McArthur Basin, southwest of the Gulf of Carpentaria—that may be 1,500,000,000 to 1,800,000,000 years old; younger granites in the Katherine–Darwin region; and the sediments and intrusive granites of the Mount Isa–Cloncurry region. The rocks of these regions are rich in mineral deposits. In South Australia, the basement rocks (gneisses) of Eyre Peninsula in the west and the Mt. Painter Complex in the northeast, and extending to Broken Hill in New South Wales (Willyama Block), may be of the same age as the rocks of the Carpentarian System, although the iron formations of the Middleback ranges have been generally considered to be as old as the early Proterozoic iron formations found in the Pilbara region.

Post-Archaean regional rock units

The Adelaidean System is made up of rocks of Late Precambrian age. Consolidation of the Musgrave Block in central Australia and intrusion of various molten rocks took place during the time interval 1,000,000,000 to 1,400,000,000 years ago, forming an extension of the Western Australian Shield. At the same time, sedimentary rocks were laid down in the Adelaide Geosyncline, a vast downwarping of the Earth's surface lying to the southeast. Sedimentation continued into mid-Cambrian time in a shallow marine trough extending from the coast south of Adelaide at least 400 miles northward, through the Mt. Lofty and Flinders ranges, and measuring 400 kilometres from west to east, from Lake Torrens to beyond Broken Hill. These rocks, with a total maximum thickness of over 10 miles, formed in an intermittently

The Adelaide Geosyncline

sinking trough in which the accumulating sediments were subjected to moderately strong folding and faulting in Late Precambrian and Early Paleozoic time. This Adelaidean sedimentary sequence has characteristic features of outstanding importance for Earth history: most of the sediments, which have remained unaltered, contain definite evidence of a major glacial period; they also contain the oldest known rich and varied assemblage of fossil animals, all of which were essentially soft-bodied. Rocks of similar age also occur in the Peake and Denison ranges west of Lake Eyre, in the Amadeus Basin, and on the margins of the Kimberley Block. In the area there is also clear evidence of a Precambrian glaciation. Its earlier phase has been dated at about 740,000,000 years, while the later phase was little older than 660,000,000 years. This is the likely time range of glaciation in the Adelaide Geosyncline and probably also of related glaciations in other continents: it was probably one of the most extensive periods of cold climate in the Earth's history. No definite Precambrian animal remains are known from rocks that are older than the onset of this glaciation; on the other hand, primitive aquatic plant fossils have been found abundantly in earlier Precambrian strata.

Paleozoic history of eastern Australia. The Adelaide Geosyncline is often considered as a precursor of the more extensive fold belts of eastern Australia. These form another great downwarp known as the Tasman Geosyncline. While the rocks of the Adelaide Geosyncline were folded in Late Cambrian time, about 500,000,000 years ago, and elevated so that sedimentation ceased, the Tasman Geosyncline began to form in Cambrian time, the first period of the Paleozoic Era, which was to last for the next 300,000,000 years.

The Tasman Geosyncline

Cambrian strata. Cambrian strata, with marine fossils indicating their age, are known only from a few areas in eastern Australia: Tasmania, central Victoria, and northeast of Broken Hill in western New South Wales. It is possible that Cambrian rocks outcrop also on the coast of southern New South Wales. These few occurrences are insufficient to support any well-founded reconstruction of the geography of Australia in Cambrian time, but they do indicate a fundamental difference in conditions of sedimentation in the east where the rocks are similar to those deposited in deep geosynclinal troughs generally, and the large areas in southern, central, and northern Australia, including the Amadeus and Georgina basins, where the Cambrian rocks were mostly formed in shallow water. These differences are the expression of the relative stability of the western areas as compared with the greater geological mobility of eastern Australia during Paleozoic time, although any boundary between these two areas is likely to be gradational rather than a definite line.

A generalized western margin of the Tasman Geosyncline might be drawn from the north Queensland coast, at about longitude 144° E and latitude 14° S, around the Precambrian Georgetown area to Charters Towers, south-southwestward to near Wilcannia on the Darling River, and thence either due south or southwestward to Kangaroo Island. The discontinuous folded and granite-intruded Paleozoic rocks east of this somewhat hypothetical boundary are now separated by generally flat-lying younger rocks deposited in separate sedimentary basins. As there is no obvious continuity of folded zones and of belts of contemporaneous folding from the south coast to the north of eastern Australia, it has been suggested that a Lachlan Geosyncline in the southeast (mainly in Victoria and south central New South Wales) should be distinguished from the New England Geosyncline, the western boundary of which extends from Newcastle to south of Townsville. They are two component parts of the Tasman geosynclinal belt, similar in rock types, but different in age and geographic position.

The Lachlan Geosyncline

Ordovician rocks. The geography of eastern Australia in Ordovician time, from 430,000,000 to 500,000,000 years ago, is sufficiently well known to permit some general statements. The Lachlan Geosyncline was the site of sedimentation that took place in a series of troughs separated by rising upwarped ridges. No western shoreline can be defined, but the characteristics of Ordovician rocks in the Broken Hill region, and the evidence of bores in northeastern South Australia, indicate that these localities lay outside the geosynclinal belt in platform areas where subsidence was less intense. The geosynclinal nature of most of the rocks of Victoria, and southern and central New South Wales, is indicated by the great thicknesses of marine rocks deposited partly in deep quiet water (as in the case of black shales) and partly by mud-laden currents flowing from higher areas of the sea floor, producing the muddy sandstones known as graywackes. The rocks in the central part of the geosyncline were altered by heat and pressure, and volcanic rocks are widely distributed. In many parts of the Lachlan Geosyncline, folding movements (known as the Benambran orogeny, or mountain-building movement) occurred at the end of Ordovician and in early to mid-Silurian time. Accompanied by granite intrusions, these movements are thought to have caused the changes in composition and texture of the Ordovician rocks in the Snowy Mountains.

Silurian rocks. The Benambran mountain-building movements changed the geographic framework of the sedimentation that occurred during Silurian times (from 395,000,000 to 430,000,000 years ago). The eastern margin of the Lachlan Geosyncline now extended from the Melbourne area northward through Cobar to the Adavale Trough. In the Melbourne Trough there are thick Silurian graywackes and mudstones with graptolites and other fossils, and sedimentation extended into Tasmania, where shallow-water rocks were laid down. Farther east, in southern New South Wales, the Yass Shelf was an area of volcanic rocks, limestones, and shales that are now famous for their fossils. Silurian rocks are not well known in the New England Geosyncline and in southern Queensland, but farther north there is another peripheral shelf development, with Silurian limestones occurring along the western margin of the Tasman geosynclinal belt and the Chillagoe Shelf and its southward extension.

Devonian rocks. Deposition in the Lachlan Geosyncline generally continued from Silurian into Lower and Middle Devonian Periods, from 350,000,000 to 400,000,000 years ago, although the earth-movements of the Bowning orogeny occurred at the end of the Silurian and through early Devonian. Evidence of this can be seen as an unconformity, or break, in the rock layers of the sedimentary series of the Canberra–Yass area: molten rocks were intruded into the sedimentary rocks during this period. This activity again changed the geography of sedimentary areas in the Lachlan Geosyncline. In particular, a shallow-water platform with limestone deposition extended from eastern Victoria (Buchan Caves) to the Yass–Taemas area. Geosynclinal deposition during early and mid-Devonian time was widespread in the New England Geosyncline and its extension in southeastern Queensland, but only corals preserved in isolated limestones permit precise dating of the rock layers.

The Tabberabberan earth movements

The Tabberabberan period of earth movements, which occurred at the end of mid-Devonian time, had a profound effect on the geographic development of eastern Australia. Marine sedimentation in the Lachlan Geosyncline ended, and nonmarine rocks, in part red sandstone beds resembling similar rocks in northern Europe, were deposited. Discoveries of abundant remains of armoured fishes—notably *Bothriolepis,* which is also found in central Australia, North America, Eurasia, and Antarctica—have been made in western New South Wales. Remains of the scale-tree *Leptophloeum* are also common. Erosion of uplifted areas in central Australia, Victoria, and most of New South Wales must have produced the material for extensive Late Devonian and Early Carboniferous lake and river deposits. These include sandstones of the Grampian Mountains in western Victoria.

Carboniferous and Permian rocks. In the eastern troughs, from New England to eastern Queensland, geosynclinal deposition continued under the influence of volcanic activity. In the Carboniferous Period, about 300,000,000 years ago, nonmarine rock deposition occurred in the south and west, while marine sediments ac-

cumulated in the east. The central part of New England was uplifted. The earliest Paleozoic glaciations in eastern Australia are of Late Carboniferous age and have been considered as the result of mountain glaciation.

The youngest rocks in the New England Geosyncline that were deposited before final deformation are of Permian age and marine origin. In Middle and Late Permian time the great New England batholith was emplaced in the older rocks, which were heavily folded toward the west. A line from the mouth of the Hunter River near Newcastle in the south to the eastern margin of the Bowen Basin in the Rockhampton–Bowen area marks the western limit of the Hunter-Bowen orogeny, which was the last of the major mountain-building phases in the Tasman geosynclinal belt and which ended its existence as a belt of troughs of sedimentation.

The Hunter-Bowen earth movements

Sedimentary basins and the Mesozoic history of Australia. Quite distinct from the history of the successive, more or less elongated, highly mobile (in geological terms) troughs discussed above is the development of sedimentary basins over the Australian continent. Some of these developed at various times on the Precambrian basement of the western and central parts of the continent, while in other areas this type of sedimentation followed the consolidation of folded belts of Paleozoic rocks and interrupted their continuity. Others are superimposed on differently shaped pre-existing basins.

Like the Perth Basin, which adjoins it to the south, the Carnarvon Basin of Western Australia began to form in Silurian time and contains Late Paleozoic deposits, including Early Permian glacial sediments, followed by Lower Triassic and, in places, nearly 13,000 feet of Jurassic sediments, dating from about 140,000,000–180,000,000 years ago. During the Upper Cretaceous Period, about 100,000,000 years ago, sedimentation in the Carnarvon Basin changed from sands and shales to limestones and chalks, and this may be related to a change to warmer water conditions, which continued in the north until Miocene time, less than 25,000,000 years ago. The west coast of the continent was, to varying extents in the course of the last 400,000,000 years, a geologically mobile shelf area, with an alternation of marine and nonmarine deposits and of transgressions and regressions of the sea.

In northwestern Australia the shallower Canning Basin with the adjoining deeper Fitzroy Trough formed a large subsidence area between the Western Australian Shield and the Kimberley Block. The Joseph Bonaparte Gulf and Ord basins extend along its northern and eastern margins on the West Australian–Northern Territory border. These basins date back to Ordovician time. The Canning Basin may have been linked eastward, through the Officer and Amadeus basins of central Australia, with the Tasman geosynclinal belt in the east, and, again in Permian time it may have extended southeastward in a similar manner. Such temporary configurations are exceptional in ancient Australian geography. As a rule, the structural independence of the basins is supported by differences in their fossil remains. An outstanding development of Devonian reef complexes is known from the northern edge of the Canning–Fitzroy basins, while Permian glacial deposits occur on its southern margin and continue into South Australia, Victoria, and New South Wales.

The Amadeus Basin. The Amadeus Basin in central Australia is a large depression extending east–west for 450 miles and north–south for no more than 160 miles and filled with many varieties of ancient sedimentary rocks. It is situated between the so-called Musgrave structural block in the south and the Arunta structural complex in the north, and both have moved toward, and

Australian landscapes.
(Top left) St. Mary Peak, Flinders Range, South Australia. Mineral traces are evident in upper crests. (Top right) Macdonnell Ranges, west of Alice Springs, Northern Territory. The low parallel ridges, cut in folded strata, run practically unbroken for 150 miles. (Bottom left) Simpson Desert, central Australia, one of the most desolate areas of the continent, contains neither water nor habitation. In the foreground are sand humps covered with spinifex, the scattered vegetation characteristic of the desert. (Bottom right) Mt. Olga, a huge red sandstone monolith, rises 1,500 feet above the plain, south of Lake Amadeus in the Northern Territory.

folded sediments of, the basin at different times. Some sediments were deposited during the folding of the Macdonnell Ranges near Alice Springs, which later erosion shaped into spectacular scenery. The isolated sandstone masses of Ayres Rock and Mt. Olga are now considered to be of Cambrian age.

The Canning Basin continued to exist as a depositional trough during Jurassic time, when only its northwestern margin received marine sediments, and through the early Cretaceous Period when a great marine transgression joined it again southeastward with the Eucla and Officer basins and eastward with the Great Artesian Basin.

The Eucla and Officer basins. The Eucla Basin is a large but shallow depression lying between the Western Australian Shield and the basement rocks of Eyre Peninsula. Permian and Cretaceous rocks are known to exist from the evidence of bores. Above them lie Tertiary limestones, which are no more than a few hundred feet thick, perfectly flat-lying, with their surface forming the arid Nullarbor Plain. They are riddled with caves, many of which remain unexplored. The Officer Basin, south of the Musgrave Block, is filled with late Precambrian and Cambro-Ordovician rocks.

The Great Artesian Basin. The Great Artesian Basin is a large (670,000 square miles) and complex, generally slowly subsiding area, in which, by Jurassic time, several previously separate basins (such as the Cooper Basin, with its rich gas-bearing Permian sands) had been incorporated. The Jurassic nonmarine sands of the Great Artesian Basin, which spread from the eastern highlands to the western margins of the basin, provide its most important sources of water. By mid-Cretaceous time the sea invaded the basin from the northeast and southwest, but the early Upper Cretaceous is represented by marine fossil-bearing deposits only near the northern coasts. The northernmost part of the Great Artesian Basin is separated from its main body by a basement ridge that hardly reaches the surface; north of it only Cretaceous and younger rocks are found. The southern boundary is formed by extensive basement outcrops in the Broken Hill–Wilcannia–Cobar areas, and the lowlands to the south are considered a separate unit, the Murray Basin. Permian and Mesozoic rocks play only a minor part in its filling. Its rocks are mostly of Tertiary age, marine in the west and mainly nonmarine in the east. A range of granitic hills in the south, the Padthaway Ridge, extending southeastward from Murray Bridge, forms a persistent boundary between the Murray and Otway basins. The Otway Basin, which extends into western Victoria and the continental shelf offshore, contains much greater thicknesses than the Murray Basin, of Cretaceous and Tertiary rocks in alternating marine and nonmarine development. Oil exploration in the Murray and Otway basins, and in the adjoining submarine Bass Basin between Victoria and Tasmania, had not been commercially successful by the early 1970s, but significant oil and gas reserves had been found offshore in the Gippsland Basin, in rocks of early Tertiary age.

The Murray and Otway basins

The Sydney Basin. The Sydney Basin was superimposed on a part of the folded rocks of the Tasman geosynclinal belt in Permian time and was filled with a considerable thickness of Permian and Triassic marine and nonmarine rocks. Overlapped by the Great Artesian Basin in the northwest, it continues southeastward under the continental shelf. The Permian begins with shallow-water marine sediments with erratic blocks indicating continued glaciation of the adjoining land, and volcanic material. The plant fossils are typical of the Permian of the southern continents. Coal deposition followed, and after another marine interlude, the Permian Period ended with the formation of further coal-bearing sediments, while volcanic activity and some earth movements continued. The Triassic sequence of the Sydney Basin consists of the Narrabeen Group of sandstones and shales, the Wianamatta Group, and the Hawkesbury Sandstone, which forms conspicuous cliffs around Sydney Harbour and is much used as a building stone.

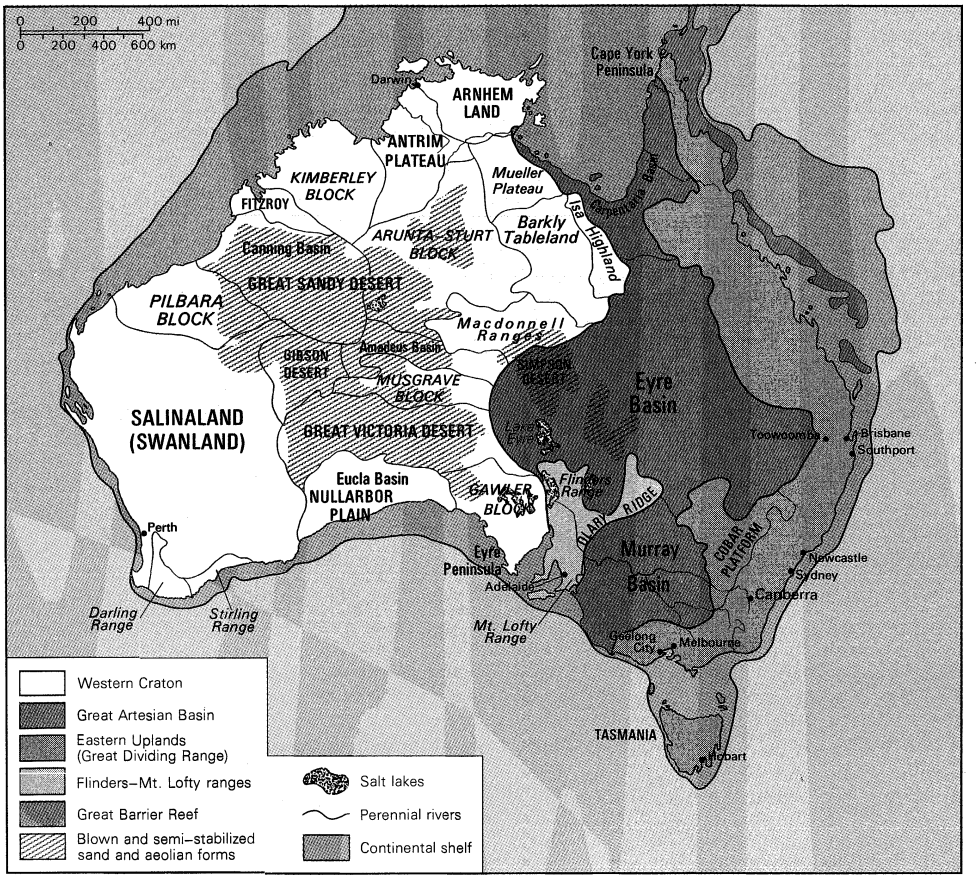
The Clarence–Moreton and Maryborough basins. On the border between New South Wales and Queensland, from south of Grafton to north of Brisbane, the Clarence–Moreton Basin developed in Triassic time as an offshoot of the Great Artesian Basin. It contains basic volcanic rocks and coal measures of several ages. The Maryborough Basin is the easternmost of the sedimentary basins. It is filled with nonmarine Triassic and coal-bearing Jurassic strata, followed by volcanic rocks, Lower Cretaceous marine sediments, and coal measures. These beds are the most strongly folded post-Paleozoic rocks in eastern Australia. It is now known that in other basins the Mesozoic and Tertiary rocks are slightly folded, but it is believed that the observed folds, such as those in the central part of the Great Artesian Basin, are due to movements of the underlying older rocks. The more intense folding on the eastern seaboard has been thought to be related to intrusions of Jurassic granites and a late structural phase in the development of eastern Australia.

Tasmania. The most important Mesozoic event in Tasmania was the large-scale (covering 2,000 cubic miles) intrusion of dark, layered volcanic rocks in Early to mid-Jurassic time. This process produced rocks similar to those in the Karroo region of South Africa, in Brazil, in Antarctica, and also in the Palisades of the New York area, in the Northern Hemisphere.

Cenozoic history of the Australian continent. During the Cenozoic Era, occupying the last 60,000,000 years of geological time, true mountain-building movements were confined to the island arcs in the north and east, but the Australian continent was not altogether stable. On the mainland, movements of the basic structural blocks produced some folding in the sedimentary cover of the basins, and uplifts and downwarps restricted or extended their boundaries. Faulting in the southeast and east led to outpouring of large fields of basalts in Victoria in mid-Cenozoic and Late Cenozoic time, and also to scattered but important volcanicity along the east coast. The mid-Miocene (20,000,000 years old) volcanoes of the Warrumbungle Mountains and the Tweed River areas in northern New South Wales and the spectacular Glass House Mountains in southeastern Queensland are the most important examples of this activity. In Victoria and parts of New South Wales, basaltic lava flows followed ancient valleys and buried their stream-deposited gravels. Known as "deep leads," they are locally gold bearing.

Late volcanic activity

The relative ages of the geological events that took place during Cenozoic time are still under study. There is no doubt about the late Cenozoic age of the uplift of the eastern highlands and also of the Flinders Ranges in South Australia, and the corresponding retreat of the sea from the Murray Basin. This process seems to have occurred intermittently throughout Tertiary time, perhaps culminating in a Pliocene–Pleistocene phase that has been named the Kosciusko Epoch, after the highest mountain on the continent (7,316 feet [2,230 metres]). During the Pleistocene ice age, an area of some 400 square miles around this mountain, and some surrounding valleys, were glaciated, as were large areas of the Tasmanian highlands. This weak but obvious expression of a worldwide climatic change is only one phase in a sequence of changes that affected Australia during Cenozoic time. Like the sequence of structural movements with which it is likely to be connected, the history of climatic changes is still disputed. The evidence of plant and animal fossils, together with determinations of the temperatures of the period, indicate that the climate in Early Tertiary (Eocene) time, some 50,000,000 years ago, was temperate in the south to tropical in the north. It was also humid, with rivers flowing to the south coast and coal-forming swamps existing in the areas of Eyre Peninsula and south Gippsland. Currents warmer than at present reached the south coast in early Miocene time (some 25,000,000 years ago), while during the late Miocene and Pliocene epochs there was a fall in temperature and a change in the plant life. This came to be dominated by eucalypts and acacias, replacing the southern beech (*Nothofagus*) that had been dominant in Early and mid-Tertiary time. Climatic change is also reflected by other evidence, for example by the large extent of lateritic weathering, causing the formation of red, iron-rich residual deposits as the result of



Physiographic regions of Australia.

Recent climatic changes

alternating wet and dry seasons. Whether the change to the present arid conditions of the inland regions was gradual and progressive is uncertain. Some soil scientists and biologists have postulated a period of greater aridity than the present, dated a few thousand years ago, but this is disputed by others. There is no doubt about changes of sea level as well as earth movements during the Pleistocene ice age: the eastern highlands were uplifted by some 2,600 feet, as was the western plateau, and there were corresponding changes of wind and ocean water-current patterns. These factors combined in an intricate manner with worldwide climatic changes to alter the climate during the last few million years. The last of the great hippopotamus-like marsupial herbivores (*Diprotodon*, *Nothotherium*) and giant flightless birds (*Genyornis*) died out when the great lakes in the centre of the continent (Lake Eyre [*q.v.*], Lake Callabonna, etc.) turned into salt pans only a few thousand years ago.

(M.F.G.)

PHYSICAL GEOGRAPHY

Relief. *Overall characteristics.* Australia is a land of great plains. The island continent is almost 3,000,000 square miles in area, but of this, only 6 percent is above 2,000 feet elevation. Its highest peak, Mt. Kosciusko, rises to only 7,316 feet. This situation stems in part from Australia's position at the edge of a zone of significant and recent earth movement and in part from the long periods of geological time during which Australia has been subject to weathering and erosion.

Patterns of faulting and folding in large measure control the distribution and attitude of rocks and thus play a significant part in determining the shape of the land surface. But the nature and intensity of the processes at work at and near the land surface also give rise to characteristic assemblages of forms. Australia is an arid continent; fully one-third of its area is occupied by desert, another third is steppe or semidesert, and only in the north, east, and southeast is rainfall adequate to support a vegetation that significantly protects the land surface.

The Western Craton. The ancient west Australian core area, known geologically as a shield, or craton, is subdivided, most obviously in the north and west, by long, straight (or only gently arcuate) fractures called lineaments. These fractures delineate prominent rectangular or rhomboidal blocks, some of which have been raised to form uplands, others of which have been depressed to form lowlands or topographic basins. The lineaments display strong northwest–southeast and northeast–southwest trends in the northern, northwestern, and southeastern parts of the shield, but east–west alignments are prominent in the centre, and major structural lines are more nearly meridional in the west and southwest. In all areas, however, trends other than those locally dominant can be discerned.

The role of lineaments

Within such structurally defined areas as the Kimberleys, the Isa highlands, and the Pilbara, the nature of the land surface varies according to the type and disposition of the rock outcrops. In the Kimberleys and the Mueller Plateau there are extensive outcrops of flat-lying massive sandstone that have been dissected to give rise to the striking isolated rock features known variously as plateau, mesa, and butte. Under these circumstances, local joints and bedding planes in the rocks, combined with the permeable nature of the bedrock, control the local landforms. Similar plateau forms dominate the Pilbara and Arnhem Land, though in the former region horizontally bedded or only gently warped massive ironstone formations, together with massive sandstones, give rise to prominent bluffs bordering the plateau assemblages; and in the latter karst landforms (greatly eroded by solution) are developed where limestone occurs at the surface. At the margins of the Kimberleys (in the Fitzroy region and in the Durack Range) and in the southern part of the Pilbara, in the Ophthalmia Range, dipping rock strata have been differentially eroded to form ridges and valleys. Such features are also extensively and well developed in the uplands of central Australia (the Macdonnell, James, and Kirchauff ranges), in the Isa highlands, and in the Stirling Range of the southwest. In all of these areas

it is the sandstones and quartzites that underlie the upstanding ridges, the intervening valleys being eroded in siltstones or shales; and in all these areas the pattern in plan of ridge and valley reflects the pattern of folding in the underlying rocks.

In the far southwest, the Darling Range forms an upfaulted block underlain mainly by granite but capped by laterite, a reddish, iron-rich product of weathering rock. The Gawler Block in the southeast, is complex. There are crystalline and sandstone uplands in the east, sandstone plateaus in the northeast, and, in the centre and north, the rounded Gawler Ranges built of Precambrian lava flows.

Isolated inselbergs

Much of Eyre Peninsula is occupied by a rolling plain traversed by fixed sand dunes, but in the northwest numerous low isolated granite rocks of spectacular appearance, called inselbergs, stand above the plain. These epitomize the isolated ranges and hills widely developed in the northwest of South Australia, in the Musgrave, Everard, Birksgate, Mann, and Tompkinson ranges.

The lowlands between these raised blocks also display varied topography. The so-called Barkly Tableland is in reality a high plain of remarkable flatness, partly eroded in Cambrian sedimentary rocks and partly underlain by Tertiary swamp deposits. The Nullarbor Plain, is approximately coincident with the Eucla Basin. A vast area of the southwest of Western Australia is occupied by Salinaland, an extensive high plain traversed by elongate ribbons encrusted with salt, the desiccated and disrupted remnants of former river courses. The Gibson Desert consists in large part of a laterite-capped plain, but huge areas of the plains of central and northern Australia are occupied by active sand dunes, and large areas of southern South Australia and Western Australia are covered by fields of fixed dunes.

Actively developing and moving sand ridges occupy the Canning Basin (the Desert Basin), the Great Victoria Desert, the Amadeus depression and large areas of the Arunta–Sturt Complex. The dune fields extend to the east into the Great Artesian Basin, where the dunes constitute the well-known Simpson Desert. These dune deserts reflect the prevailing aridity of most of Australia, and the dune trend displays a huge swirl around the centre of the continent.

But even in these most arid areas—the area around Lake Eyre averages less than five inches of precipitation per year—rain falls from time to time, and the rivers run occasionally. Because of the scarcity of vegetational protection, and because of the common development of impermeable rock layers of various types, runoff in the arid lands tends to be rapid and to achieve dramatic and significant results. Hillslopes are scoured and washed bare of weathered debris; streams erode gullies and transport large volumes of sediment from the uplands to the plains; broad braided river channels are developed; and extensive alluvial plains are formed. It is the alluvium, carried to the lowlands by rivers and deposited on the plains, that is, in large measure, the source of the sand out of which the desert dunes are molded by the wind.

Effects of rapid water runoff

In the far southwest of the shield, and especially in the northern areas, rainfall is sufficient to support a considerable vegetation and is regular enough for streams to flow seasonally. Here the work of rivers in shaping the land surface is more obvious and widespread; the landscape consists essentially of valleys and intervening divides, the precise form of each depending on local structure. But in such areas the rate of landscape change is more rapid than in the arid zones.

Many of the landforms of the shield are inherited from the past, when different climatic conditions obtained. Remnants of laterite are widespread in many parts of Australia: the Darling Range, Salinaland, the Isa highlands and Mueller Plateau, the Darwin area, southern Eyre Peninsula. Clearly, at some time or times in the Tertiary Period, these areas had been reduced to low relief, and humid tropical climates prevailed, for laterite is at present forming only under such conditions in such areas as Southeast Asia and the Congo Basin. The disrupted former drainage system of Salinaland has already been referred to, and remnants of similar old stream networks occur in the Amadeus depression, on the Nullarbor Plain, and in the Great Victoria Desert. A large swamp formerly occupied the south of the Barkly Tableland; and Lake Woods, near Newcastle Waters, is now dry, with a bed of some 70 square miles in extent, but shorelines indicate that the lake formerly occupied some 1,100 square miles. Fossil remains also suggest wetter climates in the past in many parts of Australia, and subsequent deterioration toward aridity. But in the south the occurrence of dunes now fixed by vegetation shows that the climate there has recently become moister.

Finally, it may be mentioned that in several parts of the shield remnants of eroded surfaces, planed off and covered with hard, silicified crusts of weathered rock cut across local bedrock and are preserved either high in the relief or buried beneath later sedimentary deposits. They attest to changes in the disposition of the land surface (either base-level changes or regional warping or faulting) and also indicate that at times in the past surfaces of low relief similar to those that exist at present were widely developed. Reference has already been made to the distribution of the laterite surface. At the eastern margin of the shield there are remnants of a still older surface, of late or middle Mesozoic age, which has been warped by subsequent earth movements and now disappears beneath the sediments of the Great Artesian and similar basins. Evidence of the existence of this surface has been forthcoming from northwestern Queensland, central Australia, and South Australia.

The Flinders–Mt. Lofty ranges. Adjacent to the southeastern extremity of the shield, these uplands occupy the site of the Adelaide Geosyncline, or downwarp in the Earth's surface. These sediments were folded and faulted, principally in the early Paleozoic, though recurrently since. The Flinders Ranges are a much-eroded fold mountain belt characterized by ridge and valley forms in which sandstone ridges and bluffs are dominant. The Willochra Plain occupies an elongate intermontane basin excavated from a major upwarped structure and achieved through the erosion of some 20,000 feet of sediments. There are remnants of old land surfaces of low relief, and, in the north, extremely rugged relief developed on a much-shattered granite outcrop.

The Willochra Plain

To the south, the Mt. Lofty Ranges are a much dissected and complex horst, or ancient uplifted structural block. Bounded on both east and west by meridional or gently arcuate fault scarps, which developed initially in the Early Paleozoic but which have suffered recurrent movements since (and which indeed are still active), the ranges are surmounted in many areas by the remnants of a lateritic plain. In many other areas, such a hard capping of rock, if ever present, has been eliminated by stream erosion. Sandstones again form prominent ridges and residuals (isolated relief features), like Mt. Lofty itself; small granite outcrops give rise to boulder-strewn surfaces; and exposures of gneiss form slablike blocks known as tombstones, monk stones, or penitent rocks.

Between the Mt. Lofty and the Flinders ranges is the midnorth, a region of broad simple folds in which the sandstone ridges run for the most part north–south and in which the broad open valleys were in some instances occupied by lakes during the Tertiary Period, some 50,000,000 years ago. Similar upland areas of low relief, but with domes of crystalline rock standing above the general level, dominate the Olary Arc, which swings northeastward from the midnorth region.

The Great Artesian Basin. This platform area consists of three major basins, the Carpentaria Basin, the Eyre Basin, and the Murray Basin. Between the Carpentaria and Eyre basins the Euroka–Kynuna Plateau barely rises to reach the surface in such minute residual relief elements as Mt. Brown and Mt. Fort Bowen, in northwest Queensland. The Wilcannia threshold separates the Eyre and Murray basins, and the latter is separated from the Otway Basin and the Southern Ocean by the Padthaway Ridge. The two southern basins are entirely terrestrial, but the Carpentaria is partly inundated by the sea.

The Carpentaria plains, occupying the basin of the same name, form a narrow lowland corridor between the Isa

highlands and the Einasleigh uplands (part of the Eastern Uplands). They are drained by the Leichhardt, Flinders, and Gilbert rivers, and in the south take the form of broadly rolling plains underlain by heavy gray lime-enriched (pedocalcic) soils and known as the Rolling Downs. In the north, however, there are extensive flat depositional plains, some of them related to Pleistocene swamps, some associated with the present floodplains of the braided river systems. Standing above the plains, for example around Normanton, are considerable plateau and mesa remnants of the Tertiary laterite surface.

Similar rolling plains with laterite residuals standing above them occur in the Eyre Basin, particularly around the headwaters of the Diamantina, near Kynuna. But to the south, toward the more arid interior, the plains become flatter and are protected by a veneer of stones—the well-known stony desert with its mantle of gibber (hammada, serir, desert armour). In many parts of southwestern Queensland, northeastern South Australia, and northwestern New South Wales there are plateau and related relief remnants similar to those found in other parts of the lowlands, although these are capped and protected not by laterite but silcrete, another hard rock residue. This region is folded in places, and the subsequent dissection by erosive forces has brought about disintegration of the silcrete, which is of Middle Tertiary age and which formerly extended over vast areas of central Australia. This process provided much stony debris for the gibber plains so characteristic of much of central Australia and particularly of the Lake Eyre depression.

Lake Eyre

The catchment of Lake Eyre (*q.v.*) extends over some half million square miles of central and northern Australia. It occupies the lowest point of the Australian continent (46 feet [14 metres] below sea level) and many large river systems drain into it. These rivers drain the driest part of the continent. But no desert is rainless, and floodwaters cover the bed of Lake Eyre about twice each century, the waters deriving not only from central Australia but also from the higher rainfall areas drained by the headwaters of the Georgina, Diamantina, Thomson, Barcoo, and similar rivers. It is now clear that during the late Pleistocene period, more than 10,000 years ago, the rainfall of central Australia was heavier than it is now; as a consequence, these rivers, past and present, have brought vast quantities of sediment and salt to the interior drainage basin. As a result, there is ample source material for the Simpson Desert dunes, and many of the normally dry lake beds, including all the large ones, are encrusted with salt. Most of the very large salinas, or salt pans (Eyre, Frome, Torrens, Gregory, Blanche), are, at least in part, of structural origin, having been formed by downfaulted blocks. Torrens and Gregory are surfaced mainly by gypsum, but the remainder carry a crust of sodium chloride, common salt. Around the major salinas there are extensive alluvial plains.

Under the prevailing arid conditions, fine dust is winnowed from the surface sediments and can be carried high into the air in dust storms. Some is carried long distances, even reaching New Zealand from time to time. The sand of the alluvium is molded into dune ridges.

Sand dunes also occupy large areas of the Murray Basin. They are, by contrast, fixed (or "fossil") dunes, which developed at some time in the recent past and have since been stabilized by higher rainfall conditions. In the east of the basin, near the foothills of the Eastern Uplands, there is evidence of former higher rainfalls in the numerous abandoned river channels of the Riverina. But the western Murray plains are a stony as well as a climatic desert. The plains are underlain by Miocene limestones and, in many areas, by calcrete, a calcareous soil accumulation. There are instances of water-dissolved sinkholes and enclosed depressions, and lack of surface drainage characteristic of this type of topography. Only the Murray, which originates outside the area in a different environment, crosses the basin, flowing in a narrow trench in its lower reaches.

In the east of this region there are extensive alluvial plains associated with major tributaries of the Murray. One feature of interest is the diversion of the Murray, near Echuca, by a rising structural block bounded by fault zones and known as the Cadell Fault Block.

The Eastern Uplands. This complex series of high ridges, high plains, plateau, and basins extends from Cape York Peninsula in the north to Bass Strait in the south, with a southerly extension into Tasmania and one extending westward into western Victoria. The uplands are the eroded remnants of an ancient mountain range recently rejuvenated by block faulting. They occupy the site of the Tasman geosynclinal belt, the sediments of which were folded and faulted in late Paleozoic times. Granite batholiths were intruded into this region, and during the Cenozoic Era lavas appeared extensively in areas as far apart as north Queensland and Tasmania. Characteristic features associated with this process were lava fields, with stony rises, soil-filled depressions, and lava caves. Extinct cones and craters survive in southeastern Queensland, in the Monaro district of New South Wales, and in western Victoria.

Volcanic landforms

The landforms, in considerable measure, reflect these various geological events. Uplifted structural blocks, many of them trending north to south, are common in some areas, while straight river courses reflect the control exercised by fault zones. Ridge and valley forms, as found in the Grampians of Victoria, reflect the differential erosion of broken and folded rock strata. On the exposed granitic batholiths, massive domes or clusters of boulders are common. The lava plains and plateaus display stony rises, shallow alluvial depressions, and volcanic vents and plugs of various types and ages.

Other features reflect the erosional history of the region. Wide areas of the upland had been reduced to a uniform low relief by the time of the later Mesozoic Era, about 100,000,000 years ago, and many remnants of this ancient surface, exhumed by erosive action from beneath a Later Cretaceous cover, survive in the landscape, notably in north Queensland. The Middle Tertiary leaching of rocks by weathering in humid climates with the formation of iron-rich residuals (laterization) also affected the uplands, from northern Queensland to Tasmania.

Lastly, during the Pleistocene Epoch, some 2,000,000 years ago, small glaciers developed in the Kosciusko area of New South Wales and the central plateau of Tasmania. Small, ice-scoured hollows and small moraines (ridges of glacial debris) attest to these events, while over rather wider areas frost shattering of rocks and resulting down-slope flowage of soil (solifluction) have helped shape the surface. No snow normally survives through summer in either of these areas now, but in winter the snowfields of the Kosciusko area alone are more extensive than those of all of Switzerland.

The Great Barrier Reef influence

The Great Barrier Reef (*q.v.*) is related in important respects to the Eastern Uplands. Lying off the Queensland coast, this great system of coral reefs and atolls owes its origin in part to Pleistocene changes in sea level but in most part to long-continued subsidence, related to faulting, of the offshore region. This slow subsidence has enabled a great thickness of coral to develop, and it is on this basement that the present reefs and coral atolls have grown in the clear warm waters of the Coral Sea.

The coming of man. Though neither aboriginal man nor the later European settlers have been long in Australia, they have already achieved widespread, and in most ways deleterious, effects on the landscape. European man in particular has been responsible for initially minor, but later significant and widespread, changes, notably considerable soil erosion. The clearing of vegetation for agricultural purposes, overgrazing, the introduction of exotic plants and animals, the making of tracks and roads, even the clearing of stones from paddocks—all have rendered the land surface more susceptible to soil erosion. Man has set in train his own great cycle of erosion, similar to that which beset many parts of western Europe in the 18th century and which has assailed many parts of the American West since late in the 19th century.

Climate. Australia is the arid continent. Over two-thirds of its landmass rainfall per annum averages less than 20 inches and over one-third of it is less than 10

Eastern Highlands (Great Dividing Range).

inches. Only just over 10 percent receives more than 40 inches per annum. As has been noted, in winter the snowfields of Tasmania and the Kosciusko area can be far more extensive than those of Switzerland, but on the whole Australia is a very hot country with a high incidence of heat waves, in consequence of which evaporation losses are high and the effectiveness of the rainfall received is reduced. In addition, the severity of climate, the predominance of the outdoors in the minds and lives of many, and the national importance of agricultural and pastoral pursuits, all make Australians perhaps more climate-conscious than most. In no country of comparable development do climate, the weather map, and the latest forecast loom so large in the lives and conversation of the common man.

Major influences on climate

The principal features of Australia's climate stem from its position, shape, and size. Australia is a compact tropical and near-tropical continent located between latitudes 10°41′ S and 43°39′ S. No major arms or embayments of the sea penetrate far into the landmass. The only extensive uplands occur near the east coast, and even they are not, by world standards, very high.

In summer, when the sun is directly overhead in northern Australia, temperatures are extremely high. The sea exerts little moderating influence, and the uplands are not sufficiently extensive or high to have more than local effects. Because of the lack of cloud over most of the interior, however, while maximum temperatures commonly soar over the 100° F mark, there is considerable radiation loss at night, and daily temperature ranges are quite high. But, on the whole, high temperatures dominate the Australian summers in all but Tasmania. Heat waves are common, and though the highest amounts of radiation are received in northern South Australia, the highest temperatures and most extensive heat waves are recorded in the northwest of Western Australia. Marble Bar, for instance, has recorded a maximum temperature of 100° F or more on 162 consecutive days. Temperatures in winter remain moderate except in the uplands of Tasmania and southeastern Australia, where snow is common. Night frosts are common in winter throughout southern Australia and in the interior.

Because of its latitudinal position, Australia comes under the influence of the southeast trade winds in the north and the westerlies in the south. Northern Australia is affected by a northerly monsoon, partly because of

the latitude and the seasonal migration of planetary wind zones and partly because of the summer heating of the continent and the indrawing of surface winds. The monsoon brings summer rains to the northern coastal area and extends inland for variable distances. These summer rains are all the more important because most of northern Australia is in the sheltered rain shadow of the Eastern Uplands so far as the southeast trades, which are dominant in winter, are concerned. The trades, forced to rise by the uplands, bring heavy rains to the Pacific coast of Queensland and of northern New South Wales. These areas, which are also affected by tropical cyclones, receive the heaviest rains of any part of Australia, and, within this coastal fringe, the north Queensland area around Cairns is the wettest.

Southern Australia receives winter rains from depressions associated with the west-wind zone. Again there are local topographic controls, with uplands receiving more than the adjacent plains. Parts of the southern Mt. Lofty Ranges, in South Australia, average over 40 inches of rainfall per annum, but Adelaide, to the west, averages only 21 inches, while the Murray plains, in the rain shadows of the ranges, receive 15 inches or less rainfall annually.

The dry interior

In the great mass of the interior of Australia, rainfall averages less than 20 inches per annum, and over vast areas the total is less than 10 inches; the Lake Eyre region averages less than 5 inches. Rainfall in these areas is unreliable and capricious, with long droughts broken by damaging rains and floods. Over Australia as a whole, rainfall is indeed extremely variable. Only in the far north, around Darwin, in the southwest of Western Australia, in southern South Australia and Victoria, in Tasmania, and in eastern New South Wales is the recorded annual rainfall not more than 10 percent above or below the long-term average in different years.

Drainage. Permanently flowing rivers are found only in eastern Australia and in Tasmania. The major exception is the Murray, a stream that rises in the Kosciusko region in the Eastern Uplands and is fed by melting snows. As a result, it acquires a volume sufficient to survive the passage across the arid and semi-arid plains that bear its name and to reach the Southern Ocean southeast of Adelaide. All other rivers in Australia are seasonal or intermittent in their flow, and those of the arid interior are episodic.

Many areas—notably the Nullarbor Plain, underlain by limestone, and the sand ridge deserts—are without surface drainage. A map of Australia can be misleading;

though many "lakes" are depicted in the interiors, the fact is that many of them are now salt lakes that contain no water for years on end (see also below, *Natural resources: water resources*).

Soils. In broad view, the continental pattern of soils is closely related to climatic factors; mineral or skeletal soils exist over much of arid Australia, with virtually no organic content and little development to any depth. They may consist merely of a rough mantle of weathered rock. Gypsum is present in many of the desert loams and arid red earths. The soils of the semi-arid regions (where annual rainfall is from 8 to 15 inches) are also alkaline, with gypsum and lime a common feature. The organic content of the soils is again low in the solonized (salt-enriched) brown soils and the gray and brown soils of heavy texture that are common in these areas.

In both the arid and semi-arid regions gilgai—patterns of swells and depressions due to the alternate swelling and contraction following wetting and drying of clay soils—have developed. They are especially well represented in areas of seasonal rainfall. In areas with 15 to 25 inches of annual rainfall, black earths, brown soils, and red-brown earths are the most common soils. In the wetter areas the leaching out of minerals is a prominent feature of the soils. Podsols—sandy, with much humus at the surface and acid throughout—are the characteristic soil types. In the alpine regions humus soils—surface peats over a mineral—are noteworthy.

Local soil variations

Superimposed on these broad, climatically determined, soil patterns are local variations due to topography, groundwater conditions, and parent materials. For example, red soils of one kind (krasnozems) are developed on the basalt outcrops so common in eastern Australia, and those of different composition (terra rossas and rendzinas) on calcareous bedrock. In addition, laterite and silcrete originated in remote geological times, when conditions were very different from those of today. Laterite is represented in every state, including Tasmania, though it is forming nowhere in Australia at the present time, while silcrete is restricted to arid Australia and parts of subhumid Western Australia, South Australia, and Queensland. PLANT AND ANIMAL LIFE

Plants and vegetation. *Overall characteristics.* Less than 200 years ago, Australian vegetation was still in its primal stage; the older plants in its present woodlands and forests began their lives before the continent was invaded by civilized man. So close is the continent's prehistory that many a eucalypt still bears the great scar of a canoe or shield cut from its bark by Aborigines. Others can be found bearing blazes and inscriptions dating back to the first years of exploration and settlement.

In the short history of modern Australia, vast changes have been wrought in the continent's vegetation. Agricultural expansion stripped whole regions, substituting introduced crops, pastures, and plantations, while uncleared areas near the new settlements, ranging from the densest forest to the sparsest woodland, were cut through for timber. Enormous central and northern areas, too arid for agriculture or too remote for timber getting, were stocked with millions of sheep and cattle. In addition, many weeds were introduced, along with rabbits, other herbivorous vermin, and frequent bush fires. The native vegetation is still in that moment of destructive upheaval that marks the passing from aboriginal man to technological man and domestic flocks. By the 1970s, reserves and wilderness areas held some native vegetation as national heritage, although it remains doubtful if these are adequate or sufficiently protected.

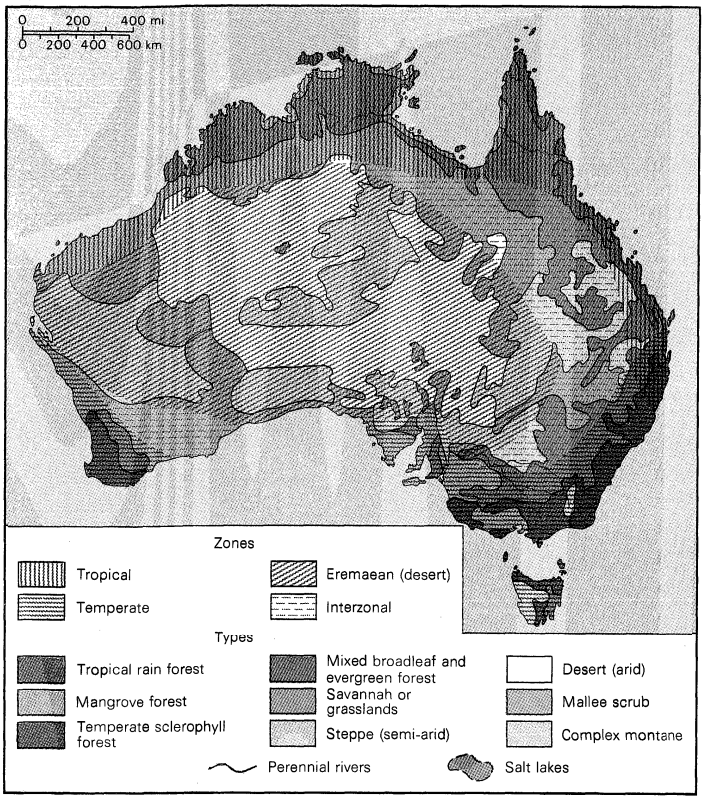
Plant life. Australian federal and state governments maintain institutions for the scientific collection and study of the kinds (or taxa) of plants. Cumulative knowledge of Australia's flora stems mainly from these endeavours and is partly available in handbooks (Floras) listing species, together with appropriate "keys" for their recognition. G. Bentham's *Flora Australiensis* (1863–78), based on 19th-century collections sent to Europe, remains—although much outdated—the only comprehensive survey of Australian flora. More up-to-date information, scattered in the botanical literature, is not easily accessible except to professionals.

Plant origins

Australia's phanerogamic (seed plant) flora is estimated at 15,000 to 20,000 species, believed to be a blend of elements from various original sources and the outcome of a long and complicated history. One contribution to the present plant patterns is thought to have originated, in the remote past, from some southern landmass which then linked all the present southern continents. There is evidence to support this view: Australia shares with South Africa, Madagascar, New Zealand, and South America such plants as the southern beech (*Nothofagus*) and characteristic genera in other families, which constitute an Antarctic element.

Australia also shares many more kinds of plants with its northern neighbours. Also, typically Australian genera such as *Callitris* (native pine), *Banksia,* and *Eucalyptus,* extend into the Indo-Malaysian area, some as far as the Celebes. This evidence has given rise to the idea of an Indo-Malaysian element in the Australian plant life, in a process that involved some two-way exchanges. These, and other links with plant life elsewhere, have prompted various hypotheses invoking the development of species, migrations, and extinctions throughout geological time, along with changes in the disposition of land, sea, and climate.

That characteristic part of Australia's plant life that is not much shared with other lands, together with those specialized characteristics that apparently originated in the continent long ago, form what has been designated as an Australian (or autochthonous) element. It includes many of the plants lending character to typical Australian vegetation scenery. It also shows a marked tendency to sclerophylly (formation of hard leaves) and wide-ranging adaptation in many genera, extending their species throughout the whole range of the continent's environmental habitats. Most obvious to the visitor are the gum trees (*Eucalyptus*), which are represented by over 600 species, ranging in size from diminutive mallees, smaller than a man, to forest giants matching in bulk



Zones and types of vegetation in Australia.

and height the world's biggest plants. Their habitat is similarly varied, ranging from rain forest to snowfield to hot desert fringe. *Acacia* has undergone similar adaptive radiation; its species range from mulga and myall—the dominant trees of vast areas—to small leafless blades at ground level. The banksias and hakeas (Proteaceae), the grass trees and blackboys (Xanthorrhoeaceae), and the kangaroo-paws (Haemodoraceae) are examples of the many other characteristically Australian plants.

Vegetation. Vegetation, as opposed to plant life, implies the structure and communal relations of the landscape's plant cover, whether it be forest, grassland, or marsh. There is no standard, or worldwide, classification system (such as exists for describing flora) for this aspect of the environment. Initial attempts to apply European and American classification ideas and methods to Australia were not particularly satisfactory, as a result of the peculiarities of the continent's vegetation and environment. For example, climatic control of local vegetation zones was often found insufficient to support vegetation analysis; on the contrary, soil patterns and geological history quite override climatic control in many localities. Similarly, structural descriptive schemes useful for Northern Hemisphere coniferous and deciduous vegetation proved quite inappropriate when confronted by the great variety of evergreen vegetation—notably mallees and scrubs—found in Australia. By the 1970s, mapping of Australian vegetation was based largely on factual descriptive features, and by this means such comprehensive and detailed accounts and maps as those contained in the *Atlas of Australian Resources* and *The Australian Environment* (see *Bibliography*) had been produced. Scientific vegetation analysis, as opposed to mapping, is also well advanced in Australia, contributing modern ideas equal to those anywhere else in the world.

Classification difficulties

Modern Australian plant life is distributed in three main zones—the Tropical, the Temperate, and the Eremian—which reflect overall climatic conditions. The first zone, arced east and west across the north margin of the continent and extending halfway down the eastern seaboard, has a mainly dry monsoonal climate, with very wet patches. The second, with a cool to warm temperate to subtropical climate and mostly winter or nonseasonal rainfall, is arced across the southern margin, embracing Tasmania and extending up the eastern seaboard to overlap slightly with the Tropical Zone. The third zone covers the whole of central Australia, through to the central west coast; its climatic characteristic is aridity.

The major structural units comprising this geographical distribution are rain forest, sclerophyll forest (dominated by hard-leaved plants such as eucalypts), woodland, scrub, savanna, and grassland forms, each with a range of subforms. The bulk of the Tropical Zone carries mixed deciduous woodland and sclerophyll low-tree savanna, with areas of tussock grassland, coastal mangrove complexes, and tropical rain forest. There is a high occurrence of exotic vegetation, particularly in the northeastern part of Cape York Peninsula, in Queensland, and a strong Indo-Malaysian influence occurs throughout the entire zone. The rain forests, with large trees with stem buttresses, and multiple vegetation layers with interlaced canopies, lianas and epiphytes growing parasitically on the trees, qualify technically as jungles.

The Temperate Zone

The Temperate Zone is characterized by dry and wet sclerophyll forests, temperate mixed woodlands, savannah woodlands, mallees, and scrubs, with areas of Alpine vegetational complexes, temperate rain forest, and sclerophyll heath. Native plants form a much higher proportion of the vegetation cover, much of which is typically and recognizably Australian. Within this zone the southwest corner of Western Australia is outstanding, both for the high proportion of Australian plants and for the richness of the plant life, while the vegetation of Tasmania is notable for its southern beech forests and for its links with New Zealand and South America. In marked contrast to the tropical rain forests, the predominant trees throughout the majority of the Temperate Zone communities are either *Eucalyptus* or *Acacia*. Much of the Temperate Zone vegetation has been cleared for agricultural purposes, leaving only the vegetation communities of infertile or inaccessible localities.

The vegetation of the Eremian Zone ranges from barely vegetated desert sand hills through a variety of semi-arid shrub savannas, shrub steppes, semi-arid tussock grassland, and sclerophyll hummock grasslands. Many shrubs have adapted themselves similarly to the arid conditions so that in their vegetative state representatives of numerous families look alike. *Acacia*, *Eremophila*, and *Casuarina* are examples of genera that tend to displace *Eucalyptus* as the dominant tree shrub. Much of this vegetation is badly degraded. (R.T.La.)

Animal life. Human activities had a modifying and generally destructive influence on Australian animal life, or fauna. The arrival, about 30,000 years ago, of the Aborigines was in this respect less significant than European occupation, which has had profound effects over a period of only two centuries. The Aborigines brought only the dingo, a placental carnivore that must have affected the native marsupials. The Aboriginal hunters and food gatherers lived in ecological balance with their environment, and their demands were not large enough nor their technology sufficiently developed to upset it. There is even less scientific evidence to link them with the extinction of the large Pleistocene mammals than there is in other continents. All this changed with the advent of the Europeans: their cats, rats, foxes, rabbits, cattle, and sheep and their technology modified and largely destroyed important habitats of the Australian fauna. The inhabited coastal region (and even part of the arid inland regions) of the continent now contain a very much modified fauna compared with the indigenous life of only 200 years ago, which cannot now be reconstructed.

Destructive effects of Europeans

The Australian fauna is markedly different from that of the nearest land areas, the islands of Indonesia. A 19th-century biologist, Alfred Russel Wallace, designated an Australian zoogeographic region in 1876 and drew the boundary separating it from the Oriental region of Southeast Asia between Bali and Lombok and between Borneo and Celebes. This division, which became known as Wallace's line, is still recognized in modern biogeography as the boundary of a transitional zone, across which animals spread according to their ability to cross

narrow seaways. These passages were much narrower during the Pleistocene glacial periods of the last 600,000 years, when so much oceanic water was frozen at the poles that the sea level fell to or beyond the edges of the continental shelf that now fringes Australia. At such times, the continent had land connections with New Guinea and Tasmania, while remaining separated from the Indonesian Archipelago during all of Cenozoic time (*i.e.*, for the last 50,000,000 years). The history and origin of the distinctive Australian fauna has led to much controversial speculation and searching for relationships among the southern continents.

A published count (Keast *et al.*; see *Bibliography*) indicates the existence of 108 placental mammal species, 119 marsupials (125 according to a later count), 2 monotremes (the spiny anteater and the platypus), 520 birds, about 380 reptiles, 122 frogs, and 180 freshwater fish. There are also more than 54,000 species of insects (Mackerras, 1970; see *Bibliography*) and about 750 species of mollusks. The placental mammals (apart from those introduced by man) belong to groups that can swim (seals), fly (bats), or drift on logs (rodents).

The role of marsupials

The marsupials are considered distinctive Australian animals because they are more abundant and more differentiated on the Australian continent than in America, where few, and in Europe, where none, has survived. They are not closely related to any fossil or living species found elsewhere. Their history in Australia has been traced back to fossil remains not more than 25,000,000 years old; that is, for less than one-half of the time of their presumed existence in isolation in Australia. There isolation from placental predators and competitors gave them time to differentiate. The kangaroos, herbivores of the open woodlands and grasslands (occupying the habitat of horses or antelopes elsewhere); the tree-dwelling cuscuses (*Phalanger*) and flying phalangers or gliders (*Petaurus*), resembling flying squirrels; the "native bear" or koala (*Phascolarctos*), which is specialized to live on eucalypt leaves; the burrowing wombat (*Vombatus*); the native cats (*Dasyurus*); the marsupial mice (*Sminthopsis* and *Antechinus*); the numbat or banded anteater (*Myrmecobius*); the dog-sized Tasmanian wolf (*Thylacinus*); and, finally, the marsupial mole (*Notoryctes*) are examples of the adaptive differentiation of these mammals.

The only surviving monotremes (egg-laying primitive mammals) are the duck-billed platypus (*Ornithorhynchus anatinus*) and the echidna or spiny anteater (*Tachyglossus aculeatus*). The echidna is common and widely distributed; the platypus, now completely protected by law, is common in streams and lakes in eastern Australia.

There is much concern among nature lovers and conservationists in Australia about the obvious and increasing losses suffered by the marsupial fauna. These are due both to increases in rangeland agriculture and to the largely uncontrolled exploitation of the kangaroos. According to one observer,

> The lands of arid Australia have been grazed by sheep, cattle and rabbits for periods varying from a few years in the most recently occupied areas to a little over a century in the oldest settled parts, a period short in comparison with most other arid lands of the world. In that short period we have caused far more degeneration of land resources than the aborigines caused in twenty to thirty millennia. Australia is fortunate indeed that the period has been so short. (From R.O. Slatyer and R.A. Perry [eds.], *Arid Lands of Australia;* Australian National University Press, 1969).

To this progressive destruction of habitat has to be added the effect of loosely controlled, or uncontrolled, shooting of kangaroos for meat and fur. The export value of kangaroo products doubled from 1960–65 to reach over A$3,000,000 and the kangaroo harvest in Queensland alone exceeded A$1,000,000 in 1965.

> The crop must be controlled or the resource will be brought so low that it will be lost and these wonderful animals be reduced, like the American bison, to a small remnant confined to reserves. (From W.D.L. Ride, *A Guide to the Native Mammals of Australia*, 1970.)

Discussions of the feasibility of commercial kangaroo farming was just starting in the 1970s, although popular opinion had forced the government to take measures for the strict protection of the koalas, which were in danger of extermination, some 50 years earlier. Many small marsupials are also threatened, and some have been eliminated in their original habitats by marauding cats and foxes. Conservationists hope that the increasing number of national parks and reserves will assist in the preservation of the native fauna, though supervision in the vast, almost uninhabited inland areas, where natural conditions remain least disturbed, is a serious problem.

Australian birds

Dangers similar to those threatening the marsupials also affect the birds of Australia, many of which are also native to the continent and, therefore, of great scientific interest. The best known typically Australian birds are the flightless emu (*Dromaeus*), the mallee fowl (*Leipoa*, which builds a mound-shaped nest for hatching its eggs and actively controls the mound's temperature), the spectacularly abundant cockatoos (*Cacatuinae*), the lyrebirds (*Menura*), fairy wrens (*Malurus*), honey-eaters (Meliphagidae), Australian magpies (Cracticidae), and bowerbirds (Ptilonorhynchidae).

Australia has one freshwater crocodile (*Crocodylus johnstoni*), which lives in the tropical north but is also represented in rock engravings made by Aborigines in South Australia. There are ten freshwater tortoises belonging to a family (Chelyidae) that is also known from South America. Lizards include geckos, skinks, legless lizards, and goannas, or monitor lizards (*Varanus*), which have relatives in Southeast Asia and Africa. There are many poisonous snakes, of which the taipan (*Oxyuranus scutellatus*), the tiger snake (*Notechis scutatus*), the death adder (*Acantophis antarcticus*), and the brown snake (*Pseudonaja textilis*) are most dangerous to man.

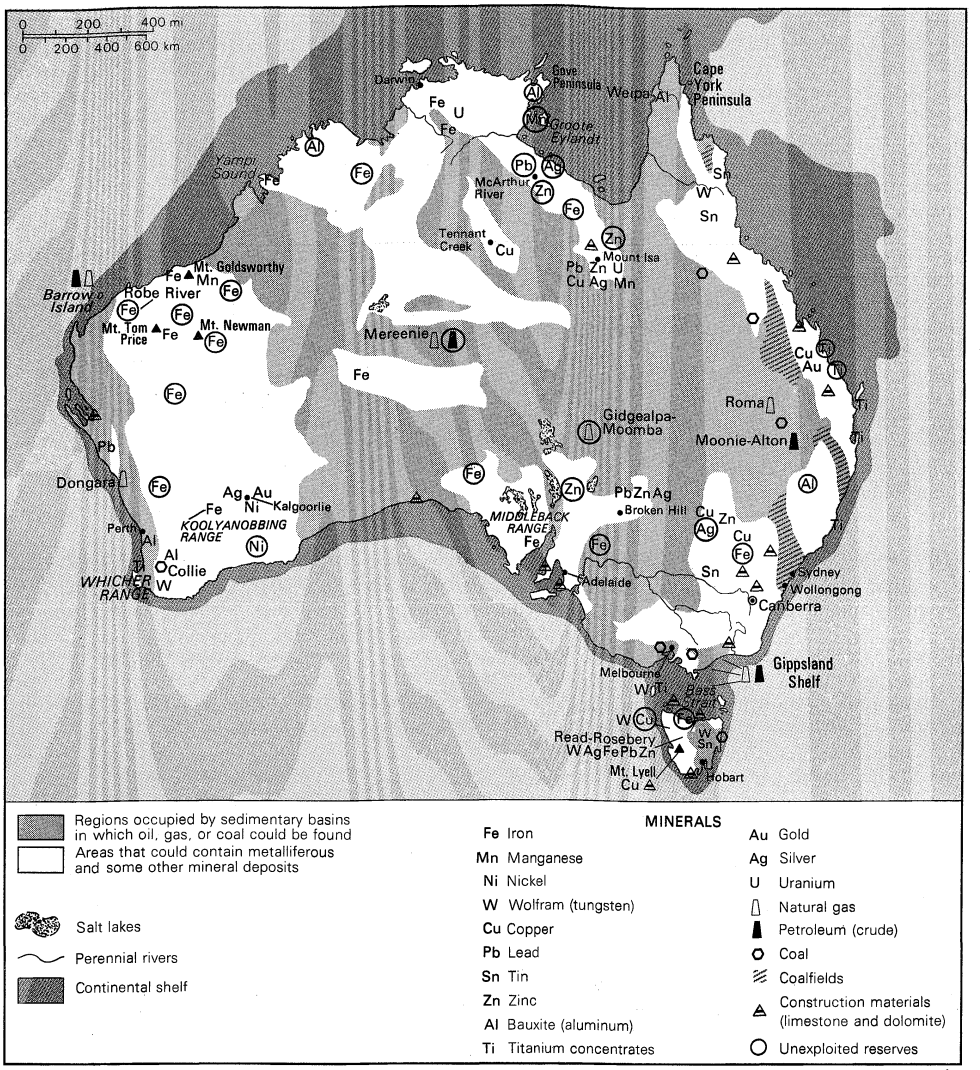
The isolation and predominant aridity of Australia makes its freshwater fish fauna an interesting object for study. The Queensland lungfish (*Neoceratodus*) has lived in Australia without change for millions of years and is very much like its European ancestors of 200,000,000 years ago; it is very different from African and South American lungfishes. European fishes introduced recently into some Australian rivers and streams seem to be a danger to the survival of native species.

Insects have been as successful in Australia as in other continents, showing many adaptations to hot and dry conditions, particularly by adjusting the timing of drought-resistant developmental stages. Leaf-eating insects, including locusts, may be plagues in pasture regions. Other insects attack timber, and the destructive, as well as the constructive, activities of the widespread termites are well known. Bloodsucking insects attack cattle and sheep, and some are disease carriers. The larvae of blowflies (Calliphoridae) attack the living tissues of sheep and continue to cause sheep farm losses of millions of dollars. (M.F.G.)

NATURAL RESOURCES

Mineral resources. The first settlers, who arrived in Australia at the beginning of the Industrial Revolution in Europe, soon reported the existence of coal near Sydney and elsewhere. Discoveries of alluvial gold west of Sydney, later in Victoria, and finally in Western Australia led to great movements of population across the continent and to extensive immigration. Prospectors discovered many rich mining areas throughout the continent, particularly in the west, the area around Adelaide, Victoria, Tasmania, western and central New South Wales, northern New England, coastal and western Queensland, and the Northern Territory. More recently, in 1949, Australia began a period of almost continuous mineral discoveries. This period continued into the 1970s, the rate of discoveries and, more importantly, of mineral production, rapidly increasing (see AUSTRALIA, COMMONWEALTH OF for a consideration of the role of minerals in the national economy).

Mineral fuels. The coal resources of eastern Australia were attracting much interest from overseas buyers by the 1970s, and new mining ventures ensued. Black coal is found in the Permian sediments—some 250,000,000 years old—in the Sydney Basin and in Queensland.



Mineral resources of Australia.

Western Australia has a small Permian coal basin at Collie, and South Australia has a Triassic coalfield—dating from 200,000,000 years ago—at Leigh Creek. Large brown-coal deposits are exploited for electricity production at Yallourn and Morwell in Victoria, and west of Melbourne. The total coal reserves of Australia were estimated in 1971 at 24,000,000,000 tons of which 7,000,000,000 tons in New South Wales and Queensland are described as coking coal.

Commercial gas fields

The fuel supply situation in Australia changed fundamentally with the discovery of commercial gas fields and the opening of pipelines to capital cities in 1969. The Roma area of Queensland supplies gas to Brisbane; the Gippsland offshore area supplies Melbourne; gas from the Gidgealpa–Moomba area is brought to Adelaide and may be supplied to Sydney; while the Dongara field, in the Perth Basin, is being connected by pipeline with Perth. Over 8,000,000,000 cubic feet of gas were used in Australia in 1969, the first year of major production, and over 110,000,000,000 cubic feet in 1972. A gas reserve of over 500,000,000,000 cubic feet in the Ordovician sandstone (some 450,000,000 years old) of the Mereenie field, 150 miles west of Alice Springs, remains unused, pending decisions on pipeline construction and other matters. Recoverable reserves of natural gas in Australia were estimated at 37,750,000,000,000 cubic feet in the early 1970s.

The first commercial oil discoveries in Australia were made, in 1961 and 1964, respectively, at Moonie and Alton, in the Surat Basin. Cumulative production by the end of the decade amounted to over 15,000,000 barrels, although production was declining in these two fields in the early years of the 1970s. The Barrow Island oil field, located off the coast of northwestern Australia, by the early 1970s had an average daily production rate of 43,000 barrels from 348 producing wells, with estimated

G.R. Roberts—Photo Researchers

Open-cast coal mine, Muswellbrook, Hunter Valley.

reserves of 200,000,000 barrels. Crude oil production from the offshore fields in Bass Strait off the Gippsland coast of Victoria began in 1969, and within a year the first two fields were producing at an average daily rate of 105,000 barrels, with an increase to 330,000 barrels scheduled. The recoverable oil reserves of the known

structures were estimated at 1,800,000,000 barrels in the early 1970s.

The output of indigenous crude oil in Australia in 1969 met only 10 percent of the total Australian demand; but by the early 1970s indigenous production was meeting more than 60 percent of the continent's crude oil requirements. In addition, exploration drilling was in progress at the rate of about 100 wells per year.

Uranium. Post-World War II exploration efforts, linked to the world demands of a growing atomic energy industry, led to the discovery and opening of uranium mines in northwest Queensland, South Australia, and the Northern Territory. The completion of export contracts concluded at that period had brought active mining to a standstill by the early 1970s, but the prospect of new overseas markets led to a revival of exploration and to new discoveries.

Major uranium deposits

In northwest Queensland, the Mary Kathleen uraninite deposit is situated between Mt. Isa and Cloncurry. It has reserves of over 3,000,000 tons of rich ore, ready for open-cut mining. The Radium Hill mine, located near Olary in South Australia, was based on a deposit discovered in 1906 and worked from 1954–60, producing about A$35,000,000 worth of uranium in the form of davidite. Uraninite deposits have long been known in the South Alligator River area, and deposits at Narbalek, on the lower reaches of this river in Arnhem Land, 150 miles east of Darwin, have reserves estimated at 10,000 tons. The announcement of the first large discovery of a sedimentary uranium deposit in Australia was made during the same period. This deposit lies, at a shallow depth, under the Lake Frome plains in South Australia, and is clearly derived from the uranium-bearing Mt. Painter Complex in the adjoining northern Flinders Ranges.

Iron ore. Iron ore is produced in Australia for iron and steel production and for export: the physical and chemical properties of the iron ores control the value of the ore for modern technological processes. These processes facilitate the use of otherwise valueless fine-grained ore, although strict control of phosphorus and nickel content is required; upgrading (known technically as beneficiation) of low-grade jaspilite-hematite ores could add thousands of million of tons to the available reserves.

After a long period of concern about the continued availability of reserves for the Australian steel industry from the two known iron-ore-producing areas, an export ban, which had been imposed in 1938, was lifted in 1960. Indications that major additional resources existed proved correct, and with the stimulus of large contracts for the export of iron ore (with Japan as the main destination), reserves of many thousands of tons of limonite and hematite ores were developed.

The old ore-producing areas are in the Middleback Range on Eyre Peninsula in South Australia, and in Yampi Sound and Koolyanobbing Range in Western Australia. The Middleback Range contain 12 ore bodies of banded hematite-jaspilite iron formation. High-grade ore production had exceeded 100,000,000 tons by the 1970s and reserves were estimated at 200,000,000 tons. The Yampi Sound deposits, 85 miles north of Derby, have reserves of about 65,000,000 tons.

New iron ore discoveries

The new discoveries are on a vast scale: the Mt. Goldsworthy deposit, 60 miles east of Port Hedland, contains 65,000,000 tons of hematite lode. The newly developed Hamersley iron province contains thousands of millions of tons of ore in iron formations. The largest high-grade ore deposits are Mt. Tom Price, with reserves of about 500,000,000 tons of ore; Mt. Whaleback; and Mt. Newman. Other ores occur in vast quantities in the Robe River area; reserves are estimated at 5,000,000,000 tons, with an iron content of 56–57 percent. The Savage River iron deposits, in Tasmania, were also being developed in the early 1970s for export to Japan. They contain reserves of 100,000,000 tons of magnetite ore.

Ferroalloy metals. Tungsten has been produced in Australia since the end of the 19th century, but since 1920 its contribution to world output has been minor. It is produced from wolframite and scheelite found in Queensland, New England, King Island (in Bass Strait), and the Northern Territory. Manganese has been mined from many small deposits, but over 500,000 tons of ore are produced annually from the recently discovered deposits on Groote Eylandt, in the Gulf of Carpentaria. One of the most significant of the many new economic mineral occurrences recently discovered in Australia is that of nickel. The Kambalda deposits, 35 miles south–southeast of Kalgoorlie, were discovered in 1964, and many other similar deposits in the old goldfields area of the Western Australian Shield were explored in the late 1960s and early 1970s. Recent finds in the Windarra area, in the northern part of the nickel belt, have attracted much attention. In addition, there are large areas of lower grade nickel ores in the Musgrave Block, near the borders of Western Australia, South Australia, and the Northern Territory.

Nonferrous base metals. The Australian continent has long been one of the world's principal producers of lead and zinc. The Broken Hill lode, in western New South Wales, discovered in 1883, produced over 85,000,000 tons of ore in the next 75 years. At Mt. Isa, in western Queensland, there are important lead-zinc and also copper ore bodies, discovered in 1923. By the early 1970s, another lead-zinc deposit was being developed in the McArthur River area of northern Australia. Copper is widely distributed in the Precambrian and Paleozoic rocks of the continent, although most occurrences are small. The principal producing mines are at Mt. Isa and Mt. Morgan in Queensland, Mt. Lyell in Tasmania, and Tennant Creek in the Northern Territory. The South Australian copper mines, at Wallaroo–Moonta and Burra, were of great importance to the early economic development of that state, up to about 1920. With changed mineral economics and improved mining technology, it was found practicable to reopen the Burra and Kanmantoo Mines, near Adelaide, in 1971. Vast resources of bauxite for aluminum production have been discovered at Weipa (on the Gulf of Carpentaria) and at Gove (Arnhem Land) in northern Australia. Tin is produced in both eastern and western Australia, and in the Darwin area; it occurs in lodes connected with granites, and as alluvial deposits. Production declined to a few thousand tons during the early part of the 20th century. Rutile (titanium oxide) and zircon are heavy minerals that are now extensively mined from beach sands, mainly on the east coast.

Copper production

Precious metals. Gold discoveries, which first occurred near Orange, in New South Wales, in the mid-19th century, and later in Victoria, north Queensland, and Western Australian, were important stimulants for the growth of population in Australia. From a peak production of nearly 4,000,000 fine ounces in 1904, output had declined by the 1970s to about 700,000 fine ounces, most of it coming from the Kalgoorlie–Norseman area of Western Australia. Silver occurs in the rich lead–zinc ores in Broken Hill and Mt. Isa, and small amounts of platinum and palladium have been found during the search for nickel.

Nonmetallic deposits. As can be expected from its size, the Australian continent has abundant deposits of such industrial minerals as clays, mica, salt, dolomite, building materials of all kinds, refractories, abrasives, talc, and asbestos. An intensive search for phosphates to offset the declining production of Nauru and Ocean Island led to the discovery of large deposits in the Cloncurry–Mt. Isa area, but the economics of marketing these resources were still under investigation in the early 1970s. Gem minerals occur in many localities, but mechanized industrial prospecting and mining had barely got under way by the early 1970s. The Australian white and "black" opals, mainly from Andamooka and Coober Pedy in South Australia and White Cliffs and Lightening Ridge in western New South Wales, are world famous. The sapphires and topaz from Queensland and the New England district, are also well known.

Mining of gems

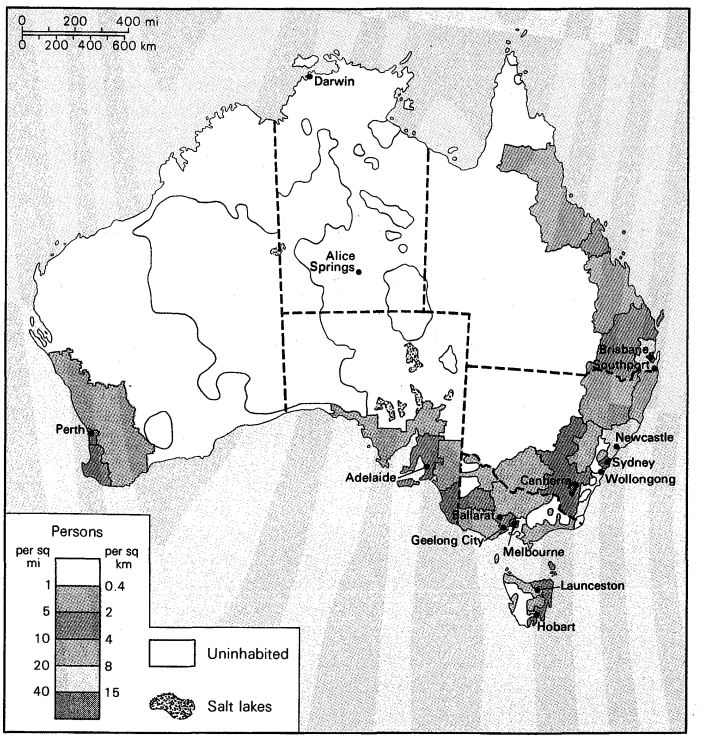
Water resources. If not the oldest continent, Australia is certainly the driest. The average annual rainfall is 17 inches, with less than 10 inches falling in more than

one-third of the continental area. The more significant index of average variability from average annual rainfall is over 20 percent, and reliable rainfall occurs only in the southeast, southwest, and in the north around Darwin. In the interior, the low and unreliable rainfall, the high evaporation rate, and the flat topography combine to reduce the streamflow. The catchment area of the Murray River system, the largest in Australia, is almost a third that of the Nile, but the average annual flow is only one-sixth (12,000,000 acre-feet). The control of water runoff and the general development of storage dams are of great importance in the management of water resources in Australia. An elaborate development scheme for the waters of the southeastern highlands for storage, irrigation, and power, the Snowy Mountains hydro-electric scheme, is nearing completion as one of the greatest projects of this kind ever undertaken. Some of the waters of the Snowy River, which takes the meltwaters of snow from the eastern highlands straight to the sea, are turned into the Murray Basin to be used for irrigation. The total storage capacity of the 15 large dams of the Snowy Mountains scheme will be well over 6,000,000 acre-feet.

The Snowy Mountains scheme

In the Great Artesian Basin there are over 18,000 recorded water bores. The quantity of water drawn from the basin apparently exceeds the rate of recharge, but the need for further investigations and reassessment of data on the hydrology of the Great Artesian Basin is recognized. The underground water resources of the Murray Basin and of other sedimentary basins are significant but insufficiently known. Considerable underground water supplies are available for the development of Alice Springs in central Australia, and drilling has also supplied sufficient water for the mining developments in the northwest. An important problem—at least until desalination becomes economically feasible—is the quality of underground water; the water from the Great Artesian Basin bores is used only for livestock. The groundwater at Kalgoorlie, in Western Australia, is as salty as the sea, and at Norseman salinity is twice as high. Investigations are in progress concerning better use of Australia's water resources as knowledge of their limited amount increases.

Biological resources. The natural biological resources of the Australian continent, as distinct from introduced plants and animals, are limited. Native timber resources in the form of eucalypts are used for papermaking, and the jarrah and karri forests of southwestern Australia provide valuable sawmilling timber. In many parts of the country the virgin native plants still provide the principal pasture component, but in the more arid parts of the country overstocking has destroyed much of this resource and damaged the soil. The arid part of the continent carries only one-third of the total livestock, but introduction of types of cattle more suited to the country and a greater awareness of the limits of its carrying capacity have improved the utilization of these regions. In the zones of better climate, introduced pasture plants such as lucerne and clover, together with the use of superphosphate as fertilizer and of trace elements for soil improvement, has greatly improved Australian pasture resources.



Population density of Australia.

THE OUTLOOK

Australia is a vast continent with a geological history which is long and almost as complex as that of other continents. It has produced a distinctive environment for plants, animals, and man. The Australian environment has clearly recognizable disadvantages: over much of the continent the surface is flat, the soils are leached, sandy or salty, and the climate is arid. Isolation from other major landmasses, possibly itself an effect of geological events (continental drift) has been a significant factor, until modern times of rapid communications. The flora and fauna, in isolation, has adapted itself to its environment in a remarkable manner and has become highly distinctive.

The complex geological history of Australia has provided man not only with a unique challenge but also with rich mineral resources, to the knowledge of which intensive exploration is making significant additions every year. The greatest remaining challenge is that of resources management and conservation of the environment, with the aim of enhancing the productivity of the land, rationalizing the use of the limited water resources, and assuring suitable conditions for the survival of the indigenous flora and fauna and of human populations. (M.F.G.)

Australia, Commonwealth of

The Commonwealth of Australia is located in the Southern Hemisphere between the Indian Ocean and the South Pacific, on an island continent that has been called both the Oldest Continent and the Last of Lands. Neither description is accurate. It is the oldest continent only in the sense that much of Australia is formed of rocks laid down during the Precambrian (4,600,000,000 to 570,000,000 years ago), and has altered relatively little since life first appeared on earth. It is the last of lands only in the sense that it was the last continent (if we except Antarctica) to be discovered and explored by Europeans. Thousands of years before the explorers Abel Tasman and James Cook sailed into the South Pacific, the Aborigines had crossed the land bridge from Asia formed by the Malaysian archipelago and had spread throughout the mainland and Tasmania. They remained, however, a sparse, primitive, and nomadic people. When Captain Arthur Phillip of the British Royal Navy landed with the First Fleet at Botany Bay in 1788, the true beginning of modern Australia, there were probably not more than 300,000 Aborigines altogether, and there was no structure on the continent more solid than a bark hut.

Today the Commonwealth of Australia is a prosperous, independent nation of some 12,700,000 people united under one government, of whom about 80 percent are of British stock and only 1 percent nonwhite. A British dominion and a member of the British Commonwealth of Nations, it had become the most important monument to the British Empire in the Southern Hemisphere. Australians were fortunate in that they did not have to share their continent—which, with almost 3,000,000 square miles (8,000,000 square kilometres), is only a little smaller than the United States—with any other nation. It was all their own. Their nearest neighbours, apart from Papua-New Guinea, which was administered by Australia, were the Indonesians to the north, the Polynesians and Melanesians of the Pacific islands to the east, and New Zealand, which, like Australia, was a British dominion and a member of the British Commonwealth, to the southeast. On the other hand, Australia was remote from its two principal allies: it is 12,000 miles from Australia to Britain via the Indian Ocean and the Suez Canal; it is 7,000 miles across the Pacific to the West Coast of the United States.

Like Canada and the United States, contemporary Australia is a political federation with a central government (the Commonwealth) and six states (New South Wales, Victoria, Queensland, South Australia, Western Australia, and Tasmania), each of which has its own government enjoying a limited sovereignty. The Commonwealth also directly administers two internal territories, the Northern Territory and the Australian Capital Territory, and the external territories of Papua-New Guinea, Norfolk Island, Cocos Islands, Christmas Island, Ashmore and Cartier Islands, Coral Sea Islands, Heard and McDonald Islands, and the Australian Antarctic Territory.

This article describes the landscape, people, economic development, and political, constitutional, and cultural aspects of the contemporary Commonwealth of Australia, taken as a whole. The article AUSTRALIA treats in detail geological evolution and the physical environment; AUSTRALIA, HISTORY OF, deals with the historical development of the nation.

THE LANDSCAPE

Regional variations. Australia is both the flattest continent and the driest. Seen from the air it is hard to believe that its vast plains, sometimes the colour of dried blood, more often tawny like a lion's skin, are not one huge desert. One can fly the 1,900 miles to Sydney from Darwin in the north, or the 2,000 miles from Perth in the west, without seeing a single town or anything but the most scattered and minute signs of human habitation. A good deal of the central depression and western plateau is indeed desert. Yet appearances can be deceptive. The red and blacksoil plains of Queensland and New South Wales have long supported the world's greatest wool industry, while recent discoveries have revealed that some of the most arid and forbidding areas of Australia conceal great mineral wealth.

Moreover, the coastal rim is, almost everywhere, an exception to these rules. In particular the east coast, where European settlement began and where the majority of Australians now live, is hilly, well watered, and fertile.

Inland from the coast runs a chain of highlands known as the Great Dividing Range, from Cape York in northern Queensland to the southern seaboard of Tasmania. From the coast itself this range, which may be anything from 20 miles (32 kilometres) to 200 miles (320 kilometres) distant, often appears as a bold range of mountains, though few of its peaks exceed 5,000 feet (1,500 metres). In fact, it is more like the escarpment of a giant plateau, formed of gently rolling hills, which then slopes imperceptibly down to the western plains. There are similar, though smaller, stretches of hilly, well-watered land all around the rim of the continent except on the south coast where the Nullarbor Plain stretches to the sea; but everywhere the rainfall diminishes rapidly as one penetrates further from the coast.

The "Outback"

To Australians the land beyond the Great Dividing Range and the coastal rim is the Inland, or the "Outback." For them it still retains some of the mythical quality it had for the first explorers searching for inland seas and great rivers. It is their Frontier: the land of hope and adventure. Yet in fact it is still very sparsely populated and perhaps always will be. The real heart of Australia lies in the industrial cities of the east and west coasts.

In this huge continent there are wide variations in scenery and climate. The thickly wooded ranges of the Great Divide have little in common with the treeless, sun-dried plains of the Inland. There is a vast difference between the red rocks and monumental hills of central Australia and the tropical rain forests and sugar plantations of north Queensland. Yet visitors to Australia usually detect a certain uniformity created, perhaps, more by the red earth, the brilliant light, and the drab, olive-coloured leaves of the ubiquitous eucalyptus than by any real resemblance. And if visitors from the Northern Hemisphere are at first repelled, as the English novelist D.H. Lawrence was, by "the vast, uninhabited land and by the grey charred bush . . . so phantom-like, so ghostly, with its tall, pale trees and many dead trees, like corpses," they should remember that to Australians born in the country

the bush is friendly and familiar. Australia is not a pretty country, but it has a unique and haunting beauty that exerts a powerful fascination on those who get to know it.

If there is no real uniformity in the Australian landscape, there is certainly uniformity among the Australian people. No marked regional differences have emerged in the 200 years of European development, and steadily improving means of transport and communication have constantly worked to erase such differences as did exist. Today there is a strong similarity in the speech, manners, and customs of all Australian states, and everywhere the culture of white Australia is immediately recognizable as characteristic of Anglo-Saxon culture in Britain and North America.

The pattern of settlement. Australia did not yield easily to development by white men. Even on the relatively favoured eastern seaboard, the first settlers found it hard to cross the rugged mountains of the Great Divide. When they did so they had to fight an endless battle against savage droughts, sudden floods, and fierce bush fires. Though they had little to fear from the Aborigines or from the gentle and harmless Australian animals, the land itself often appeared as a harsh and implacable foe. The long struggle by these settlers to tame the Australian Outback helped to form the tough and independent character of modern Australians just as the struggles of the pioneers and frontiersmen helped to mold the national character of the United States.

By the second half of the 20th century, the automobile, the airplane, and the radio had greatly eased the harshness of life in country districts. Although many families still live in astonishing isolation by the standards of most other countries—it is nothing for a grazier to live 50 miles from the nearest country town and perhaps 10 or 15 miles from his nearest neighbour—most of them are linked by telephone and by well-surfaced roads. Even those who live on the great sheep and cattle stations beyond the Darling in New South Wales or in northwest Queensland are linked by radio and can call the radio doctor and the flying ambulance in emergency. Many of the bigger stations own their own airplanes.

Sheep and cattle stations

In Australia a sharp distinction has been made in the past between the grazier, who runs sheep or cattle on his "station" or "property," and the small farmer who grows wheat or fruit or raises dairy cattle on the coast or in the irrigation areas. That distinction had been blurred in the early 1970s by the subdivision of the biggest properties and by the fact that many graziers, faced by rising costs and the falling price of wool, had been forced to grow wheat or other crops to supplement their income. But Australia is still one of the last countries where one can find huge properties of 100,000 acres or more where sheep and cattle graze over land unbroken by the plough. Life on a big sheep station is still a privileged one where a comfortable income, the pride of owning wide acres, and the spacious dignity of life on these sunburnt plains more than compensates for the loneliness and the inevitable hazards of drought and bush fires.

The life of the small farmer in Australia is less attractive and, consequently, less envied. Most of them struggle against the same hazards of drought and fire without the reassurance of broad acres to fall back on. Very often their homes are modest, and their cash income may not equal that of an industrial worker on the basic wage. Many of them could not survive or compete with imported produce without generous government subsidies.

Because of the vast distances and sparse settlement, nothing like the European village has ever developed in Australia. Instead, there are country towns that serve a wide area and vary a great deal in size and amenities.

Many of the Outback towns are dusty little settlements with one wide main street, a store, two or three hotels, and not much else. But in the areas of closer settlement nearer the coast, many substantial country towns have grown to a point where they offer excellent medical and educational services and first-class shopping. Very few towns in the Outback, however, have more than 25,000 inhabitants.

Commonwealth of Australia, Area and Population

	area		population	
	sq mi	sq km	1966 census	1971 census*
States				
New South Wales	309,433	801,428	4,238,000	4,590,000

The great paradox of Australia, however, is that in this huge continent with its small population, relatively few people live in the country at all. By 1971 some 60 percent of the population lived in the seven capital cities, 25 percent in smaller urban areas, and only about 15 percent in rural areas. The average density was then four persons per square mile, and the Northern Territory had a population of only 86,000. Against this, 5,000,000 people lived in Sydney and Melbourne. Many Australians regard this balance of the population as unhealthy and deplore the concentration of people in the conurbations of Sydney and Melbourne. Most Australian politicians pay lip service to the principle of decentralization even though they have done little to put it into practice.

Urbanization

Yet there are compensations in this imbalance. Both Sydney and Melbourne are large, modern, sophisticated cities that can compare in the services and amenities they offer with any city in the world except, perhaps, London, New York, and Paris. Although neither is the federal capital, they are still the most important cities in Australia, the natural centres both of business and the arts. After Sydney and Melbourne the biggest cities (1971 census) are the state capitals of Queensland (Brisbane: 817,000); South Australia (Adelaide: 809,000), Western Australia (Perth: 640,000), and Tasmania (Hobart: 130,000).

All of these cities grew naturally as centres of local trade and commerce. Canberra, on the other hand, was artificially created as the federal capital of Australia. Although building did not begin until 1913, by the early 1970s it had become the most rapidly growing city in Australia, with a population in excess of 140,000.

The original plan for Canberra was designed by Walter Burley Griffin, an American architect of the Chicago School, as the result of a competition held for the purpose. Though Griffin's plan was later modified, Canberra is still a conspicuously well-planned city, with broad avenues lined with trees and an artificial lake in the centre of the city. It has often been praised as a model of town planning but, more than half a century after its inception, very few of the important public buildings had been completed.

For all its advantages of site and plan, Canberra has not quite escaped the main criticism levelled against Australian cities—that they have allowed suburbia to run riot. Because of the availability of land and the determination of the average Australian to own his own house and garden, all the main cities stretch for miles around their centres, putting an inevitable strain on public transport and services. The rising price of land, particularly in Sydney, has slowly brought a change to apartment dwelling and higher density housing, but, by the decade of the 1970s, it was still true that most Australians lived in suburbs, and some critics have found in this an explanation for a certain suburban outlook in contemporary Australia.

THE PEOPLE

Origins. The population of Australia is remarkably homogeneous. By the early 1970s some 80 percent were of British stock, though this proportion was declining each year with the increase of migrants from other European countries. (In another generation intermarriage may make this distinction virtually meaningless.) Other Europeans made up the balance, and only one percent of the total population was nonwhite. This included about 130,000 Aborigines, of whom only 46,000 were full bloods. There was also an Asian minority of about 37,000, most of whom were students or visitors, though there were a few thousand Chinese Australians, the descendants of Chinese coolies and diggers who entered Australia during the gold rush of 1851 before the White Australia policy was adopted.

Until the end of World War II almost all immigrants to Australia came from the British Isles. This should not be equated with England. Among these immigrants there was always a high proportion of Scots, Welsh, and especially of Irish. The ancestry of present-day Australians has been estimated as roughly 50 percent English, 20 percent Irish, 10 percent Scottish, and 2 percent Welsh. (The remaining 18 to 20 percent are of non-British origin, largely from continental Europe.) There is a strong Celtic strain in Australia.

After World War II it was decided to try to increase the population of Australia by encouraging migrants from other European countries, including refugees who had been rendered homeless by the war. Missions were sent to many of these countries and Government assistance was extended to European as well as British immigrants. As a result, a steady stream of migrants has come to Australia from Europe since 1945 at an annual rate of from 100,000 to 180,000 a year. About half of these, however, still came from Britain. For example, of the 16.39 percent of the population recorded in the 1966 census as being born in Europe, the distribution was as follows: U. K. and Republic of Ireland, 7.87 percent; Italy, 2.31 percent; Greece, 1.21 percent; with other countries each contributing less than 1 percent.

This migration program has been remarkably successful. On the whole, the European immigrants have been easily assimilated and most apply for Australian citizenship after the statutory five years residence. Few return to their homelands, though, curiously enough, it has been estimated that one of every six British families who came to Australia during this period returned to the United Kingdom.

This homogeneity, of course, has been achieved only by enforcing a White Australia policy. Strictly speaking, there is no such policy. The phrase does not appear in any act of Parliament. In fact, however, since 1901 all Australian governments have seen to it that black, yellow, and brown immigrants (politely called non-Europeans) were not admitted to permanent residence in Australia. Since the late 1950s exceptions have been made for the wives, children, and parents of Australian citizens, and since 1966 non-Europeans have been able to apply for admission as migrants. Non-European people, mostly Asians with skilled qualifications, are now settling in Australia at the rate of 3,500 annually; and people of partly non-European descent are settling at the rate of 6,000 a year.

The White Australia policy

Naturally this policy, based on racial discrimination, has not won the approval of all other nations. It is still, however, supported by all the major political parties in Australia, though recently minority groups have urged that it should be modified still further to allow a substantial quota of Asian immigrants.

Australia has one nonwhite minority that is too often forgotten. That is the Aborigines, of whom about 150,000 had, by the 1970s, survived two centuries of white persecution and indifference. (There is no true definition of an

Aborigine. Only about 46,000 full bloods remained, but anyone with a recognizable amount of Aboriginal blood tended to be counted as an Aborigine.)

Aborigines

These people have had little share in Australia's growth and prosperity. Most of the full bloods are to be found in the Northern Territory, the north of Queensland, and Western Australia, where some of them still live in tribal societies and a few—a very few—still follow the nomadic, hunting life of their ancestors. Others find appropriate employment as stockmen on the cattle stations. But most of them tend to live on mission stations or government reserves, depending on handouts or earning a little money as casual workers.

The same is largely true of the part-Aborigines in the southern states, although they have had greater opportunities for employment. There are no Aborigines in Tasmania, where they were exterminated early in the 19th century, and, by the decade of the 1970s, only an estimated 4,000 in Victoria, 8,000 in South Australia, 24,000 in New South Wales, and 26,000 in Western Australia.

Official policy is to help the Aborigines become an integral part of Australian community life. So far, however, they have been held back by white prejudice or indifference, by their own deep suspicions, and, most of all, by the vicious circle of poverty, ignorance, and disease in which they are trapped. Their birthrate is high, but infant mortality is three and a half times that for white Australian children. Those who survive tend to suffer from malnutrition and other diseases, which gravely handicap their development at school and afterward.

Recently, however, public opinion has become concerned at the plight of the Aborigines, and the federal and state governments have, since the mid-1960s, taken several measures that give some hope of improvement. All acts discriminating against Aborigines have been repealed except in Queensland; Aborigines vote in all federal and state elections. There has been a marked improvement in their treatment and conditions in many areas. With the exception of Victoria, however, no government has yet granted the Aborigines the right to own the reserves on which most of them live.

Major religious groups

If Australia is overwhelmingly white and predominantly Anglo-Saxon, it is far from being overwhelmingly Protestant. The Irish immigrants have seen to that. Sectarian feeling between Catholics and Protestants has at times played an important part in Australian political and social life, and it cannot yet be said to be entirely extinct. From the beginning, the Roman Catholic Church has played an important part in Australia and by the 1970s its adherents numbered some 26 percent of the total population, as compared with some 34 percent for the Anglican Communion.

Demographic outlook. The total population of Australia passed 12,500,000 at the 1971 census. The continued growth of the Australian population must depend on two factors, natural increase and immigration, both of which may fluctuate according to political, social, and economic circumstances.

By 1970 the birth rate was 20.5 per 1,000, the death rate 9.0 per 1,000, and the excess of immigrants over emigrants approximately 125,000. The rate of annual increase, including migration, was 2.15 percent. If one were to assume that all these figures remained constant, then the population of Australia, in round figures, would be approximately 15,500,000 in 1981, 19,000,000 in 1991, and 23,000,000 in 2001. Any variation in the vital statistics figures would, of course, affect the totals. If, for instance, the excess of immigrants over emigrants was increased to 150,000 a year, then the total population would be 25,000,000.

It would, however, be rash to assume that either the birth rate or the immigration rate will remain constant. The crude birth rate began to fall in 1961 and reached a low point of 19.4 per thousand in 1965/66. It then began to rise again and by 1970 was 20.5.

The immigration rate is an even more hazardous subject. The view that prevailed from the end of World War II to the close of the 1960s—that Australia should increase its population as rapidly as possible both to develop its economic resources and to enable it to survive in an increasingly dangerous world—has recently been challenged by those who argue that quality is more important than quantity and point to the dangers of overcrowding and pollution that have threatened so many other nations.

Moreover, even if the view prevails that Australia should seek as many immigrants as it can absorb economically, it cannot be assumed that a constant supply of suitable immigrants will always be available. During the 1960s there was actually a slight decline in the number of migrants coming from the continent of Europe, though this short-fall was made up by migrants from Britain, from North and South America, and by limited immigration from such countries as Turkey, Egypt, and Lebanon.

There would presumably be no lack of prospective migrants if the door were thrown open to immigration from Asia, but this would mean abandoning the White Australia policy and would raise the fundamental question whether Australia is to continue as a white nation of European race, religion, and culture or whether it should deliberately seek to create a multiracial society in which the races of Europe and Asia commingle. (J.D.Pr.)

THE NATIONAL ECONOMY

Australia's traditional world reputation as a predominantly farming country has changed. Its meteoric rise over the 1960s from a mining nonentity to a major mining nation, and the wild fluctuations of mining share prices on Australian stock exchanges in 1969, attracted much world attention. Industrialized countries have realized that beneath this vast continent and its offshore areas lies a wealth of mineral riches. By 1970 Australia had already become one of the chief sources of minerals for the leading industries of Japan.

The minerals boom since the mid-1960s, the impressive progress of industrialization between 1950 and 1970, and the growth of service industries and other features of a sophisticated economy have added new dimensions of economic strength and transformed the nation's traditional image of a predominantly agricultural and pastoral country with vast open spaces into that of a bustling industrial nation. In the Pacific Basin area, Australia plays a vital role in trade, commerce, and investment. It also has one of the world's fastest economic growth rates; since the early 1960s the gross national product has expanded at a faster rate, in real terms, than that of the other major industrial countries, with the exception of Japan. By the 1970s, Australian living standards in terms of per capita income were comparable to those of the advanced economies, ranking third after the U.S. and Canada.

Australia exports to all the important world markets and it imports goods from most countries, particularly the leading industrialized nations.

Resources. *Mineral resources.* Australia is endowed with resources of all the major minerals, particularly coal, oil, natural gas, iron ore, lead, zinc, copper, bauxite, uranium, tin, gold, silver, nickel, and beach-sand minerals. Among these, there were spectacular discoveries in the 1960s of iron ore, bauxite, nickel, oil, and natural gas. Australia's iron ore and bauxite reserves are among the world's largest. Its reserves of lead, zinc, copper, and the rare minerals rutile, zircon, and ilmenite are also very large by world standards.

Although many discoveries have been made, it is generally believed that the surface of this vast continent has only been scratched and that the mineral exploration boom should continue at least into the 1980s with regular and spectacular discoveries adding to the nation's strongly appreciating mineral wealth.

Australia's significant mineral reserves are located in Western Australia (iron ore, nickel, bauxite, gold), Queensland (bauxite, lead, zinc, and silver), New South Wales (coal, lead, zinc, silver, and beach-sand minerals), and off the coast of Victoria (oil and natural gas).

Australia is the world's largest wool producer and a ma-

jor supplier of cereals, dairy products, meat, sugar, and fruit. About 95 percent of the wool and over a third of most of the other rural products are exported. In contrast with most other countries, by 1970 over 90 percent of the utilized land area in Australia remained in its natural state or was capable of very limited improvement; *i.e.*, was land used solely for rough grazing. The area cultivated for agriculture and intensive grazing was slightly more than 8 percent of all the utilized land. The main limiting factor in this respect is lack of water, but unsuitable soil and topography are also important determinants. By the 1970s Australia's 256,000 rural holdings had a combined land area of about 1,210,000,000 acres or about 60 percent of the total land area. (A rural holding in Australia is defined as a piece of land of one acre or more in extent used for the production of agricultural products or for the raising of livestock and the production of livestock products.)

Sheep

Animal resources. The sheep industry accounted for about 46 percent of Australia's total farming area. By 1970 Australian sheep numbers totalled over 180,000,000 head, and they constituted about one-sixth of the world's wooled sheep, producing around a third of the world's wool supplies. Merino sheep constitute the basis of the Australian wool industry and they make up over 70 percent of total sheep numbers. The Merino, which produces wool of a very fine quality, is particularly well adapted to the extreme vagaries of climate in Australia's wool producing areas. Australia's other types of sheep are crossbred and comeback varieties and dual purpose Australian and British breeds, reared mainly for fat lamb production.

Despite the adverse effects of recurrent droughts, Australian wool production more than doubled between 1950 and 1970, with peak seasonal production reaching almost 2,000,000,000 pounds in weight. This rise in production over the period was attributable to a number of factors which included: success of a myxomatosis campaign in the early 1950s; pasture land flock improvement; improved methods of pest and disease control; and better management of sheep farms.

Sheep are run throughout Australia under a wide range of climatic conditions and environments, but about a third of Australia's sheep are reared in those areas with an annual rainfall of less than 15 inches that are generally known as the pastoral zone, where lack of water and suitable fodder usually limits development. The dry conditions in the pastoral zone make the adaptable Merino the main breed. In areas of higher rainfall, up to 25 inches, sheep are often reared in conjunction with wheat and other cereals. About 40 percent of Australia's flock are found in these wheat-sheep zones, and breeds other than Merinos constitute a high proportion of the flocks. The rest of Australia's sheep are reared in the areas of relatively high and reliable rainfall, which produce most of the country's superfine wool.

Cattle

The breeding and fattening of cattle is usually carried out in different climatic zones. The better quality pastures in the relatively high rainfall areas are usually reserved for the fattening of cattle, which are often purchased seasonally and moved to rich natural pastures. Most of Australia's beef cattle are raised in the states of Queensland and New South Wales in regions of warm and coarse pastures. Victoria is the most important producer of mutton and lamb, using crossbred sheep raised in areas of high rainfall and fertility. Most of this type of grazing in Victoria is part of a mixed farming operation, where wheat is often the other principal product.

In the northern parts of Australia herds of the more recently introduced zebu and Brahman cattle are thriving and increasing; they are well adapted to the generally poor tropical pastures and resistant to heat and insects. A recent introduction from the United States, the Santa Gertrudis breed, is also offering good prospects of further development in these areas. Australia's dairy industry is mainly located in the temperate zones of high rainfall in coastal New South Wales and Victoria.

Other agricultural resources. Wheat is the most important grain crop grown in Australia; other grain crops are barley and oats. Wheat is usually grown in the medium rainfall belt in all states and it has become increasingly integrated with sheep grazing and cultivation of other crops. Wheat, barley, and oats are often grown on the same farm for grain and green fodder or hay for livestock. Most of these cereal crops are grown for grain. Sugar, Australia's most important crop after wheat, is grown from cane in coastal areas of Queensland and in northern New South Wales. The former area accounts for over 95 percent of the Australian sugar crop. The sugar industry is based on small farms, and covers an area exceeding 500,000 acres.

Other important crops grown in Australia include: tobacco, citrus fruit, grapes, apples, cotton, bananas, potatoes, and sorghum.

Forest and fishery resources. Australia is estimated to have about 60,000,000 acres of commercial or potentially commercial areas of forest, in addition to large regions of low grade forest suitable only for the production of small quantities of forest products for use in the immediate vicinity.

The main commercial forests are in the areas of high rainfall on the coast or near the coastal highlands of southeastern and eastern Australia, Tasmania and the southwest coast of Western Australia. The main types of trees in Australian forests are eucalyptus, a broad-leaved genus which provides timbers of great strength and durability for building and packaging. The rain forests of the wetter regions are the other important type with many important species of broad-leaved trees.

Australia's annual fish catch exceeds 120,000,000 pounds weight, not counting lobsters, crayfish, crabs, and prawns. It has been estimated that there are about 2,000 species of fish (including freshwater species) in Australia and the waters surrounding it. The resources include mullet, cod, bream, perch, tuna, snapper, whiting, flathead, abalone, mackerel, and Australian salmon. New South Wales and Western Australia are the most important producing states, the latter being famous for its crayfish. There has not been much change in the types of fish caught in Australian coastal waters over the years, but lobster and crayfishing has been expanding strongly in recent decades.

Hydroelectric and other power resources. By the early 1970s Tasmania was one of the few states with sufficient water resources to permit the continuous operation of large hydropower stations. Its hydroelectric resources have been estimated at about 50 percent of Australia's total. Although the use of hydropower is expected to grow, the country's potential for this form of energy is small in relation to its total area.

Coal is the most important source of energy in all the other states of Australia. About 71 percent of the total installed electric capacity in Australia is thermal power equipment. By 1970 the installed generating capacity of the main public supply electricity systems totalled almost 12,000,000 kilowatts, about 60 percent of which was located in the highly industrialized states of New South Wales and Victoria.

Sources of national income. *Agriculture.* Although the rural sector still makes a substantial contribution to Australia's national income its importance declined sharply during the 1960s. By the end of the decade the gross annual value of rural production totalled about $A2,230,000,000, or about nine percent of gross national product, a substantial drop compared with a 15 percent contribution to GNP in 1959. Rural industry generally was in a very depressed state by the early 1970s, the exceptions being such sectors as beef, cattle, sugar, and vineyards. The wool, wheat, and dairying industries have been hardest hit by falling world prices for their products and lack of export markets. The industries are in such a depressed condition that the Australian federal government was, by the early 1970s, considering measures to reorganize and rationalize them. These would involve the consolidation of numerous small uneconomic farms into more efficient units, and also the curtailing of production of such crops as wheat because of the inability of disposing of all the production.

Depression in rural industry

Although rural production has increased since World War II at twice the rate of increase in population, nonrural industries, particularly manufacturing, mining, and the service sectors of the economy have shown much faster growth rates and substantially increased their contributions to national income. Until 1969 wool was Australia's biggest single export earner, but it was subsequently displaced by minerals. In the latter portion of the 1960s, the value of wool exports nevertheless averaged about 27 percent of the total value of Australia's merchandise exports, with total annual value of wool exports approaching $800,000,000.

By the end of the 1960s Australia's wheat production totalled 540,000,000 bushels, compared with an annual average of about 180,000,000 bushels a decade earlier. Wheat is Australia's second most important rural crop but, by the early 1970s, the country faced a perhaps temporary crisis of overproduction following the lack of orders from the most important export customer, the Chinese People's Republic. Forestry and fishing contribute only an insignificant proportion, less than one percent, of Australia's gross national product.

Mining and quarrying. The story of Australia's mineral industry is one of strong expansion and development. New discoveries now being developed or yet to be exploited, particularly iron ore, bauxite, and nickel, indicate that minerals will play an increasingly important role in the Australian economy. The contribution to national income and exports from the nation's booming mineral industry is increasing at a spectacular rate. The total value of mineral production for 1970, exceeding A$1,000,000,000, compared with a 1963 figure of only A$416,000,000. The two most important contributors to mineral output are the coal and iron ore industries, which accounted for about 25 percent and 15 percent respectively of the total value of mineral production by 1970. Other minerals of economic significance are lead and zinc, the construction materials group (road metal, gravel, clays, limestone and building stone), copper, gold, tin, limestone, clays, salt, and such rare minerals as zircon.

Minerals are already Australia's largest single source of export income, and by 1970 mineral exports totalled over A$950,000,000 or about a quarter of total export income, compared with A$342,000,000 or about 12 percent of the total, as late as 1967. If the trends at the start of the decade were any indication, mineral exports might well rise to A$2,000,000,000 a year by the late 1970s.

Manufacturing industry. A vital sector of the Australian economy, manufacturing industry, has grown spectacularly since 1950, and by 1970 accounted for over a quarter of the nation's gross national product. Australia's limited home market will not support certain types of industry, such as the manufacture of highly sophisticated machines, heavy fabricating, certain types of electrical equipment, some industrial chemicals, and highly specialized scientific instruments and equipment. With the exception of these special classes of goods, however, the domestic market is well catered for with products of local manufacturers, which include the full range of items required in a modern community. Most of the industries are soundly based; only a few are carried out at an excessive cost, and require high tariff protection.

About a quarter of the nation's workforce, or around 1,300,000 people is employed in the 63,000 factories of Australia's manufacturing industries. The value of production of manufacturing industries has increased from A$406,000,000 around the year 1940 to a 1970 annual figure of over A$7,500,000,000. New capital expenditure by manufacturing industry was running at an annual rate of A$800,000,000 by the early 1970s, about double the rate a decade earlier.

Since World War II the expansion of manufacturing industry has been widely spread throughout the industrial structure, but it has been particularly strong in the engineering, vehicle, chemical, and construction materials industries.

The motor vehicle industry is a vital sector of the Australian economy and numerous other industries are dependent upon demand created by its level of activity. Its importance is underlined by the fact that Australia has the world's third highest per capita motor vehicle ownership, while most of these vehicles are locally produced or assembled. Total investment in the motor vehicle industry was estimated to be worth about A$600,000,000 by 1970, and it employs about 12 percent of the nation's workforce.

The motor vehicle industry

Iron and steel production was for long a virtual monopoly in the hands of one company, the Broken Hill Proprietary Co. Ltd., but there were plans for another producer to enter the market in the 1970s. Other important manufacturing industries include: oil refining, chemicals, textiles, and domestic appliances.

Energy. The main source of power used in Australian homes, factories, and other buildings is electricity. There was a strong rise in domestic use of electricity over the 1950s and 1960s because of the increased use of domestic appliances, extension of electricity supply into rural areas, and the high rate of home building, which has been running at an annual rate of over 100,000. Between 1958 and 1968, for example, the annual domestic consumption of electric power per consumer rose by about 50 percent. Thermoelectric power, based on either brown or black coal, is the main source of electrical energy in Australia.

Financial services. Australia has a well-developed banking system broadly similar to that operating in Britain. The system is made up of the Reserve Bank of Australia (the central bank), the trading banks, the savings banks, the Commonwealth Development Bank of Australia, and the Australian Resources Development Bank.

The federal government-owned Commonwealth Banking Corporation operates a trading bank, a savings bank, and a development bank. Some of the savings banks are owned by state governments. These savings banks operate within the borders of a particular state only and some offer checking-account facilities. The seven major trading banks and their savings-bank subsidiaries form the backbone of the Australian banking system.

The major banks in Australia operate under a branch-banking system, and most of them have branches in all cities and towns in Australia. The Australian Resources Development Bank was set up to provide finance mainly for the development of Australia's mineral projects. One of its aims is to provide finance in order to maintain a substantial proportion of Australian equity in these mineral enterprises. The Australian government planned to set up an organization known as the Australian Industries Development Corporation by the mid-1970s. This was expected to perform functions broadly similar to the Resources Bank.

By the 1970s there were over 4,600 branches and 1,900 agencies of check-paying banks in Australia.

The banking system in Australia is an important repository for savings, the most important source of finance, and the medium through which most commercial and financial transactions are settled.

The trading banks provide two types of facilities: current accounts operated on by checks and payable on demand, and fixed deposits, which are lodged for specific periods. By the start of the 1970s monthly deposits of the check-paying banks totalled some A$6,400,000,000 and deposits of the savings banks totalled almost A$7,000,000,000. The Reserve Bank applies its monetary policy to regulate the economy through the banking system, which usually bears the brunt of monetary and credit restraints during periods when the authorities consider it necessary to dampen down inflationary pressures in the economy (see below *Management of the economy*).

The next most important sources of finance in Australia are the finance companies, which grew strongly in the decades of the 1950s and 1960s, largely as a result of the restraining influence of official monetary policy on the banking system. All of the major Australian banks have substantial shareholdings in finance companies that in some instances are subsidiaries of the banks. In recent years a number of foreign banks also have acquired inter-

Finance companies

ests in finance companies in order to enter the Australian financial market, because Australian government policy prohibits the establishment of foreign banks in Australia, the exceptions being the long-established ones.

Australia has a well-developed short-term money market. There are also several merchant banks performing such functions as underwriting, company flotations, mergers and takeovers of companies, portfolio management, lending, and general financial and allied services.

Other important institutions in the financial system are the insurance companies (fire, marine, and general), life insurance companies, pastoral finance companies, and the building societies.

Besides funds available for expansion from undistributed profits, Australian companies raise large sums, averaging about A$600,000,000 a year by the start of the 1970s, by the issue of shares and fixed-interest borrowing.

Each state capital has its independent stock exchange, but a nationwide coverage is achieved by reciprocal arrangements with brokers in other capitals and agents in country centres.

The system is well-developed and sophisticated, and the stock exchanges provide a ready market for shares of listed companies and government securities. Quotations are distributed widely and quickly by special teleprinter channels and by radio and newspaper services.

Foreign trade. By 1970 Australia's exports made up about 14 percent of the gross national product; they had been growing at an annual rate of around 9 percent in previous years. At the start of the 1970s total annual export income was estimated at more than A$4,100,000,000, with imports around A$3,900,000,000. Minerals contributed about a quarter of Australia's export income; other important sources of export income were wool, wheat, meat, and manufactured goods. Japan was Australia's most important export customer, accounting for about a quarter of Australian exports, in value terms. Other important customers were the United Kingdom, the United States, the Common Market countries, New Zealand, and the rest of Asia, as a whole.

Management of the economy. The Australian economy is essentially one based on private enterprise, although government plays an important role in influencing economic conditions.

Most capital expenditure in Australia is undertaken by private business enterprises and persons. There is only limited public ownership of business enterprises. Major enterprises owned and run either directly by federal or state governments or by government corporations include the post office, Australia's international airline, one of the two major domestic airlines, the Commonwealth Banking Corporation, the Australian National Shipping Line, and the electricity and gas distribution organizations in the various states.

The government regulates economic activity through fiscal policies embodied in its annual budget and through monetary policy, which is administered by the Reserve Bank. The Reserve Bank and the federal government's Treasury Department are the government's chief source of economic advice.

An important feature of the Australian economic scene has been the strongly rising trend in government and other public authority expenditure. The chief source of this expenditure is the federal government, whose annual budget expenditures since the early 1960s have been running at an annual rate in excess of A$6,000,000,000. Public authority spending comprises over a quarter of gross national expenditure. While the private sector remains the dominant segment of the Australian economy, the public sector has grown strongly.

Taxation

In Australia taxes are levied by federal, state, and local governments. The main taxation authority is the federal government, which levies income tax, customs and excise duties, sales tax, payroll tax, estate duty, and gift duty. There are also a number of minor taxes imposed for specific purposes. There is no general duplication of taxes by the three tiers of government. The states impose a wide variety of taxes that include stamp duties, taxes on motor vehicles, land taxes, and probate duties.

The trade-union movement is well organized in Australia. Most workers are members of trade unions; in a number of instances membership is virtually mandatory. Industrial disputes are common and often disruptive in terms of loss of production. Australia has a unique arbitration system for settling disputes, but there have been signs of this system breaking down, and the trend is increasingly toward direct negotiations with employers (see below *Administration and social conditions*).

Contemporary economic policies

During the 1960s the principal aims of government economic policy were relatively high economic growth, full employment, stability of costs and prices, and balance of payments equilibrium. By the early 1970s there had been a considerable degree of success in the achievement of these aims. For instance, Australia had not experienced a major recession in the eight years following the one in 1961–62. Over that period the Australian economy grew at an annual rate of about 5 percent in real terms, employment was maintained at relatively high levels, the annual rate of inflation (about 2¾ percent) was lower than in most industrialized countries, and there had been no serious balance of payments crisis. Australia emerged from the 1960s and entered the 1970s with new dimensions of economic strength stemming from the continued powerful growth of its mineral industry. The balance of payments was very much stronger than it had been around 1960, export income had risen strongly, exports were more diversified with a greatly reduced reliance on rural exports, export markets were also more diversified, and there were prospects for further strengthening of the balance of payments.

Problems and prospects. During the 1970s Australia has the potential for achieving a rate of economic growth unsurpassed in any decade since World War II. Gross national product is expected to grow at an annual rate of at least 6 percent in real terms, compared with about 4.8 percent per annum during the 1960s. The balance of payments has been, and will continue to be, the key factor determining the rate at which the Australian economy can expand. Since the 1950s it has been the main limiting factor. During the 1970s, however, it is not generally expected to be an important obstacle to a high rate of economic expansion because exports of minerals and manufactured goods will almost certainly grow strongly. Also, domestic oil production should lead to a substantial savings in the import bill. While Australia will continue to depend on overseas capital inflow to balance its external payments during the 1970s, the extent of the dependence is likely to be considerably lessened. Mineral export earnings should be contributing over a third of export income by the late 1970s, compared with about 24 percent in 1970 and less than 10 percent about five years previously.

All told, as Australia entered the 1970s, its economic outlook was bright. (E.I.U.)

TRANSPORTATION

Overall patterns. Because of the great size and small population of Australia, transport has always been costly and has absorbed an unduly high proportion of the total work force. Moreover, the main lines of road and rail transport were laid down in the second half of the 19th century, when Australia was a collection of separate colonies, each of which looked to Britain for most of its trade. The transport system was therefore designed to maintain this trade with roads and railways radiating from the main ports. Little thought was given to internal transport between the separate colonies. An unfortunate relic of this is the existence of three different railway gauges in the continent. It was not until 1970 that it became possible to go by train from Sydney on the east coast to Perth in the west without changing trains.

Fragmentation of transport system

In spite of these historical and geographical handicaps, Australia is fairly well equipped with roads and railways, especially in the southeastern states. It has some 2.7 miles (4.3 kilometres) of railway per 1,000 persons as against 2.1 miles (3.4 kilometres) in the United States, and more than 350 motor vehicles per 1,000 as against 280 in the United States. It is one of the most highly motorized countries in the world.

Australia is almost entirely lacking in internal waterways. For a short period during the 19th century the Murray–Darling river system was widely used to transport produce (mostly wool) from the country districts of New South Wales and Victoria to the coast, but the variable flow of water in these rivers always made this method hazardous and unreliable. With the coming of the railways it was quickly abandoned.

On the other hand, Australia is in many ways ideally suited to air transport. The great distances, lack of mountains, and fine prevailing weather makes flying safe and economical. Australia took to the air age with enthusiasm. By the 1970s Australia's internal airlines carried about 6,000,000 passengers a year.

For the historical reasons already outlined, roads and railways are mainly the responsibility of the six state governments, while shipping and air transport between the states is the responsibility of the federal government. Since 1946 the Australian Transport Advisory Council, including the federal minister for shipping and transport and the six state ministers for transport, has provided machinery for coordinating transport on national lines.

Component systems. As has been noted above, the main road networks in Australia radiate from the ports, and especially from the capital cities of Sydney, Melbourne, Brisbane, Adelaide, and Perth. In recent years most of the states, aided by lavish federal grants, have also made remarkable progress in sealing thousands of miles of country roads. By 1970 Australia had some 550,000 miles (885,000 kilometres) of roads and tracks. Of these, slightly in excess of 117,000 miles (188,000 kilometres) were paved and sealed with concrete or bitumen, about 133,000 miles (214,000 kilometres) were paved but unsealed, and some 300,000 (483,000 kilometres) were merely earth roads graded to form a reasonably smooth surface.

The most serious lack is still adequate highways between the state capitals. The Hume Highway between Sydney and Melbourne and the Pacific Highway between Sydney and Brisbane were both far too narrow for the heavy traffic they were carrying in the early 1970s. The only road across the continent from east to west, which links Adelaide and Perth, is still a hazardous adventure for private cars. The only road across the continent from north to south, between Darwin and Adelaide, is not much better.

The provision of adequate expressways and throughways in the great conurbations of Sydney and Melbourne has also fallen behind. Like the industrialized nations of the West, Australia is finding it hard to keep up with the insatiable demands of the automobile.

Railways

The state governments own and operate their own railway systems. The Commonwealth government operates the Trans-Australia Railway, the Central Australia Railway, and the North Australia Railway. Vast sums of money were spent on building these railways in the latter half of the 19th century. By the end of the 1960s the total capital invested in fixed assets by all government railways was approximately $A1,577,000,000.

Today all these railways have a hard struggle to pay their way against the competition of road and air services, but rail transport still plays an important part in the development of the Australian economy. New capital is being spent in providing standard gauge lines between the different state capitals and industrial centres and in building new branch lines where mineral discoveries justify it, as in the case of northwestern Australia. Sydney is also extending its underground and suburban railway system built at the turn of the century.

There are about 66 ports of commercial significance in Australia, of which the great majority are on the east coast. The rest of Australia is notably lacking in good natural harbours. The most important port is Sydney, which has one of the finest harbours in the world. By 1970 Sydney (with Botany Bay) discharged and shipped some 17,000,000 freight tons annually, followed in order by Melbourne, Newcastle, Port Kembla, Fremantle, Geelong, Whyalla, Brisbane, and Port Adelaide. In addition, semi-artificial harbours were being constructed on the northwest coast to handle shipments of iron ore from Western Australia.

Shipping is still the lifeblood of Australia, which at the start of the 1970s imported some 28,200,000 tons and exported some 77,000,000 tons annually. Most of this shipping was in foreign hands, although Australian companies had a monopoly of interstate trade around the Australian coast. Australian registered tonnage represented only 0.9 percent of the total tonnage entering Australian ports from overseas, but the Australian National Line was attempting to extend its share by the purchase of new ships.

Air transport

Australia has one international airline, Qantas Airways, Ltd., which is owned by the federal government. It is one of the world's leading air carriers. By 1971, 17 other international airlines operated regularly in and out of Australia. Sydney has long been the site of the main international airport and a new terminal was opened there in 1970. The same year Melbourne opened a new international airport at Tullamarine.

In the same period ten airlines operated domestic services throughout Australia and Papua-New Guinea. The two major companies are Trans-Australia Airlines (TAA), owned by the federal government, and Ansett-Airlines of Australia (Ansett), owned by private enterprise. Competition between the two is strictly controlled and regulated by federal legislation. Australia is well served by its internal airways, which offer a service that compares favourably in safety, cheapness, and extent with any in the world.

ADMINISTRATION AND SOCIAL CONDITIONS

The structure of government. The constitution of Australia may be described crudely as an amalgam of the constitutional forms of Great Britain and the United States. Like Britain it is a monarchy, and the king or queen of Britain is also the king or queen of Australia. Like Britain, too, the governments both of the Commonwealth and of the states are chosen from the majority party in Parliament. Like the United States, on the other hand, it is a federation, and the duties of the federal government and the division of powers between the Commonwealth and the states are laid down in a written constitution that can be altered only by a referendum that gains the consent of a majority of all the electors and a majority in at least four out of the six states.

Any disputes arising out of the constitution are decided by the High Court of Australia.

Although the queen of Britain is also queen of Australia, Australia is wholly independent. Except when the queen is in Australia, her functions, which, by the 1970s, were almost entirely formal and decorative, are exercised by a governor-general, who resides in the federal capital in Canberra, and by governors in each of the six states. Though formally the governor-general and the governors are appointed by the queen, they are invariably recommended by the Australian governments concerned, and in recent years there has been a growing tendency to choose Australians.

The constitution defines the form and duties of the federal government in some detail. The most important of these are defense, foreign policy, immigration, customs and excise, and the Post Office. Those powers not given to the federal government in the constitution—the residual powers—are left to the states. The state governments are the direct descendants of the colonial governments of the 19th century. Originally they owed their powers to an act of the British Parliament, but these acts are short documents that lay down only the form that the parliaments shall take, not the sort of legislation they may pass.

State and territorial government

In theory the states are sovereign, with real and important powers. They are responsible for justice, education, health, internal transport, and, indeed, for most of the things that most closely concern the citizen. In practice, however, their powers have been greatly weakened by the federal government's decision in 1942, at the most dangerous point of World War II, to collect all income tax itself and then to reimburse the states on an agreed formula. This temporary arrangement has become permanent,

in spite of many political and legal challenges, so that today the states, deprived of any equivalent "growth tax," have become largely dependent on federal grants for their revenues.

The federal government directly administers the internal territories (the Northern Territory and the Australian Capital Territory) and the External Territory of Papua-New Guinea through resident administrators. The Northern Territory has a legislative council consisting of some elected and some nominated members. Papua-New Guinea has an elected House of Assembly as the first stage toward self-government.

Australia is a true parliamentary democracy. Both the federal upper house (the Senate) and the lower house (the House of Representatives) are directly elected by universal adult suffrage, with a voting age of 21. All state lower houses are similarly elected.

The political process

Preferential voting (placing the candidates in order of preference on the ballot paper) is used for all Parliamentary elections. In elections for the House of Representatives the alternative vote system is used; the 60 senators (10 from each state) are elected by proportional representation. Voting in both federal and state elections is compulsory.

Since federation the political struggle for power in Australia has been between the Australian Labor Party and a coalition of anti-Labor parties under different names. For more than two decades after 1949 the federal government was formed by a coalition between the Liberal Party, which broadly represents the interests of private enterprise, and the Country Party, which represents the interests of the farmers and graziers in rural constituencies. Australia entered the 1970s, for example, with the Liberal Party holding 46 seats in the House of Representatives, the Country Party 20, and the Australian Labor Party 59.

The Australian Labor Party is a typical Western social-democratic party, based firmly on the support of the trade unions, and normally preferring practical reforms to socialist theories. It has, however, always had a left-wing retaining a belief in Marxist principles.

There is one other political party of some significance. In 1956 the right-wing of the Australian Labor Party split away, largely influenced by Roman Catholic fears of Communist influence on the ALP (Australian Labor Party), and formed the Democratic Labor Party (DLP). The DLP, which depends chiefly on Catholic votes in Victoria, Queensland, and New South Wales, failed to win a seat in the House of Representatives by the end of the ensuing decade, but entered the 1970s holding four seats in the Senate. By exploiting the system of preferential voting it had also been able to prevent the Australian Labor Party's return to power.

The Australian Communist Party is insignificant in numbers and has no members in the federal parliament. It has retained a disproportionate influence in some trade unions.

Voting in state elections does not necessarily follow voting in federal elections. During the long rule of the Liberal–Country Party coalition in the federal parliament after 1949, Labor governments at different times held office in five of the six states. But with a few minor exceptions, the lines of battle are the same though local issues play a larger part. State Liberal and Labor governments once elected, though on different sides politically, often find themselves in alliance against the Commonwealth either in defending states' rights or in seeking more money from the federal government.

Justice. The law of Australia is based on the common law of England, and many laws are identical with those laid down in acts of the British Parliament. The administration of the law is largely in the hands of the states, each of which has a series of courts culminating in a state supreme court. Between them these courts have a comprehensive jurisdiction that extends to all matters of state, and to most matters of federal, jurisdiction. The states are also responsible for the police.

The High Court of Australia, established by the constitution, is the federal supreme court. It has a general appellate jurisdiction over all other federal and state courts, and has a special duty to decide disputes involving the interpretation of the constitution. The High Court of Australia has a high reputation among legal authorities both inside and outside Australia.

The federal Parliament has created two other federal courts, the Federal Court of Bankruptcy and the Commonwealth Industrial Court. Each federal territory has its own judiciary.

The armed forces. Australia has a proud military tradition dating from the landing of the first Australian Imperial Force on the Gallipoli Peninsula during the Dardanelles campaign of World War I. Since then Australian armed forces have served with distinction in World Wars I and II, in Malaysia, Korea, and Vietnam. The Royal Australian Navy, the Army, and the Royal Australian Air Force are separate services with distinctive uniforms and separate commands.

The Royal Australian Navy is a small but compact, flexible force with a special emphasis on antisubmarine warfare. By 1972 it had one operational aircraft carrier, three guided-missile destroyers, five Daring class destroyers and six destroyer escorts. Four new Oberon class submarines had been delivered.

The first aim of the Army is to provide a highly trained field force for limited warfare in Southeast Asia. Compulsory national service was introduced in 1964. Young men in their 20th year are selected by ballot. Recruits serve two years full-time followed by three years in the reserve. By 1970 the strength of the Regular Army including National Servicemen was 44,000. The Australian Army has made a special study of jungle warfare in which its reputation is undisputed.

The Royal Australian Air Force has three bomber squadrons, four fighter squadrons, five transport squadrons, two utility helicopter squadrons, and two maritime reconnaissance squadrons. By the early 1970s the fighter squadrons were equipped with Mirage and Avon-Sabre fighters, largely built in Australia. Twenty-four F-111C strike-reconnaissance bombers had been ordered from the United States to replace obsolete Canberra bombers.

Social services. Australia may be described as a modified welfare state. The federal and state governments have not yet gone so far as some European countries in providing free education, health, and other services for its citizens but have gone further than the United States. Government benefits include pensions for the aged, invalids, and widows; unemployment and sickness benefits; maternity allowances; and child endowment. Benefits are paid from the National Welfare Fund, which is financed from consolidated revenue. By 1970 welfare services accounted for some 20 percent of the federal budget.

On the other hand, there is a strong tradition in Australia one should buy or build his own house. There are relatively few state or municipal houses and apartments for rent, though there are various federal and state financial schemes to help citizens purchase their own homes.

Education

Responsibility for education lies primarily with the states. Free education at government schools is provided at the primary and secondary levels, though there is also a considerable private sector formed by schools run by the churches (mostly Roman Catholic) and a few grammar schools for children of the wealthy. The principle of giving some state aid to Roman Catholic schools has now been accepted by all the main political parties.

Tertiary education is not free, but the federal government awards Commonwealth scholarships to some 8,500 university students each year and another 1,500 to students at other colleges of advanced education. The federal government also makes grants toward the recurring costs of universities. Australia now has 14 universities and two university colleges. The total enrollment had exceeded 100,000 students before the end of the 1960s.

Health services are everywhere excellent. There is no national health service, but the federal government pays a portion of a citizen's medical expenses providing he insures with a recognized insurance organization. Dental care is at present outside this medical benefits scheme.

Australia's most interesting contribution to the welfare

of the ordinary man is the arbitration system, which has roused much interest in other countries. In brief this is an attempt, unique to Australia and New Zealand, to fix wages and working conditions by law.

Wage fixing

The Constitution gave the federal government the right to undertake conciliation and arbitration in industrial disputes. Armed with this power, the first federal government set up the Commonwealth Conciliation and Arbitration Commission, which began by establishing a "basic wage" necessary to keep in "frugal comfort" the average family of an unskilled worker.

From this beginning an elaborate system has been built up, involving both federal and state arbitration courts, conciliation commissioners, and wage boards, the aim of which is to prevent or mitigate industrial disputes.

If a dispute cannot be solved by collective bargaining or conciliation, then either the employers or the trade union concerned may take the dispute to the relevant court for a judicial decision that has the force of law. Strikes are not forbidden, but a union that strikes in defiance of a judicial award may be held to be in contempt of court and fined accordingly. In practice, therefore, the judges on the Commonwealth Conciliation and Arbitration Commission, after hearing argument from both sides, fix minimum wages and conditions over a large section of Australian industry.

This system has frequently been criticized as excessively cumbrous and, more recently, complaints have been heard that the judges who make the awards are not always equipped to appreciate the economic consequences of their decisions. On the whole, however, it has worked reasonably well over the years though it has certainly not prevented industrial unrest in Australia. It is still supported, with reservations, by both employers and trade unions.

Both Australia's welfare services and arbitration system spring from a deep concern for the common man. From the earliest days Australians have been strongly egalitarian in outlook, quick to resent any claims to privilege either by a class or an individual. This has not prevented class distinctions in Australia—there is a stronger class system than is often admitted—or wide differences in wealth, but it has greatly eased the conflicts inherent in a capitalist society. Australian trade unions are as militant as any in the world in the pursuit of higher wages and better conditions, but the Australian working man entered the 1970s well paid, well cared for, and living in a prosperous, democratic, and expanding country. He was widely judged to be no wage-slave, but rather the master of his own fate.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu. For the first 100 years of white settlement the arts were naturally neglected. Men were too busy exploring and developing this harsh land to have much time or energy left for the graces of life. This neglect was never total. There were always Australians who wrote poems or novels or who painted the landscape of their adopted country, but for the most part they were content to take their art and culture secondhand from England.

Early developments in the arts

The first sign of an Australian consciousness in the arts was the emergence of a small group of writers and artists in the 1890s associated with the Sydney *Bulletin*. Most of them—though not all—tended to express the radical, egalitarian, and nationalist views that were then beginning to stir political life in the colonies. Of these the most important were Joseph Furphy (1843–1912), author—under the pseudonym Tom Collins—of the long novel *Such Is Life* (1903), and Henry Lawson (1867–1922), whose short stories are still worth reading. The *Bulletin* also provided an opportunity for a remarkable collection of artists working in black-and-white, amongst whom Norman Lindsay, who lived until 1970, was the best known.

But Australia's great leap forward in the arts did not take place until World War II, when the growing wealth and sophistication of the cities, and isolation from Britain and Europe, provided a powerful stimulus. This movement began with painting and poetry and later spread to all the arts, with the possible exception of the theatre. Since 1954 the federal and state governments have subsidized the arts on an increasing scale. Both, however, tended to impose a censorship, partially on imported films and books, that was unnecessarily rigid when judged by contemporary standards overseas. In spite of this restriction, by the 1970s the cultural scene was vigorous and lively, though only a few Australian painters, writers, and musicians had won international recognition.

The arts today. The first of the arts to attract attention outside Australia was painting. Starting in Melbourne, a group of painters—of whom George Russell Drysdale, Sidney Nolan, and Arthur Boyd are the best known—developed an original school of Australian painting by adapting contemporary techniques to depict Australian myths and Australian landscape. Since then the influence of that school in Australia itself has dwindled, and young Australian painters now prefer to paint in the international styles of their contemporaries in Paris, London, and New York; but their work is marked by a freshness and vigour characteristic of their young nation. The number of galleries showing contemporary work in Sydney and Melbourne is a remarkable proof of this vigour.

Australian poets have also revealed a new maturity and sophistication, though, unlike artists in other fields, they have tended to turn their backs on the more revolutionary developments overseas and to prefer traditional metrical forms. This may be due to the powerful influence of Alec Derwert Hope and James McAuley, both professors of literature as well as poets, who have consciously set and maintained classical standards in their own work. Kenneth Slessor and Judith Wright are two older poets who have written movingly on Australian history and landscape.

Australian novelists have, on the whole, been less original and creative, though Patrick White (1912–) has won world acclaim for his lyric and visionary contemporary novels *The Tree of Man* (1955), *Voss* (1957), and *Riders in the Chariot* (1961).

The performing arts are more dependent on financial support and suffer from the fact that outstanding artists can always go overseas to Britain or the United States where a wealthier market offers greater rewards. This is particularly true of actors and singers. Australia seems to produce an inexhaustible supply of fine voices, many of whom, from Dame Nellie Melba to Joan Sutherland, have won international fame. In recent years, government subsidies have enabled Australia to maintain excellent national ballet and opera companies. The Australian Broadcasting Company also maintains symphony orchestras in all the capital cities, of which Sydney's is probably the best. By the early 1970s there was reason to hope that the completion of the Melbourne Victorian Arts Centre and Sydney's spectacular Opera House (designed by the Danish architect Jøern Utzon) would enable these cities to become international centres for opera, ballet, and theatre.

The Australian popular arts follow too closely developments in Britain and America to deserve special mention, and the remarkable Aboriginal arts, notably dancing and painting on bark, must be considered dead though efforts are being made to preserve and revive them.

Cultural institutions. The first serious attempt to organize the arts in Australia was the formation of the Elizabethan Theatre Trust in 1954. It was this body that formed the Australian National Opera company and Australian Ballet company. Since then the main work of advising the federal and state governments on the performing arts has been taken over by the Australian Council for the Arts, which was formed in 1967. It is this body that is responsible for deciding how the federal government's grant (A$2,750,000 annually by the end of the decade) should be divided among the various claimants. It has been the policy of the Australian Council for the Arts to give the bulk of federal subsidies to national companies, like the ballet and opera companies, and to encourage the states to accept responsibility for drama and music. Other official bodies are the Australian Broadcast-

The Australian Council for the Arts

ing Commission, the Music Board, the Commonwealth Art Advisory Board, and the Commonwealth Literary Fund.

The state governments have long provided museums and art galleries in their respective states. In 1967 the federal government decided to build a National Gallery in Canberra to house the national collection. Since it is accepted that it is now impossible for such a gallery to compete with the great galleries of Europe and America in collecting European painting and sculpture from the past, this gallery will concentrate on Australian art, past and present, art of the Pacific and Asian areas, and art on a worldwide basis beginning with the 20th century.

Press and broadcasting. The press of Australia is free, independent, competitive, and vigorous. It has long reached high standards in such papers as *The Sydney Morning Herald* and the Melbourne *Age*, both of which are over 125 years old, though Australia has also always had and still has popular papers that are more noted for sensationalism than for sober reporting or informed comment. All of these papers circulate only in the states in which they are published. In 1964 *The Australian* was first published with the aim of becoming a national paper. It is printed in several states and has won a small but influential readership. The Australian *Financial Review* also has a national readership.

Broadcasting and television are shared between the Australian Broadcasting Commission (ABC), a national service dependent partly on fees for licenses and partly on federal government grants, and a number of commercial radio and television stations operating under licenses granted by the postmaster-general and dependent on advertising for their revenues. In general it may be said that while the ABC provides a high quality service, especially in the broadcasting of music, it attracts only a small part of the available audience. The commercial stations, on the other hand, attract large audiences with rather second-rate programs. Commercial television in Australia is heavily dependent on material imported from Britain and the United States.

CONCLUSION

Australia has been called "the lucky country." It is indeed fortunate in its superb climate (in spite of drought), its peaceful history (it is the only continent where there has never been a war), its natural resources, and the unity and uniformity of its people. More recently Australians have also begun to recognize the exceptional privilege of living in a largely unspoiled country where there is still fresh air to breathe and clean seas to swim in. Australia has not, perhaps, escaped the reverse side of this good fortune—a certain complacency and mental laziness—but time can be counted on to cure these faults.

For the future is not likely to be as tranquil as the past. Nothing can now disguise the essential fact that Australia is the last outpost of European civilization in the South Pacific. Now that both Britain and the United States are withdrawing from Southeast Asia, it is left facing problems of great difficulty and complexity.

The first of these is whether it should involve itself in the wars and politics of its neighbours in Southeast Asia or should stand aloof, relying on its distant British and American allies, its own strength and, perhaps, on nuclear weapons. So far Australia has chosen involvement, though not without great hesitation.

The second is whether it should try to maintain its racial purity as a white nation or deliberately seek assimilation with Asia by taking in increasing numbers of Asian immigrants. No one can pretend that these are simple questions to answer. Yet Australians have courage, resourcefulness, and adaptability, which should enable them to meet any dangers and difficulties that may arise.

Australia, History of

This article deals mainly with the history of Australia since its discovery and settlement by Europeans. The ancestors of the Aborigines of Australia arrived in the land some 25,000 years ago. They came from Southeast Asia, but whether they derived from one or more racial stocks is still unknown. In the 18th century AD, Aborigines numbered about 300,000 on the northern and eastern coasts and in the Murray River Valley; some 4,000 lived in Tasmania. For a more detailed treatment of the indigenous people of Australia, see AUSTRALIAN ABORIGINAL CULTURES. This article is divided into the following sections:

I. Australia to 1900

EARLY EXPLORATION AND COLONIZATION

Early contacts and approaches. Prior to documented history, there may have been further Asian contacts. Chinese astronomers are said to have made observations in Australia during the 6th century BC; firmer evidence argues for a Chinese landing near Darwin in 1432. The incursion of Islām into Southeast Asia came within 300 miles (480 kilometres) of Australia, and adventure, wind, or current might have carried some individuals the extra distance. Both Arab and Chinese documents tell of a southern land, but with such inaccuracy that they scarcely clarify the argument. Similarly, the "jave la Grande" shown on some 16th-century European maps may or may not be a genuine representation of Australia. Bugis

(Macassar) seamen certainly fished off Arnhem Land, in the Northern Territory, from the late 18th century and may have done so for generations. Perhaps only effective resistance by the Aborigines against the Bugis reserved Australia for white colonization.

The Portuguese. The quest for wealth and knowledge might logically have pulled the Portuguese to Australian shores; and the assumption has some evidential support, including a reference that Melville Island, off the northern coast, supplied slaves. Certainly the Portuguese debated the issue of a *terra australis incognita* ("unknown southern land")—an issue in European thought in ancient times and revived from the 12th century onward. Yet hard, clinching evidence of contact is lacking.

The Spanish. Viceroys of Spain's American empire regularly sought new lands. One such expedition, from Peru in 1567, commanded by Álvaro de Mendaña, discovered the Solomon Islands; excited by finding gold, Mendaña hoped that he had found the great southern land and that Spain would colonize there. In 1595 Mendaña sailed again but failed to rediscover the Solomons. One of his officers—Pedro Fernández de Quirós, a man of the Counter-Reformation, who desired that Catholicism should prevail in the southland, of whose existence he was certain—won the backing of King Philip III for an expedition under his own command. It left Callao, Peru, in December 1605 and reached the New Hebrides. Quirós named the island group Austrialia del Espiritu Santo, and he celebrated with elaborate ritual. He (and some later Catholic historians) saw this as the discovery of the southern land. But Quirós' exultation was brief; troubles forced his return to Hispanic America. The other ship of the expedition, under Luis de Torres, went on to sail through Torres Strait but almost certainly failed to sight Australia; and all Quirós fervour failed to persuade Spanish officialdom to mount another expedition.

Oceanic exploration. The exploration and settlement of Australia began early in the 17th century.

The Dutch. Late in 1605 Willem Jansz of the Netherlands sailed from Bantam in search of New Guinea. He reached Torres Strait a few weeks before Torres himself and unknowingly saw, and also named, part of the Australian coast—Cape Keer Weer, on the west of Cape York Peninsula. More significantly, from 1611 some Dutch ships sailing from the Cape of Good Hope to Java inevitably carried too far east and touched Australia: the first and most famous was Dirck Hartog's "Eendracht," from which men landed and left a memorial at Shark Bay, Western Australia, October 25–27, 1616. Pieter Nuyts explored almost 1,000 miles of the southern coast in 1626–27, and other Dutchmen added to knowledge of the north and west.

The first landing

Most important of all was the work of Abel Tasman, who won such respect as a seaman in the Dutch East Indies that in 1642 Governor General Anthony van Diemen of the Indies commissioned him to explore southward. In November, having made a great circuit of the seas, Tasman sighted the west coast of what he called Van Diemen's Land (latterly Tasmania). He then explored New Zealand before returning to Batavia. A second expedition of 1644 contributed to knowledge of Australia's northern coast; thenceforth, New Holland was the name for the landmass.

The British. But the Netherlands spent little more effort in exploration, and the other great Protestant power in Europe, England, took over the role. In 1688 the English pirate William Dampier relaxed on New Holland's northeastern coast. On returning to England, he published his *Voyages* and persuaded the Admiralty to back another venture. He traversed the western coast for 1,000 miles (1699–1700) and reported more fully than anyone previously, but in terms so critical of the land and its people that another hiatus resulted.

The middle decades of the 18th century saw much writing about the curiosities and possible commercial value of the southern seas and *terra australis incognita.* This was not restricted to Great Britain, but it had especial vigour there. The British government showed its interest by backing several voyages. Hopes flourished for a mighty empire of commerce in the eastern seas.

This was the background for the three voyages of Capt. James Cook on behalf of the British Admiralty. The first, that of the "Endeavour," left England in August 1768 and had its climax April 20, 1770, when Lieut. Isaac Hicks sighted southeastern Australia. Cook landed several times, most notably at Botany Bay, and at Possession Island in the north, where on August 23 he claimed the land, naming it New South Wales. Cook's later voyages (1772–75, 1776–79) added only a little to Australian exploration but were both symptom and cause of strengthening British interest in the eastern seas.

Captain Cook's voyages

Later explorations. Cook's voyages led to settlement but did not complete exploration of the Australian coasts. Marion Dufresne of France skirted Tasmania in 1772, seeing more, at least of the western coast, than had Tasman. The Comte de La Pérouse, another French explorer, made no actual discoveries in Australia, but his visit to Botany Bay early in 1788 was notable. In 1791 the British navigator George Vancouver traversed and described the southern shores discovered by Pieter Nuyts years before; A.-R.-J. de Bruni, chevalier d'Entrecasteaux, of France also did significant work, especially in southern Tasmania.

Two Britons—George Bass, a naval surgeon, and Matthew Flinders, a naval officer—were the most famous postsettlement explorers. Together they entered some harbours on the coast near Botany Bay in 1795 and 1796; and Bass ventured farther south in 1797–98, pushing around Cape Everard to Westen Port. Flinders, too, was in that region early in 1798, charting the Furneaux Islands. Late that year Flinders and Bass in the "Norfolk" circumnavigated Tasmania, establishing that it was an island and making further discoveries. Several other navigators, including merchantmen, filled out knowledge of the Bass Strait area; most notable was the discovery of Port Phillip in 1802.

Meanwhile, Flinders had returned home and in 1801 was appointed to command an expedition that would virtually complete the charting of Australia. Over the next three years Flinders proved equal to this task. Above all, he left no doubt that the Australian continent was a single landmass. Appropriately, Flinders urged that the name Australia replace New Holland, and this change received official backing from 1817.

France sponsored an expedition, similar in intent to Flinders', at the same time. Under Nicolas Baudin, it gave French names to many features (including "Terre Napoléon" for the southern coast) and gathered much information but did little completely new. It was on the northern coast, from Arnhem Land to Cape York Peninsula, that more work was needed. Two Admiralty expeditions—under P.P. King (1817–22) and J.C. Wickham (1838–39)—filled this gap.

European settlement. The British government determined on settling New South Wales in 1786, and colonization began early in 1788. The motives for this move have become a matter of some controversy. The traditional view is that Britain thereby sought to relieve the pressure upon its prisons, a pressure intensified by the loss of its American colonies, which hitherto had accepted felons. Convicts went to the settlement from the outset, and official statements put this first among the colony's intended purposes. But some historians argue that this glossed a scheme, likely to provoke concern both within Britain and at the diplomatic level, to provide a bastion for British trade in the eastern seas. Supporters of the commercial-strategic view emphasize that Cook had extended hopes that the South Pacific would provide essential naval stores, especially mast timber and flax. (Its lack of documentary support notwithstanding, the argument makes considerable sense.)

British motives for settlement

Whatever the deeper motivation, plans went ahead, with Lord Sydney (Thomas Townshend), secretary of state for home affairs, as the guiding authority. Arthur Phillip served as commander of the expedition; he was to take possession of the whole territory from Cape York to Tasmania, westward as far as 135° and eastward to in-

clude adjacent islands. Phillip's power was to be near absolute within his domain. The British government planned to develop the region's economy by employing convict labour on government farms, while former convicts would subsist on their own small plots.

The First Fleet sailed May 13, 1787, with 11 vessels, including six transports, aboard which were about 730 convicts (570 men and 160 women.) More than 250 free persons accompanied the convicts, chiefly marines of various rank. The fleet reached Botany Bay on January 19–20, 1788. Crisis threatened at once. Botany Bay was poor in soil and water and even as a harbour. Phillip therefore sailed northward on January 21 and entered a superb harbour, Port Jackson, which Cook had marked but not explored. He moved the fleet there; the flag was hoisted on January 26 and the formalities of government begun on February 7. Sydney Cove, the focus of settlement, was deep within Port Jackson, on the southern side; around it was to grow the city of Sydney.

The first settlement

Phillip at once established an outstation at Norfolk Island. Its history was to be checkered—settlement was abandoned in 1813 and revived in 1825 only to provide a jail for convicts who further misbehaved in Australia. (The island served a new purpose from 1856 as a home for the descendants of the "Bounty" mutineers, who by then were too numerous for Pitcairn Island.)

Phillip remained as governor until December 1792, seeing New South Wales through its darkest days. The land was indifferent, disease and pests abounded, few convicts proved able labourers, and the Aborigines often were hostile. The nadir came in autumn 1790 as supplies shrank; the arrival of a second fleet brought hundreds of sickly convicts but also the means of survival.

An authoritarian society. While much change proceeded throughout this period, authoritarian and hierarchical elements remained strong. The reception of convicts continued and was a major fact in social and economic life. Entrepreneurs strove hard but did not yet develop a staple industry. Farmers and graziers began to fill out an arc 150–200 miles (240–320 kilometres) around Sydney: this area was designated as the Nineteen Counties in 1829, and settlement beyond that limit was discouraged. Following the discovery of Bass Strait, and in concern to secure southern waterways, new settlements were made in the south.

From Britain, David Collins sailed in 1803 to settle Port Phillip; his sojourn there was unhappy, and in mid-1804 he moved to the River Derwent in southern Tasmania, already settled (September 1803) by a group from Sydney under John Bowen. Collins resettled the amalgamated parties at Hobart. In November 1804 William Paterson founded a settlement in northern Tasmania, the precursor of Launceston. These settlements united in 1812; they were still under supervision from Sydney, although only nominally from 1825. Among penal outstations settled from Sydney were those at Newcastle (1804) and Moreton Bay (1824), the forerunner of Brisbane. Britain extended its possession over the whole of the continent in the mid-1820s, again suspecting French (or even American) intervention. The western boundary of the governor's commission shifted to 129° in 1825 to include Bathurst and Melville islands in the far north, and there was a small settlement in this region (1824–29). At Western Port, east of Port Phillip, another settlement was made (1826–27), while in January 1827 Edmund Lockyer began permanent settlement at Albany, Western Australia. His instructions stated that Britain now claimed all Australia.

British possession of the whole continent

Structure of the government. As remarked above, the constitutional structure was authoritarian. The governors were all military officers. There were no representative institutions; but the Judicature Acts of 1823 and 1828 provided for executive and legislative councils, with the major officers of government serving in both and an equal number of private individuals, chosen by nomination, in the latter. More significant at this stage was articulation of a judicial system, especially the establishment of supreme courts (New South Wales, 1814; Tasmania, 1824); normal trial by jury did not obtain.

Sociopolitical factions. Within this rigid structure, sociopolitical factions developed and affected events. Most important in the early years was the leadership of the New South Wales Corps, stationed at Sydney from 1791. Some officers of the corps sought power and profit with an avidity that led to clash after clash with the early governors; this culminated on January 26, 1808, when John Macarthur, a former officer of the corps, led a rebellion that deposed Gov. William Bligh (served 1806–08), earlier famous for the "Bounty" mutiny. In due course, the imperial government reacted and recalled the corps; but Gov. Lachlan Macquarie (served 1810–21) also clashed with the colony's "exclusives"—former officers and a handful of wealthy free immigrants. Conversely, he associated himself with the "emancipist" faction—a group that argued in favour of erstwhile convicts having a particular claim upon government and the colony's resources.

The "emancipists"

Macquarie's attitude disturbed the imperial government. After an official inquiry (1819–21) by J.T. Bigge, it encouraged the migration of men of some standing and wealth to both New South Wales and Tasmania. Such men received substantial grants of land and appeared the natural leaders of social and economic development. The emancipists continued to be strong, however, especially through the leadership of W.C. Wentworth (himself the son of a convict woman), whose newspaper, the *Australian* (founded 1824), was the spearhead of opposition, especially to Gov. Ralph Darling (served 1825–31). In Tasmania factions never formed so clearly, but there, also, the press led criticism of the government.

The convicts. By 1830 about 58,000 convicts, including almost 50,000 men, had come to Australia (the rate increasing rapidly after 1815). Many were more or less habitual urban thieves. There were a few political prisoners, while a substantial proportion of the Irish convicts (a third of the total) had become offenders through sociopolitical unrest. In Australia the convicts were either employed by government or "assigned" to private employers. Broadly speaking, conditions were not especially harsh or repressive, and "tickets of leave" and pardons provided relatively quick routes to freedom; assignment to the new settlers of the 1820s, however, often had an element of slavery. Most convicts committed some further misdeeds, although only about one-tenth were charged with serious offenses. Those found guilty went to secondary penal stations, the (sometimes exaggerated) horror spots of Australian history—Macquarie Harbour, Newcastle, and Moreton Bay in this period and, later, Norfolk Island and Port Arthur. The convicts gave Australia a large *Lumpenproletariat*, yet success stories were common enough, and many led decent lives. There were only a few militant protests—the most remarkable was an uprising among Irish convicts outside Sydney in March 1804. Altogether, the convict impact was less grim and ugly than might be expected.

Economic activity. The maintenance of convicts was essentially the economic resource of the colony for many years; this function caused very considerable expenditure by the British government. Wealth was won by supplying government stores with food and grain, or by controlling internal trade (especially in rum), which ultimately depended on the government maintaining the settlements, or by both. The officers of the New South Wales Corps were skilled in filling these roles, although civil officers, private settlers, former convicts, and even serving convicts all had their own means of doing business, and the amount of petty commercial activity was large. Farming was pursued on a widely ranging scale. John Macarthur (see above *Sociopolitical factions*) was most notable of those who early believed that wool growing would be a major economic resource; he himself received a substantial land grant in 1805 to pursue this hope, and he persuaded Bigge of its validity. By 1830 these hopes were yet to be decisively confirmed. Sealing and whaling returned a little more, although the richest seal fields (especially in Bass Strait) were soon thinned; and not until the 1820s did colonists have the wealth to engage seriously in whaling, although British and Americans early

The growth of commerce

used Australian ports for this purpose. Maritime adventure led early colonists to make contact with Pacific islands, most importantly Tahiti.

Exploration. The period saw some notable exploration by land. From early days in Sydney men sought a way over the mountains, 50–100 miles west. The task was accomplished in 1813; the journalist W.C. Wentworth (see above *Sociopolitical factions*) led the party. A surveyor, George William Evans, followed their route to Bathurst (founded 1815) and reported rich pastoral country. John Oxley further mapped the inland plains and rivers, especially the Lachlan and Macquarie, and also explored the southern coasts of future Queensland (1823), while Allan Cunningham was the great pioneer of that state's hinterland (1827). Meanwhile, in 1824–25, Hamilton Hume and William Hovell went overland southward to the western shore of Port Phillip. Charles Sturt, in 1828–30, won still greater fame by tracing the Murray–Murrumbidgee–Darling river system down to the Murray's mouth.

Culture. The writings of explorers and pioneers were Australia's first contributions to literary culture. While catering to the European appetite for natural history, they sometimes achieved literary grace. Pictorial illustrations of the new land, some by convicts, also dated from the earliest years. David Collins' *An Account of the English Colony in New South Wales* (1798) and W.C. Wentworth's *Description of New South Wales* (1817) were literate, informed, and impressive. Wentworth showed skill as a versifier, too, especially in his *Australasia* (1823). Newspapers were founded as early as 1803, and they contributed to cultural as well as political history. Outstanding was the architecture of Francis Greenway, a former convict, who, under Macquarie's patronage, designed churches and public buildings that remain among the most beautiful in Australia.

THE GREAT SHIFT: 1830–60

The three decades between 1830 and 1860 comprised the period of most rapid change in Australia's history. The impact was most evident in politics, but the economy and culture were no less affected. Patterns then established persisted.

Settlement. Four of Australia's six states were formed between 1829 and 1859. A British naval captain, James Stirling, examined the Swan River in 1827 and interested English capitalist-adventurers in colonization. Two years later he returned to the Swan as governor of the new colony of Western Australia. The Colonial Office discouraged schemes for massive proprietorial grants; still the idea persisted, with Thomas Peel—kinsman of the future prime minister Sir Robert Peel—investing heavily. But colonization was grim work in a hot, dry land, with the government reluctant to spend a penny. Western Australia's story for decades was survival, not success.

Yet the same enthusiasm quickly generated around proposals to establish a colony in South Australia, inspired by a British social reformer, Edward Gibbon Wakefield, who argued that if land were sold at a "sufficient" price, its owners would be forced to maximize its value by cultivation, while labourers would have to lend their energies to that task before being able to become landowners themselves. Highly doctrinaire, Wakefieldianism appealed to the liberal intelligentsia and to dissenting groups in England who also backed nascent South Australia. The first colonists arrived in July 1837, and Adelaide was settled soon afterward. The colony experienced many hardships, but lasting significance resulted from its founders' stress on family migration, equality of creeds, and free market forces in land and labour.

The northern and southern portions of New South Wales formed separate colonies. Settlement into the Port Phillip district in the South proceeded very quickly from the mid-1830s, colonists coming from both north of the Murray and from Tasmania; Melbourne's history began in 1835 and boomed immediately. Throughout the 1840s there were calls for constitutional independence, granted in 1851, when the Port Phillip District took the name Victoria. Northward, the Moreton Bay District was never quite so buoyant; and the creation of Queensland had to wait until 1859. Short-lived settlements included Port Essington (1838–49) and Gladstone (1847).

Development of responsible self-government

Politics. All colonies except Western Australia gained responsible self-government. New South Wales led the way when an imperial act of 1842 created a two-thirds elective legislature. The Australian Colonies Government Act (1850) extended this situation to Victoria, South Australia, and Tasmania. The act made allowance for further revision of the colonial constitutions, and in 1855–56 this took effect in the four colonies, Tasmania then abandoning the name Van Diemen's Land. Queensland followed, at its separation from New South Wales. All had bicameral legislatures, with ministers responsible to the lower houses, which by 1860, except in Tasmania, were elected on a near-democratic adult-male franchise.

While the imperial power often responded to colonial cries for self-rule, there were some tense moments. Virtually all colonists abhorred paying taxes for imperial purposes, including the costs of maintaining convicts locally; a good many disliked convictism altogether; most disputed the imperial right to dictate land policy; and many, especially in South Australia, disapproved of the imperial government directing that aid to be given to religious denominations. These were the main issues, coalescing with that of increased self-rule, which stoked sometimes quite violent debate.

From the outset of the period, the imperial government fostered a freer market in land and labour throughout the colonies, not merely in South Australia. Thus grants of land ceased in 1831, replaced by sale. Attempts to create a satisfactory system caused much friction, with colonists generally hostile to any demand for payment. In New South Wales in 1844, new regulations even prompted talk of rebellion.

Friction over convicts

With regard to labour, colonists agreed with imperial encouragement of free migration, but friction arose over the convicts. British opinion in the 1830s became increasingly critical of the assignment of convicts to private employers as smacking of slavery; it was abolished in 1840, and with it transportation of convicts to the mainland virtually ceased, although more than before were sent to Tasmania. The end of assignment removed the chief virtue of transportation from the colonists' viewpoint and so contributed to a very vigorous movement against its continuation. The British government terminated it for eastern Australia in 1852; in Western Australia transportation commenced in 1850, at the colonists' behest, and continued until 1868. Altogether some 151,000 convicts were sent to eastern Australia and nearly 10,000 to Western Australia.

In the early 1850s the most dramatic political problem arose from the gold rushes (see below *The economy: Minerals*). Diggers (miners) resented tax imposition and the absence of fully representative institutions. Discontent reached a peak at Ballarat, Victoria, and in December 1854, at the Eureka Stockade, troops and diggers clashed, with loss of life. The episode is the most famous of the few occasions in Australia's history involving violence among Europeans.

Common suspicion of the imperial authority modified but did not obliterate internal tension among the colonists. Divisions of ideology and interest were quite strong, especially in Sydney, where a populist radicalism criticized men of wealth, notably the big landholders. The coming of self-government marked a leftward, although far from revolutionary, shift in the internal power balance.

The economy. This period saw the first and greatest booms of the two bonanzas of Australian economic growth—wool and minerals.

Wool. Only now did men, money, markets, and land availability interact to confirm that Australia was remarkably suited for growing fine wool. Occupation of Port Phillip was the most vital part of a surge that carried sheep raising 200 miles and deeper in an arc from beyond Adelaide in the south, north, and east to beyond Brisbane. The "squatter" pastoralist became an arche-

type of Australian history. Although pastoralism contributed to depression in the early 1840s, the industry kept growing, and the whole eastern mainland benefitted consequently.

Pastoral expansion had one grim corollary—disaster for the Aborigines. Relations between the two races were always tense. The early governors all ordered and even practiced benevolence, but to little effect. When the European spread inland, the Aborigine fought hard, but that only strengthened the European's arm. The Tasmanians moved rapidly toward extinction, but the Australians, with further room for withdrawal, evaded that fate. Philanthropists, missionaries, and administrators stood aghast but found no remedy.

Minerals. The first significant mineral discovery was that of copper in South Australia (1842 and 1845). The discovery had the effect, to be repeated time and again, of suddenly redeeming an Australian region from stagnation. Much more remarkable, however, were a series of gold discoveries made from 1851 on, first in southern New South Wales, but then, and overwhelmingly, throughout Victoria. As a result, Australia changed from a land of exile to one of golden attraction. The Victorian economy benefitted from the flood of men and money, although the smaller colonies suffered. Despite the Eureka Stockade incident, the diggers proved quite moderate and responsible.

Culture. Governments and citizens paid considerable heed to improvement of soul and mind. From the mid-1830s, generous aid helped all Christian churches to expand. The Church of England had the highest nominal allegiance, but in the eastern mainland colonies Roman Catholicism was notably strong; Methodism had vigorous advocates throughout; Congregationalism and other forms of dissent dominated in South Australia; and Presbyterianism had its chief strength in Victoria. Most churches attended to education, especially the provision of superior schools, while the state struggled to provide a primary system. The universities of Sydney and Melbourne were founded in 1850 and 1853, respectively. Mechanics' institutes, museums, and botanical gardens were also built.

Architects created much beauty in early Australia. Artists and writers were active; drama and music developed in all towns. The first Australian novel, *Quintus Servinton* (1831), was by a convict, Henry Savery; Henry Kingsley's *Geoffrey Hamlyn* (1859) is often judged the first major Australian novel (though Kingsley was an English citizen). John West's *History of Tasmania* (1852) was a work of remarkable scope and insight.

Further exploration

Various forms of science had their investigators, but land exploration remained the richest field of discovery. Sir Thomas Livingstone Mitchell confirmed Sturt's work on the river systems (see above *An authoritarian society: Exploration*) and first opened the way from New South Wales to the rich lands of western Victoria (1836). The West Australian coastal regions were mapped by George Grey (1837–40) and by Edward John Eyre, who went overland from Adelaide to Albany (1840). Eyre and Sturt both vainly attempted to reach midcontinent from Adelaide; this was at last achieved in April 1860 by John McDonall Stuart, who in 1862 went still farther, to Darwin. Meanwhile, the central north and the northeast had been penetrated from Sydney; the most famous explorer was Ludwig Leichhardt, who led two successful expeditions (1844, 1846–47) before disappearing in an attempted traverse from the Darling Downs to Perth. An equal and more celebrated tragedy ended the expedition of Robert O'Hara Burke and William John Wills, who crossed from Melbourne to the Gulf of Carpentaria in 1860–61 but starved to death on the return. Later explorations of Western Australia in the 1870s added the names of John Forrest and Ernest Giles to the pantheon of explorer-heroes.

SEVERAL SMALL DEMOCRACIES: 1860–1900

During this period the colonies had little formal relation with each other; instead they concentrated their attention inward on their capitals. New Zealand had more in common with the eastern colonies than did Western Australia. Federation came about in 1901, but the more striking fact was its tardiness. Nevertheless, the colonies did follow similar, if independent, paths.

Politics. Democracy was largely fulfilled, save that the upper houses remained elitist in franchise and membership. Governments changed rapidly over long periods, but the constitutions survived. Political groupings were extremely intricate, often personal or power seeking in origin, but allowing some expression for liberal or conservative ideology.

Social reform

The liberals made the colonies quite advanced in matters of social reform, if not the average man's paradise that some glib publicists pictured. Breaking up the large "squatter" estates and replacing them with yeoman farming was a constant concern, meeting many difficulties yet achieving some effect where market and environment allowed. Reformers put much faith in education and strove toward providing adequate primary schooling for all. "Free, secular, and compulsory" was a slogan and roughly the final result; this entailed savage controversy with the Roman Catholic Church, which scorned the godless schools and made enormous efforts to provide its own. Other forms of state aid to religion tapered away. Factory legislation and rudimentary social services presaged the welfare state; restriction of nonwhite, especially Chinese, immigration belonged to this context, for Europeans feared these labourers would reduce living standards, but the restriction was also a matter of sheer racism.

The economy. Overall the economy prospered. Wool and metals continued as the great export income earners. Pastoralism flourished, especially up to the mid-1870s; despite land legislation, this was the heyday of the squatter "aristocracy." Expansion of sheep and cattle growing into the more distant hinterland continued the heroic-pioneer theme of earlier years. Railway construction aided rural industry and proceeded remarkably fast, notably in the 1880s: between 1875 and 1891 the mileage rose from 1,600 to above 10,000 and reached as far as 500 miles (800 kilometres) inland. Most of the required capital was raised overseas on behalf of governments, contributing to the extremely important role played by the public sector in economic growth.

Gold and copper discoveries

Mining. Victoria's gold and South Australia's copper maintained their significance as new techniques allowed more sophisticated exploitation. Gold was found in southern Queensland in the later 1860s, then in the Northern Territory, and in tropical Queensland: the Palmer River goldfield pulled men to the far north in the mid-1870s. By then Cobar, in central New South Wales, had proved the most important of many new copper fields. Tin also became significant, Mt. Bischoff in Tasmania being the world's largest lode at its discovery in 1871. The 1880s was predominantly the decade of silver; western New South Wales proved richest, and in 1883 Charles Rasp, a German migrant, first glimpsed the varied riches of Broken Hill, which were to make that city almost fabulous and to prompt the establishment of Broken Hill Proprietary Company Ltd.—in time, Australia's largest private enterprise. Also from 1883 dated another big and ramifying discovery, the gold of Mount Morgan, Queensland. Gold also became Western Australia's great bonanza in the early 1890s, the Kalgoorlie and Coolgardie fields winning world attention; the copper of Mt. Lyell, Tasmania, was another highlight of that decade. These discoveries were both product and instigator of much wider activity, creating speculation, mobility, boom, and slump of extraordinary impact.

Industry. Urban expansion and the growth of secondary industry, while less distinctively Australian and contributing little to export income, were remarkable. By the criteria of investment, employment, and relative acceleration, the growth of secondary industry outstripped that of primary industry. Secondary industry multiplied its growth some ten times over during the period, so that manufacturing and construction accounted for 25 percent of the national product in the 1880s. The population ratio shifted decisively from country to town, establish-

ing an extreme capital-city concentration and eventually putting Melbourne and Sydney among the world's large cities. Urban building and services attracted much capital; and most manufacturing was directed to providing food, furniture, and clothing for the relatively affluent townsman. City speculation contributed more than its share to a general overcapitalization, which, in company with worldwide forces, produced a depression in the early 1890s, the main impact of which was in the urban-secondary sector.

The colonies. The history of the respective colonies sharpens some points in this general background. In the later 19th century, regional characteristics consolidated, and they changed little at least until the 1960s.

Victoria. Victoria retained the impetus of the 1850s for a full generation. This was most evident in its capital, Melbourne, which had a vigorous cultural and social life. Ardent and ideological liberalism was evident in the colony's education controversy and, with greater novelty, in its adoption of protection as a means of developing its industries and living standards. Disputes between the upper (conservative) and lower (radical) houses of the parliament were frequent and sharpened political feeling. A famous clash occurred in 1865–66 over a protective tariff; another, in 1877–78, over payment of members—the liberal cause triumphed on both occasions.

Adoption of protection

New South Wales. With its longer background, New South Wales changed less in this period. Its master politician, Henry Parkes, first came into prominence in the 1840s. Parkes was involved in sectarian disputes, which were especially vigorous in the colony. Another major theme of political debate was protection versus free trade—the latter retaining greater favour, in contrast to Victoria. Sydney had its share of scandals and scalawags, especially late in the period, contributing to a rumbustious image.

Queensland. Physical expansion westward and northward dominated the history of Queensland. Cattle and sugar became industries of substantial importance. A class of small farmers was established that aspired to settle the tropics, which were usually considered unsuitable for small-scale farming by Europeans. Conversely, the established "kings" of the region used Kanakas (labourers from the Pacific islands). Thus the continued immigration of such labour provoked hot debate, which was not resolved until after federation, when the young commonwealth imposed an absolute prohibition. The Kanaka question contributed to regional feeling antagonistic to the capital.

South Australia. South Australia enjoyed less prosperity than its eastern neighbours. Agriculture remained significant in its economy but saw much disappointment; in the decade around 1870 farmers pushed out into semi-arid country, hopeful that rain would follow the plough, only to learn with cruel certainty that it did not. Settlement drew back toward Adelaide, the sole sizable town. Landholding did prompt South Australia's most famous contribution to reform: that land transfer proceed simply by registration, rather than through cumbrous title deeds. Another notable contribution was the institution of woman suffrage (1894), which effectively brought nationwide application of the principle at federation; appropriately, South Australia was the home of Catherine Helen Spence, the most remarkable Australian woman of the time, who published a significant novel, *Clara Morison* (1854), and became active in many social and political movements.

Woman suffrage

In 1863 South Australia took over the administration of the area thenceforth known as the Northern Territory, which earlier had remained technically part of New South Wales; the change entailed adjustment of boundaries. (The Northern Territory became the concern of the federal government in 1911.) South Australia set up its administrative centre at Darwin. In 1872 the construction of an overland telegraph line linked Australia with the outside world via Darwin.

Tasmania. The 1860s imprinted a "sleepy hollow" image on Tasmania, which persisted. The mineral discoveries at Mt. Bischoff and elsewhere were correspondingly important in reviving the economy. Nevertheless, living standards remained lower than in Victoria, and in Tasmania there were still property qualifications for voting in 1900. The colony contributed to democratic practice, however, by experimenting with proportional representation.

Western Australia. Western Australia ceased to receive convicts in 1868; it gained a partly elected legislature in 1870 and responsible government in 1890. Premier throughout the 1890s was John Forrest, as adept at politics as at exploration. Until the gold rushes, economic growth was slow and primitive; in the 1890s the colony was fastest in relative growth, and little short of that in absolute terms. Farming (in the southwest), town and railway building, and social legislation all followed.

Social movements. Working class and radical movements stretched back to the 1830s, although substantial trade union organization came only after midcentury.

Labour. The unions won some job benefits, including widespread adoption of the eight-hour day. The 1870s and 1880s saw extensive mass unionism, notably among miners and sheep shearers. Trades halls arose in the cities, and organization, extending beyond colonial boundaries, began to knit together. The unions early considered using political pressure and gaining political representation. This inclination strengthened in the early 1890s, helped by tougher times and by employers' stiffening resistance to union demands. Thus arose the labour parties, which gained quick success, especially in New South Wales and Queensland. At first the labourites' aim was simply to influence ministries, but for a few days in December 1899 Anderson Dawson was Labor premier in Queensland.

Rise of the labour parties

Other radicals reacted differently to the pressures of the 1890s. A few hundred of them set off for Paraguay in 1895 to establish there a Utopian "New Australia"; they failed. Republicanism was probably stronger in the 1890s than at any other time, sometimes accompanying a Marxist-like militance.

Movement toward federation. Federation was another ideal of the times. Most important politicians supported the cause, with more or less altruism. They could operate on more positive factors than common background and apparent common sense. Since the Crimean War (1853–56) Australians had feared incursion from the north by Europeans or Asians or both; the most emphatic result came early in 1883, when the government of Queensland, fearful of Germany, took possession of Papua, forcing Britain's reluctant connivance. Better defense was one motive for association, and so was the prospect of more effective Asian immigration restriction; intercolonial free trade was another desideratum. The Australian Natives Association (Australian-born comprised 64.5 percent of the population in 1901) rallied to the cause.

Yet the mills ground slowly. A federal council existed from 1885, but this was only a standing conference, without executive power. New South Wales never joined the council; the senior colony was jealous of a movement that would reduce its autonomy, the strength of which was in Victoria. Conventions met in 1891 and 1897–98 to prepare draft constitutions. These then went to referenda, which gained "yes" majorities. The Commonwealth of Australia came into existence on January 1, 1901.

The Commonwealth of Australia

The constitution was federal, with the states (as the colonies now became) forsaking only limited and specified power to the commonwealth government—these included defense, immigration, customs, marriage, and external affairs. While the lower house, the House of Representatives, was elected by single-member constituencies of roughly equal size, each state had an equal number of representatives in the upper house, the Senate. Ministers were to be members of Parliament. A high court would interpret the constitution.

Culture. Men of learning had contributed to the nationalist surge. Especially in the 1890s and through the Sydney *Bulletin*, verse and prose portrayed the "Outback" as the home of the true Australian—the bush worker:

tough, laconic, and self-reliant, but ever ready to help his mate. The *Bulletin* was nationalist, even republican, and much more radical than the federalist politicians. Henry Lawson and Joseph Furphy were the supreme writers of the nationalist school, and the latter's *Such Is Life* (1903) was an outstanding novel. Painters and poets also extolled the nationalist ideal.

Not all cultural achievement belonged to the nationalist context, however. Henry Kendall was a lyricist of nature, and A.L. Gordon wrote of horses and countryside with a skill that won him a memorial in Westminster Abbey. "Rolf Boldrewood" (Thomas Alexander Browne) wrote tales of outback adventure, while the great 19th-century Australian novel was Marcus Clarke's *For the Term of His Natural Life* (1874), based upon convict records and legends. The older universities remained small, but with some outstanding men on their faculties; the universities of Adelaide (1874) and Tasmania (1890) were new foundations. Ferdinand von Mueller was an outstanding botanist who worked primarily at the Botanic Gardens, Melbourne. That city was the hometown of the great coloratura soprano Nellie Melba (Helen Porter Mitchell, born 1861), not quite the first but certainly the most famous of numerous Australian singers to achieve international renown.

Popular culture

Popular culture followed the British model, with music halls, novelettes, and especially sport to the fore. "Australian Rules" football developed first in Melbourne and became strong throughout southern Australia; in cricket, a victory over the mother country in 1882 established one area of colonial equality. Admiration combined with fear to create a sporadic cult of the bushranger (rural desperado-thief): its most famous expression came with the capture of Ned Kelly's gang and Kelly's execution in 1880. Urban youths joined in gangs, or "pushes," and won the epithet larrikin.

II. Australia since 1900

NATIONHOOD AND WAR: 1901–45

The world's passions and conflict of the early 20th century were to shape the new nation's history, despite its physical distance from their epicentres. By many standards, this was the least attractive of the five major periods of Australian history. Nationalism strengthened, but it killed and sterilized rather more than it inspired; egalitarianism tended to foster mediocrity; dependence on external power and models prevailed. Yet creativity and progress survived.

The economy. Drabness was most evident in economic affairs. At the broadest level of generality, the period did little more than continue the themes of the 1860–90 generation. The most important such themes were the improvement of communications (railways reached their peak of 27,000 miles in 1941, and meanwhile came the motor boom) and increasing industrialization. In the primary field, there was significant expansion of exports, with wheat, fruits, meat, and sugar becoming much more important than hitherto. But just as manufactures received increasingly high tariff protection, so the marketing of these goods often depended on subsidy; and so the sheep's back continued to be the nation's great support in world finance. Metals, gold especially, were important in the early years; but thereafter this resource conspicuously failed to provide the vitality of earlier and later times. The worldwide economic depression of the 1930s affected Australia, especially its primary industries; otherwise the overall rate of growth, and probably of living standards, too, scrambled upward—a little more quickly than average in the mid-1920s and perceptibly so in the 1940s.

Politics and government. In national politics, men fought for office with increasing vigour and resource, while their administrative performances generally began well but then ebbed. Retrospect can espy a strangely regular pattern wherein four crisis episodes—the establishment of national policies, World War I, depression, World War II—alternate with three periods dominated by a political party enjoying its climacteric. The Labor Party filled this role in 1904–15; the Country Party, 1919–29; and the United Australia Party, 1931–41. At the state level politics were more confused, if not impenetrable.

Strengthening of the central government

A constant theme was the strengthening of the central government as against the states. This complemented the high degree of homogeneity, especially in personal and social matters, that extended through Australia's great physical spread; it was expressed primarily through the commonwealth's financial powers—at first especially relating to customs but later by direct taxation. From World War I both levels of government imposed such taxes, but in 1942 the federal government virtually annexed the field, with the high court's approval. The establishment of a national capital at Canberra, where Parliament first sat in 1927 after meeting in Melbourne since federation, symbolized this situation.

Culture. The period produced not only Furphy's *Such Is Life* (see above *Social movements: Culture*) but also the work of Henry Handel Richardson (H.H.R.; pseudonym of Ethel F.L. Richardson, later Robertson), another contender for "the great Australian novelist." In *The Fortunes of Richard Mahony* (three volumes, 1917, 1925, 1929), H.H.R. told the anguish of the central character, modelled on her father, as he sought to come to terms with Australian life. The tension of dual loyalties to Britain and Australia was a major concern also of Martin Boyd, whose long career as a novelist began in the 1920s. A more exclusively nationalist tone pervaded many tales of outback life and historical novel sagas. The first notable novel of urban life was Louis Stone's *Jonah* (1911); a later contributor to this genre was Vance Palmer (especially *The Swayne Family*, 1934), who, with his wife Nettie, won fame as a literary critic and selfless patron of the aspiring young.

The most significant contribution in poetry came from a group in Sydney influenced by the German philosopher Nietzsche and the late-19th-century French innovators. Outstanding was Christopher John Brennan, a major theorist of symbolism. While calling on the Australian background, these men gave a sophistication to their poetic world that lifted it far from outback balladry. Associated with this group was Norman Lindsay, an artist, novelist, sculptor, and seer.

In art, the rural landscape held domination. Revolutionary changes in European art were markedly slow in affecting Australia, but a few artists did produce some notable work of imaginative technique. Musical composition was hackneyed and mediocre, although in Percy Grainger Australia produced (but did not retain) a musician of remarkable originality and ability. Architecture promised an interesting chapter with the selection of the American Walter B. Griffin's design for the city of Canberra; in practice this was much mutilated, but Griffin did do some interesting work in both Melbourne and Sydney.

Education

One outstanding area to which the universities contributed was anthropology; a chief protagonist was A.R. Radcliffe-Brown (professor of anthropology at Sydney, 1925–31). Australians increasingly filled faculty posts, although most who did so had Oxbridge degrees, while some of the most able native intellects worked overseas. The University of Western Australia, founded in 1911, drew on one of the most substantial philanthropic bequests in Australian history (from the newspaperman Sir Winthrop Hackett) and initially charged no fees. Other university foundations were Queensland (1909) and colleges at Canberra and Armidale. The states developed their own secondary schools throughout the period, although the achievement was scarcely comparable to the development of primary education in the early period.

Australia was in the forefront of film making early in the century, but this early promise soon faded. A.B. Paterson's "Waltzing Matilda" became Australia's best known song—part folk hymn and part national anthem. Radio had an impact in Australia equal to that elsewhere; radio stations became a mark of medium-town status, and the Australian Broadcasting Commission became a major force in culture and journalism. Radio

helped make the 1930s probably the most sports-conscious decade in Australia's history. Cricket, tennis, swimming, boxing, and horse racing were areas of athletic excellence. Aviation moved from sport to enterprise to business; Charles Kingsford-Smith was the most famous hero and Qantas the most successful airline.

Early ministries

Growth of the commonwealth. The first two prime ministers were Edmund Barton (served 1901–03) and Alfred Deakin (served 1903–04), who had led the federation movement in New South Wales and Victoria, respectively. They were liberal protectionists. Their ministries established the "White Australia" (*i.e.*, exclusion of Asians) immigration policy, a tariff, an administrative structure, the high court, and a court of conciliation and arbitration that carried probably to the highest point anywhere in the world the principles of industrial arbitration and judicial imposition of welfare and justice through wage and working-condition awards.

In 1904 J.C. Watson led the first, brief Labor cabinet, followed by G.H. Reid's conservative free-trade ministry. Deakin led again (1905–08); then Andrew Fisher was Labor's second prime minister (1908–09), his ministry defeated when liberals and conservatives "fused" in Deakin's third term (1909–10). Then Labor won its first clear majority at election, which it barely lost in 1913 and regained, still under Fisher, in 1914. This kaleidoscope did not hinder—perhaps it even prompted—ambitious governmental policies. Social services were extended with old-age pensions (1908) and maternity grants (1912); protection rose markedly in a 1908 tariff; the Commonwealth Bank was established; and an army and navy developed.

The new nation was psychologically as well as physically prepared for war. Fear of attack became increasingly directed against Japan, and it prompted pressure on Great Britain for a firmer policy in the New Hebrides (since 1886 supervised jointly by Britain and France)—achieved in 1906–07. Although many Australians criticized Britain when the latter appeared negligent of local interests, the dominant note was overweening loyalty to the empire. Colonial troops had fought in both the Sudan and Boer wars. In 1914, when World War I began, politicians of all hues rallied to the imperial cause.

World War I. Some 330,000 Australians served in World War I; 60,000 died, 165,000 suffered wounds—few nations made such relatively heavy sacrifice. The most famous engagement of the Australia and New Zealand Army Corps (ANZAC) was in the Dardanelles campaign (1915); the day of the landing at Gallipoli—April 25—became a day of national reverence, honoured far beyond any other. Even before Gallipoli, Australian troops had occupied German New Guinea, and the Australian vessel "Sydney" sank the German cruiser "Emden" near the Cocos Islands (November 9, 1914). After the Dardanelles, Australians fought primarily in France—Ypres, Amiens, and Villers Bretonneux were among the battles, all redolent with slaughter. In Palestine, the Australian light horse and cavalry corps contributed to Turkey's defeat.

Effects of war

The war profoundly affected domestic affairs. In economic development, it acted as a supertariff, benefitting especially textiles, glassmaking, vehicles, and the iron and steel industry. Such products as wool, wheat, beef, and mutton found a readier market in Britain, at inflated prices. But the shock of war affected politics much more, especially by giving full scope to the furious energy of W.M. Hughes, who supplanted Fisher as Labor prime minister in October 1915. Soon afterward he visited Britain. There his ferocity as a war leader won acclaim, and he became convinced that Australia must contribute still more. He advocated military conscription for overseas service; but a referendum in October 1916 declared negatively for this proposal, and immediately afterward the Labor parliamentary caucus moved no confidence in Hughes's leadership. But he continued as prime minister of a "national" government, even after losing a second conscription referendum in December 1917. The referenda in particular and war stress in general made these years uniquely turbulent in Australian history. The Labor Party lost other men of great ability along with Hughes. The split cemented a long-standing trend for Roman Catholics to support the party. Hughes's enemies also included the small but growing number of extremists—most notably the Sydney section of the Industrial Workers of the World (IWW)—who opposed the war on doctrinaire grounds.

The postwar years. The aftermath of war echoed, but finally resolved, this turbulence. Some radicals hoped that returning servicemen would force social change; but instead, the Returned Servicemen's League became a bastion of conservative order, its supporters ready to use physical force against local people they considered "Bolsheviks." The Labor Party faltered, its members adopting a more radical socialist type of platform in 1921, but with far from uniform conviction. When the challenge came to Hughes's leadership early in 1923, it arose partly from the conservative-business wing of Hughes's own Nationalist Party (its representative S.M. Bruce becoming prime minister) and partly from the Country Party, which from late 1922 held a crucial number of parliamentary seats. Although led by wealthy landowners, the Country Party won support from many small farmers: it benefitted too from its former-soldier image and from widespread country-versus-city feeling. Its leader, E.C.G. Page, had considerable, if erratic, force.

"Men, Money, Markets"

Bruce continued as prime minister until 1929, with Page his deputy in Nationalist–Country coalitions. Bruce declared his policy to be the discovery of "Men, Money, Markets" and worked hard toward this end. The cost was high, however: tariffs, bounties, prices, and public indebtedness all rose. There was considerable administration innovation—*e.g.*, the Loan Council regulated all governments' overseas borrowing—and the successful Council for Scientific and Industrial Research (later, the Commonwealth Scientific and Industrial Research Organisation [CSIRO]) was established in 1926 to apply scientific expertise to developmental problems. The worldwide development of consumer industry had its impact: the revolution in transportation provided by the automobile is the best example, although full-scale car production was still in the future.

With much economic activity subsidized—the exception being one primary product (wool)—Australia was particularly vulnerable to the Great Depression of the 1930s. It struck hard: unemployment exceeded 25 percent of the work force and imposed a degree of social misery unknown in Australian history. The rate of recovery was uneven, manufactures doing better than primary industry. Population growth slowed; at the nadir, emigration exceeded immigration.

Politics reflected the impact. J.H. Scullin succeeded Bruce as prime minister in 1929, and his Labor ministry suffered the real squeeze of events; within the Labor Party there was considerable division as to how government should react to the Depression. Some favoured a generally inflationist policy, with banks facilitating credit issue and governments extending public works. Right-wing Labor men distrusted such a policy; radicals would have gone further, by renouncing interest payment on overseas loans. Orthodox opinion argued for deflationary policies—curtailed government expenditure, lower wages, balancing the budget, and the honouring of interest commitments. In June 1931 the commonwealth and the state governments agreed on a plan—the Premiers' Plan. Albeit having some inflationary features, this foreshadowed a one-fifth reduction in government spending, including wages and pensions—a considerable affront to Labor's traditional attitudes.

Against this background, the government disintegrated. Before the Premiers' Plan, some right-wingers, led by J.A. Lyons, had crossed to the opposition. In November some leftist dissidents voted against Scullin, forcing his resignation. In the elections that followed, Labor suffered a heavy defeat. The new prime minister was J.A. Lyons, whose followers had coalesced with the erstwhile Nationalists to form the United Australia Party (UAP). Lyons led a wholly UAP government until 1934 and UAP–Country coalitions until his death in 1939.

The governments of J.A. Lyons

The Lyons governments provided stability and not much more. Recovery was uneven and sporadic, quicker in manufacturing than in primary industry, aided more by market forces than by governmental planning. Two policies failed badly to fulfill expectations—the Imperial Economic Conference, held at Ottawa, Ontario, in 1932, improved trade slightly, but the integrated economic community for which some had hoped never developed; and Australia's "trade diversion policy" of 1936, which tried to redress the imbalance of imports from Japan and the United States, offended those countries and actually reduced exports further. A plan for national insurance, the Lyons governments' most ambitious social legislation, also aborted. These mishaps did not much bother the electorate; improvement, even if meagre, was enough to retain favour.

Internal division was the greater threat to the government. This became manifest after Lyons' death. The UAP elected Robert Menzies as its new leader (and therefore prime minister); but the decision was hard fought, and it was criticized publicly and vehemently by Page, still leader of the Country Party. Nevertheless, Menzies retained office; but internal division persisted, the coalition's parliamentary majority was tiny, and Menzies resigned in August 1941. A.W. Fadden, the new leader of the Country Party, then took office, but in October he gave way to John Curtin and a Labor ministry.

Communist and Fascist movements

While the electorate generally voted conservative, Australia shared the common Western experience of the interwar years in the rise of a small, vigorous Communist movement. Founded in 1922, the Australian Communist Party made most headway in the big industrial unions and in Sydney; it also had some influence and supporters among the intelligentsia, especially during the 1930s. Overall, the party suffered a fair share of internal factionalism but for the most part was able to present a united face to the public.

Fascism achieved no formal political recognition in Australia, but there were hints of sympathy toward Fascist attitudes—D.H. Lawrence wrote of such in his novel *Kangaroo*, based on a brief visit in 1922; and an "Australia First" movement began in literary nationalism but drifted into race mystique and perhaps even treason. An intellectual movement of more lasting force developed among a group of young Roman Catholic intellectuals in Melbourne in the mid-1930s. They developed a commitment to social justice and against Communism somewhat in the manner of G.K. Chesterton. This was the "Catholic Social Movement," which had considerable influence on Australian Catholics.

Whereas Australia had been virtually spoiling for war before 1914, passivity became the international keynote after 1920. At the Paris Peace Conference that formally concluded World War I, Hughes was his fire-eating self, especially in defense of Australia's interests in the Pacific; thus he won a mandate for erstwhile German New Guinea and Nauru (an atoll in the central Pacific) and effectually opposed a Japanese motion proclaiming racial equality, which he thought might presage an attack on Australia's immigration laws. In the League of Nations, Australia was an independent member from the outset. Bruce's succession as prime minister marked a new emphasis. Very much an Anglo-Australian, Bruce led the nation into a period when "the empire" became the object of yet more weighty rhetoric and more desperate hope than earlier. Australia did not ratify the Statute of Westminster (1931, embodying the 1926 Balfour Declaration as to the constitutional equality of the Dominions) until 1942. The UAP governments followed Britain closely concerning the totalitarian expansion of the 1930s; if Australian influence counted for anything, it was to strengthen appeasement of Germany and Japan. Although fear of Japan continued, that country's accession to the Fascist camp did not provoke a tougher governmental line. The Labor Party meanwhile was even more incoherent and variable in matters of foreign policy than were its social-democratic counterparts elsewhere in the Western world: isolationism and anti-Fascism were equal and opposing forces.

World War II. When war came again, however, the nation's response was firm—some 30,000 Australians died in World War II and 65,000 were injured. From early in the war, the Royal Australian Air Force was active in the defense of Britain. The Australian Navy operated in the Mediterranean (1940–41), helping to win the Battle of Cape Matapan (March 1941). Australian troops fought in the seesaw battles of North Africa. In mid-1941 Australians suffered heavy losses both in the Allied defeats in Greece and Crete and in the victories in the Levant. Meanwhile, the German general Erwin Rommel was scoring his greatest triumphs in North Africa; out of these emerged the successful Allied defense of Tobruk, substantially by Australians (April–December 1941).

After the Japanese attacked the United States naval base at Pearl Harbor, Hawaii (December 7, 1941), however, the focus shifted homeward. The Japanese victories of the following months more than fulfilled the fantasies that fear and hate long had prompted in Australia. On February 15, 1942, 15,000 Australians became prisoners of war with Singapore's fall, and four days later war came to the nation's shores, when Darwin was bombed. Then came a Japanese swing southward, by August threatening Port Moresby, New Guinea.

Relations with the United States

The United States became Australia's major ally. In a famous statement (December 1941), Prime Minister Curtin declared: "I make it quite clear that Australia looks to America, free from any pangs about our traditional links of friendship to Britain." A sharper note of independence from Britain came when Curtin insisted (February 1942) that Australian troops recalled from the Middle East should return to Australia itself and not help in the defense of Burma, as British prime minister Winston Churchill wished. Conversely, American needs prompted total response to Curtin's call. U.S. general Douglas MacArthur established his headquarters first in Melbourne and then in Brisbane; the Australian Navy assisted in the U.S. victory in the Battle of the Coral Sea in May, which retrospectively appears a turning point in the war; and the two nations' troops thereafter fought in many joint land battles. The American soldier became a common figure in the Australian capitals, forging the biggest single link in the social relations between the two countries (although not always a harmonious one, as competition for girls and grog sparked jealousy).

On land, the fortunes of war turned against the Japanese in August–September 1942, beginning with an Allied victory at Milne Bay, New Guinea. More prolonged—and of more heroic dimension in Australian eyes—was the forcing back of the Japanese from southern New Guinea, over the Kokoda Trail. Then followed a long attrition of Japanese forces elsewhere in New Guinea and the islands, with Australia playing a role secondary to American forces but nevertheless significant—initially in New Guinea, and at war's end especially in Borneo. Australian volunteers and conscripts fought in these campaigns, the government and people having accepted the legitimacy of sending conscripts as far as the Equator and between the 110th and 159th meridians.

The war brought some passion into domestic affairs, albeit less than that of 1914–18. Curtin's government exercised considerable control over the civilian population, "industrial conscription" being scarcely an exaggerated description. Overall this was accepted—partly because of the sheer crisis, partly because the government showed purposefulness and capacity. Curtin easily won the 1943 elections; thereafter his ministry and the bureaucracy gave considerable thought to postwar reconstruction, hoping to use war-developed techniques to achieve greater social justice in peace.

Wartime growth

The war carried industrialization to a new level. The production of ammunition and other matériel (including airplanes), machine tools, and chemicals all boomed. Meanwhile, primary production lost prestige, aids, and skills, so that the 1944 output was but two-thirds that of 1939–40. Urban employment was bountiful, and concentration in capitals became more marked than ever; many families had two or more income earners. Thus

affluence quickened; federal child endowment from 1940 and rationing of scarce products helped distribute this wealth. The gross national product, estimated at $1,089,000,000 in 1918–19 and $1,860,000,000 in 1938–39, rose to $2,936,000,000 in 1942–43.

The states. As noted above, the period saw a steady loss of state power to the federal centre and a general lessening of local consciousness. Nevertheless, repeated referenda showed the people reluctant to expand commonwealth powers formally. At many levels state loyalties and state governments still mattered most.

New South Wales. New South Wales resumed its primacy as the most populous, wealthy, and industrialized area. Most of the generalizations made in any account of Australia derive from the particular experience of New South Wales; the federal Labor and Country parties both drew their major strength from it. Its internal politics illustrated the common theme that Labor did much better in state than in commonwealth elections. The dominant Labor figure, J.T. Lang, as premier of New South Wales in 1925–27, emphasized child endowment and other welfare services. Again in office in 1930–32, Lang refused to endorse the play-safe policies with which the federal and other state governments responded to the Depression; feeling became high and a "New Guard" organization, led by military officers from World War I, pledged itself to save the state from Lang's radicalism. Finally, the state governor dismissed Lang, who broke also with the federal Labor Party and fought it for years afterward.

Federal parties' major strength

Victoria. Victoria offered much less drama; the dynamism of the colony's first half-century never returned. Deakin, Bruce, and Menzies were all Melbourne men, and Lyons had his power base there—indicative that this city remained the bastion of financial interests. Yet in state politics the Labor and Country parties generally supported one another and the Nationalists did poorly. The generation of electricity from brown coal deposits in eastern Victoria was especially important in maintaining economic development.

The smaller states. The smaller states probably lost economically by federation. Interstate free trade meant that there could be no local tariffs to offset Sydney's and Melbourne's advantages in industrial production. As fiscal matters generally became more complex, the states were left farther behind the commonwealth and more at its mercy. Tension developed, most famously in Western Australia, where in a referendum the people voted for secession in 1933. The federal government then established the Commonwealth Grants Commission, which thereafter administered subsidies intended to ensure approximate equality in living standards.

Each of the smaller states strove vigorously, if not very effectually, to close the gap between itself and New South Wales–Victoria. Chief reliance fell on sugar and cattle in Queensland; timber and gold in Western Australia; apples, other fruit, and hydroelectric power in Tasmania. South Australia sank into deepening gloom until the mid-1930s; revival then came through the success of a campaign to attract industry.

AUSTRALIA SINCE 1945

Social and economic history. The rate of change in Australia after 1939 was greater than that during the preceding 80 years (in both centuries the '50s were especially dynamic). Sheer affluence was an important factor. Australians had long been among the world's wealthy, and, relatively speaking, this situation remained much as before. In absolute terms, however, "middle" Australia acquired appreciably more consumer goods and comforts. Large-scale *embourgeoisement* was all the more significant in a society in which working class attitudes had always set overall norms. By 1970 automobile numbers rose to more than one-third of the population, and three-fourths of all families owned their domiciles. These basic possessions were the lodestones of much Australian life.

In the midst of Australia's prosperity and its relative freedom from tensions and problems, there were those who bewailed the mediocrity of its ruling elites—business, academic, administrative, political. This criticism had considerable force. Wealth seemed as often to dampen as to inspire a drive for excellence. Yet probably there were more exceptions to mediocrity than earlier. Canberra—with its buildings and its institutions, as developed from the mid-1950s—probably had the most excellence to offer: the federal public service was efficient and skilled, while the Australian National University and the National Library of Australia reached international calibre.

The affluence of the 1960s did not reach rural industry. Both the small farmer (his life often a grim compound of debt, drought, and disaster) and the big farmer (who continued to form a wealthy caste atop the social pyramid) seemed certain to diminish; and the life-style of the remainder might have to alter radically. Australian leaders had long worshipped industrialization, and the masses had preferred urban living; still the "bush" had meant much in national mythology, and the shrinkage of its economic importance was thereby significant for all.

Second to affluence in shaping a new Australia was the federal government's assistance of mass European-wide immigration from 1946 until restrictions were imposed in December 1974. Roughly 100,000 migrants entered Australia each year; fewer than one-third came from Britain, about one-sixth from Italy, and almost one-tenth each from Germany and The Netherlands. Thus not only did migration ally with increasing birth rates to increase the population, but the traditional homogeneity of British background (often exaggerated in vernacular, but sizable enough in fact) ended. The inner suburbs of Melbourne and Sydney became polyglot communities. For many years rhetoric insisted that immigration had vitally aided economic development; around 1970 criticism of migration began to develop, as part of a conservation-cum-population-control syndrome, and this included the charge that the costs of immigration at least matched its benefits.

Immigration

At other points, too, ties with Britain loosened. After 1941–42 the Royal Navy was no longer Australia's shield against the world. The United States and Japan became trading partners and investors of comparable weight—and the West Indies became a more stimulating opponent at cricket. Thus, no longer could an Australian speak of Britain as "home" without appearing ridiculous. The change was not absolute—Australia remained an active member of the British Commonwealth—but it was enough to leave a vacuum in Australian life.

Discoveries of minerals accelerated in the 1960s. Iron in Western Australia was the most considerable; bauxite, especially in north Queensland, and nickel, in Western Australia, ranked next. Uranium was a more exotic but transitory resource, while tin, copper, lead, and zinc all rallied. Petroleum and natural gas were discovered in substantial quantities in southern Queensland and off the coast of southeastern Victoria. Japanese capital was particularly important in the development of these resources.

Stock exchange speculation became commonplace in talk and action. The scale of business multiplied. In terms of economic activity and profitability, Australia placed high among the world's second-rank nations.

Government played a part of some significance. The Labor governments before 1949 believed in fiscal supervision as a matter of ideology, and this tendency survived the change of administration. "Protection all round" remained a basic policy, although it had some opponents, and in July 1973 the new Labor government reduced import tariffs by 25 percent. Tariff preferences for less developed nations were instituted in January 1974. Through membership in the General Agreement on Tariffs and Trade (GATT) and other organizations, the government sought beneficial trade agreements, especially for primary resources; marketing boards and commissions came even to include wool in 1970–71. Markets, both for wool and for wheat, were particularly scarce in 1971. Yet investors and managers, including those from overseas, went comparatively without restraint. Legislation directed against monopolies, for example, was insignificant, and overseas investors were not obliged to reinvest profits. Restrictions on foreign investment were imposed by the Labor ad-

Protective tariff policy

ministration early in 1973, but they were cancelled in August 1974.

Industrial relations became a matter of enormous complexity, involving executive and judicial arms of government as well as employer and employee organizations. They seemed to work, with generally less controversy than in earlier periods and in other places, although a strike in the petroleum industry in 1972 was especially disruptive. In May 1975 Australian workers began a trial period of wage "indexation," imposed by the Conciliation and Arbitration Commission, to be based on the consumer price index. The Australian Council of Trade Unions was one of the nation's powers.

Change in attitudes toward Asia

Attitudes toward Asia also changed, in ways difficult to generalize. Arrogant antipathy diminished; sympathy, interest, and knowledge increased. Relations with Japan became vital to the economy, many Asian students attended Australia's universities, and revisions of immigration policy in 1956, 1966, and 1973 caused an increasing number of Asians to be allowed to enter. Yet foreboding remained; its bases were Australia's heritage of Western history and Eastern geography and the end of European, especially Anglo-Saxon, world supremacy.

Not everyone shared the nation's affluence. Some European immigrants worked hard at unpleasant jobs. Overall, about one-tenth of the population might be considered underprivileged, with old-age pensioners suffering most. Social services, though expanded considerably by the Labor government in 1973–75, were not adequate to meet these problems. A new national health scheme called Medibank began operation in July 1975 under the Australian Health Commission.

The Aborigines' experience remained the nation's atrocious scandal. A mining boom in northern Australia continued the long story of territorial expropriation. A mere handful of Aborigines achieved distinction—the best known were Lionel Rose, who became the world bantamweight boxing champion in 1968, and Evonne Goolagong, women's tennis champion. In politics, the professions, or the academy, they had no counterparts. That the Aborigines' subordination derived more from custom than from force scarcely mitigated the situation. Early in 1973 an expanded Aboriginal welfare program was begun (mostly in Queensland), but a year later the program was declared a financial disaster.

Some Aborigines were among those who voiced the Western world's new discontents in the late 1960s. Rejectors of society, above all opponents of Australian participation in the Vietnam War in alliance with the United States, they followed the example of their dissenting U.S. counterparts. But the radical movement was not especially strong. (As with many other sociopolitical movements in Australian history, an analyst must hover between noticing their interest and remarking their weakness in terms of international comparison.)

State boundaries and loyalties suggested a more significant internal division. The crises of the nation's first half-century had forced unity, or at least the acceptance of federal power. The relative calm of later years was accompanied with growing antagonism to "dictation" from Canberra. Growing wealth in Western Australia especially reduced the economic dominance of the southeast corner.

Culture. Painting, sculpture, poetry, and the novel all flourished in the postwar period. The writing of Australian history produced some notable prose. Ray Lawler might have produced "the great Australian play" with *The Summer of the Seventeenth Doll* (1955), its heroes two Queensland sugarcane cutters. Affluence enabled architects to build more private homes of distinction.

Sydney Opera House

Construction of an opera house in Sydney was begun in 1957 and, after expenditure of unprecedented technical ingenuity and A$100,000,000, was finally completed in 1973. Melbourne had its cultural centre that housed an art gallery of splendid quality.

The commonwealth government assisted theatrical work; national opera and ballet companies developed considerable reputations. A Council for the Arts was established in 1967 (with increased authority in 1973) to administer state support for cultural activities. At the same time a small group of established writers and composers was invited to compose a new national anthem; "Advance Australia Fair" was chosen in 1974 to replace "God Save the Queen." The soprano Joan Sutherland achieved overseas fame almost comparable to that of the earlier soprano Nellie Melba.

Universities grew enormously after World War II with the admission of former servicemen. The effort outreached resources, and not until the late 1950s did federal government expenditure redress the situation. The large cities acquired two or three universities, while in the late 1960s colleges of advanced education began to diversify higher education. Meanwhile, governments had reversed the generations-old policy of refusing aid to nonstate (*i.e.*, denominational and especially Roman Catholic) schools. Considerable sums were spent on education, but many found much to criticize.

Scientific research

Medical research advanced notably. The first Australians to win Nobel Prizes, Macfarlane Burnet (1960) and J.C. Eccles (1963), both worked in this area. Astronomy also merits particular emphasis: the Mt. Stromlo observatory was another of Canberra's world-ranking institutions, and Australian scientists were in the forefront of radio and X-ray astronomy. This was one of several fields in which the Commonwealth Scientific and Industrial Research Organisation (see above *Growth of the commonwealth: The postwar years*) contributed much, departing from narrow limits of applied research. The CSIRO and the universities dominated research, but some minor bodies were important: Burnet directed one such, the Walter and Eliza Hall Institute of Medical Research.

Australia was one of the few countries to participate in all the modern Olympic Games; and in 1956, when Melbourne was host city, Australian swimmers dominated the scene. From time to time, golf, track and field sports (especially for women), cycling, and pugilism occupied the spotlight in Australia. European immigrants played soccer, but the old Australians still flocked to see "Australian Rules," especially in Melbourne.

Television, introduced in 1956 and so able to capitalize on interest in the Olympic Games, soon became dominant in everyday entertainment. Many programs came from Britain and the United States, but the Australian contribution slowly increased. Radio diminished as television boomed but later (partly from the use of the transistor) found a continuing audience. The cinema was forced to accept a more modest role. Popular live entertainment followed a different graph: it benefitted much from the boom, especially in Sydney, with clubs that provided liquor, gambling (poker machines), and variety shows.

Domestic politics. J.B. Chifley succeeded John Curtin as Labor prime minister in mid-1945, Curtin having died in office. A growing efficiency and enthusiasm in pursuit of social justice led to extended social welfare, national development, the establishment of the National University, and the provision of university scholarships. Public servants provided the expertise for more sophisticated supervision of the economy. Chifley won the elections of 1946 fairly comfortably, although the government's majority fell.

But the Australian Labor Party soon became the victim of the Cold War. During World War II Communists had increased their influence throughout Australian society and especially within the labour movement. Many believed that the Labor Party itself was Socialist. This judgment exaggerated the truth, but Chifley's belief in controlling the economy gave it some force; when he planned to nationalize all banks (1947), the reaction was accordingly intense. Although declared unconstitutional in 1948, this banking nationalization counted heavily against the government in the electorate's eye.

Meanwhile, Communist influence was in large measure responsible for many strikes; the culmination came in the coalfields of New South Wales in 1949. These strikes also aroused public concern and hostility. The Labor government suffered heavy defeat in the election of December 1949. The defeat was intensified by a restructured elec-

toral system: thenceforth the House of Representatives had about 120 members, representing single-member electorates of approximately equal size; the Senate had 60 members, each state electing five members every three years by proportional representation, the members serving for six-year terms.

Menzies and the Liberal Party

Liberal and Country party coalition governments ruled continuously after the 1949 election until 1972. The Liberal Party, formed in the mid-1940s, was largely based on the erstwhile United Australia Party. Its founding genius was Robert Menzies, and as its head he was prime minister from 1949 until 1966. Menzies and his governments provided the framework for the development of contemporary Australia.

Reverberations of the Cold War helped Menzies stay in office. In 1954 the defection from the Soviet Embassy in Canberra of the Soviet agent Vladimir Petrov led to a royal commission into alleged espionage within Australia. This not only revitalized the Communist threat, which Menzies often invoked, but prompted the Labor opposition to defend some of those implicated in the commission's inquiries. This in turn antagonized the right-wing and Roman Catholic elements in the Labor Party—the groups that had been the most vigorous elements within the Labor Party in opposing Communists in the trade unions. In 1955 this group established the Democratic Labor Party (DLP); although it won few parliamentary seats, the DLP took enough votes from the Labor Party to lessen the latter's chance of federal office.

The DLP contributed what little ideology there was in Australian politics after 1950. The Labor Party increasingly disowned any Socialist belief but found no alternative doctrine; two successive party leaders, Herbert Vere Evatt in 1951–60 and Arthur Aloysius Calwell in 1960–67, were frustrated in spending years as leaders of the opposition. The Communist Party split between Soviet and Chinese factions, each small and increasingly sterile.

In the late 1960s politics took a bizarre turn. Harold Holt, Menzies' successor as prime minister, had scarcely established himself when he died by accidental drowning (December 1967). There followed a Byzantine contest for his office, won by John Gorton. But Gorton failed to provide solid, consistent leadership, and early in 1971 the Liberal Party replaced him with William McMahon. In December 1972 a new Labor government under Gough Whitlam took power and entered upon a program of social, economic, and political reform.

Labor Party in power again

The Labor program included a large increase in appropriations for social welfare, including a national health service, urban development, a doubling of aid to education, and the removal of investment incentives for the mining industry. Opposition to Whitlam's program was effective in the Senate as early as the following May in its defeat of his electoral reform bill; in December 1973 the nation defeated a referendum that would have permitted federal price and wage controls. Increased spending meant increased inflation, and this became a campaign issue in April 1974 when Whitlam dissolved Parliament in the hope of winning a majority in the Senate. He succeeded in eliminating the DLP from the Senate and increasing his numbers so that he could pass his program through a joint sitting of Parliament. A sudden increase in unemployment in July 1974, a 16 percent loss in state elections in Queensland in December, and a financial scandal in the Cabinet in early 1975 plagued Whitlam's Labor government.

New leadership came to the opposition in March 1975 with the election of Malcolm Fraser to head the Liberal Party. By October 1975 Labor strength in the Senate had been reduced by two states having filled vacancies with members from the opposition parties (an unconventional practice). Fraser took advantage of the situation to refuse to pass necessary appropriations bills, thereby forcing another election. Whitlam refused to submit to this pressure, so the Whitlam-appointed governor general, Sir John Kerr, dismissed the prime minister—the first time a representative of the crown had dismissed an elected prime minister in 200 years. With assurances from Fraser that the appropriations bills would be passed, he was made caretaker prime minister, and a new election for both houses was set for December 13. A bitter campaign ensued, with inflation and unemployment as the primary issues. The results were sweeping majorities for the Liberal–Country party coalition. With the loss of more than 30 seats, Labor was reduced to a weak opposition, and the equilibrium of the Menzies era of the 1950s and early '60s was returned.

Foreign affairs. The Labor governments of the 1940s, and especially Labor's minister H.V. Evatt, hoped that Australia would play an independent, substantial part in creating a stable international situation. Thus it was active in support of the early United Nations, Evatt himself serving a term as its president in 1947. Support of Indonesian independence was another important policy of those years, and there was advance toward building a civil service that was expert in international affairs.

Support of the United Nations

These positive trends continued with the Liberal victory of 1949. It was the next year, for example, that Australia signed the Colombo Pact, under which substantial aid, especially through education, was sent to Asian countries. Australia remained an active supporter of the United Nations and other international agencies. Menzies, especially, was a great admirer of Britain and its empire-commonwealth.

Meanwhile, the movement of world politics soured the optimism of the 1940s. Turbulence in Asia, especially a Communist victory in China, gave a new edge to Australia's traditional fear of attack from the north. In response, the country moved increasingly close to the United States, which alone offered the possibility of replacing Britain as a protector. Thus Australians fought along with United Nations troops in Korea; in 1951 the country accepted the U.S. view of Japan as a bulwark against Communism, while simultaneously the ANZUS (Australia, New Zealand, United States) Pact promised U.S. help in case of attack; and in 1954 Australia joined the Southeast Asia Treaty Organization (SEATO), which extended U.S. responsibility throughout the area. The U.S. built significant missile bases throughout Australia, and Australia's increasingly large defense expenditure bought much U.S. equipment. Australia also supported the U.S. commitment in Vietnam, and it sent troops (including conscripts) to fight there, but these troops were withdrawn between August 1971 and February 1972.

With the return of Labor to power in December 1972, a much greater emphasis was put on relating Australia to Asia. The People's Republic of China was recognized immediately and North Vietnam in February 1973. Whitlam visited Indonesia in February and India in June, at which time a joint statement was made that the Indian Ocean "should be free from international tensions, great-Power rivalry, and military escalation." A visit to China followed in November. Closer relations with the new Labor government of New Zealand began at the outset, and ties to Britain were lessened, including reduced military support in Singapore and Malaysia. Early in 1974 Whitlam toured six nations in Southeast Asia, again emphasizing his government's interest in the Eastern Hemisphere. At the end of the year Whitlam visited seven of the nine members of the European Economic Community, declaring that Australian prime ministers had neglected this important area, second only to Japan as Australia's trading partner. He also visited Yugoslavia and the Soviet Union.

Papua New Guinea, composed of the Australian external territory of Papua and the Australian-administered UN Trust Territory of New Guinea, became a self-governing state in December 1973. After several postponements, it achieved complete independence in September 1975. Papua New Guinea was the largest recipient of Australian aid.

Australian Aboriginal Cultures

Before the arrival of Europeans in Australia, Aborigines occupied the entire continent, including Tasmania. The usual estimate of their numbers at that time is about 300,000. Population density was highest in more fertile riverine and coastal areas; in arid zones, the exigencies of gaining a livelihood made distribution over much larger territories necessary. These broad environmental differences had direct sociocultural implications for mobility and for control over natural resources. Aborigines in the drier inland moved camp more frequently, had a narrower margin of survival in bad seasons, and relied more directly on ritual supplication as a necessary aid to everyday living.

There were approximately 500 tribes and subtribes—tribe being a convenient label for a constellation of interacting groups the members of which acknowledge certain features in common. Most tribes had specific names for themselves; other names, sometimes less flattering, were applied to them by their neighbours. They occupied recognized territories and were distinguished by characteristic features in culture, language, or dialect.

Early writers on the subject spoke of "nations," usually referring to a group of tribes identifying themselves by the same word for "man." But, although there was interaction between neighbours, there was no direct social communication across the continent, and the Aborigines were certainly not a nation in the modern sense: they had no overarching political system and no overall name.

TRADITIONAL SOCIOCULTURAL PATTERNS

All Aborigines, coastal and inland, were directly dependent on their natural environment. They were semi-nomadic, wandering across limited stretches of the country, hunting, and collecting food. This basic economic circumstance had several concomitants: (1) food-gathering groups were fairly small and usually scattered, and all members of a tribe rarely came together, even for ritual occasions; (2) cooperation was essential for survival; (3) over and above particular techniques and skills, Aborigines believed that something else was required for survival, namely religion.

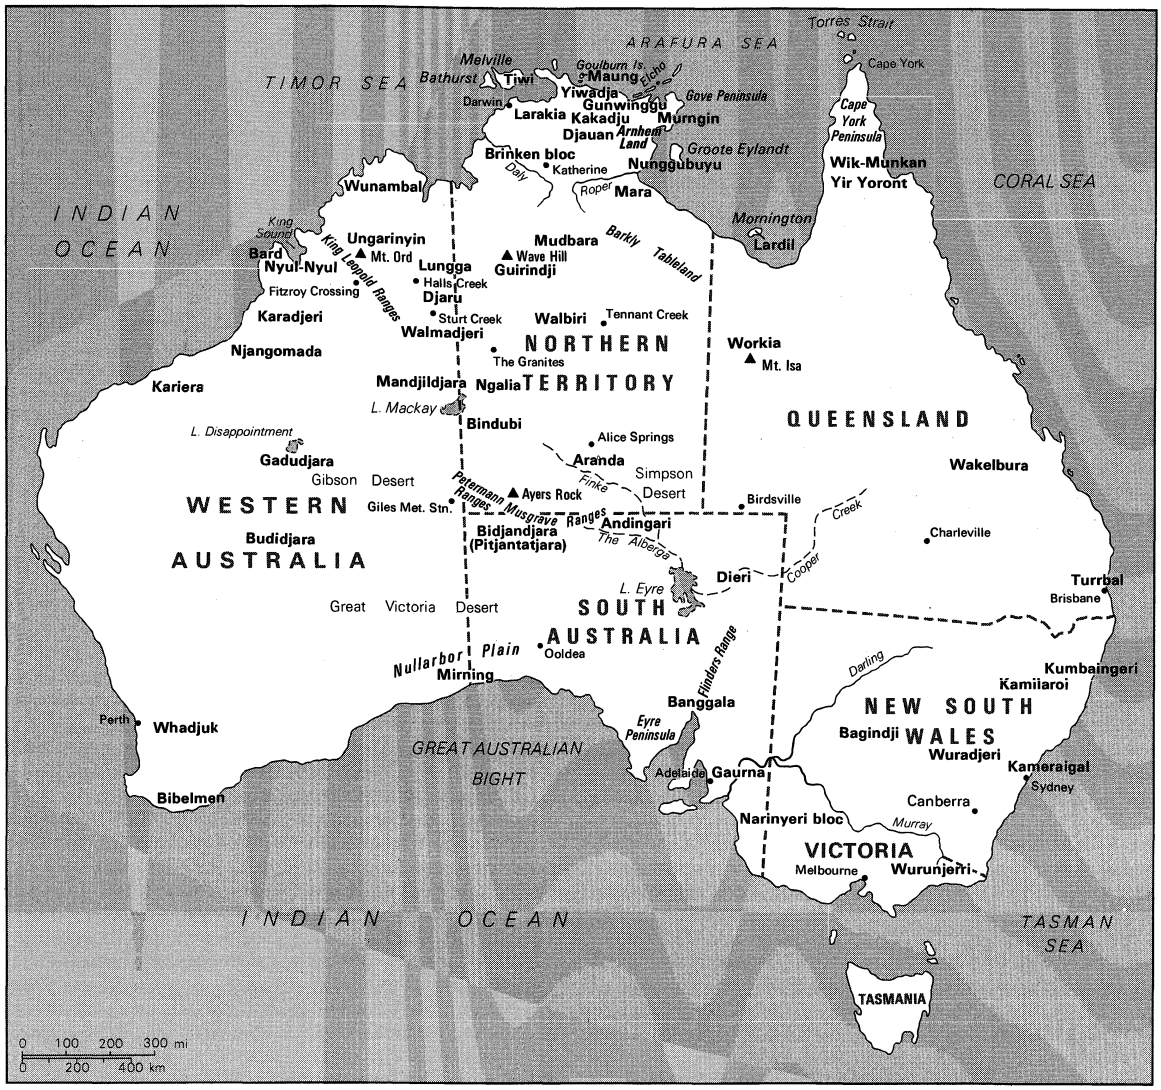
Aboriginal cosmogony

The Aborigines' view of their place in the world was summarized in their concept of "the dreaming," or "eternal dreamtime." This does not refer to dreams in an ordinary sense. In one of its meanings the dreaming was the formative or creative period at the dawn of time, when mythic beings shaped the land, brought various species into life, and established human life and culture. Although these mythic beings died or were transformed, they lived on eternally in spirit. They left tangible evidence of their physical presence on earth and were actually identified with or manifested through particular species and natural elements. The Aborigines also believed that these spirits were manifested through and in man, that the mythic creatures of the dreaming were not basically different from man, and that man, supernatural beings, and natural species were interdependent and mutually sustaining. Hence, an Aboriginal person was never isolated; he saw himself as acting and interacting with others, and the bonds of kinship were extended outward, embracing the nonhuman and nonempirical world.

Social groups and categories. The main issues in Aboriginal social life were religion and economics; these were seen as interdependent and were reflected in the two kinds of social units to which all Aborigines traditionally belonged. One of these social units was the local descent group, always patrilineal (descent through the male line), exogamous (marrying outside the group), and associated with a particular stretch of territory—the "estate." Its adult males were responsible for the upkeep of the traditional campsites and for the appropriate ritual—that is, for renewing and sustaining the land. Ownership of land was nontransferable: its members held land in trust collectively through an unwritten charter deriving from the dreaming. The second, larger kind of unit was the horde or band, the group concerned with the ordinary practical business of getting a living. This was a land-occupying and land-utilizing group, exploiting all the available natural resources. It comprised members of several families—that is, of more than one local descent group; and the range over which they normally travelled included several estates. It fluctuated in size and composition; in good seasons, a larger number of people could camp together.

In addition to membership in a local descent group and horde, an individual identified himself by reference to larger social groups: moieties, semimoieties, sections, subsections, and clans. A moiety is one of two basic complementary parts into which a tribe divides itself. Sections and subsections are further subdivisions, splitting the tribe into four and then eight parts. Such social divisions among the Aborigines governed marriage and other contracts. A person in one moiety, for instance, could marry only a person in the other moiety. When there were section or subsection systems, everyone was incorporated in such a system from before birth. The main advantage was that it represented a widely understood grid for categorizing everyone a person was likely to meet. With this went a shorthand statement of basic rules or conventions, which was a simple guide to everyday behaviour, especially useful for classifying distant kin and strangers. Close, genealogically traceable kinship virtually always took precedence over nominal kinship when priorities were at issue.

Aboriginal Australia was not socially stratified in the sense of having more or less fixed classes or strata arranged hierarchically on the basis of descent or acquired status. Status was clearly marked only within the religious sphere; females, for example, were mostly excluded from an executive role in secret-sacred ritual, and areas of privilege were further defined by graded acceptance of youths and adults passing through rites of learning. Essentially, however, Aboriginal society was "open"—there were no social barriers operating against a man becoming a leader in religious matters. Such achievement depended primarily on his own efforts, his kin's, and his observance of ritual obligations. Men acquired prestige through knowledge of religious practices and expertise in directing ritual. In matters of economics, entrepreneurial leaders did have considerable status in one or two areas—



Original distribution of the larger Aboriginal tribes.

among the Tiwi and Murngin, for example—but this was derived not so much from commercial activities as from their ability to manipulate certain kin, to arrange polygynous marriages for themselves and remunerative betrothals for their children, and to establish a network of alliances.

Kinship, marriage, and the family. The Aborigines were deeply conscious of social relations, especially of kinship. All Aboriginal kinship systems were basically classificatory—that is, a limited number of kin terms was extended to cover all known persons: terms for lineal relatives, such as "father," also referred to collateral relatives, such as uncles. This did not mean that a person could not recognize his actual father, mother, son, or other relative. The terms simply indicated the kind of behaviour that was appropriate—filial, brotherly or sisterly, fatherly, or whatever.

Function and significance of kin terms

Kin terms were behavioural signals, indicating, for example, the expectation of sexual access, restraint, avoidance, or responsibilities. Affines (relatives by marriage) were often classified with consanguineous (blood) relatives, although qualifying terms might be used. Certain terms indicated potential spouses or affines. A husband and wife were ideally, before marriage, always related to each other as kin, either actual or classificatory. Some relationships were more prominent than others. The brother–sister relationship, for example, was one of the most emotionally charged and often marked by some form of avoidance. The most outstanding avoidance relationship was between a man and his actual or potential mother-in-law—not just his wife's mother but all women and girls who on the basis of kinship and the recognition of preferred potential spouses, might become his mother-in-law.

Reciprocity was a fundamental rule in Aboriginal kinship systems and also in marriage. Marriage was not simply a relationship between two persons; it linked two families or groups of kin, which, even before the union was confirmed and most certainly afterward, had mutual obligations and responsibilities. Generally, throughout Aboriginal Australia those who received a wife had to make repayment either at the time of marriage or at some future time. In the simplest form of reciprocity, men exchanged sisters; and women, brothers. Such exchanges took place between different moieties, clans, or local descent groups or between certain types of kin. Most kinship-and-marriage systems provided for the possible replacement of spouses and for parent surrogates. At any one time, a man or woman had available a number of persons, who, because of their kinship, were termed spouses. Access to them depended on several factors, but, as far as premarital and extramarital liaisons were concerned, it was conventionally in this direction that partners should be sought.

Infant betrothal was common. If arranged before the birth of one or both of the prospective spouses, it was a tentative arrangement subject to later ratification, mainly through continued gift-giving to the girl's parents. In some Aboriginal societies, parents of marriageable girls played one man against another, although this was always a potentially dangerous game. Also, there might be a considerable age discrepancy between an affianced

pair. Generally, a long-standing betrothal, cemented by gift-giving and the rendering of services, had a good chance of surviving and fostering a genuine attachment between a couple.

For a marriage to be recognized it was usually enough that a couple should live together publicly and assume certain responsibilities in relation to each other and toward their respective families; but it might be considered binding only after a child was born. All persons were expected to marry. A girl's marriage should be settled before she reached puberty, and, ideally, a husband should be older than his wife.

Apart from formal betrothal, there were other ways of contracting marriages, such as elopement, capture during feuding or fighting, and redistribution of widows through the levirate (compulsory marriage of a widow to her deceased husband's brother) or patriate (distribution of a father's widows to his sons, unless they were actual or close mothers). Elopement was often supported by love magic, which emphasized romantic love, as well as by the oblique or direct approval of extramarital relations.

Polygynous marriage

Although most men had only one wife at a time, polygyny was considered both legitimate and "good." The average number of wives in polygynous unions was two or three. The maximum, in the Western Desert, was five or six; among the Tiwi, 29; among the Murngin, 20 to 25, with many men having 10 to 12. In such circumstances, women had a scarcity value. Having more than one wife was usually a matter of personal inclination, but economic considerations were important; so were prestige and political advantage. Some women pressed their husbands to take an additional wife (or wives), since this meant more food coming into the family circle and more baby-sitters. To terminate a marriage, a woman might try elopement. A man could bestow an unsatisfactory wife on someone else or divorce her. A formal declaration or some symbolic gesture on his part might be all that was necessary. In broad terms, a husband had more rights over his wife than she had over him. But, taking into account the overall relations between men and women, their separate and complementary spheres of activity in marriage and in other aspects of social living, the status of women in Aboriginal society was not depressed.

Socialization. A child's spirit was held to come from the dreaming to animate a fetus. In some cases, this was believed to occur through an action of a mythic being who might or might not be reincarnated in the child. Even when Aborigines acknowledged a physical bond between parents and child, the most important issue for them was the spiritual heritage.

In his early years a child's focus was on his actual parents, and especially on his mother, but there were others close at hand to care for him. Weaning occurred at about two or three years of age but occasionally not until five or six for a youngest child. Through observation of camp life around him and informal instruction, a child built up his sociocultural perspective, learning through participation. At the same time, he became familiar with his natural environment. Small children often went food collecting with their mothers and other women; as girls grew older, they continued to do so, but boys were thrown more on their own resources. Parents were, on the whole, very indulgent. Infanticide, even in arid areas, was much rarer than has been suggested.

Children learned quite early with whom they were allowed to play and whom they must avoid; brothers and sisters, for instance, or "mothers-in-law" and "sons-in-law," would not normally play together. Betrothal put special restraints on a girl, and, at or even before puberty, she normally went to live with her husband, assuming the status of a married woman.

With initiation, a boy's life changed drastically. His formal instruction as a potential adult began, and he was prepared for his entry into religious ritual. His future was henceforth in the hands of older men and ritual leaders who exercised authority in his community. But he was not among strangers: the relatives who played an active role in his initiation would also have significant roles in his adult life. A boy's age at the first rite varied: in the Western Desert it was about 16; in the Kimberleys, about 12; in northeastern Arnhem Land, six to eight; and among the Aranda 10 to 12 or even older. Generally, once he had reached puberty and facial hair had begun to show, he was ready for the initial rituals.

Initiation in Aboriginal Australia was a symbolic reenactment of death in order to achieve new life as an adult. As a novice left his camp, the women would wail and other noises would be made, symbolizing the voice of a mythic being who was said to swallow the novice and later vomit him forth into a new life. The initiation rites themselves were a focal point in discipline and training; they included songs and rituals having an educational purpose. All boys were initiated, and traditionally there were no exceptions.

Initiation rites

Circumcision was one of the most important rites over the greater part of Australia. Subincision (incisure of the urethra) was especially significant in its association with secret-sacred ritual. Other rites, according to the area, included piercing of the nasal septum, tooth pulling (in New South Wales this was central in initiation), and the blood rite, which involved bloodletting from arm vein or a penis incisure—the blood being used for anointing or sipping (red ochre was used as a substitute for blood in some cases). Hair removal, cicatrization (scarring), and playing with fire were also fairly widespread practices. Among the Aranda, fingernails were torn out and heads gashed open and bitten. All such rites were usually substantiated by mythology.

For girls, puberty was marked by either total or partial seclusion and by food taboos (also applied to male novices). Afterward, they were decorated and ritually purified. Ritual defloration and hymen cutting or both were widspread (in the Western Desert, for instance), while on Groote Eylandt the labia majora were removed.

Boys, after circumcision, became increasingly involved in adult activities. Although they were not free to marry immediately, even if they had reached puberty, they might do so after undergoing certain rites, such as subincision. Initiation was a prelude to the religious activity in which all men participated. It meant, also, learning a wide range of things directly concerned with the practical aspects of social living. Adulthood brought increased status but added responsibilties. A vast store of information had to be handed down from one generation to the next. Initiation served as a medium for this, providing a basis of knowledge upon which an adult could build. This was a process that continued through life and that was especially marked in men's religious activity.

For Aborigines birth and death were an open-ended continuum: a spiritual religious power emerged from the dreaming, was harnessed and utilized through initiation (as symbolic death–rebirth) and through subsequent religious ritual, and finally, on death, went back into the dreaming. Life and death were not seen as being diametrically opposed: the dreaming provided a thread of life, even in physical death.

Social control. Pressures toward conformity began and were formalized during initiation. There were rules and standards, right and wrong ways of doing things, and some allowance for variation. Sanctions upheld the accepted codes and were either positive or negative or a combination of both. Probably the strongest were fear of supernatural punishment and fear of sorcery.

Traditionally, most dissension arose over women, religious matters, and death. Women had trouble with husbands, eloped, and engaged in unsanctioned extramarital liaisons. Such behaviour could mean serious fighting, involving relatives of the parties concerned. Infringement of sacred law was less direct in its social repercussions but was nevertheless regarded as the most serious of all. In many cases, an ordinary or accidental death had wide ramifications, particularly if there were accusations of sorcery. An inquest was held, and, through divination, a supposed "murderer" was found. Punitive measures might or might not be taken against him.

The maintenance of law and order was quite narrowly

localized. Authority was limited and qualified by kinship claims. Precedents were sought in order to guide or influence actions resulting from a breach, and in all tribes there were approved procedures for maintaining the peace. There were no judicial bodies as such, though on the lower Murray River a formal council, or *tendi*, of clan headmen and elders did arbitrate disagreements between adjacent tribes. Generally, simple informal meetings of elders and men of importance dealt with grievances and other matters. There was also settlement by ordeal—the most outstanding example of this sort being the *magarada*, or *maneiag*, of Arnhem Land. During a ritualized meeting, the accused ran the gauntlet of his accusers, who threw spears at him; guilt was proved if the accused was wounded in the thigh.

Maintenance of law and order

Although it is inaccurate to speak of a gerontocracy in Aboriginal Australia, men of importance were easily distinguished. They were usually "elders," who had this status not necessarily because of their age or grey hair but because of their religious position and personal energy. This gave them considerable control over the affairs of others in matters not directly related to religion.

Economic organization. Dependence on the environment and on its resources was reflected in seminomadic living. The Aborigines had to be intimately acquainted with all the country within their range of movement. At the same time, their economic system was not conceptually separate from their religious system. Both before and after initiation, graphic stories (or myths) served as guides to specific localities, detailing what people could expect to find there. In other words, information used in obtaining a living was preserved and transmitted in a religious context. Religious ritual, furthermore, was believed to ensure the maintenance of the natural species and the proper fluctuation of the seasons.

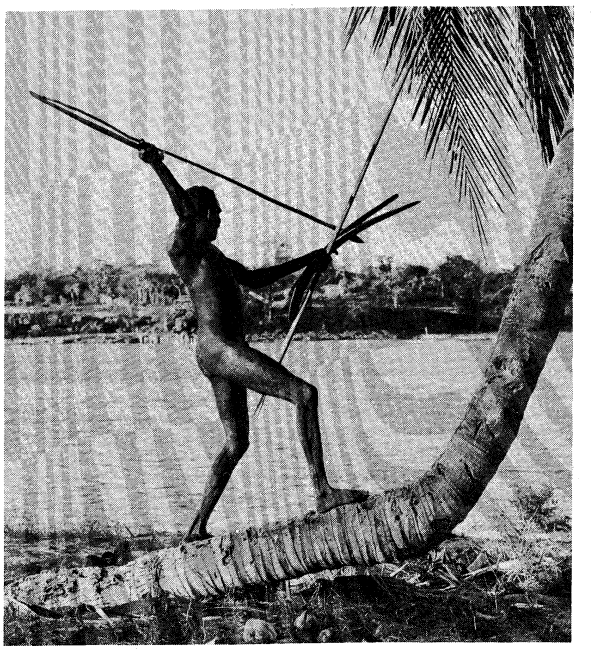
Before modification of their economic organization as a result of contact with Europeans, large groups of people did not remain in the same camp over a prolonged period. There were two basic patterns. Generally, in fertile regions of Aboriginal Australia, time-honoured camping areas were recognized, always in close proximity to water and usually with mythological associations; they were places where people always camped at certain times of the year. Camps were bases from which people made forays into the surrounding bush for food, returning in the late afternoon or spending a few days away. The second pattern involved a much larger territory in arid or desert areas across which Aborigines moved from waterhole to waterhole along well-defined tracks in small family groups. The whole camp moved and rarely established bases. Only in good seasons and at sizeable permanent waters was it possible for a large number of people to remain for an extended period.

These two patterns were reflected in domestic arrangements. In the north, people made bark shelters, and during the monsoonal rains used caves and stilted huts as protection against flood, mosquitoes, and sandflies. In the desert, windbreaks—bough shelters or saplings covered with brush or bark—were common. During fine weather most Aborigines preferred to sleep in the open, with a windbreak; when it was too cold, dogs helped to provide warmth. Fires were kept alight, and, when moving from one place to another, or even when hunting, people carried live fire sticks.

Aborigines, with rare exceptions (southwest of Darwin and northeastern Arnhem Land, for example), had no form of cultivation and no domestic animals, except the tamed dingo. They preferred to go naked, except for small pubic coverings or decorations. In certain areas, fur cloaks were a protection against cold.

Tools and artifacts

Outside the sphere of religion, material objects were minimal. Grinding stones and platters were left at certain camps, ready for use. Men carried spears and spear throwers and, in some areas, boomerangs. There were bark canoes and rafts and dugout log canoes, some with pandanus-mat sails. Women's digging sticks could double as fighting weapons. Their large deep wooden dishes held seeds, vegetables, or water, even babies. In some areas, painted bark baskets, plaited pandanus bags, and net bags served the same purposes. Rarer objects were the kangaroo-skin waterbags of the arid central areas and the skull drinking vessels of the Coorong in South Australia. Implements included a large selection of stone tools, wedges, bone needles, bobbins, and sharkskin files.



Aboriginal spearfishing near Darwin, Northern Territory.
Douglass Baglin

Generally, men were hunters, women food collectors; and, unless they were on the move, they carried out these tasks separately. A woman's economic pursuits were focussed on her own family and children. A man's obligations were wider. Providing for his own family was often of secondary importance: ideally, his ritual duties and his network of reciprocal obligations took priority. He was expected to provide meat for his family; but women bore the main responsibility, supplying vegetable foods and small game or shellfish. Although this was primarily a subsistence economy, even life in the desert was not reduced to a constant struggle for the bare essentials. It nevertheless called for skill, tenacity, and continuing social involvement. A person could not "opt out" and survive. Reciprocity was basic to economic life, and all adults were caught up in a web of rights and duties.

As far as trading was concerned, goods passed along defined routes from one group to another in an intricate crisscross patterning over the continent. Boomerangs, for example, went in one direction, red ochre in another; pearl shells from the Kimberleys found their way, gradually, to the Great Australian Bight; and central Australian shields appeared in the Canning Stock Route area.

In traditional Aboriginal society acquisition and gain were important, but the idea of making a profit was almost irrelevant. What really counted was the social relationship inherent in the exchange. The more organized trading partnerships entailed a debtor-creditor association; but prestige still hinged on retaining an equitable balance in the exchanges, on "solvency," and on not dropping out of the network. Private property was recognized, the claims of others upon an item not affecting an individual's right to exclusive use of it until such time as he decided to relinquish it. Traditionally, however, land was inalienable, being held in trust by members of various local descent groups.

BELIEF AND AESTHETIC VALUES

Religion. The Aborigines were concerned that the seasons should come and go in an orderly, predictable way; that human life should continue; and that they themselves should go on living in much the same way as they had always done. Religious beliefs and values gave tradition its power and force in influencing life in the present.

Totemism

Both before and since the French sociologist Émile Durkheim's study of *The Elementary Forms of the Religious Life* (1915), much has been written about Australian totemism. The concept rests on the belief that human beings are an integral part of nature, like all other living things. Totemism has been defined as a representation of the universe, seen as a moral and social order; as a philosophy that regards man and nature as one corporate whole; or as a set of symbols forming a conventional expression of the value system of a society. Such symbols provided intermediate links, both personal and social, between man and the mythic beings. Many of the mythic beings in Australia were "totemic" in the sense of exemplifying in their own persons, in their outward form, the common life-force pervading particular species. Others, originating in human or near-human form, at the end of their wanderings entered some physiographic feature or were metamorphosed as hills or rocks or turned into various creatures or plants. Totemism is another illustration that a sharp dichotomy between sacred and mundane cannot be drawn in Aboriginal Australia, where religion was directly relevant to everyday living.

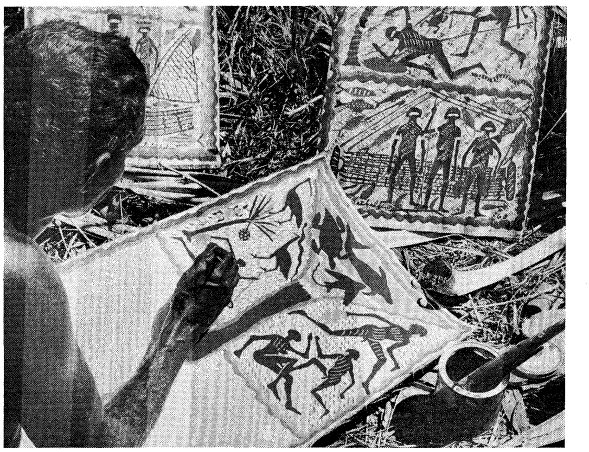
Among most Aboriginal tribes, the main ritual roles in the big religious sequences were reserved for men. Ordinarily, in such cases, women were forbidden to enter ritual grounds, and what went on there was secret and sacred. But women usually had complementary actions to perform or observed special taboos. In other rituals both men and women participated. Among some tribes, women had their own secret-sacred rites. Generally, any large ritual affair concerned a whole community and involved all its members in some measure.

Aesthetics. Sacred ritual provided immense scope for aesthetic expression, especially in dramatic performances with stylized posturing and complicated dance movements. Less intense but sometimes almost as elaborate were the nonsacred ceremonies (or corroborees) designed for entertainment and relaxation. Songs ranged in style from the succinct verses or couplets of central Australia and the Western Desert, which were made up of three, four, or more words repeated in linked sequences, to the more elaborate songs of northeastern Arnhem Land, which were long verses building up complex word pictures through symbolic allusion and imagery. There was no poetry in terms of spoken verse, but there were chants, some of them outstandingly beautiful. The majority of secret-sacred songs comprised mythic cycles, each containing several hundreds of verses. There was also a wide repertoire of songs on everyday events, such as the "gossip" songs of western Arnhem Land, composed by songmen with the aid of spirits. Instrumental music in the north was provided by the didgeridoo (drone-trumpet) and by clapping sticks. In southern and central regions, boomerangs or clubs were rhythmically beaten together or pounded on the ground; in southeastern Australia, women used skin beating pads. Tunes and rhythms varied greatly from area to area.

Songs, chants, and instrumental music

Oral literature was rich. In addition to sacred mythology, there were ordinary stories and tales, either historically true or presumed to be true. Some existed in several versions, depending on the situation in which they were told and on the individual background of the storyteller.

Each cultural area had its own distinctive style of art. *Tjurunga* (sacred object) art, consisting of incised patterns on flat stones or wooden boards, was representative of a large area of Australia, although centralized in Aranda territory. In central Australia, body decoration and elaborate headdresses on ritual occasions, using feather down, blood, and ochres, were especially striking. Everywhere, sacred ritual provided the incentive for making a large variety of objects—mostly impermanent, because the act of making them was itself one of the appropriate rites. In western Arnhem Land, *maraiin* objects—realistic and stylized carved representations of various natural species—were made. The *rangga*, or ceremonial poles, of eastern Arnhem Land, many of durable hardwood, bore ochre designs and long pendants of feathered twine. For mortuary rituals, the Tiwi made large wooden grave posts, and shaped and decorated receptacles for bones were common in eastern Arnhem Land. Also common were carved wooden figures of mythic beings and of contemporary persons, some used in sacred ritual, others as memorial posts for the dead.



Aboriginal artist working on a bark painting, Queensland.
Douglass Baglin

Paintings in ochre on sheets of bark were indigenous to Arnhem Land, although examples could be found in the Kimberleys and in southeastern Australia. They were used mostly on the initiation ground for the instruction of novices. In western Arnhem Land, naturalistic patterns showing figures against an open background were the norm; there was also a unique kind of "X-ray" art that depicted the internal organs of animals and human beings. Also found in various parts of Australia were cave and rock paintings or engravings.

For an outstanding artist or songman, the rewards lay mainly in prestige and in religious advancement. He was not absolved from earning a living in the ordinary way and shouldering routine responsibilities.

ABORIGINES IN AUSTRALIAN SOCIETY

The heritage of early alien contact. Traditionally, the Australian Aborigines had little knowledge of other peoples and were ill-equipped to withstand the rapid inroads of an alien and culturally different people.

Early contact with Indonesians

Two qualifications are necessary here. First, the Aborigines excelled in adjusting themselves to their natural environment. Secondly, in the north they came into contact with Indonesians at an early date (at least two to four centuries ago). The visitors came as sea-going traders to the Arnhem Land coast and made a powerful impact on local art, music, ritual, and material culture. On Cape York Peninsula, the influence of New Guinea and the Torres Strait Islands was evident in the adoption of masked ritual dancing and the use of the drum.

But the coming of Europeans, in 1788, was entirely different. Initially, many Aborigines were willing to welcome them, even regarding them as returning spirits of the dead or as manifestations of the mythic beings. European settlement soon expanded, however, making inroads into tribal territory and interfering with natural resources, excluding the Aborigines from their sacred and other areas and drawing them—often forcibly, always uncomprehendingly—into the life of the developing colony. Communication was minimal. Clashes marked virtually all situations in which Aborigines and Europeans pursued conflicting interests. In the period of "pacification by force," up to the 1880s, a large number of Aborigines were killed. Others were driven into the bush or remained in small pockets subject to the "civilizing" influence of missions, or were left to fend for themselves in the fringe settlements of cities and towns; still others remained in camps or pastoral and cattle stations to become the nucleus of a labour force. Diseases took their toll. The Colonial Office in London had instructed that the Aborigines' rights should be safeguarded and that they were to be accorded the benefits of British subjects. The actual situation was different.

The Aborigines reacted with spasmodic guerrilla warfare and stock killing or with passive resistance. But they soon learned that the only alternative was to adapt, at least to some extent. The result was pauperization. Gradually, missionaries and government welfare agents began to have some effect, and questions of humane treatment came to have a more practical meaning. But in outlying areas, maltreatment and violence lingered on into the early 1940s. Further, wherever European settlement was intensive, miscegenation took place, and part-Aborigines came to replace the full-blooded population. Their traditional life ceased to exist as a living reality over much of the southwestern, southeastern, and middle eastern areas of the continent. In the central and northern regions traditional life remained, even on some pastoral, mission, and government stations, although in a modified form. In more remote areas it was still possible for Aborigines to live approximately in the way they had before but with notable modifications, particularly in the sphere of law and order. It was for some time believed that the Aborigines would eventually die out, and reserves were established in the late 1920s and early 1930s to serve as a buffer between them and Europeans. But many were attracted to the fringe settlements, where they formed tribally and linguistically mixed communities. This meant the emergence of a new form of living, structurally linked to the wider Australian society.

Developments since World War II. From the early 1940s, government policies have been changing. But growing support for the goal of assimilation (in effect, Europeanization) did not include adequate programs for achieving it. Many Aborigines were resistant, skeptical, and disillusioned—the aftermath of neglect and the not-too-distant memory of the traumatic events of early contact. In the early 1950s, some sought withdrawal and a magico-religious escape in the *kurangara* (Kimberleys) or in a revival of quasi-Aboriginal religion (as in the north coast of New South Wales). The Pindan Cooperative at Port Hedland in Western Australia is a further example of a movement concerned with maintaining group cohesion on a quasi-traditional basis.

No Aborigines exist who have not had some contact with modern Australian society. By 1960 only about 7,500 Aborigines still kept even a modified traditional orientation. The great majority of the total population of some 45,000 "full bloods" and 78,000 mixed bloods (1971) were living in southern cities and country towns—more European both in physical appearance and in manner of living. Generally, within recent years, the emphasis has been on drawing Aborigines more closely into the wider Australian society and, in the process, erasing unfavourable forms of discrimination. All Aborigines are now Australian citizens, eligible to vote, to receive social service benefits, and to drink liquor. Facilities for primary and secondary education and for technical training have been improved, and more people of Aboriginal descent are taking advantage of this. Nevertheless, many remain poorly trained and educated, caught in the lowest socio-economic level of Australian society. Prospects are brighter for the younger generation, but social acceptance by many white Australians is still limited.

Population figures

Two major developments are significant. A Commonwealth (Federal) conference in 1965 nominally redefined assimilation policies by giving Aborigines a choice between an Aboriginal and an Australian–European orientation. The trend toward social and cultural alteration has actually proceeded so far that, in most areas, such choice is unreal. But it has left the door open in some areas where Aborigines still have an informed appreciation of the value of their traditions. The other development has been an increasing uniformity between state and Commonwealth policies, partly a result of the Federal Office of Aboriginal Affairs, which serves in an overview capacity and provides economic aid.

The last decade has seen the emergence of more articulate part-Aboriginal groups in the south, who insist on integration rather than assimilation—that is, on retaining Aboriginal identity as a unique status symbol marking them off from other Australians. This movement toward pan-Aboriginality has implications for all people of Aboriginal descent. In the north, the focus has been on questions of land ownership and control, including compensation (and not just royalties) for and a share in the mineral exploitation that is occurring on Aboriginal reserves. The Commonwealth has done little about this and in some cases has been aligned with mining bodies that oppose such Aboriginal claims. Generally, there is wide dissatisfaction with the progress of socio-economic development. A likely consequence of this is a reinforcement of the movements mentioned above toward maintaining what remains of the traditional life, reflecting a belief that the last significant aspects of the Aborigines' social and cultural identification should not be dissipated.

BIBLIOGRAPHY. The best general accounts of traditional Aboriginal life are A.P. ELKIN, *The Australian Aborigines* (1964); R.M. and C.H. BERNDT, *The World of the First Australians*, 3rd ed. (1969); F.D. MCCARTHY, *Australia's Aborigines: Their Life and Culture* (1957); R.M. and C.H. BERNDT (eds.), *Aboriginal Man in Australia* (1965); and R.M. BERNDT (ed.), *Australian Aboriginal Anthropology* (1970). H. SHEILS (ed.), *Australian Aboriginal Studies* (1963), also gives a general coverage focussed on research problems. Most of these volumes include sections on change; but see especially M. REAY (ed.), *Aborigines Now* (1964); I.G. SHARP and C.M. TATZ (eds.), *Aborigines in the Economy* (1966); W.E.H. STANNER, *After the Dreaming* (1969); D.E. HUTCHINSON (ed.), *Aboriginal Progress: A New Era?* (1969); and, related to Aboriginal policy and practice, C.D. ROWLEY, *The Destruction of Aboriginal Society* (1970), *Outcasts in White Australia* (1971) and *The Remote Aborigines* (1971). A large series of monographs on various aspects of Aboriginal life has been produced by the Australian Institute of Aboriginal Studies.

Separate and detailed studies of Aboriginal societies are by W.L. WARNER, *A Black Civilization* (1937); C.W.M. HART and A.R. PILLING, *The Tiwi of North Australia* (1960); M.J. MEGGITT, *Desert People: A Study of the Walbiri Aborigines of Central Australia* (1962); L.R. HIATT, *Kinship and Conflict: A Study of an Aboriginal Community in Northern Arnhem* (1965); and R.M. and C.H. BERNDT, *Man, Land and Myth in North Australia: The Gunwinggu People* (1970).

Among the classic studies of the pre-anthropological era are those by R.B. SMYTH, *The Aborigines of Victoria*, 2 vol. (1878); J.D. WOODS (ed.), *The Native Tribes of South Australia, Comprising the Narrinyeri* (1879); E.M. CURR, *The Australian Race*, 4 vol. (1886–87); W.B. SPENCER and F.J. GILLEN, *The Native Tribes of Central Australia* (1899, reprinted 1938); A.W. HOWITT, *The Native Tribes of South-East Australia* (1904); W.B. SPENCER, *The Native Tribes of the Northern Territory of Australia* (1914); B. MALINOWSKI, *The Family Among the Australian Aborigines* (1913); and H. BASEDOW, *The Australian Aboriginal* (1925).

The basis of professional anthropological work was established by A.R. RADCLIFFE-BROWN—see his *Social Organization of Australian Tribes* (1931) and *Structure and Function in Primitive Society* (1952); and A.P. ELKIN, *Studies in Australian Totemism* (1933) and *Aboriginal Men of High Degree* (1946); in the contact sphere, A.P. ELKIN'S article on "Reaction and Interaction: A Food Gathering People and European Settlement in Australia," *Am. Anthrop.*, 53:164–186 (1951), is significant. In regard to studies on Aboriginal women, see P.M. KABERRY, *Aboriginal Woman, Sacred and Profane* (1939); and C.H. BERNDT, *Women's Changing Ceremonies in Northern Australia* (1950); also F. GALE (ed.), *Women's Role in Aboriginal Society* (1971). On Aboriginal art, see F.D. MCCARTHY, *Australian Aboriginal Decorative Art*, 5th ed. (1958) and *Australian Aboriginal Rock Art* (1958); C.P. MOUNTFORD, *The Tiwi: Their Art, Myth, and Ceremony* (1958), and (ed.), *Art, Myth and Symbolism* (1956); and R.M. BERNDT (ed.), *Australian Aboriginal Art* (1964).

Controversies have stimulated discussion on certain aspects of traditional Aboriginal life. One arose from W.L. WARNER'S and A.R. RADCLIFFE-BROWN'S interpretation of the so-called "Murngin" kinship system. See also J.A. BARNES, *Inquest on the Murngin* (1967); and R.M. BERNDT in F.L.K. HSU (ed.), *Kinship and Culture* (1971). The concept of the local group vis-à-vis the horde, also arising from Radcliffe-Brown's earlier contentions, has been discussed by R.M. BERNDT in *Oceania*, 30:81–107 (1959–60); W.E.H. STANNER, *Oceania*, 37:1–26 (1965); and L.R. HIATT, *Oceania*, 32:267–286 (1962), and 37: 81–92 (1966); as well as by J.B. BIRDSELL, with a commentary by students of Aboriginal affairs, in *Cur. Anthrop.*, 11:115–131, 138–142 (1970). The issues of law and order in the absence of clearly defined political authority, the relevance of kinship in this respect, and the place of tribal elders are the subject of conflicting views. R.L. SHARP in *Systems of Political*

Control and Bureaucracy in Human Societies, ed. by V.F. RAY (1958); M.J. MEGGITT, *Indigenous Forms of Government Among the Australian Aborigines* (1962); and L. HIATT, "Social Control in Central Arnhem Land," *South Pacific*, 10: 182–192 (1959), have taken one approach against A.P. ELKIN and R.M. BERNDT in *Aboriginal Man in Australia* (1965); and T.G.H. STREHLOW in *Australian Aboriginal Anthropology* (1970). However, the most long-standing controversy, deriving from Durkheim, has centred on totemism and has recently been revived by C. LEVI-STRAUSS in *Le Totémisme aujourd'hui* (1962; Eng. trans., 1963).

(R.M.B.)

Australian Aboriginal Languages

There are approximately 260 Australian Aboriginal languages. This group of genetically interrelated tongues embraces the entire Australian continent as well as the western islands of Torres Strait, but apparently excludes Tasmania. The languages are characterized by great similarities in their sound systems and considerable agreement in grammar but often by markedly few similarities in vocabulary. Intelligibility between neighbouring forms of speech is common, and dialect chains stretching over amazing distances occur, though the two extremes of such a chain seem to be quite distinct languages.

Every tribe speaks at least a distinct dialect, but bilingualism and multilingualism are common in many areas.

Secret languages and special vocabularies

Many individual languages have parallel forms, characterized by special vocabularies and sometimes by special sounds that are used in cultural avoidance situations (*e.g.*, to mothers-in-law) or as secret languages among initiated men on certain occasions.

No genetic link is known to exist between the Australian languages and any outside language. It is believed that languages ancestral to the present-day ones were introduced into Australia by peoples that crossed Arnhem Land in northern Australia many millennia ago. With the apparent exception of the influence of Papuan languages on the languages of the Cape York Peninsula, the Australian languages remained free from outside influence until the arrival of European settlers late in the 18th century.

The great majority of the Australian languages were nearing extinction in the fourth quarter of the 20th century, with about 50 or more extinct, predominantly in the east, south, and west of the continent. Speakers of languages believed extinct for decades are, however, occasionally discovered. Most languages have very few surviving speakers; still-vigorous languages have, for the most part, only a few hundred speakers each, though Mabuiag, the language of the western Torres Strait islands, and the Western Desert language have 7,000 and 4,000 speakers, respectively. About 47,000 Aborigines may still have some knowledge of an Australian language, but accurate figures of the speakers of individual languages are almost impossible to obtain.

Extensive research on the Australian languages has been carried out since 1960, largely through the Australian Institute of Aboriginal Studies in Canberra. The results of this and earlier research have shown the Australian languages to be interrelated and have made it possible to explain their structural differences in terms of a typological development from a simple to a complex structure. In addition, a considerable amount of detailed information on the grammar of numerous languages has been recorded.

Classification. Earlier classifications regarded the northern and northwestern languages, which are structurally rather different from the southern languages, as genetically distinct from the latter. (The interrelationship of the southern languages was recognized quite early.) Later, various classifications based on language type were established, and these demonstrated the ultimate unity of all Australian languages. The most recent classification is based on the degree of lexical (vocabulary) interrelationship between the languages; it subdivides the languages into 28 families, of which 27 are located in the north and northwest, covering about one-eighth of the continent, and a single family is found occupying the remaining seven-eighths of Australia. This skewed picture may be the result of the thorough spreading of a language form referred to as Common Australian (dated at about 5,000–6,000 years ago) from somewhere in northwestern Australia through most of the continent except the north and northwest regions. This diffusion appears to have coincided with that of an archaeologically recognized cultural revolution. The spreading of this Common Australian language may have brought about greater linguistic uniformity in much of Australia. Most of the 28 families are subdividable into groups and often into subgroups of individual languages. In the following list of language families these abbreviations are used: G = group or groups; SG = subgroups; L = language or languages.

Genetic relationship of all Australian languages

Family

Ngewinan (1L)	Nyul-Nyulan (4L)
Yanyulan (1L)	Pama-Nyungan (41G, 50SG, 177L)

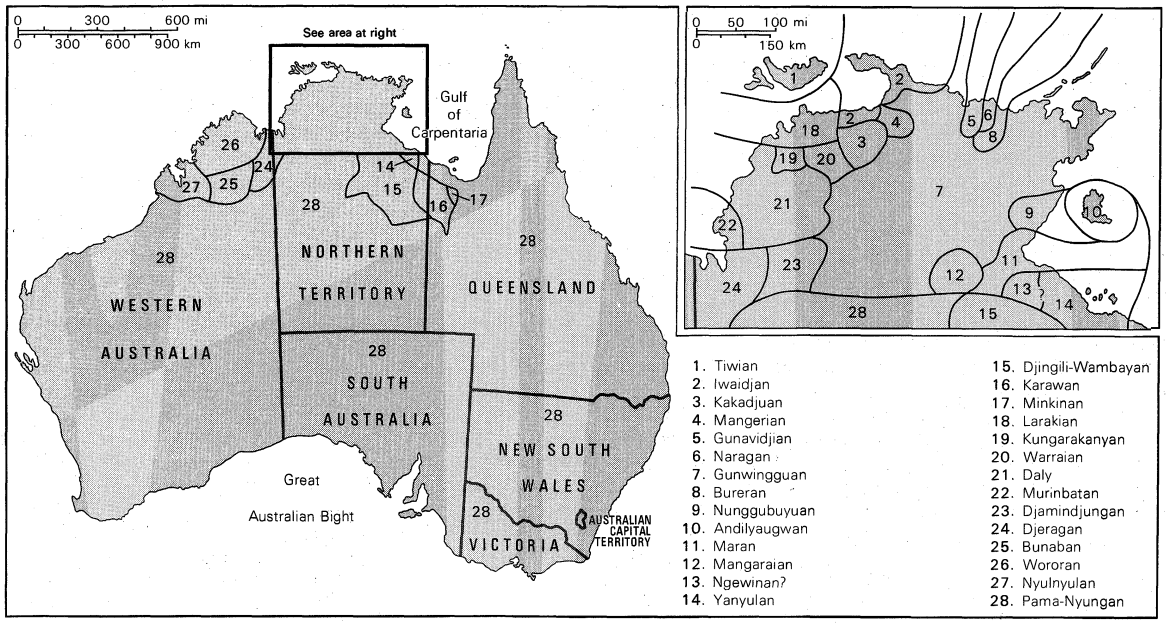
Some aspects of this classification are only tentative. The locations of the families are shown on the accompanying map.

In most areas in which Australian languages are still in daily use, individual languages have gained prominence over others and have become lingua francas (common languages), as a result either of their use as mission languages or of social and cultural factors active among the Aborigines themselves. One of the dialects of the Western Desert language, Bidjandjara (Pitjantjatjara), has become the Aboriginal lingua franca over a sizable portion of the western half of the continent.

Bidjandjara

Grammar. The Australian languages generally show considerable grammatical complexity. Affixes (word parts added initially, internally, or terminally) play an important role; prefixes used initially and suffixes used terminally are found in northern and northwestern Australia, and suffixes, for the most part, are used elsewhere. A peculiar feature of many languages is the suffixing of markers indicating the subject and object of the verb to the first word of the sentence, irrespective of what it is, or to special particles not connected with the verb. An example from Wanman of the Pama-Nyungan family is the use of the suffixes -*ŋa* and -*ŋku* in *paralʸi-ŋa-ŋku tʸiŋka-ŋa*, literally, "boomerang-I-you make-past," or "I made a boomerang for you." Another widespread feature is an ergative or agentive suffix, attached to nouns and pronouns, that indicates the actor of an action referred to by a transitive verb. In the Dungidjau language of the Pama-Nyungan family, *tʸa:n-tu pukinʸ-nʸa pumi* is directly translated as "*man*-ergative *dog*-object *hit*-past." Here *-tu* is the ergative suffix; attached to *tʸa:n* ("man"), *-tu* signifies that "man" is the actor of the verb, thus rendering the meaning "the man hit the dog." Great freedom of word order is a feature of many Australian languages. A number of languages, mainly northern ones, have gender and noun class systems, with adjectives, numerals, and demonstratives showing special forms for each of the classes of nouns and often, also, for their number. For example, in Andilyaugwa of the Andilyaugwan family, "where is (located)" is expressed as *ŋi-ŋampa na-mpilʸa* when referring to one man, but as *wunala-ŋampa wu-pilʸa* when referring to two men, *wura-ŋampa na-mpilʸa* in regard to three or more men, *ta-ŋampa iŋa mpilʸa* to one woman, and *ma-ŋampa numa-mpilʸa* to a ship.

Phonology. The sound systems of the Australian languages are extremely similar. Most of them share from four to six different points of articulation for stop consonants (made with complete stoppage of the breath from



Distribution of the Australian Aboriginal languages.
Adapted from S.A. Wurm, *Languages of Australia and Tasmania* (1971); Mouton & Co.

the lungs) and nasal consonants (made with the airstream passing through the nose), with many languages having such consonants produced with the tip of the tongue placed between the teeth (interdental consonants), indicated as $\underline{t}$, $\underline{n}$, or curled up against the hard palate (retroflexed consonants), written as $\underline{t}$, $\underline{n}$. The series of consonants may thus include labial consonants (*p*, *m*), interdental consonants, alveolar consonants (*t*, *n*), retroflexed consonants, palatalized consonants (t^y, n^y), and velars (*k*, and ŋ as the *ng* in "sing"). In addition, most Australian languages show no distinction between voiced and voiceless stops (such as voiced *b* and voiceless *p* in English), no fricative consonants (*e.g.*, *f*, *v*, *s*, *z*), only three vowels (*a*, *i*, *u*), but two or three distinct *r* sounds.

Common Australian words

Vocabulary. In spite of the great vocabulary differences among the Australian languages, a number of common words are encountered in a great many languages all over the continent. These are believed to constitute a Common Australian element. In the vocabulary of a given language, various classes of words, such as nouns, verbs, and others, are clearly distinguishable and definable, and word formation is through the use of affixes. Australian languages have contributed to Australian English mainly animal and plant names and objects in nature—kangaroo, wallaby, kookaburra, budgerigar, galah, coolibah tree, billabong.

Collections of mythological and other text materials have been and still are being made in a number of languages. Native literacy in Australian languages is limited but is on the increase as a result of members of the Summer Institute of Linguistics (an association of Protestant missionaries that specializes in studying primitive languages) who, like the people from the Methodist, Anglican, and Australian Inland missions, use specially adapted versions of English alphabets to write the languages.

BIBLIOGRAPHY. A concise, up-to-date discussion of all aspects of the study of Australian Aboriginal languages, with extensive bibliography, is provided in S.A. WURM, *Languages of Australia and Tasmania* (1971); extensive information may be found in the contributions by A. CAPELL, G.N. O'GRADY, and S.A. WURM in T.A. SEBEOK (ed.), *Current Trends in Linguistics*, vol. 8, *Linguistics in Oceania* (1971); and in G.N. O'GRADY and C.F. and F.M. VOEGELIN, *Languages of the World: Indo-Pacific Fascicle Six*, vol. 8, no. 2, *Anthropological Linguistics* (1966). Numerous articles and monographs on Australian languages appear in the serials: "Australian Aboriginal Studies," Canberra; "Pacific Linguistics," Canberra; "Oceania," Sydney; "Oceania Linguistic Monographs," Sydney.

(S.A.W.)

Australian External Territories

Apart from claims in Antarctica, the External Territories of the Commonwealth of Australia are made up entirely of islands, spanning almost one-third of the Southern Hemisphere and contending with the greatest possible range of climate and physical environment. They comprise the Australian Territory of Papua, occupying the southeastern section of the tropical island of New Guinea, immediately to Australia's north, with related archipelagos; innumerable small reefs, cays, and atolls between Queensland's Great Barrier Reef and longitude 157°10′ E; and several remote and diverse islands in the Pacific and Indian Oceans.

These latter oceanic outposts, far beyond the boundaries of the shelves that fringe the continental land masses, occupy the tips of submerged mountain ranges, many of volcanic origin. Those in the tropics often support fringing coral reefs, or atolls, where the sea level has risen sufficiently relative to the basic rock. With the exception of the mainland and islands of the Territory of Papua, none of the Australian External Territories was inhabited when they were first annexed by Great Britain, and subsequent development and exploitation has been carried out by migrant and recruited labour. The rugged terrain of New Guinea—the highest peaks in the Territory of Papua are frequently over 10,000 feet (3,500 metres)—was occupied by indigenous peoples long before any European contact. Dusky, woolly-haired Melanesians of the coastal and island regions and Papuans, the highly variable greater part of the inland population, with some Negrito traits in the central uplands, form the basic demographic elements. Polynesian and Micronesian incursions, from the Pacific generally, have further diversified these groups; and there is an almost inconceivably wide range of physical characteristics and of languages, with a rich, colourful, and varied accompaniment of ornaments, weapons, and other artifacts. The Australian Territory of Papua is bounded on the north by a trust territory (see NEW GUINEA, TRUST TERRITORY OF), which is currently administered by Australia under a United Nations Trusteeship Agreement, through the Papua and New Guinea Act (1949–68) of the Commonwealth of Australia. The Territory of Papua is bounded on the west by the Indonesian province of West Irian. The western boundary, settled by an agreement between Britain and Holland in 1895, lies along the 141st east meridian of longitude, except in the southern portion, where a small bulge to the west incorporates the most westerly point of the Fly River. South of this incursion, the boundary runs along the

line of 141°47′54″ E. The northern boundary roughly follows the complex mountain divide running across New Guinea (see NEW GUINEA, MOUNTAIN RANGES OF). The 86,100 square miles (223,000 square kilometres) of the Papuan territory contained, by the early 1970s, a population of approximately 670,000, most of whom still made their living by a combination of subsistence farming, hunting, or fishing.

Territorial composition

In detail, the composition of the remainder of the Australian External Territories is as follows: Norfolk Island, in latitude 29°02′ S, longitude 167°57′ E, and with an area of about 13.5 square miles (34 square kilometres), is a fertile and beautiful island famous for its indigenous pine. Associated with the earliest European settlement of Australia, its major industry today is tourism. Australia's newest territory (created by Act of the Commonwealth on Sept. 30, 1969) is also found in the Pacific Ocean. The Coral Sea Islands Territory, scattered over 400,000 square miles of tropical waters, is uninhabited except by the observers of the Commonwealth meteorological station on Willis Islets, latitude 16° S, longitude 150° E (established 1921).

The Cocos (Keeling) Islands, consisting of two groups of 27 islands with a total area of 5.5 square miles (14.2 square kilometres) are located in the Indian Ocean in latitude 12°5′ S and longitude 96°53′ E. By their transfer from Britain to the Commonwealth of Australia, under the Cocos (Keeling) Islands Act (1955), they ceased to be part of the Republic of Singapore. Christmas Island, 52 square miles (135 square kilometres) in area, in latitude 10°25′ S and longitude 105°40′ E, is a source of high-grade rock phosphate. Like the Cocos (Keeling) Islands, it was also transferred to Australia from Britain, under the Christmas Island Act (1958), having been previously governed and administered as part of the Republic of Singapore. The claim comprising Australian Antarctic Territory consists of all islands and territories, other than Adélie Land, situated south of the 60th parallel of south latitude and between the 45th and 160th eastern meridians. This territory, over which the British government formerly asserted the crown's sovereign rights, was transferred to Australia under the Australian Antarctic Territory Acceptance Act (1933; see ANTARCTICA). Heard Island, latitude 53° S, longitude 73°23′ E, and approximately 215 square miles (557 square kilometres) in area, is perpetually ice-capped; the McDonald Islands Act of the Commonwealth (1953–63) defines Australia's claim.

The northern districts of Papua New Guinea are bound by the Equator; Australian Antarctic Territory reaches to the South Pole. Heard Island, farthest west of all Australian territories except the Enderby Land section of Antarctica, is 2,500 miles southwest of Fremantle, Western Australia; Norfolk Island, most easterly, is located 1,035 miles east-northeast of Sydney, New South Wales. To contend with this diversity, radio networks provide channels for administrative and commercial interests and for an extensive meteorological service. Physical contact between the Commonwealth and its territories varies from daily jet air services between the Australian capitals and Papua New Guinea to the annual relief of its Antarctic stations by vessels strengthened for ice.

Administrative responsibilities

The Commonwealth Department of External Territories provides administrative services for the territories of Papua and New Guinea, Norfolk Island, the Cocos (Keeling) Islands, Christmas Island, and the Coral Sea Islands, except in matters of defense and civil aviation, for which separate ministries exist. For the inhabited territories, an administrator or official representative is appointed by the governor general of Australia to direct the government of the territory on behalf of the department. The department is concerned with matters relating to the United Nations Trusteeship Agreement for New Guinea and for other international aspects of Australia's territories. It recruits personnel for the territorial public services and, through the Australian School of Pacific Administration, in Sydney, it trains staff appointed to or serving in the various administrations. The department is pledged by the Commonwealth to "advance the people of Papua and New Guinea to self-determination." With increasing numbers of local government councils and a majority of indigenes in the House of Assembly and in the public service, considerable progress has been made toward political awareness and self-government. During the course of the parliament of 1972–76, internal self-government has been recommended by the UN Visiting Mission of 1971. Full political independence by 1980 has been forecast.

Although the former Trust Territory of Nauru gained independence as a republic on Jan. 31, 1968, the British Phosphate Commissioners, who manage and supervise the mining, shipment, and sale of phosphates from the island deposits, are responsible to the Minister for Australia's External Territories. The Commonwealth Department of Supply administers Australia's Antarctic interests and the enactments defined by the Antarctic Treaty Act (1960), the Australian Antarctic Territory Acceptance Act (1933), and the acts of 1953–63 relating to Australian Antarctic Territory and to Heard and the McDonald Islands. The Department of Supply, through its Antarctic Division, is responsible for the logistics of the annual relief operations of Australia's southern scientific stations (for which such departments as that of the Interior and of National Development supply certain scientific and technical personnel) and for their continuous general function and administration.

THE AUSTRALIAN TERRITORY OF PAPUA

Papua comprises the southeastern mainland of New Guinea with the islands of the Gulf of Papua and, east of this territory, to longitude 154°14′ E, between latitudes 8° S and 12° S, a considerable archipelago including the coral Trobriands, the Woodlark, Laughlan, D'Entrecasteaux, and Conflict groups, with the Louisiade Archipelago, and Samarai.

The northern boundary of Papua spans the New Guinea highlands to latitude 8° S, beyond which, for 300 miles, the territory occupies the whole southeastern cape centred by the Owen Stanley Range (highest peak Mount Victoria, 13,363 feet [4,073 metres]). Severe earthquakes, occasional volcanic activity, and continuing coastal uplift or subsidence testify to the geological instability of the region. The counterparts of the jagged and abrupt mountains are deep and precipitous gorges with swift and turbulent streams, which, apart from the Fly River in the west, are unnavigable for any great distance by cargo vessels. The Fly, an important river, is navigable for 500 miles by vessels of eight-foot draft. West of the Fly Delta is the low and stable Oriomo Plateau, formed of limestone and alluvial deposits.

Climate of Papua

Because Papua lies wholly within the tropics, there is little seasonal change of atmospheric temperature or humidity, both of which are uniformly high throughout the year. The mean maxima and minima of temperature rarely fall outside the range 70°–90° F (21°–32° C), the daily variation being 10°–15° F (6°–8° C), while the range of relative humidity is approximately 65 to 85 percent. A general lowering of temperatures occurs in the highlands, but the permanent snow line is not reached in Australian territory.

In all parts of New Guinea rain may fall throughout the year, for the northwest monsoon is active from December to March and the moisture-laden southeast trade winds blow from May to October, with brief, calmer, but unsettled, weeks during the transition periods. Though most places receive more than 100 inches, the disposition of mountains and coast causes remarkable variations in rainfall. The monsoon rains regularly exceed those of the trades except in the islands and at those places where rising ground forms a direct barrier to the winter winds from the southeast.

Such an area surrounds Kikori, on the Gulf of Papua, receiving 200–250 inches (510–635 centimetres) of rain annually. By contrast, Port Moresby, the administrative headquarters of Papua New Guinea, located only 250 miles away, receives little rain from the trades because the Owen Stanley Range runs parallel with their course. As a result of the rain-shadow effect of the central cordil-

lera, it also receives a minimum from the monsoon; the annual aggregate is about 40 inches (100 centimetres).

Although the greater part of Papua is clothed in dense tropical rain forest, varying in type with altitude, most of the inland soils are of low fertility, thin, and washed out by continual rain. Cleared land rapidly becomes unproductive, except for small areas in the highland valleys and in regions where there has been an accumulation of alluvial or volcanic soils. Swamp forest and rank grass clothe much of the valley of the lower Fly River; parts of the coast and many of the islands are fringed by mangroves and palms—coconut, nipa, and sago palms—and, in lower rainfall areas, by savanna grasses and scrubs.

The indigenous peoples of Papua, Papuans of the west and of the interior and Melanesians of the islands and eastern mainland, numbering (1971 estimate) 671,000, in general exist in small, egalitarian communities of 300 or less, building huts of local materials—timber, grass, or palm fronds—and cultivating native gardens, frequently moved as soil fertility decreases, growing yams, taro, and sweet potatoes. Sago palms and, in some parts, bananas provide a staple in the diet. Hunting supplements such supplies, domestic pigs provide prestige as well as seasonal feasts, and, in coastal areas and along the rivers, fishing is important. Indigenous food plants, other than those already mentioned, include sugarcane, ginger, and several kinds of nuts.

The people and their life

There is great diversity of language, mostly mutually unintelligible. On the coast, Motu and pidgin English are widely understood. In the more than 850 schools, administration and mission (of many different Christian denominations), English is taught; there are 17 primary schools where the curriculum is Australian-oriented. By the start of the 1970s, about half of the children of school age were receiving some formal education. There were also limited facilities for secondary education. In 1965 the University of Papua and New Guinea was founded at Boroka, near Port Moresby, and within a year had faculties of arts, law, and science, with an enrollment of about 600 indigenous students.

The average Papuan man or woman is about five feet tall and weighs between 100 and 130 pounds. Because of the ravages of malaria, dysentery, and hookworm and other parasites, the proportion living beyond the age of 50 is still small. There are significant exceptions from the general pattern, and modern medicine is slowly but successfully combating disease and malnutrition; the infant mortality rate has been lowered consistently. In all districts of Papua, hospitals and medical services are provided both by the missions and the administration.

Everywhere in Papua, outside the main coastal town of Port Moresby and the few centres such as Popondetta with extended road communications, interest is still basically confined to the local community and its affairs. The aggregate length of vehicular roads had, by 1970, exceeded 690 miles, with a further 1,560 miles of roads and tracks usually allowing access. No region in Papua is more than 50 miles from an aircraft landing field, of which there are about 100 in the various districts.

Over the greater part of the country, however, magico-religious practices, taboos, and indulgences, based on the worship of ghosts and ancestral spirits, continue in some form, not infrequently blended with Christian derivatives. It is significant that in the most recent census more than nine-tenths of the population claimed membership in one of a dozen Christian religious denominations. From the beginnings of European administration, head-hunting, cannibalism, and vendetta have declined and in Papua today perhaps scarcely exist. The village sorcerer is still influential in many parts where the affairs of crops, hunting, and society are believed affected by social or antisocial magic. Otherwise, power is held by the men of the community in consultation, with leadership, single or multiple, generally based on skills of various kinds, such as weapon making and gardening, and on personality and possessions.

The Papuan animal life is largely related to that of Australia, marsupials being common and the largest of these being the tree kangaroo. The spiny anteater is present, as are numerous bats and rodents. Reptiles include numerous snakes, many venomous, and both estuarine and marine crocodiles and species of both turtles and tortoises. Birds are colourful, with both Australian and Malaysian affinities. The gorgeous bird of paradise and the large, flightless cassowary are distinctive of the region. There are myriad insects, spiders, scorpions, centipedes, and mites, including the typhus and malarial hosts against which precautions and vigilance are required.

Since the affairs of Papua first concerned Australia in 1906, the district organization has spread, gradually, through the disparate communal and geographical structure. This is made up of thousands of individual villages with virtually no common interests, hundreds of distinct languages, and a dozen markedly different environments. The district system has ultimately provided a system of communications; a means of dispersing knowledge and policy; and legal, medical, educational, and agricultural services. This made possible the beginnings of native government and, eventually, the formation of local government councils. The latter, established in 1950, had, by the 1970s, increased to more than 50 in Papua (with a further 90 in the Trust Territory of New Guinea), representing about 85 percent of the population.

Administration of Papua New Guinea

The Department of District Administration of the Public Service of Papua New Guinea provides for six Papuan districts, from west to east, Western, Southern Highlands, Gulf, Central, Northern, and Milne Bay—all except the Southern Highlands with access to the sea—and 12 in the trust territory. Part of the district of Chimbu (mainly in the trust territory) enters Papua east of the Southern Highlands. Each district is administered by a district commissioner, a deputy district commissioner, several assistant district officers and patrol officers, and medical, agricultural, and educational officers, resident in the chief local centres or the subdistricts. The Public Service in general, with 16 departments, having headquarters in Port Moresby, is responsible for implementing government policy for the political, social, and economic development of Papua and the Trust Territory of New Guinea. A majority of its employees, assisting in all departments, are natives. Through their local government councils, the indigenous peoples are becoming politically aware and are taking more part in community management; working with the district administration; and assisting with the construction of roads, bridges, aircraft facilities, meeting halls, schools, and other public buildings.

Representation of the indigenous population of Papua New Guinea on a national basis commenced with the provision, in 1951, for three representatives to be elected to the Legislative Council. The number was increased to 12 elected members in 1960. In 1964 the Papua and New Guinea House of Assembly replaced the Legislative Council, the present constitution (1968) allowing for 84 elected members and 10 official members appointed by the governor general of Australia, on the nomination of the Administrator. The 1972–76 (third) House of Assembly contained 4 official members. The body, whose chief minister, Michael Somare, was New Guinean, has power to make ordinances for the peace and good government of the territory and is advisory to the Administrator's Executive Council, which also includes a majority of elected members nominated by the House of Assembly (with the concurrence of the administrator), who must assent to all ordinances before they take effect. The Australian Commonwealth's grant to revenues at present equals that raised internally. The judiciary of Papua New Guinea consists of the Supreme Court, with a chief justice and other judges, and district, local, and children's courts under the jurisdiction of stipendary and resident magistrates, an increasing number of whom are indigenes.

Virtually all of the commercial agricultural production of Papua, as distinct from the subsistence crops of villagers, is obtained from plantations, mainly near the coast or on the islands and occupying less than 1 percent of the land. Slightly more forest land is being exploited for timber. Copra is produced from all districts except

the Southern Highlands, which, with the mountainous areas of the Central District, grow high-quality coffee. Other than copra, rubber is the principal crop, and some cacao plantings are promising. The Southern Highlands support small crops of pyrethrum (a plant whose pungent root is used in medicine); a growing number of native-owned cattle are also pastured in high grasslands.

Economic development

About 16,600 tons of copra were exported annually by the 1970s, together with 5,756 tons of rubber; other exports included sawed timber, cocoa beans, fish and crustaceans, and shells. The value of present imports is about five times that of export goods. Mineral production in Papua, by contrast with that of the Trust Territory of New Guinea, has been trivial, but the considerable quantities of copper ore reported to exist in the inaccessible Star Mountains in the far northwest may be exploited.

Hydroelectric power stations are gradually being established. Port Moresby, Popondetta, Daru, Mendi, and Samarai possess hydroelectric or thermoelectric stations with a total installed capacity (1971) of 35.9 megawatts.

NORFOLK ISLAND

Norfolk Island, with a total area of about 13.3 square miles (34.5 square kilometres), is volcanic in origin and has a mean altitude of 350 feet; two high points, Mount Pitt and Mount Bates, just exceed 1,000 feet. The climate is pleasant and equable, with an annual rainfall of 52 inches (132 centimetres) and a mean annual temperature of 61° F (16° C). Although most of the island has been cleared for cropping and pasture, the once-dominant Norfolk Island pines are still a notable feature of the landscape. The beautiful island is famed for the ruins dating from its cruel convict era, and for the "islanders" who are descendants of the mutineers of H.M.S. "Bounty." The latter, in 1789, cast off the captain of the vessel, Lieut. William Bligh, in a provisioned boat, which ultimately reached Timor; while they themselves, with some Tahitian women, first settled on lonely Pitcairn Island. After many vicissitudes, the majority of their descendants were resettled on Norfolk Island in 1856, taking over the evacuated convict establishment. Among the contemporary islanders, there are many residual traits and customs, including some of Tahitian origin.

Descendants of the mutineers

The 20th-century population (including immigrants from the mainland) first exceeded 1,200 as recently as 1970; but tourists, numbering about 10,000 annually, have created a great change in the island's economy. There is considerable competition for the visitors' custom and at times a local scarcity, formerly unknown, of island produce. Norfolk Island is served by regular air services from Sydney and by less frequent shipping from Sydney, Noumea, and New Zealand ports.

An administrator, appointed by the Australian governor general, is at the head of a small civil service in Kingston, the main settlement. He is also chairman of the Norfolk Island Council, an advisory body consisting of eight elected local representatives. The legal system includes a Supreme Court with visiting mainland judges, and a Court of Petty Sessions under the jurisdiction of local magistrates.

Tourism, some fresh-fruit produce, and the sale of bean, palm, lemon, pine, and flower seeds, with some hides, underlie the economy; while the important items of revenue are the philatelic sale of postage stamps, customs duty, and the sale of liquor, which is a government monopoly. Australian currency is legal tender.

CORAL SEA ISLANDS

Australia's Coral Sea Islands Territory includes the Flinders Reefs, Herald Cays, Holmes Reefs, Moore Reefs, Bougainville Reef, Ospray Reef, Willis Islets, and others in the northwest of the Coral Sea, and a southeasterly group embracing Frederick Reef, Saumarez Reef, and Cato Island; all except Willis Islets are uninhabited, but they are occasionally visited by scientists, fishermen, and prospectors for oil or minerals.

British naval vessels—H.M.S. "Cato" (1803), H.M.S. "Frederick" (1812), and H.M.S. "Herald" (1854–60)—discovered and surveyed these low coral islands, all of which are either topping volcanic foundations or the dissected remnants of submarine plateaus.

The automatic weather station (1966) on Cato Island supplements information from the manned Australian Bureau of Meteorology station (1921) on Willis Islets.

Since 1967 extensive surveying of the numerous and variable cays, and of the low reefs and islands has been undertaken by the Australian Department of National Development.

CHRISTMAS ISLAND

At several points exceeding 1,100 feet in altitude, Christmas Island, 52 square miles (135 square kilometres) in area, is the summit of an oceanic mountain surrounded by depths of 6,000 feet. The abyssal Java Trench (24,500 feet at its deepest) is to the northeast. The rock is mainly limestone stratified with old volcanic flows, with valuable deposits of phosphate of lime near Flying Fish Cove and on the Southern Plateau. The island is 815 miles from Singapore, only 224 miles from Java Head, and 1,630 miles from Fremantle, Western Australia. Its climate is salubrious and warm (70°–90° F [21°–32° C]), with little seasonal variation but a tropical rainy season between November and April. Rich forest clothes the island, and both flora and fauna are varied and numerous. The latter includes birds, small, harmless reptiles, crustaceans, insects, spiders, scorpions, and centipedes.

The island was first sighted by Capt. William Mynors, of the British East India Company, on Christmas Day in 1643. It was annexed by Great Britain in 1888. A lease granted to the local families of George Clunies-Ross and Sir John Murray was transferred six years later to the Christmas Island Phosphate Company. These interests were acquired by the Australian and New Zealand governments (1948). In 1958, when the island became an Australian territory, a new agreement ratified the existing legislature; the British Phosphate Commission, on behalf of both governments, quarried and shipped the valuable deposits. The existence of some 200,000,000 tons of phosphate of various grades has been confirmed; present production exceeds 1,000,000 tons annually.

Phosphate deposits on Christmas Island

The population is 3,600, consisting mainly of recruited Chinese and Malay labourers from Malaysia, Singapore, and the Cocos (Keeling) Islands, working for the commission, with Australian or British management personnel, and the island administration.

An administrator of Christmas Island is appointed by the Australian governor general, with a staff for secretariat, education, police, radio, and harbour duties. The judiciary consists of a Supreme Court, District Court, and Magistrate's Court. The functions of the latter, empowered to try minor offences, are exercised by resident magistrates, usually both Chinese and European. Revenue is gained from royalties paid by the British Phosphate Commission, with small contributions from customs duty, duty on liquor, and from the philatelic sale of postage stamps.

Although, since settlement and exploitation of the island's resources, some of the unique original animal life of Christmas Island has become extinct, the mass movement of millions of red land crabs, which annually deposit their eggs along the coast and return to the inland jungles, still provides a remarkable phenomenon.

COCOS (KEELING) ISLANDS

The Cocos (Keeling) Islands, 2,290 miles almost due west of Darwin, comprise 27 small coral exposures in two atolls, the northern and much smaller North Keeling Island lying about 15 miles from the larger circular group of West Island, South Island, Home Island, and numerous smaller isles. The climate is governed largely by the southeast trade winds and is warm, with temperatures consistently between 70° and 89° F (21° and 32° C), average relative humidity 75 percent, and rainfall about 70 inches. The population (1971 estimate) was 671: 143 Europeans and most of the rest descendants of the original Muslims of Malayan origin brought to the islands in the early 19th century. Between 1948 and 1951, an extensive emigration movement, aided by the management of

the Clunies-Ross Estate and the government of Singapore, reduced the islands' population by more than 1,600 Cocos Islanders, who were mainly settled on estates in Sabah, Malaysia (then North Borneo).

An official representative of the Australian government is resident, and various instrumentalities of the Commonwealth provide essential services in aviation, communications, meteorology, and in legal and fiscal matters. The indenture of 1886, granting all land in the territory to the Clunies-Ross family, subject to the crown's resumption of areas necessary for public purposes, was still valid in the early 1970s.

HEARD AND THE MCDONALD ISLANDS

Antarctic research on Heard Island

Heard Island was occupied continuously from 1947 to 1954 by the Australian National Antarctic Research Expeditions (ANARE), the scientific program then being transferred to stations on the Antarctic mainland, at Mawson, and then Davis. The deserted station on Heard is visited occasionally by relief expeditions bound for the more southern bases and has been used by U.S. scientists and technicians concerned with satellite tracking and other space programs. The island was first sighted in 1833, and many teams exploited the island's elephant seals and penguins for their oil during the second half of the 19th century.

The summit of the volcanic Big Ben (9,000 feet [2,700 metres]) was reached by an Australian expedition led by W. Deacock in 1964–65.

The McDonald Islands have not been occupied. Like the lower parts of Heard Island, they are sparsely vegetated with cushion plants, rough tussock grass, mosses, and lichens; and they are visited by large numbers of elephant seals, leopard seals, and penguins, chiefly the gentoo, the rock hopper, and the macaroni. Several petrels, albatrosses, and skuas that breed on Heard Island probably also inhabit the McDonald Islands.

FUTURE STATUS OF THE ISLANDS

Until virtually the end of the 20th century, under the terms of the international Antarctic Treaty, territorial claims and ambitions in the Antarctic are effectively dormant, and the concept of a United Nations or other international control of the whole continent in perpetuity shapes itself.

The other Australian territory that, it would seem, must eventually change its status is the Territory of Papua, as part of the jointly administered Papua New Guinea, the two entities being seldom differentiated in terms of their future by Australian, if not by Afro-Asian, opinion.

In recent years there has been increasing pressure from the United Nations General Assembly's trusteeship committee to speed the processes leading to the self-determination of the Trust Territory of New Guinea.

Within the Territories of Papua and New Guinea and in the local government councils themselves, there is an increasing native realization that the course toward nationhood connotes progress in economics, industry, and communications inimical to an age-old group cultural and social context. Paradoxically, constitutional development committees, led by indigenes, have reported widely held opposition to many of the inevitable changes contingent on the transition from tribal decentralization to the national unity, and there have been proposals of a necessary interim of self-government before complete independence is achieved.

Australopithecus

Australopithecus is a name applied to fossilized remains of manlike higher primates known primarily from Africa. The remains range in time from late Pliocene to middle Pleistocene, a period of at least 3,000,000 years, probably more. Because of their anatomical structure and because stone implements have been found associated with some of the specimens, the australopithecines are generally believed to be closely related to man.

Discovery of the australopithecines

The first known australopithecine was found at Taung, South Africa, in 1924 and taken to Raymond Dart, then professor of anatomy at the University of the Witwatersrand, Johannesburg. Dart identified the fossil as an incomplete juvenile skull of a fossil primate not previously recognized. He named it *Australopithecus africanus* ("southern ape of Africa") and suggested that it was a form of ape transitional between typical apes and man. The scarcity of fossils of earlier forms of man at that time, coupled with the interpretive difficulties because the specimen is immature (skulls of young apes appear more manlike than those of adults), led to the rejection of Dart's view. There the matter rested for a decade, with the Taung skull unaccepted as a prehuman type.

In 1936 R. Broom, one of the few people who had accepted Dart's belief as to the possible relationship between the Taung skull and man, was shown fossil re-

mains discovered in mining operations at Sterkfontein, near Johannesburg. These he classified tentatively as australopithecine and began the search for more australopithecine fossils. Between 1936 and 1941, and again after World War II, many more fossil australopithecines were found by Broom and others in South Africa, eastern Africa, and Asia (see Table). Not all of these fossils were immediately identified as australopithecine, and in the case of one of these, *Gigantopithecus blacki,* it is now assumed that *Gigantopithecus* is not an australopithecine but may be ancestral to the australopithecine line. All other australopithecine fossils are generally accepted as belonging to the genera *Australopithecus* or *Paranthropus.*

Taxonomy of the australopithecines

Opinions differ greatly with respect to both the extent of the differentiation within the australopithecine group and whether any or all of the known forms are directly ancestral to modern man. The resolution of the latter problem will depend upon how the former is viewed. Most students incline to the view that all known australopithecines, placed in one genus, *Australopithecus,* were essentially similar in anatomy, behaviour, and ecology. This view is represented by such reputable scholars as Dart, who described the first australopithecine in 1925, and Sir Wilfrid E. Le Gros Clark. In contrast, since 1954 J. T. Robinson has argued that the australopithecines include two forms, which differ anatomically, behaviorally, and ecologically: *Paranthropus,* robust and apelike, and *Australopithecus,* gracile and manlike. In this view the latter is directly ancestral to early true man, *Homo erectus,* and is itself an offshoot of the *Paranthropus* lineage. Latterly this view has received increased support and many students accept that at least some differentiation—into two species—was present, but the majority still prefer to place these species in a single genus *Australopithecus.* The controversy over the role of australopithecines in the ancestry of man concerns primarily whether *Paranthropus* was directly in that ancestry or not; most students accept that *Australopithecus* was. Even here opinions differ; for example, P.V. Tobias and J. Napier believe, as did L.S.B. Leakey, that another lineage existed (*Homo habilis*) that was directly ancestral to true man, while *Paranthropus* and *Australopithecus* were closely related, but not directly ancestral, to it.

There is general agreement that the study of australopithecines is the study of the emergence of man; at the very least that it throws much light on the transition from apes to man. Much present understanding of this area of study, however, is tentative and speculative. This is partly because fossil evidence can at best represent a once-living population only incompletely, partly because of gaps in the known fossil record, and partly because samples are too small to reveal the range of variation in many significant features. Without knowledge of such variation the significance of differences is difficult to assess.

INTERPRETATION OF THE EMPIRICAL EVIDENCE

Interpreting the australopithecine material is difficult because the only direct evidence of the hominids themselves

Several specimens may belong to the same individual; a specimen is a bone fragment or bone. †Gracile forms all *A. africanus;* robust forms either *A. robustus* or *P. robustus,* depending on school of thought. *Homo erectus* is man, not man-ape. *Meganthropus* and *Gigantopithecus* are apes. ‡Date and author of name, if different from date of discovery and discoverer.

concerns parts of the skeleton and, in some cases, some aspects of material culture (occasional stone or bone tools). Much information needed to understand the lives of the early hominids—functional, behavioral, and ecological aspects—must be deduced from the narrow segment of the life and times of these creatures represented by the empirical evidence. Fortunately, the evidence also contains some information about climate and associated animals. An added difficulty is that the soundest available criterion of human status is the capacity to use conceptual thought; but this capacity cannot be deduced from the anatomical evidence available. Hence it is possible to properly classify as a hominid a fossil exhibiting accepted anatomical criteria of hominid status without its necessarily having been capable of conceptual thought. This dilemma appears at present to be insurmountable; cultural evidence has helped a little, but has not resolved it.

Physical characteristics of the australopithecines

Objective traits. The major characteristics of the australopithecine phase of hominid evolution are small brain size, within the size range of modern apes; dentition, manlike with canines not projecting significantly beyond adjacent teeth, tooth row compact and without diastemata (gaps between canine and premolars, common in animals with large, cutting canines); presence of anatomical adaptation for at least a moderately erect bipedal posture. The anatomical features associated with bipedal posture include low, relatively horizontal nuchal plane of the occiput (the area of the back of the head where the neck muscles attach; see Figure 1); pronounced lumbar curvature of the spine; reduced height of the iliac blade of the pelvis (see Figure 2); clearly defined greater sciatic notch produced by backward expansion of the iliac blade; presence of a zone of strengthened bone running upward from the acetabulum (cup-shaped joint for the thigh bone), associated with specialization of the gluteus medius and minimus muscles for lateral balance control; and proportionately increased width of the sacrum (base of the spine).

From W.E. Le Gros Clark, *The Fossil Evidence for Human Evolution* (1964); The University of Chicago Press

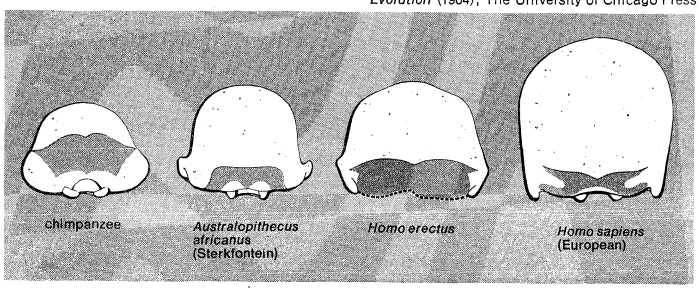

Figure 1: Occipital view of skulls with nuchal plane shaded.

These hominids had thus not departed noticeably from the ape grade of organization in brain volume but had departed entirely from the ape grade and become strongly manlike with respect to the dentition and with respect to erect posture. That they had these features in common does not mean that they were all alike. Most

The robust and gracile distinction

workers accept that two distinct forms are known, one robust (*Paranthropus*) and the other gracile (*Australopithecus*).

Considering anatomical characters, the division into robust and gracile forms is fairly clear-cut. A few major features will serve to illustrate the point. Although endocranial volume was apparently much the same in the two, in the gracile form the braincase rose relatively high above the upper orbital (eye sockets) margins; convexity of the frontal region produced a well-defined forehead; compound cranial crests (bony ridges along the top of the head to anchor heavy jaw muscles) were apparently rare, and the mastoid region below and behind the ear projected laterally to a moderate extent only. By contrast, in the robust form the braincase was proportionately low, within the ape range of variation and well away from that of the gracile form and of later human forms; the frontal region was flat and apelike, not convex; cranial crests (usually sagittal only) were normally present, and the mastoid region was well developed and laterally protuberant.

Similarly, although the dentitions of the two forms are more manlike than apelike, they differ significantly. That of the gracile form closely resembles that of *Homo erectus* (see HOMINIDAE) morphologically and in proportions along the tooth row. In contrast, the robust form has large cheek teeth, consistent with its robustness, but canines that are absolutely smaller than those of the gracile form, of *H. erectus,* and even of some races of modern man, and proportionally smaller than all of them. This curious proportionate smallness of canines—and to some extent of incisors also—occurs in the specimens from South and East Africa (*Paranthropus*) and Java (*Meganthropus*) throughout the several million years in which the robust form is known. It was thus a significant, stable, long-term characteristic of the robust lineage. The normal presence of a sagittal crest (ridge along the top of the head from front to back) resulted from the large size of the temporal muscles attached to a robust jaw; in larger individuals these produced partial compound crests in conjunction with the nuchal muscles.

Both forms have the essential pelvic, lumbar, and nuchal features associated with erect posture, but, again, they are not identical. The gracile form had the short ischium (see Figure 2) and long lower limb of modern

From W.E. Le Gros Clark, *The Fossil Evidence for Human Evolution* (1964); The University of Chicago Press

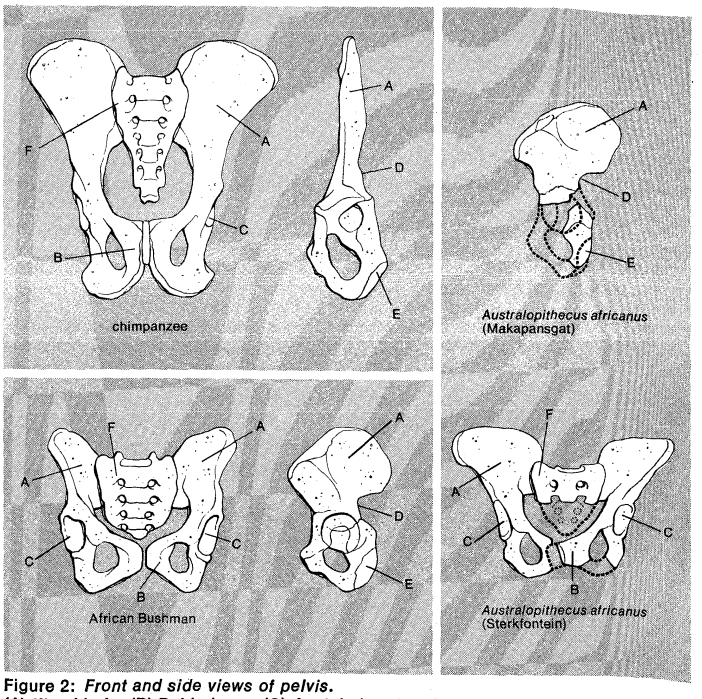

Figure 2: *Front and side views of pelvis.*
(A) Iliac blade. (B) Pubic bone. (C) Acetabulum (hip joint). (D) Sciatic notch. (E) Ischium. (F) Sacrum.

man and a remarkably modern foot. The robust form, in contrast, had a long, apelike ischium apparently associated with a proportionately short lower limb. Very scanty evidence suggests a mobile and flexible foot intermediate in character between ape and human feet.

On available evidence the two forms are distinguishable on any known part of the skeleton. Larger samples, by providing better knowledge of the normal range of variation among australopithecines, might show the degree of difference between the forms to be less important. The features discussed, however, are ones that do not vary widely within species of living higher primates and since they concern major adaptations, they are hardly likely to vary widely within the same population. The smallness of the samples is partially offset by this fact.

Behavioral and ecological inferences. *Posture and gait.* Both types of australopithecine regularly used erect posture. This conclusion follows from such anatomical features as the low area of attachment for neck muscles

on the back of the head (Figure 1), well-developed lumbar curvature, wide sacrum, and low iliac blade strongly expanded backward and more laterally placed than is that of apes. The strengthened buttress of bone passing upward from the hip joint indicates a fully established and regularly used lateral balance control mechanism. Moreover, the long lower limb and short ischium of the gracile form strongly suggest that it was able to stride and that the propulsive mechanism worked as it does in modern man. The robust form, however, with a power-oriented propulsive mechanism and mobile foot, was not as manlike as the gracile form and in this respect evidently represents a compromise between ape and man. Possibly it spent some time climbing trees, which would explain the need for shorter and more power-oriented lower limbs; when on the ground it probably used erect posture but almost certainly did not have a fully developed striding gait.

Tool use. There is no clear evidence that either form used or made tools in the earliest levels from which they are known. Since investigation of the earliest forms is very new, further work may change the evidence on this point. Stone tools do occur in the lower Pleistocene (about 2,000,000 years ago); *e.g.*, in the excavation known as Bed I at Olduvai Gorge in Tanzania. Good evidence indicates that bones and other objects were used as tools; one may speculate that such activity preceded stone tool making, though there is no clear evidence of this. There is no evidence that at that time hominids more advanced than australopithecines existed. The presumption is thus that either or both australopithecine forms had developed the capacity to use and make tools. It is difficult to say which group made the tools. On three grounds it is more likely to have been the gracile form: (1) this form is anatomically much more manlike than the robust form; (2) in Beds I and II at Olduvai the artifacts improve with time during a period when the gracile australopithecine appears to become more manlike, possibly even altering into a true *H. erectus*, which is already present by the end of Bed II time; but there is no evidence of similar change in the robust form; (3) cultural capacity represents so powerful an adaptive mechanism that it is improbable that two hominids as anatomically different as the australopithecines could have been developing it simultaneously and yet have lived in the same region over at least 1,000,000 years. If only one form had culture, it is reasonable to believe that it was the more manlike one of the two.

Use of tools

Hunting and diet. For much of his history man appears to have been a hunter-gatherer, as some technologically less advanced peoples are today. But nonhuman, higher primates are virtually exclusively herbivores of some sort, following a way of life widely different from that of man. Presumably this will also have been true of the apelike ancestors from which man came; hence at some stage the herbivorous ecology will have given way to an omnivorous hunter-gatherer ecology based on culture. It is commonly assumed that the australopithecines had already made this transition and were primitive hunters. The presence of stone tools in the record during the latter half of their known history supports this conclusion, since it is unlikely that herbivores would have developed an active stone technology. The argument that the plentiful associated animal bones prove the same point is less secure. The South African specimens occur in ancient limestone caverns that are commonly regarded as having been dwelling sites and the associated fossils as food remains. During the period of accumulation, however, the caverns were deep underground and could not have been occupation sites; instead they were traps for material lying about on the surface. Moreover, the accumulation rate was so slow that one bone falling in per decade or even one per century would account for the accumulation. Australopithecine activity may have been involved; but so was that of many other animals.

Evidence of hunting technology

The hunter-gatherer type of ecology is reasonably associated with the gracile form. It was erect and efficiently bipedal, had a masticatory apparatus quite similar to that of *H. erectus* and later forms of man, was able to live in arid plains conditions, and evidently used bones and other objects as tools and made tools of stone in its later history.

The robust form was anatomically more primitive than the gracile form, had a masticatory apparatus somewhat unlike that of *H. erectus* and later forms of man, was not as efficiently bipedal as the gracile form, probably needed a wetter environment, coexisted with both the gracile form and later with *H. erectus*, and as a herbivore is less likely to have been actively culture-bearing than the gracile form. These considerations make it doubtful that it was a hunter-gatherer and are more in keeping with the suggestion that it had not seriously embarked upon the transition to a manlike way of life.

Geologic age and geographic distribution. Until quite recently all known australopithecines were of late lower Pleistocene or early middle Pleistocene age (1,000,000–500,000 years old). The rich South African sites are difficult to date; the only usable technique so far is faunal comparison. By this method, the sites yielding the gracile form, *Australopithecus africanus,* are all of late lower Pleistocene age, Taung and the lower strata of Sterkfontein probably being slightly older than Makapansgat, while the stone-tool-yielding middle levels at Sterkfontein probably was the latest in this sequence. Swartkrans is apparently only a little later, from the end of the lower or beginning of the middle Pleistocene. Still later, of middle Pleistocene age, is Kromdraai. Swartkrans and Kromdraai yielded the robust form, while *H. erectus* is also present at Swartkrans. The gracile form sites all reflect arid climates, with the latest, the Sterkfontein middle levels, beginning to trend to moister conditions. Swartkrans was from somewhat wetter times and Kromdraai wetter still.

Dating the australopithecines

Relative dating methods suggest that the Bed I and II sequence at Olduvai covers much the same time period as do the South African sites. Fortunately, the Olduvai beds include volcanic material that provides suitable minerals for the use of the potassium-argon radiometric dating method. This method is not without its difficulties and much remains to be settled about the Olduvai dates. The available evidence, however, indicates that the age ranges from approximately 2,000,000 years at the base of Bed I to about 500,000 years at the top of Bed II. This dating is part of the evidence that has recently led to the acceptance of an age of 2,000,000 or 2,500,000 years for the Pleistocene, rather than 1,000,000. The age of the Sangiran specimens is more controversial but probably falls near the later end of the Olduvai Bed I and II sequence.

The newer East African and Ethiopian material has not been studied sufficiently for the dating to be well established. Some of the Omo specimens have potassium-argon dates of between 3,000,000 and 4,000,000 years, and there is some suggestion of dates in Kenya reaching back even further. It would be premature to accept these dates now, but they do indicate the probability that the earlier material is of late Pliocene age. Since both the robust and the gracile forms appear to be represented at these early times in East Africa and Ethiopia the presence of the gracile form well before the robust one in the South African sequence is not due to the former being the older of the two. Evidently the robust form did not occur there during the more arid climatic time but moved in from the north when the climate ameliorated.

The australopithecines are found in eastern and southern Africa and in southern Asia. The gracile form thus far is known from Africa only; it is well represented in both East and South Africa. According to present evidence, it existed in Africa as early as the robust form, but in both South and East Africa it apparently disappeared from the record somewhat earlier than the robust form. Its disappearance seems to coincide approximately with the appearance of *H. erectus*. The robust form apparently had a wider distribution; it is well represented in South and East Africa, and many, though not all, workers accept that *Meganthropus* from Java is also a representative of the robust form, although others consider it a representative of *H. erectus*. In Sangiran, Java, at Swart-

krans in South Africa, and in East Africa good evidence indicates that the robust form and *H. erectus* simultaneously occupied the same region. In East Africa, there is evidence of simultaneous presence of the robust and the gracile australopithecines. There is as yet no sound evidence of the gracile form and *H. erectus* living together. On present evidence, then, the robust form had a wide distribution in the Old World; the gracile form was apparently confined to Africa.

CONTROVERSIES CONCERNING CLASSIFICATION

As already noted, the view that two forms are represented in the early hominid material is now commonly accepted: the gracile *Australopithecus africanus*, and the more robust form usually referred to as *Australopithecus robustus*, but as *Paranthropus robustus* by some. Followers of this two-stream hypothesis differ concerning the magnitude of the difference between them. The majority believe that the differences are relatively slight and can best be represented by treating the two as species of one genus.

Some workers (*e.g.*, Le Gros Clark and Dart) believe that even species separation may be unwarranted; the two forms are seen as variants of the same species much as two races of modern man are variants of the species *Homo sapiens*. This hypothesis has recently appeared in extreme form as the view that the robust and gracile forms are merely males and females of the same species. This latter hypothesis need hardly be taken seriously in view of the South African evidence. It is difficult to accept that during the thousands or hundreds of thousands of years that Sterkfontein was accumulating, only females were present or only female remains were preserved, and that for similar periods in Swartkrans time only males were present or preserved. Moreover, the nature of the variation present in these samples suggests that each contained two sexes. Finally, if it is true that the gracile form disappears from the record before the robust form, the implication would be that males survived long after females were extinct.

The racial-variant hypothesis is probably almost as difficult to support. Animal subspecies or races are local geographic variants of a species; by definition, subspecies of the same species are not sympatric (*i.e.*, occupying the same territory), except in exceptional circumstances such as the overlapping ends of a ringlike distribution. Modern man is also unusual because relatively advanced means of travel can bring widely different races together quickly, hence a number of racial variants can be found together. But history shows, and theory predicts, that interbreeding soon begins to break down and submerge the differences between them. It is very improbable that the simultaneous occurrence in one region of different racial variants of man could continue over a period of millions of years, as in the case of the early hominids. The existence over millions of years of a sharp distinction between the two australopithecine forms implies that they were genetically isolated from each other and hence that they were at least distinct species.

In the two-stream hypothesis, the species seems to be the lowest taxonomic level at which the two forms may reasonably be placed, and this is the present majority view. The alternate to this view of the two-stream hypothesis is that the anatomical, behavioral, and ecological differences between the two are so pronounced that assigning separate generic status is preferable. This interpretation was originally proposed by J.T. Robinson, continues to be defended by him, and is supported by some other workers. This view interprets the masticatory apparatus differences and cultural evidence as meaning that *Paranthropus* was an essentially cultureless herbivore but *Australopithecus* was a culture-bearing, hunting omnivore. It interprets the anatomical evidence on posture and locomotion as indicating that *Paranthropus* was specialized for a combination of a moderately efficient, erect, bipedal posture on the ground with some arboreal climber activity, while *Australopithecus* was a highly efficient, ground-dwelling biped. Interpreted in this manner, the levels of organization of the two are very different, *Paranthropus* being a somewhat hominized ape, *Australopithecus* a primitive man with evolutionary potential vastly superior to that of *Paranthropus*. This view recognizes a common taxonomic viewpoint that the genus defines a clear-cut way of life and that the species within the genus represent specializations within that way of life.

An objection raised to this view is that differences as great as those observed between *Paranthropus* and *Australopithecus* occur within a single genus of living pongids (anthropoid apes) or within the modern species *H. sapiens*. Dental, cranial, and pelvic characters, however, tend to indicate that this belief is mistaken.

Finally, some workers believe that more than two basic lineages occur in the known australopithecine material. This view is represented, for example, by that of Leakey and Tobias, who accepted a single genus, *Australopithecus*, for all hominids regarded by them as australopithecines but that three different forms of equal status were involved. These are *A. africanus*, *A. robustus*, and *A. boisei* (Olduvai) in Tobias' view but subgenerically distinct in Leakey's view as *A.* (*Australopithecus*) *africanus*, *A.* (*Paranthropus*) *robustus*, and *A.* (*Zinjanthropus*) *boisei*. Both excluded the Olduvai Bed I and II material named *Homo habilis*, believing this to represent another independent lineage. They disagreed, however, on which specimens belong in *H. habilis* and on what its affinities are. Tobias labels only the Bed I material *H. habilis* and believes it to be directly ancestral to the Bed II material, which he believes is *H. erectus*, ancestral to *H. sapiens*. Leakey, in contrast, believed that both the Bed I and Bed II material belongs to *H. habilis* and that this lineage was directly ancestral to *H. sapiens*. In his view, *H. erectus* is yet another independent lineage. This is the most multilineal of the current interpretations of the early African hominids. Most observers believe, however, that *H. habilis* is not separable from the *A. africanus* lineage and that *H. erectus* is a stage between *A. africanus* and *H. sapiens*.

This very brief review of opinion about australopithecine history and affinities shows how much uncertainty exists in the field. Much more detailed study and more material is needed to introduce more certainty into the picture. Because of the difficult nature of this field, however, which in some respects must remain speculative, considerable difference of opinion may always exist and absolute certainty will always be impossible.

Austria

Located in the centre of Europe, Austria, a federal republic with a scenic and largely mountainous terrain of 32,375 square miles (83,850 square kilometres), and a population exceeding 7,000,000 in the 1970s, is one

of the smaller nations of the world. In the decades following the collapse, in 1918, of the multinational Austro-Hungarian Empire of which it had been the heart, Austria experienced more than a quarter-century of social and economic turbulence and a Nazi dictatorship. Yet the establishment of permanent neutrality in 1955, associated with the withdrawal of the four-power troops that had occupied the country for a decade, enabled Austria to develop into a stable and socially progressive nation, with a flourishing cultural life reminiscent of its earlier days of international musical glory. Its social and economic institutions, too, have been characterized by new forms and a spirit of cooperation, and although political and social problems remain, they have not erupted with the intensity evidenced in other countries of the Continent.

Geographical position

Much of Austria's current status can be attributed to its geographical position: it is the centre of European traffic between east and west along the great Danubian trade route, and between north and south through the magnificent Alpine passes. Austria is bordered on the west by Switzerland, and together the countries form what has been characterized as the neutral core of Europe. The tiny Principality of Liechtenstein also forms a small enclave on the west. Hungary on the east; the Federal Republic of Germany (West Germany) and Czechoslovakia on the north; and Italy and Yugoslavia on the south, illustrate the variety of political and economic systems within which contemporary Austria is embedded (for further details see ALPS MOUNTAIN RANGES; ALPINE LAKES; AUSTRIA, HISTORY OF; and VIENNA).

THE LANDSCAPE

The natural landscape. *Relief features.* Mountains and forests give the Austrian landscape its character, although in the northeast of the country the Danube winds between the eastern edge of the Alps and the hills of Bohemia and Moravia, heading toward the Hungarian Plain. Vienna, the national capital, and one of the great cities of Europe, lies in the area where the Danube emerges from the mountains into the drier plains.

The landscape of the eastern Alps offers a complex geological and topographical pattern, with the highest elevation—the Grossglockner (12,457 feet [3,797 metres])—being reached toward the west. The Austrian Alps may be subdivided into a northern and southern limestone range, each of which is composed of rugged mountains, separated by a central range, softer in form and outline, and composed of crystalline rocks. North of this massive Alpine spur, which forms the physical backbone of the country, lies a hilly subalpine region, stretching in a zone between the northern Alps and the Danube, while to the north of that river lies a further, richly wooded, foothill area. The lowland area downstream from Vienna may be regarded as a western extension of the great Hungarian Plain.

Drainage. Austria is a land of lakes, many of them a legacy of Ice Age erosion, which scooped out mountain lakes in the central Alpine district, notably around Salzkammergut. The largest lakes—lying partly in the territory of neighbouring countries—are the Bodensee (Lake of Constance) in the west and the marshy Neusiedlersee (Neusiedler Lake) to the east.

Ninety-six percent of Austrian territory drains to the Danube River system. The main watershed between the Black Sea and the North Sea runs across northern Austria, in some places lying only 22 miles from the Danube, while to the west the watershed between the Danube and the river systems emptying into the Atlantic and the Mediterranean coincides with the western political boundary of Austria. In the south, the Julian and Karnische Alps, and, farther to the west, the main Alpine range, mark the watershed of the region draining into the Po River of northern Italy.

Climate. The wooded slopes of the Alps and the small portion of the plains of southeastern Europe are characterized by differing climatic zones: the wetter western regions of Austria have an Atlantic climate with a yearly rainfall of over 39.4 inches (1,000 millimetres), whereas the eastern regions, in particular those under the influence of the drier, more continental type of climate, have less.

In the lowlands and the hilly eastern regions, the median temperature ranges between 30.4° F (−0.9° C) in January and 68.6° F (20.3° C) in July. In those regions above 10,000 feet, by contrast, the temperature range is between 11.8° F (−11.3° C), with a snow cover of about 10 feet in January, and 35.8° F (2.1° C) in July, with about five feet of snow cover.

The prevailing wind direction is from the west, and the humidity, therefore, is highest in the west, diminishing toward the east.

Vegetation and animal life. Two-thirds of the total area of Austria is covered by woods and meadows, and the country is the most densely forested nation in central Europe. Spruce dominates the forests, with larch, beech, and oak also making a significant contribution. In the Alpine and foothill regions coniferous trees predominate, while leaf-bearing deciduous trees are more frequent in the warmer zones.

Wild animals, now protected by conservation laws, include the brown bear, the eagle, and all buzzard species, as well as falcons and owls, cranes, swans, and storks. Game hunting is restricted to certain periods of the year: deer and rabbits are the most frequent quarry. Austrian rivers nurture river and rainbow trout, grayling, hake, pike, perch, and carp.

Traditional regions. Western Austria, comprising the *Bundesländer* (states) of Vorarlberg, Tirol, and Salzburg, is characterized by high Alpine regions with majestic mountains and magnificent scenery. This high Alpine character also extends to the western part of Kärnten (Carinthia), the Salzkammergut of central Austria, to the Alpine blocks of Steiermark (Styria), and to the eastern rim of the Alps.

Alpine scenery

The outer fringes of the Alps dominate the northern portion of Oberösterreich (Upper Austria) with their subalpine characteristics, while the richly wooded Bohemian massif extends across the Czechoslovak border. This part of Austria is furrowed by many valleys that, for centuries, served as passageways leading to the east and southeast of Europe and even, in the case of medieval pilgrims and crusaders, to the Holy Land.

A hilly vineyard district extends into the *Bundesland* of Burgenland. This region, together with the eastern part of the state of Steiermark, lies at the gateway to the Hungarian Plain. Taken together, Burgenland, Steiermark, Kärnten, and Niederösterreich (Lower Austria) form a region, throughout which agriculture abounds. The city of Vienna and its peripheral suburbs and industrial settlements border both Alpine and lowland regions.

Human influence on the landscape. The pattern of rural settlement in Austria was shaped centuries ago by the exigencies of the Alpine environment, and new rural building is still influenced by these ancient traditions, particularly in the west and the centre of the country. Rural housing in the eastern parts of the nation, particularly in the lowlands, is, in contrast, dominated more by agricultural needs than by harsh weather conditions.

Forty-four percent of Austria's population in 1971 lived in cities and towns with more than 10,000 inhabitants: Austria is thus not only a mountainous but also a highly urbanized country. Over one-fifth of the total Austrian population lives in Vienna. Furthermore, the state capitals have, as a consequence of national economic and social development, grown somewhat in population since the end of World War II. Graz, Austria's second-biggest city with 249,000 inhabitants in 1971, is the gateway to the Balkans; Innsbruck is the rail and road centre through which national north–south traffic of western Austria passes; Salzburg is one of the best-known European centres of musical culture and Baroque architecture; the Linz of the 1970s has become an important industrial centre; and Klagenfurt lies astride routes giving access to both Italy and Yugoslavia.

Major Austrian cities

THE PEOPLE

Ethnic and linguistic heritage. The Austrian population had almost reached 7,500,000 by the early 1970s,

and 99 percent of this total was German-speaking. The 1 percent belonging to other nationalities was made up of about 30,000 Croats and 11,000 Magyars living in Burgenland; 24,000 Slovenes living in the southern part of Kärnten; and some 5,000 Czechs living in Vienna. In terms of religion, the population is 89 percent Roman Catholic; 6 percent are Protestant; 0.5 percent are so-called Old Catholics; some 0.2 percent are the remainder of a once much bigger Jewish community; and 3.8 percent profess no religion at all.

The westernmost states, Vorarlberg in particular, are inhabited by Alemanic groups whose dialect is similar to the Swiss-German dialect, while the dialect of the people in Salzburg and Oberösterreich, and also the eastern states, resembles that spoken in Bavaria. People in Steiermark and Kärnten speak a dialect which is clearly distinguishable from that of their western fellow citizens. In general, the German spoken in Austria has a softer, more drawling, and melodious sound than that of Germany.

Demographic trends. The birth rate varies within the Austrian states: the yearly national average of live births was 15.1 per thousand at the start of the 1970s, but in the strongly Catholic western states and rural areas birth rates are higher, reaching a peak of 19.2 in Vorarlberg. In Steiermark, the birth rates rank above the national average, whereas in Vienna the rate is only 10.9.

There has also been a distinct population shift from the east to the west of Austria: Vienna, Niederösterreich, and Burgenland have suffered losses in population, while the western states have gained, during the decades following World War II. The most remarkable of these changes has taken place in the capital itself: Vienna had 1,918,600 inhabitants in 1923 but only 1,603,408 according to the 1971 census.

Population shifts

The almost complete destruction of Vienna's Jewish population (about 500,000 in 1938) during the Nazi era was only partly compensated by an influx from rural areas and by refugees after World War II. Increased urbanization, associated with the industrialization of some of the western states, is the main cause of the population growth in those areas.

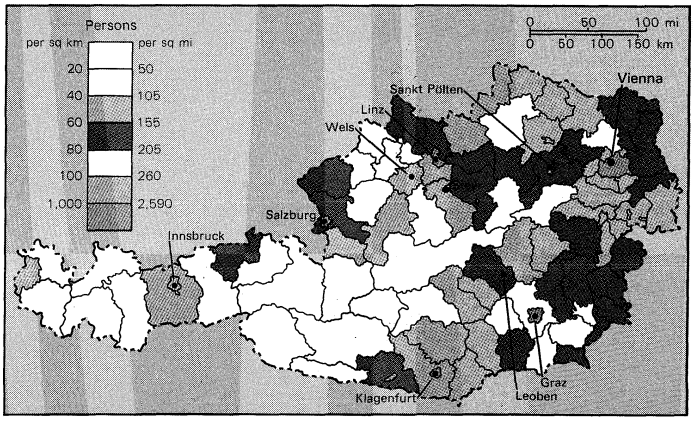
Emigration resulted in some losses in national population during the disastrous post-World War II years, although a stream of expellees from eastern European countries helped to make up some of the deficit. Most of these refugees were soon integrated into Austrian society. As a result of the turmoil in Hungary in 1956, some 180,000 Hungarians crossed the frontiers into Austria, creating a new refugee problem. By the end of the 1960s fewer than 9,000 remained in Austria, as most had migrated to other countries.

Life expectancy for Austrian citizens has been rising constantly since the beginning of the century. Around 1900 a boy born in Austria could expect to live about 39 years: by 1970, his life expectancy had risen to about 67 years. The life expectancy of women rose even higher, from 41 to about 73 years over the same period.

With a birth rate increasing as a result of growing prosperity and rising life expectancy, a continued increase in Austria's total population can be expected, unless economic conditions change for the worse. Further urbanization is also probable: in the decades since World War II the number of persons engaged in forestry and agriculture declined as more jobs became available in industry, and the trend is continuing. The associated depopulation of rural areas has been highest in Kärnten, Burgenland, and in certain districts of Niederösterreich. A decline in agricultural population has also been noted in Oberösterreich, where steel and aluminum have, from the 1950s onward, become important industries. The same process has taken place in the westernmost parts of Austria, where the textile industry has expanded. Tourism also attracts rural manpower. The loss to agricultural population has been smallest in the Tirol and Salzburg areas where there has been less industrialization.

Rural depopulation

In general, the future development of Austria's population will depend chiefly on further industrialization and the growth of tourism. Due to domestic labour shortages some workers have been imported from abroad, chiefly from Yugoslavia and, to a lesser degree, from Italy, Spain, and Turkey; but to a smaller extent than, for example, in West Germany.



Population density of Austria.

THE NATIONAL ECONOMY

The Austrian economy has been shaped by two factors: firstly, the nation occupies a mountainous country, only half the area of which is even potentially usable for food production; secondly, and as a result, the success of industrial production, exports, and trade is basic to the viability of the entire economy. The natural resources available within the country for industrial exploitations are, therefore, of considerable significance.

The extent and use of resources. *Mineral resources.* Austria is the world's leading producer of magnesite, a natural magnesium carbonate used extensively in the chemical and other industries, with Kärnten being the main centre of production. In recent decades, new methods of smelting and processing magnesite have been developed, and production, by the 1970s, exceeded 1,500,000 tons annually.

Iron ore deposits are found in the Erzberg in Steiermark—which produces 75 percent of Austria's total iron production—and in the Hüttenberg region in Kärnten. Resources have been estimated at 300,000,000 tons, and the ore has an iron content of some 30 percent. Iron production reached a record high of almost 4,000,000 tons annually by the start of the 1970s. During the same period, Austria's oil production, almost 3,000,000 tons of crude oil per year, ranked third in Europe (after Romania and West Germany), a remarkable achievement for an industry of comparatively recent origin (it was set up in 1927). Potential oil sources, chiefly located in Niederösterreich, are estimated at about 60,000,000 tons, with vast additional natural gas resources.

Developing oil production

Coal, found only in small quantities and mostly of the soft variety, is mined chiefly in Steiermark, Kärnten, and Burgenland. Over 200,000 tons of salt are also produced annually.

Hydroelectric and other power resources. Austria is one of Europe's foremost producers of hydroelectric power: the nation's total potential capacity is estimated to be at least 40,000,000,000 kilowatts per year. A large portion of the hydroelectric power resources were put to use only in the years following World War II. By the 1970s, a national network maintained a steady power-production capacity even in the winter months, when river levels are low.

Sources of national income. Industry and trade form the most important sources of national income. The other main contributors to the national economy are public service, construction, and manufacturing.

Since barely half of Austria's territory can be used for food production, an intense program of agriculture modernization was introduced after World War II. The number of tractors, for example, rose from 1,800 in 1939 to 260,000 thirty years later. The rural economy is dominated by smallholdings, although some large forest estates still remain. As a result of the modernization program, the yield of the most important agricultural products has risen considerably.

In the lowland regions of the country, the abundance of pastures and the production of feed has promoted cattle breeding. Dairy products are plentiful, resulting in an overproduction in terms of national need. With the exception of horses, Austria's livestock has grown in numbers over the period of agricultural modernization.

Austrian food consumption rose to an average daily intake of almost 3,000 calories by the 1970s. The modernized domestic food industry was, nevertheless, able to supply 83 percent of the national requirements.

Timber from the vast national forest cover is only partly processed within the frontiers of Austria, and untreated lumber figures prominently in the national export statistics. More than half of the forests are in the hands of smallholders, the rest partly in large, centuries-old estates and partly government-owned.

Manufacturing. Manufacturing has also strengthened its position in recent decades. Iron and steel production, in particular, increased greatly after World War II: pig iron production, for example, rose from under 900,000 tons in 1950 to almost 3,000,000 tons twenty years later, while raw steel output grew from 950,000 to almost 4,000,000 tons in the same period. Despite an abundance of domestic iron ore, scrap iron and iron ore had to be imported, due to increased steel production. A newly developed oxygen blast furnace, based on the so-called L.D.-process (called after the cities of Linz and Donawitz [now Leoben], where it was developed), succeeded in reducing the need for imported scrap iron, and is now used in many countries under license agreements.

The iron and steel industry

Aluminum has recently become one of the most important Austrian manufacturing industries, and the Ranshofen works, in Oberösterreich, was among the largest in Europe by the 1970s. Aluminum output has risen in a spectacular manner, from 1,100 tons in 1946 to over 90,000 tons in 1960, and almost 125,000 tons by 1970.

Other manufacturing includes the paper industry, based on the nation's extensive forest reserves: paper, one of Austria's largest foreign exchange earners, is exported to over 80 European and overseas countries. The chemical industry is dominated by two giant chemical plants—a nitrogen works in Linz and the Lenzing staple fibres factory. Plastics, a more modern industrial product, were being produced in 100 large, and over 300 smaller, plants by the 1970s.

Financial services. Monetary policy is jointly determined by the Ministry of Finance and the National Bank of Austria. Although the authorities grant a large measure of freedom to those individuals and institutions engaged in international transactions, as much as 38 percent of the total gross fixed investment in the country, including housing, is controlled by the federal government.

The Austrian National Bank operates under a Bank Law of 1955, as amended in 1969; this law changed both ownership and management of this important institution: the government now holds 50 percent of the shares, with the balance being allotted by the government to individuals or economic organizations.

Financial affairs are also executed through a wide range of other institutions: joint-stock commercial banks; private commercial banks; provincial mortgage organizations; saving banks; and agricultural, as well as industrial, credit cooperatives.

Foreign trade. Austria's foreign trade steadily increased in the decades following World War II.

Austria's main trading partners are her neighbours, West Germany and Switzerland, who between them account for almost half of Austria's imports and one-third of its exports. Trade with the European Economic Community (Common Market) as a whole is also important: at the start of the 1970s, its members provided 56 percent of Austria's imports and received 39.4 percent of its exports, whereas only 19.1 percent of Austria's imports and 25.3 percent of its exports came from dealings with countries of the European Free Trade Association (EFTA). Trade with eastern European countries amounted to an even smaller proportion: only 9.3 percent of Austria's imports and 12.9 percent of its exports. Timber, iron, and steel are the most important items in the export trade, accounting together for over a quarter of the total.

The Common Market's important role in Austria's foreign trade has prompted the national authorities to seek a "special arrangement" with that organization (full membership would not be compatible with Austria's policy of neutrality). Protracted negotiations were concluded by an agreement in July 1972.

The tourist trade is Austria's outstanding invisible export. The number of nights spent by foreign tourists in Austria rose from 6,000,000 in 1951–52 to over 50,000,000 some 20 years later, and the amount of foreign currency spent showed an even greater increase. The outlook for tourism continued to be healthy in the 1970s.

Management of the economy. The private sector, comprising roughly three-quarters of Austria's mixed economy, is concentrated in agriculture and food processing; forestry and timber; paper mills; textile and clothing; food and beverages; the retail and wholesale trade; and department stores. Private enterprise has, as yet, a relatively low degree of monopolistic concentration, although ties among the guildlike cooperatives (Berufsgenossenschaften und Innungen) are not without influence.

Nationalization of industry

In 1946, the Austrian parliament nationalized a large segment of Austrian industry which, at that time, was being held under Soviet control as alleged former German property. After the State Treaty of 1955 established Austrian neutrality and brought about the end of Soviet authority, all these enterprises passed into exclusive Austrian control. The 1946 nationalization covered the three biggest banks and some 70 larger industrial enterprises, chiefly in the fields of iron and steel, aluminum, and machinery. Subsequent reorganization reduced the number of nationalized enterprises to 19. By the 1970s, when Austrian industry as a whole employed over 850,000 persons, over 100,000 worked in nationalized undertakings, and the net value of their output reached about 25 percent of the total industrial production.

Most nationalized industries are organized as joint-stock corporations, and their central direction by the government has undergone several changes, for both political and managerial reasons. Until 1966, for example, a cabinet member supervised the nationalized industries, but after that date they were handed over to the government-owned Austrian Industrial Administration (Österreichische Industrie–Aktian–Gesellschaft—OIAG). Its board of directors, although representing the government, is independent as far as managerial decisions are concerned.

The tax income of the federal government amounted to over 80,000,000,000 schillings annually by the 1970s. The most important source of federal tax revenue was the income tax, which has a progressive scale reaching up to almost 70 percent of taxable income. Corporation taxes

take from 30 percent to 60 percent of corporation profits, and the capital gains tax is fixed at just under 20 percent. The second biggest source of tax income is a sales tax of 5.5 percent on all sales and transactions, with a lower rate of 2 percent for privileged wholesale trade, while a special trade tax also provides for a 2 percent payroll tax. In 1970 the government started preparations for a major tax reform.

Contemporary economic policies, problems, and prospects. Full employment, stability of prices and currency, a certain government influence on investment and economic growth, and the distribution of national income for conscious social goals, without impairing a free-market, consumer-oriented economy, were taken to be the main aims of Austrian economic policies by the 1970s. To avoid price increases, chiefly of imports from West Germany, the Austrian schilling was up-valued by 5 percent during the international currency crisis of May 1971.

Maintaining or expanding foreign trade, particularly with the Common Market countries; securing price stability in a generally inflationary era; and ending overproduction in certain branches of agriculture were some of Austria's problems in the same period. The booming economy, full employment, a growing tourist trade, and modernization of an expanding industry and agriculture were considered as hopeful and healthy signs in the early 1970s.

TRANSPORTATION

Austria's location in the centre of Europe determines its role in European road, rail, air, and river traffic, whether flow is from north to south or from east to west. Austria is consequently not only a tourist country but in many aspects also may be thought of as a freight clearinghouse, supplying the great trade routes running across the Alps and along the Danube River.

Roads. The road system, heavily damaged during World War II, was subsequently adapted to vastly increased traffic requirements. A federally built east-west highway was in operation between Vienna and Salzburg by the early 1960s. It will eventually lead to the western frontier. A north-south autobahn, or federal highway, ultimately to run from Vienna to the Italian frontier, has been started. The total Austrian road network excluding city streets, much of which leads over spectacular Alpine passes, covers some 20,000 miles. The total number of motor vehicles has shown a remarkable increase in recent decades, rising from some 285,000 units in 1950 to 2,290,000 some 20 years later.

Railroads. Forty-one percent of the Austrian railroad network and 381 bridges were destroyed during World War II and had to be repaired as well as modernized in subsequent years. By the early 1970s, nearly half of the rail network, carrying 80 percent or more of the traffic, had been converted to electric traction. Passenger and freight traffic has shown a proportionate increase. The Austrian railroads are state-owned, although, by a law of 1969, the railroad administration, which had formerly been part of the Transportation Ministry, became an independent commercial enterprise.

Importance of the Danube

Water transport. The Danube (*q.v.*) is the most important river connection between Germany and the Black Sea, and the federally owned Austrian Danube Steamship Company plays an important role in both freight and passenger traffic along this waterway. Although Austria is landlocked, Austrian shipyards, owned by the Steamship Company, build vessels not only for Austria but also for Bulgaria, Yugoslavia, Pakistan, Egypt, and Nigeria.

Air transport. Austrian Airlines, which began operations in March 1958, has since established service to 33 airports in 21 countries of Europe and the Middle East. Austria's main airport is at Wien-Schwechat, southeast of Vienna.

ADMINISTRATIVE AND SOCIAL CONDITIONS

The structure of the government. *Constitutional framework.* Under the constitution of 1920—with minor changes made in 1929—Austria is a ". . . democratic republic: its power derives from the people. . . ." A federal state, Austria consists of nine self-governing states: Burgenland, Kärnten, Niederösterreich, Oberösterreich, Salzburg, Steiermark, Tirol, Vorarlberg, and Wien (Vienna).

In 1934 the Austrian constitution was replaced by an authoritarian regime under chancellors Engelbert Dollfuss and Kurt von Schuschnigg. This, in turn, was eliminated by Hitler after Nazi Germany annexed Austria in 1938. With the liberation of Austria in 1945, the constitution of 1929 was revived, and subsequently became the foundation stone of constitutional and political life in the "Second Republic."

The federal president and the cabinet share the executive authority. The president is elected by popular vote for a term of six years. He acts as head of state, appoints the cabinet, and calls parliament into session. He can dissolve parliament during the four-year legislative period, unless it dissolves itself by law, and can order new elections. The president also acts as commander-in-chief of the armed forces.

The president appoints the federal chancellor and, at his suggestion, the other cabinet members. The cabinet cannot remain in office if it and its members do not enjoy the confidence of the majority of the National Council.

The Austrian parliament

The parliament consists of two houses: the National Council (Nationalrat), wielding the primary legislative power; and the Federal Council (Bundesrat), representing the states. The National Council, which, since 1920, had had 165 members, was expanded to 183 members under a law passed in November 1970 which took effect at a national election in October 1971. The National Council is elected by all citizens over the age of 20, and every citizen over the age of 26 is eligible to run for office. The distribution of parliamentary seats is based on a system of proportional representation.

The members of the Federal Council represent the states, and the state assemblies, or diets, elect the members by a proportional system based on the population of the state.

The legislative process originates in the National Council. Each bill—except for the budget, which is the sole prerogative of the National Council—must be approved by the Federal Council. The National Council is nevertheless empowered to override a Federal Council veto by a simple majority vote.

Each of the nine states is administered by a government headed by a governor elected by the legislative diet, elected by general and equal ballot.

Local municipalities elect their mayors and city councils. Vienna is a unique case: as both municipality and state, its mayor also functions as a governor.

The political process. The first popular election of a president, although provided for by the 1929 amendment to the constitution, did not take place until after the death of the first post-World War II president, Karl Renner (1870–1950), who had been unanimously elected by the National Assembly after the liberation of 1945 and the ensuing unsettled political circumstances. A succession of Socialist presidents, starting with the former mayor of Vienna, General Theodor Körner, has occupied the post since.

In the eight elections held from the immediate post-World War II period to the early 1970s, the stability of the two main Austrian political parties—the People's Party and the Socialist Party—is shown by their respective shares of the vote, which has fluctuated, in each case, around 45 percent of the total votes cast. The Liberal Party has polled an average of but 5 percent of the votes, and the Communist Party has polled an even smaller share. From 1945 until 1966 the two main parties maintained coalition governments with the chancellorships held by the People's Party. In 1966 the latter, with a slim majority of parliamentary seats, formed the government alone, but after the 1970 elections, in which the People's Party lost its majority, the Socialists, as the strongest party, formed a minority government as the first of the new decade. Its first budget was passed with the help of the votes of the Liberal Party. In the parliamentary election in October 1971 the Socialist Party won more than

50 percent of the popular vote, the first party to do so in Austrian history.

The major parties

The People's Party is the successor of the Christian Social Party, founded in the 1890s. It represents a combination of conservative forces and various social and economic groups forming semi-independent federations within the overall party. The divergencies of economic and social interests exhibited by these groups—the farmers, the businessmen, blue- and white-collar workers—necessitate policy compromises, which are not always easy to implement.

The Socialist Party, which followed a democratic Marxist program during the 1918–34 period, has adopted a more pragmatic approach since 1945. The new party program, adopted unanimously in 1958, stressed these new tendencies. Emphasis was placed on social problems; on government influence on an expanding and socially oriented economy; on full employment; and on a rising standard of living, with a more equal distribution of wealth. The Austrian Socialists are no longer an exclusive party of the working class: by the 1970s they had a much wider appeal.

The Liberal Party has undergone several changes in emphasis since being admitted into the political arena by the occupying powers in 1949, at which point it could be characterized as a third party with nationalistic tendencies. The initially prominent influence of former Nazis has diminished.

The Communist Party, always negligible in Austrian politics, reached its high point during the Soviet occupation of the eastern zone of the country, when it attained 5 percent of the popular vote. By 1970, it had lost representation in parliament, in all of the provincial diets, and most municipal councils.

The participation of the citizens. The Austrian constitution provides for two kinds of popular initiatives: one is the so-called popular demand (*Volksbegehren*) by which 400,000 vote-eligible citizens can petition parliament for approval of any bill; it can also be initiated, in the case of any bill or proposal, by a majority of the National Council. A total revision of the constitution must be approved by plebiscite.

Justice. The administration of justice is independent of Austrian legislative and administrative authorities. Judges are not subject to any government influence: they are appointed by the cabinet upon nomination by judicial panels, and can neither be dismissed nor transferred without their agreement.

Austria has three high courts: one sitting as the highest body of appeal in civil and criminal matters; a top administrative court to which citizens aggrieved by administrative decisions can appeal; and a constitutional court that decides on all constitutional matters, civil rights, and election disputes.

The armed forces. Under the State Treaty of 1955 Austria is permitted armed forces of 50,000 men for the defense of its territory. The armaments permitted Austria specifically exclude all atomic weapons and rockets. Only the four signatory powers—the United States, Great Britain, the Soviet Union, and France—can permit such armaments, and they must do so by a unanimous decision.

All male citizens between the ages of 18 and 50 are liable to military service, and conscripts are called up for a normal tour of duty of six months. Volunteers may serve for 12 or 15 months, or may enlist for careers up to 12 years. Expenses for the armed forces amount to about 4.1 percent of the national budget.

Services. *Educational services.* Austria's educational system is based on obligatory school attendance between the ages of 6 and 14, with a ninth school year provided under certain circumstances. A major reform of the school administrative structure, providing for a unitary school system with access to higher education, was in preparation in the early 1970s.

Intermediate schools include those preparing for university and other higher studies, teachers' and commercial colleges, and other specialized institutions.

Austrian universities

Austrian universities are among the oldest German-speaking universities of Europe: the University of Vienna, for example, was founded in 1365. Austria entered the 1970s with 16 universities, including two technical universities and academies for fine arts, music, and drama. Austria also has a huge adult-education system, with 350 centres and an additional 1,900 dependent local institutions.

Health and welfare services. Public health in Austria is the responsibility of the Health Department within the Ministry of Social Administration, which supervises 14 subsidiary institutes responsible for the prevention of infectious diseases and inspection of drugs and food. The provincial governments also have public-health centres, and each municipality must employ a public-health physician.

National-health insurance covers expenses of medical and hospital treatment: blue- and white-collar workers and salaried employees are protected in cases of sickness, disability, unemployment, maternity, and in their old age. There are also survivors' pensions. Pension systems for self-employed persons and farmers have also been established.

Housing. After the reconstruction of war-damaged houses, a building boom started in 1950. Between 1951 and 1961, 22 percent of all apartment dwellings were newly built, according to official statistics; from 1961–69 the figure was 16 percent. In the western states the increase was even higher.

Forty-four percent of all dwellings are one- or two-family houses. In the capital, only 6.6 percent of the population live in such houses; large apartment houses, many of them built by the city or with public assistance, predominate. Vienna, since the middle 1920s, has had a record of intense apartment building by the city, and some 20 percent of all dwellings are municipally owned. Nationally, two-thirds of all Austrian homes are privately owned; 26 percent of all apartments are one-room and 34 percent are two-room.

Police services. Austria's main police force is federal. By the 1970s it comprised almost 15,000 persons, about 10,000 of whom were in uniform, with a further 2,000 plainclothesmen. The police are under the jurisdiction of the federal minister of the interior.

Austria also has about 10,000 "gendarmes" responsible for public safety in rural areas and also attending to certain administrative functions.

Social conditions. *Wages and cost of living.* During the later years of the 1960s, the consumer price index in Austria rose by about 10 percent, while, during the same period, the net weekly income of workers rose by some 20 percent. Living standards have improved during the 1960s as a whole, but particularly since 1966, although Austria's wages still lag behind those of neighbouring industrial countries.

Cooperative wage-price policy

Government, management, and labour have followed a wage-price policy that has attempted to avoid social cleavages and strikes through cooperative participation in a joint wage-price commission. The representatives of the various segments of the economy, the chambers of commerce, of agriculture, and of labour, together with the federation of trade unions, the association of industry, and the farmers' federation, have tried, with the active cooperation of the government, to coordinate wage and price movements. It is within this framework that collective bargaining takes place, and agricultural prices are also negotiated by the wage-price commission without infringement of the market economy.

Social and economic divisions. The three important economic groups in Austria—labour, management, and the farmers—have similar structures: each has its own independent organization: the trade unions, the management association, and the farmers' federation. At the same time, laws provide for semi-official "chambers" for each grouping. This type of guild organization promotes cooperation in the governmental wage-price commission. Despite the divergent interests of the various groups, their cooperation has resulted in relative economic stability, and labour-management relations have remained unmarked by major crises.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu. The contemporary cultural milieu of Austria has a rich heritage: in architecture and poetry this goes back to the Middle Ages, and in medicine and science it can be traced to the 18th and 19th centuries. Similarly, Vienna's art galleries are among the most famous in Europe because of their wealth of old Dutch masters. Austria's most highly recognized cultural contribution has been in the field of music, and this tradition still dominates its present cultural achievements. Austrian cultural life has exerted attraction beyond its borders. Such great musicians as Beethoven (a native of Bonn), Brahms (from Hamburg), Mahler (from Bohemia) and, to a certain extent, Richard Strauss (from Munich) are considered as much a part of Austria's musical life as the native Austrian giants Haydn, Mozart, and Schubert. The Vienna waltzes emanating from the Johann Strauss dynasty, as well as the Vienna operetta, whose presiding genius was Franz Léhar, round out the rich traditions of Viennese musical life. Austria has also been the birthplace of modern and especially 12-tone music.

Musical tradition

Although in literature Austria has often been considered a segment of German culture, writers such as Franz Grillparzer, Johann Nestroy, and Ferdinand Raimund in the postclassic era, and Hugo von Hofmannsthal and Arthur Schnitzler in the 20th century, have all developed special Austrian traits. Austrian culture was also strongly influenced by the various cultural elements of the multinational Austro-Hungarian Empire, with its Slavic and Magyar traces. They still exist, making the Austria of today a bridge between various parts of Europe and attracting performing artists from East and West.

Austrian cultural and scientific life had to recover from the severe wounds inflicted by the Nazi domination and the loss of intellectuals and artists to emigration and persecution after 1938. A ten-year occupation by four great powers promoted recovery of an independent cultural life only to a small degree. Austria has, nevertheless, managed—particularly since the later 1950s—to regain something of its past cultural posture.

The state of the various arts. Austrian expressionism in literature has gained world renown through the visionary novelist Franz Kafka, who hailed from Prague (where he was born in 1883) and who died near Vienna in 1924. As part of a general Kafka revival, one of his haunting novels, *Der Prozess* (*The Trial*), was made into an opera by Austria's best-known contemporary composer, Gottfried von Einem.

Georg Trakl, a promising Expressionist who was killed in the war in 1914; Franz Werfel, an Expressionist novelist and playwright (born in 1890, died as refugee in the United States in 1945); Karl Kraus, a critical lyricist and essayist; and Robert Musil, who wrote along Expressionist lines, have all played a considerable role in contemporary Austria. Hermann Broch, a novelist with symbolic tendencies (1886–1951, also died in the United States) is also recognized beyond Austria. Heimito von Doderer (1896–1966) is considered the most remarkable post-World War II novelist. Modern playwrights who are well known include Alexander Lernet-Holenia (born 1897) and Fritz Hochwälder (born 1911), who has created historical dramas that have been produced all over the world.

Austrian theatre and opera

The Austrian theatre and opera recovered quickly after the war. The Vienna Burgtheater, considered to be the best German-speaking theatre in the 19th century, may again be counted among the foremost German stages. It presents the classics, as well as modern English, American, and occasionally Russian and Czech, plays. A new trend in the Vienna theatre has developed in so-called cellar-theatres ("off-Broadway" stages) that favour the theatre of the grotesque.

The Vienna Staatsoper (State Opera), which was completely rebuilt after the war, ranks today with La Scala in Milan and the Hamburg and Munich operas, while the Vienna Philharmonic Orchestra has played in almost all the musical capitals of the world. Austrian theatre life is intense, with large and enthusiastic audiences and a bewildering succession of shows. The theatre has spread to small stages in the Vienna suburbs, while state capitals have also become theatre and light-opera centres, developing their own identities. Special performances for students aid an early participation in cultural life.

Modern music was born in Vienna, and Arnold Schoenberg, Alban Berg, and Anton von Webern are considered among its major creative founders.

Clemens Holzmeister, the best-known contemporary Austrian architect, was responsible for the two festival theatres in Salzburg, which combine a classic and modern theatre style. Artur Perotto, of Linz, has designed several striking skyscrapers in western Austria, while in Vienna, public apartment building has had a strong overall influence on architecture.

In sculpture, Fritz Wotruba is an internationally recognized figure. His style is often compared with that of the leading English sculptor, Henry Moore.

Austria's most famous contemporary painter is Oskar Kokoschka, truly a world figure: he and Alfred Kubin can be regarded as two of the foremost creators of modern painting in Austria. In addition, a young group of Surrealists has shown its works in international exhibitions.

Folk art and folk traditions, supported by provincial governments, have survived in western Austria, especially in Tirol.

The oldest Austrian academic research institution is the Academy of Science, whose traditions reach back to the end of the Middle Ages. More modern scientific foundations, notably the Körner Foundation and the Renner Foundation, support scientific research and other cultural endeavours: their main support comes from government sources. A new federal Ministry of Science was established in 1970 with the aim of reviving or increasing scientific and cultural activities.

Press and broadcasting. By the 1970s, the Austrian press had undergone far-reaching changes. These were particularly marked at the end of the 1960s, when the so-called Boulevard-press, offering light reading material and pictures, and occupying an intermediate status between the "quality" and "yellow" press, made extensive headway.

A second development has been the demise of the party-political press. Whereas the Socialist Party, with considerable financial effort, has been able to maintain its rather elderly *Arbeiter-Zeitung* (founded 1889), the People's Party was forced to cease publication of its organ in Vienna in November 1970.

The only Viennese paper with a conservative slant that tries to project a worldwide picture, *Die Presse*—namesake of one of the best-known papers prior to World War I—survives with the help of the federation of business.

Another change has been brought about by the shift of population and a measure of social life to the states: the latter have thus developed their own newspapers.

Growing popularity of television

The main reason for the changes that have taken place in the newspaper field has been the growing popularity of television. Austrian networks are state-owned but controlled by the Austrian Broadcasting Company, an entity which came into being in 1957, following a popular initiative leading to a legal reorganization. The company is established along the lines of an independent private enterprise, with a capital of 115,000,000 schillings, 112,800,000 of which are contributed by the federal authorities and 2,200,000 by the states. The Austrian radio network is made up of some 300 stations (including relay stations), with the most important being located in provincial capitals: they broadcast three different programs.

Regular television service in Austria started on January 1, 1957; in 1971, Austria had over 120 television stations. Commercials are strictly limited.

THE FUTURE

In a difficult period of slow adjustment from its status as the century-old centre of a multinational empire to a small neutral nation, Austria has experienced a crippling depression in the early 1930s; two civil wars in 1934; an authoritarian regime until 1938; a Nazi regime and

World War II; and a ten-year occupation by four great powers during the Cold War era. Yet Austria has emerged as a stable country whose neutrality is challenged neither by the super-powers, nor by its various neighbours.

This status has been, in part, the result of, and, also in part, the stimulus behind, recent favourable economic and social developments. Only since 1955 has Austria been able to develop, effectively and independently, its natural resources—chiefly oil and hydroelectric power—and also to make more efficient use of its iron ore and magnesite deposits. Agriculture, as a result of modernization, is now able to cater to most of the country's food requirements. Flexibility in adjusting foreign trade to the changed commercial and political environment, together with the great expansion of the tourist trade as a foreign-currency earner, have also contributed to the country's prosperity. All these factors, combined with a progressive social policy, have caused the resurgence of a new and distinctive Austrian national consciousness.

BIBLIOGRAPHY. FEDERAL PRESS SERVICE IN VIENNA, *Austria: Facts and Figures*, 8th ed. (1970); and CENTRAL AUSTRIAN STATISTICAL OFFICE, *Introducing Austria* (1968), are publications giving comprehensive statistical, as well as other, information on the various fields of economic, and, to a certain extent, cultural developments in Austria since 1945. PRESS SERVICE OF THE AUSTRIAN GOVERNMENT, *Austria: Land of Music* (n.d.); CULTURAL NEWS FROM AUSTRIA, *Austrian Short Story in the Twentieth Century* (n.d.), and *The Modern Austrian Drama* (n.d.), deal with various fields of Austrian cultural life. KURT SKALNIK, *Die Oesterreichische Presse* (1964), is a survey of the Austrian press, giving an objective description of the far-reaching changes in the make-up of the Austrian information media. JACQUES HANNAK (ed.), *Bestandaufnahme Oesterreich 1945–1963* (1963); C.T. GRAYSON, *Austria's International Position, 1938–53: The Re-establishment of an Independent Austria* (1953); RICHARD HISCOCKS, *The Rebirth of Austria* (1953); and ALLARD SVEN, *Diplomat in Wien* (1965), review Austria's immediate post-war development as well as the first period of independence following the conclusion of the State Treaty. HEINRICH SIEGLER, *Austria: Problems and Achievements Since 1945* (1967), provides a comprehensive documentary of Austria's political and diplomatic history after 1945. E.E. BAUMANN, *Crossroads of European Art: A Concise History of Art and Architecture in Austria* (1964), is an extensive history of Austria's cultural and art history. For statistical information, see *Oesterreichisches Jahrbuch 1969* (1970); *Wirtschaftsstatistisches Handbuch (Jahrbuch), 1968* (1969); and BUCHVERLAG SCHMIDINGER, *Austrian by Origin* (in six languages), 2 vol. (1969). See also the recent work by KARL R. STADLER, *Austria* (1971).

(O.L.)

Austria, History of

This article begins with a brief history of the area of the Austrian Republic from ancient times; it covers in greater detail the emergence of Austria as a German principality in medieval time, and the history of the Austrian-centred Habsburg state until 1918; it concludes with the history of the Austrian Republic. The article is divided into the following sections:

I. Austria to 1740

PREHISTORY AND ROMAN TIMES

In the territories of the Austrian Republic the first traces of human settlement date back to the Early Paleolithic Period. The archaeological material becomes richer and more varied for subsequent periods, giving evidence of several distinct cultures succeeding one another or co-existing. The Austrian site of Hallstatt gave its name to the principal culture of the Early Iron Age (*c.* 800–450 BC). Celtic tribes invaded the eastern Alps around 400 BC and eventually founded the kingdom of Noricum, the first "state" on Austrian territory known by name. In the west, however, the ancient race of Raetians was able to maintain its seat. Then, attracted by the rich iron resources and the strategic importance of the region, the Romans began to assert themselves. After an initially peaceful penetration during the last two centuries BC, Roman troops finally occupied the country in *c.* 15 BC, and the lands as far as the Danube became part of the Roman Empire, being allotted to the Roman provinces of Raetia, Noricum, and Pannonia.

Occupation by Roman forces

The Romans opened up the country by an extensive system of roads. Among the Roman towns along the Danube, Carnuntum (near Hainburg) took precedence over Vindobona (Vienna), while Lauriacum (Lorch, near the confluence of the Enns and the Danube) belonged to a later period. Roman municipalities (*municipia*) also grew up at Brigantium (Bregenz), Juvavum (Salzburg), Ovilava (Wels), Virunum (near Klagenfurt), Teurnia (near Spittal an der Drau), and Flavia Solva (near Leibnitz). North of the Danube the Germanic tribes of the Naristi, Marcomanni, and Quadi settled. Their invasions in AD 166–180 arrested the peaceful development of the provinces, and even after their repulse by the emperor Marcus Aurelius the country could not regain its former prosperity. In the 3rd century the Roman frontier defenses began to be hard pressed by invasions from the Alemanni. Finally, in the 5th century, heavy attacks by the Huns and eastern Germans put an end to the Roman provincial defense system on the Danube.

There is archaeological evidence of a Christian cult in this area from the 4th century, and the biography of St. Severinus by Eugippius constitutes a unique literary source for the dramatic events of the second half of the 5th century. At that time several Germanic tribes (Rugii, Goths, Heruli, and later Langobardi) settled on Austrian territory. In the year 488 part of the harassed Norican population withdrew to Italy.

EARLY MIDDLE AGES

Germanic and Slavic settlement. After the departure of the Langobardi to Italy (568), further development

was determined by the Bavarians in a struggle with the Slavs, who were invading from the east, and by the Alemanni, who settled in what is now Vorarlberg. The Bavarians were under the political influence of the Franks, whereas the Slavs had Avar rulers. At the time of their greatest expansion the Slavs had penetrated as far as Styria, Carinthia, and eastern Tirol. After 624 the western Slavs rose against the Avars under the leadership of the Frankish merchant Samo, whose short-lived rule may also have extended over the territories of the eastern Alps. Around 700 the Bavarian lands again bordered on Avar territory, with the lower course of the Enns forming the approximate frontier. On the death of the Frankish king Dagobert I (639) the Bavarian dukes from the house of Agilolfing became virtually independent.

Christianity had survived only here and there among the remnants of the Roman population, when around 600 and then again around 700 Christian missionaries from the west became active, with the support of the Bavarian dukes. At the end of the 7th century St. Rupert, who came from the Rhine, founded the church of Salzburg. When they were threatened once more by the Avars, the Alpine Slavs (Karantaner) placed themselves (before 750) under the protection of the Bavarians, whose mission was extended to them. At the same time, Bavarian settlers penetrated into the valleys of Carinthia and Styria. Charlemagne, emperor of the neighbouring Franks, however, defeated the Bavarian duke Tassilo III, wiping out the Bavarian dukedom for a century. During the following years (791–796) Charlemagne also led a number of attacks against the Avars and destroyed their dominion. Surviving Avars were made to settle in the eastern part of Lower Austria between the rivers of Fischa and Leitha, where they soon disappeared from history, most probably mixing with the native population.

Frankish domination in the 8th and 9th centuries

As was the usual Frankish practice, border provinces (Marken, or marches) were instituted in the newly won southeastern territories. The Avar March on the Danube and Lower and Upper Pannonia and Karantania were to form a border fortification; but this soon became less effective because of frequent disagreements among the nobility. To that unrest was added a threat from the Bulgarians and from the rulers of "Great Moravia." Nevertheless, the process of Germanization and Christianization went on, in the course of which the churches of Salzburg and Passau came into conflict with the eastern mission led by the Slav apostles Cyril and Methodius. The Frankish kingdom richly endowed the church and nobility with new lands, which were settled by Bavarian and Frankish farmers.

In 881 the beginning of incursions by the Magyars led to a first clash near Vienna. By 906, they had destroyed greater Moravia, and, in 907, near Pressburg (Bratislava), the Magyars defeated a large Bavarian army that had tried to win back lost territory. Liutpold of Bavaria and Theotmar, the archbishop of Salzburg, were killed in battle. The Lower Austrian territories as far as the Enns River and Styria as far as the Koralpe fell under Magyar domination. Nevertheless, a certain continuity of German–Slav settlement was maintained, so that, after the victory of the German king Otto I (955) and the further repulse of the Magyars in the 960s, a fresh start could be made.

The Babenberg period. The first mention of a ruler in the regained territories east of the Enns is of Burchard, who probably was count (burgrave) of Regensburg. It appears that he lost his office as a result of his championship of Henry II the Quarrelsome, duke of Bavaria. In 976 his successor, Leopold I of the House of Babenberg, was installed in office. Under Leopold's rule the eastern frontier was extended to the Vienna Woods after a war with the Magyars. Under his successor, Henry I, the country around Vienna itself must have come into German hands. New marches were also created in what was later known as Carniola and Styria. Wars against Hungarians and Moravians took up the reign (1018–55) of Margrave (a count who ruled over a march) Adalbert. Parts of Lower Austria on both sides of the Danube were lost temporarily; after they were retaken, they became the so-called Neumark (New March), which for some time enjoyed independence—as did the Bohemian march to the north of the Babenberg territories. The position of the Babenbergs was at that time still a modest one; their territorial rights were no greater than those of other leading noble families. Their power within their own official sphere was further diminished by ecclesiastical immunities (Passau in particular, but also Salzburg, Regensburg, and Freising), with numerous monasteries owning large territories as well.

Involvement in the papal-investiture controversy

Austria was repeatedly drawn into the disputes of the investiture controversy in which the Pope and the Holy Roman Emperor fought for control of the church in Germany. In 1075 Margrave Ernest, who had regained the Neumark and the Bohemian March for his family, was killed in the Battle of the Unstrut, fighting on the side of the king (later emperor) Henry IV against the rebellious Saxons. Altmann, bishop of Passau, a leader of church reform and a champion of Pope Gregory VII, influenced the next Babenberg margrave, Leopold II, to abandon the cause of Henry IV. As a result, Henry roused the Bohemian duke Vratislav II against him, and in 1082 Leopold II was defeated near Mailberg and his territories north of the Danube devastated. The Babenbergs, however, managed to survive these setbacks. Meanwhile, the cause of church reform gained ground, with its centres in the newly founded monasteries of Göttweig, Lambach, and, in Styria, Admont.

Under Leopold III (1095–1136) the history of the Babenbergs reached its first culmination point. In the struggle between emperor and pope, Leopold avoided taking sides until a consensus had built up among the German princes that it was Emperor Henry IV who stood in the way of a final settlement. Then Leopold did not hesitate to side with Henry's rebellious son, Henry V (1106). For this he was rewarded with the hand of Henry V's sister Agnes, who had formerly been married to the Hohenstaufen Frederick I of Swabia. The intermarriage with the reigning dynasty not only increased Leopold's reputation but no doubt also brought him additional power. Leopold was even proposed as a candidate to the royal throne, but he declined. It was apparently his intention to concentrate on consolidating his position in Austria. He was the first Austrian margrave to describe himself as the holder of territorial principality (*principatus terrae*), and during his time Austrian common law is mentioned for the first time, another proof of the developing national consciousness.

Leopold's reputation with the clergy was high, and he was eventually canonized (1485). He gave generous endowments to religious communities, establishing the Cistercians at Heiligenkreuz, and he founded, or at least restored, the monastery of Klosterneuburg, which he gave to Augustinian canons. It was in Klosterneuburg as well that he built a residence in which he stayed even after he had acquired Vienna.

Conflict of the Hohenstaufen, Welfs, and Babenbergs

On the death of Leopold III, the Babenbergs were drawn into a conflict between the two leading dynasties of Germany, the Hohenstaufen and the Welfs—on the side of the Hohenstaufen because of their family ties. In 1139 the German king Conrad III bestowed Bavaria, which he had wrested from the Welfs, on his half-brother, Leopold IV. After the latter's untimely death, Henry II Jasomirgott succeeded to the rule of Austria and Bavaria.

Emperor Frederick I Barbarossa tried to put an end to the quarrel between the Welfs and the Hohenstaufen, and in the autumn of 1156 at Regensburg he arranged a compromise. Bavaria was restored to the Welf, Henry the Lion, duke of Saxony, while the Babenbergs were confirmed in their rule of Austria, which was made a duchy, and were given the "three countships," the actual location of which is disputed. Also, the obligations of the dukes of Austria toward the empire were reduced. Their attendence at royal court days was only called for when court was held in Bavaria, and they were compelled to participate only in campaigns of the empire that were directed against Austria's neighbour; that is, Hungary. Henry II Jasomirgott and his wife, Theodora, a Byzantine princess, were granted succession through the female

line and the right, in the event of the premature death of their children, to appoint a candidate for the succession. The Babenbergs also were given the right of approving the exercise of jurisdiction by other powers within the new duchy, permitting Henry to exert pressure against such rival internal powers, secular as well as ecclesiastical. The rights of the duke were laid down by imperial charter (*Privilegium Minus*). For centuries, however, Austria continued to contain territorial dominions not subject to the duke. Henry moved his residence to Vienna, where he also founded the monastery of the "Scottish" (actually Irish) monks.

Acquisition of Styria by the Babenbergs

In 1192 the Babenbergs' territory was greatly extended when they won the duchy of Styria. In Styria the margraves of the family of the Otakars of Steyr had gradually asserted themselves—under conditions similar to those of the Babenbergs—over their rivals, the noble families of the Eppensteiner, Formbacher, and Aribonen. The most successful among the Styrian margraves had been Otakar III (reigned 1130–63). Then, in 1180, Emperor Frederick I, in the course of a renewed anti-Welf policy, raised Styria to the status of a duchy and granted it complete independence from Bavaria. A few years later, a treaty of inheritance (Georgenberg; 1186) was concluded between the dukes Leopold V of Austria (reigned 1177–94), a son of Henry Jasomirgott, and Otakar IV of Styria, the ailing last Otakar ruler. When Otakar died in 1192, Leopold succeeded him, and thus the Babenbergs came into the inheritance.

With the exception of a short intermission (1194–98), the reigning Babenberg henceforth ruled both duchies, Austria and Styria. Styria then included parts of the Traungau, which eventually was to become part of Upper Austria, and the province of Pitten, north of the Semmering, afterward assigned to Lower Austria. In logical continuation of the Babenberg policy, Leopold VI the Glorious and his successor, Frederick II the Warlike, the last representative of the dynasty, extended their domains farther south, gaining fiefs in Carniola.

Before he had inherited the duchy of Styria, Leopold V had taken part in the Third Crusade, during which, on the ramparts of Acre, he had become involved in a quarrel with the English king, Richard I the Lion-Heart. Later, on his return journey to England, Richard tried to make his way through Austria in disguise but was recognized near Vienna, taken prisoner, and later handed over to Emperor Henry VI. England had to pay a heavy ransom, a share of which Leopold obtained and invested in the foundation, extension, and fortification of towns as well as in the stamping of a new coin, the so-called Wiener Pfennig. The road connecting Vienna and Styria was improved, and the new town of Wiener Neustadt was established on its course to protect the newly opened route across the Semmering Pass.

On Leopold V's death the Babenberg domains were divided between his sons for four years, until the death of one of them, Frederick I, in 1198. His brother Leopold

The rule of Leopold VI

VI, the most outstanding member of the family, then took over as sole ruler (1198–1230). This was a time of great prosperity for the Babenberg countries. In imperial politics Leopold VI again took sides with the Hohenstaufen, backing Philip of Swabia. In church matters the Duke was a great supporter of the monasteries, founding a Cistercian monastery at Lilienfeld (*c.* 1206). He tried to concentrate patronage rights over ecclesiastical property in his own hands and took rigorous action against the heretics (Cathari and Waldenses). He participated in several crusades in Palestine, Egypt, southern France (against the Albigenses), and Spain (against the Saracens). Leopold VI's efforts to emancipate Austria ecclesiastically by creating a separate Austrian bishopric in Vienna came to naught because of the opposition of the church in Passau and especially Salzburg; nor did his son Frederick II succeed in the same matter. Leopold VI played some role in imperial politics, bringing about the peace Treaty of San Germano between Emperor Frederick II and Pope Gregory IX (1230). He met his death in San Germano, and his body was transported to Lilienfeld to be buried there.

A change came about under the last representative of the dynasty, Frederick II the Warlike, Leopold's son. His harsh internal policy and military excursions against neighbouring lands, together with his opposition to the emperor Frederick II, led in 1237 to the temporary loss of both Austria and Styria. The crisis, however, was overcome, and fresh opportunities were about to open for the Duke when, on June 15, 1246, he was killed in battle against the Hungarians on the Leitha River. With him the male line of the family came to an end.

The political history of Austria from the end of the 10th to the middle of the 13th century is marked by the establishment and consolidation of territories. This process was most advanced in the Babenberg domains, but was not confined to them. Dukes Herman (1144–1161) and Bernhard (1202–1256) of Carinthia achieved a comparable status, and Count Albert of Tirol (died 1253) moved in the same direction. The archbishops of Salzburg strove to eliminate all secular powers and patrons of their see, but in the other territories, secular princes strengthened their rule.

Another milestone of this period was the completion of the colonization of the Austrian territories. New settlements were now established by clearing the woods and advancing to more remote mountain areas. Several old and new settlements grew into market centres and towns and were eventually granted charters. The colonization movement also affected the ratio of German to non-German population. Except for some places in the Alpine regions, the Slavs were gradually assimilated, and the same holds true of the remnants of the Roman population in Salzburg and northern Tirol.

The intellectual life of the period deserves mention, too. The Babenberg court was famous enough to attract some of the leading German poets. At the beginning of the 13th century the Nibelung saga was written down by an unknown Austrian. Historical writing flourished in the monasteries. The era also produced first-rate Romanesque and early Gothic architecture.

LATE MIDDLE AGES

The contest for the Babenberg heritage. Upon the death of Frederick II the Warlike, the Babenberg domains became the political objects of aspiring neighbours. The Emperor and the Pope also tried to intervene. Two female descendants of the Babenbergs, Frederick's niece Gertrude and his sister Margaret, were considered to embody the claims to the heritage. Gertrude married first the Bohemian prince Vladislav and afterward the Margrave Hermann of Baden, who died in 1250. After Hermann's death, Otakar II (Přemysl Otakar II), prince of Bohemia (from 1253 king), married the widowed Margaret. Thereupon Hungarian forces intervened. Under the Treaty of Ofen (1254) Otakar was to rule Austria, while King Béla IV of Hungary received Styria. Troubles in Salzburg, stemming from a conflict between Bohemia and Hungary, inspired a rising among the Styrian nobles. Otakar intervened and in the Treaty of Vienna (1260) took over Styria as well. The state of anarchy that prevailed in Germany during this period proved advantageous to Otakar, who was granted both Austria and Styria in fief from Richard, earl of Cornwall, the titular German king. The grant, however, was only by writ and was invalid according to German law. During the following years Otakar's energetic rule met with growing opposition among the Austrian nobility. He introduced foreigners into important official positions, broke fortresses that had been erected without his consent, and dissolved his childless marriage with Margaret. Otakar had two of the opposition leaders, Otto of Meissau and Seifried of Mahrenberg, executed. The inhabitants of the cities, on the other hand, and the gentry, as well, generally favoured Otakar, who supported the churches and the monasteries. To complete his success, Ulrich of Spanheim, duke of Carinthia, willed Carinthia and Carniola to Otakar in 1269.

Rise of Přemysl Otakar of Bohemia

Reverses came only when Count Rudolf IV of Habsburg was elected German king as Rudolf I on September 29, 1273. Cautiously but nevertheless energetically,

Rudolf set about to undermine the powerful position Otakar had created for himself. He challenged the legitimacy of Otakar's acquisitions and finally placed the Bohemian king under the ban of the empire. In 1276 Rudolf and his allies invaded Austria, forcing Otakar to do homage and to renounce his claims to Austria. Two years later, while trying to recover what he had lost, Otakar was defeated by the united forces of Rudolf and the Hungarians and was killed on the battlefield near Dürnkrut (August 26, 1278).

The accession of the Habsburgs. As the German princes had not cared to give Rudolf adequate support against Otakar, he did not feel bound to them and set about to acquire the former Babenberg lands for his own house. In 1281 he made his eldest son, Albert (later Albert I, king of Germany), governor of Austria and Styria; on Christmas, 1282, he invested his two sons, Albert and Rudolf II, with Austria, Styria, and Carniola, which they were to rule jointly and undivided. As the Austrians were not used to being governed by two sovereigns at the same time, the Treaty of Rheinfelden (June 1, 1283) provided that Duke Albert should be the sole ruler. In 1282 Carniola had already been pawned to Meinhard II of Tirol (of the counts of Gorizia), one of the most reliable allies of Rudolf who, in 1286, was also invested with Carinthia.

Rule of Albert of Habsburg

At first the Habsburg rulers were far from popular in Austria. Albert's energetic and relentless rule roused bad feeling, and the Swabian entourage that had arrived with the new dynasty to occupy key positions was despised by native nobles. There were conflicts with Bavaria, Salzburg, and Hungarian nobles who violated the Austrian frontier. After the death of King Rudolf (1291), all the neighbours and rivals of the Habsburgs and the counts of Gorizia united. Albert, however, succeeded in negotiating a peace with his most dangerous foes, the Hungarians and the Bohemians, and he broke the fortresses of the rebel nobility. Meanwhile, Meinhard II had stifled the uprising in Carinthia.

In 1292 Albert had been passed over in the German election, and Adolf of Nassau was called to the throne. When Adolf fell out with the electoral princes, however, they went over to Albert, who had just subdued another rebellion in Austria. After Adolf was defeated and killed near Göllheim (1298), Albert had himself elected a second time. In his Austrian lands Albert's main concern was to provide for an effective administration, in which he was assisted by his privy councillors, most of whom were foreign. Records were set up to codify the prerogatives and returns of the ducal property. Eventually Albert did not spare the church, either. When the Přemysl family died out in 1306, Albert aspired to the Bohemian throne. He had his eldest son, Rudolf III, elected Bohemian king, but Rudolf died the following year. Albert was preparing for a new campaign when he was murdered by his nephew, John, and some accomplices (1308).

On Albert's death the anti-Habsburg movement flared up again in Austria, but his sons, Frederick I the Fair and Leopold I, managed to maintain control. Frederick stood for election as German king (as Frederick III), and for the next years the Habsburg countries had to support the cost of the war with his rival, Louis IV of Bavaria, until 1322, when Frederick was defeated near Mühldorf. Earlier, another more decisive battle had been lost by the Habsburgs to the Swiss at Morgarten in 1315. From that time on, the Habsburg domains in the territory south of the Rhine and the Bodensee (Lake Constance) began to crumble away. Frederick the Fair spent his last years in Austria and was buried in the Carthusian monastery of Mauerbach (1330). He seems to have been the first of the Habsburgs for whom Austria meant home. From his time on, Habsburg rule and Habsburg territories were known as the Austrian domains (*dominium Austriae*), a term that was replaced, in the course of the 14th and 15th centuries, by the new concept of the House of Austria.

After Frederick's death the Habsburgs were for some time ruled out as possible candidates for the German throne; but, under the brothers Albert II and Otto, Habsburg Austria received its first important accession of territory. In 1335 Carinthia and Carniola were acquired after the death of Henry of Gorizia; while, with the help of Luxembourg troops, Henry's daughter Margaret (surnamed Maultasch) managed to retain the Tirol. Albert and his brother Otto had not gotten on too well, but when Albert came to rule on his own, he proved to be of sound judgment and keen on preserving the peace. It was a time of severe catastrophes: bad harvests, floods, and earthquakes, and in 1348–49 the plague, which brought a persecution of the Jews that was suppressed, however, by the Duke. Albert arranged several tours around his domains to establish contacts with the populace and improve jurisdiction. Two campaigns against the Swiss failed to yield any spectacular results, but they helped once more to consolidate the weakened Habsburg position. At his death in 1358, Albert left four sons. Though in 1355 a family ordinance had decreed that all the male members of the family were to rule jointly over the undivided domains, only the eldest among them, Rudolf, was then fit to rule. Throughout his short reign (1358–65), Rudolf IV showed himself extremely energetic and ambitious. He started to rebuild St. Stephen's Cathedral in the Gothic style, and he founded the University of Vienna (1365). With these two projects he imitated and rivalled his father-in-law, the emperor Charles IV, at Prague.

Acquisition of Carinthia, Carniola, and Tirol

In 1359 Rudolf's forged charter, the Privilegium Majus, by which he claimed immense privileges for Austria and its dynasty, as well as the title of archduke, caused a breach between him and the emperor Charles IV. Charles was not prepared to accept the Privilegium Majus to its full extent (although it later was sanctioned by the Habsburg emperor Frederick III in 1442 and again in 1453). Upon news of the death of Duke Meinhard in 1363, Rudolf prevailed upon the Duke's mother, Margaret, to make over the Tirol to him. On this occasion the Emperor backed the Habsburgs against the Wittelbachs, and the Tirol thus passed to the House of Austria.

The division of the Habsburg lands. Rudolf was succeeded in 1365 by his two brothers, Albert III and Leopold III. After some years of joint rule, however, they quarrelled and in 1379, by the Treaty of Neuberg, partitioned the family lands. Albert, as the elder brother, received the more prosperous countries on the Danube (Upper and Lower Austria). The rest of the widespread domains fell to Leopold (including Styria, Carinthia, Tirol, the old Habsburg countries in the west, and central Istria). The treaty also contained several points on mutual wardship, preemption rights, and common titles, by which some connection between the two lines was to be preserved.

Treaty of Neuberg of 1379

In 1381 the resourceful Duke Leopold took advantage of the weak position of Venice in its war with Genoa and seized Trieste, which had broken away from Venice. His efforts to expand his rule in the west, however, were less successful, though he seemed lucky enough at first. Envisaging a connection between the original Habsburg territories in the west and the new domains in the Tirol, the Habsburgs looked for a foothold in the region west of the Arlberg (modern Vorarlberg). Neuberg on the Rhine was won in 1363 and Feldkirch in 1375. Another important acquisition was the city of Freiburg in the Breisgau. But then Leopold came into conflict with the Swiss, which led to defeat and his death at Sempach in 1386. An army of his brother, Albert III, was likewise defeated near Näfels in 1388, and the Habsburgs suffered heavy territorial losses. Leopold's sons recognized the wardship of Albert, who acquired Bludenz and the Mantafon Valley west of the Arlberg in 1394. In his own domains Albert was forced to check the dynasty of the Schaunbergs (in Upper Austria), who tried to create an independent domain around Wilhering and Eferding. Albert III especially favoured the city of Vienna as his capital, and it was because of his reorganization that the university Rudolf IV had founded there was able to survive.

After Albert's death in 1395, new Habsburg family troubles arose, differences that the treaties of Hollenburg (1395) and Vienna (1396) tried to settle. Under the Vienna treaty, the line of Leopold III split into Styrian and Tirolian branches, resulting in three complexes of Aus-

trian territories—a state of affairs that was to reappear in the 16th century. The individual parts came to be known by the names of Niederösterreich (comprising modern Lower and Upper Austria), Innerösterreich (comprising Styria, Carinthia, Carniola, and the Adriatic possessions), and Oberösterreich (comprising the Tirol and the western domains, known as the Vorlande, or Vorderösterreich).

The early diets of the nobility, church, and towns

In 1396 the Austrian estates, or diets, were first assembled to consider the Turkish threat and henceforth were to play an important political role in Austria. In them the nobility usually took the lead, but they also included representatives of the monasteries, the towns, and the marketplaces. In the Tirol, in Vorarlberg, and, at times, in Salzburg, the peasants also sent their representatives to attend the diets. Because of the Habsburg partitions and frequent regencies, the estates were able to gain in importance. They did not obtain the right to pass laws, but they obstinately insisted on the privilege to grant taxes and duties.

After the short rule of Albert IV (1395–1404) and a troublesome tutelary regime (1404–11), Albert V came into his own, and with him the Danube countries again enjoyed a strong and energetic rule (1411–39). Albert, however, had married the daughter of the emperor Sigismund and was thus drawn into the Hussite religious wars, in the course of which the Austrian lands north of the Danube were ravaged. In the Austrian west, Duke Frederick IV of the Tirolian branch lost the Aargau to the Swiss but was able to assert himself in Tirol against a rebellion of his nobles.

When Sigismund died, Albert inherited his positions. In 1438 he was first elected Hungarian king, with the German (as Albert II) and the Bohemian crowns to follow later. Albert no doubt had many of the qualities of a born ruler, but he died prematurely in 1439 on an unsuccessful campaign against the Turks. Soon thereafter, his widow gave birth to a son and heir, Ladislas Posthumus, to whom Frederick V of Styria, as the senior member of the house, became guardian. Frederick also had Sigismund, the son of Frederick IV of Tirol, under his tutelage.

Thus began the long reign of Frederick V (as Roman emperor he was to become Frederick III). His reign was marked by almost ceaseless strife with the estates, with his neighbours, and with his jealous family. When he tried unsuccessfully to take advantage of a conflict among the Swiss Confederates, the Tirolians made Frederick release Duke Sigismund from tutelage (1446). A few years later, on his return from Rome, where he had been crowned emperor, his enemies at home and abroad in 1452 forced him also to give up Ladislas, who was then the recognized king of Hungary and Bohemia. The boy king's policies were made by Count Ulrich of Cilli. Ulrich was murdered at Belgrade in 1456, however, and a year later King Ladislas died. In Bohemia and Hungary national kings came to power. Frederick now won himself a foothold in the Austrian domains on the Danube and succeeded in acquiring the rich estates and fiefs of Ulrich.

The Burgundian and Spanish marriages. Maximilian I, the son of the emperor Frederick III, was married to the Burgundian heiress, Mary, at Ghent (1477). By that tie to Burgundy the Habsburgs became involved in long struggles with France. After Mary's death (1482), Maximilian, moreover, met with increasing difficulties in the Burgundian countries themselves. In the meantime, another crisis had arisen in the eastern Habsburg domains. Disagreement about the Bohemian succession and a political error of Frederick III, who tried to install the former archbishop of Gran (Esztergom) at Salzburg, led King Matthias I Corvinus of Hungary to march against Austria. Vienna was besieged and finally taken by the Hungarians (1485), as was Wiener Neustadt (1487). The harried Maximilian came into even greater distress in the Low Countries, where the rebellious citizens of Bruges put him under arrest (1488). Sigismund, the Habsburg ruler of the Tirol, who was heavily encumbered by debts, planned to sell his country to the Bavarians. A complete breakdown of the House of Habsburg threatened, but Maximilian was ultimately released. He prevailed upon Sigismund to abdicate in his favour. In 1490 the Habsburgs were able to take over Lower Austria. Maximilian even attacked Hungary but in the Treaty of Pressburg (1491) renounced claims to Hungary, though reserving the succession rights of his family.

Near collapse of House of Habsburg

After the death of his father, Emperor Frederick III, Maximilian came into a heritage that surpassed the endowments of all his predecessors. Furthermore, his son, Philip I the Handsome, who governed the Low Countries, was betrothed to the Spanish infanta, Juana (later Joan the Mad), and through the unexpected death of male members of the Spanish dynasty this marriage was to raise the Habsburgs to the throne of Spain. In the German Empire as well as in Austria, Maximilian introduced sweeping administrative reforms that were the first steps toward a centralized administration. In 1508 Maximilian assumed the title of elected emperor as he was unable to pass through hostile Venetian territory to go to Rome for his coronation, and henceforth Rome and the pope had no more say in the creation of new emperors.

During Maximilian's last years, Eastern politics again came to the fore. The great crusade he planned against the Turks, however, never materialized. In 1515 Maximilian arranged a double marriage between his family and the Jagiellon line that ruled Bohemia and Hungary, thus reviving earlier Habsburg claims to these countries. Maximilian's energetic reign added greatly to the prestige of the Habsburgs. Thus, his grandson Charles (V) was able to prevail against French intrigue to inherit the imperial crown. Charles's younger brother, Ferdinand I, took over the rule of the Austrian countries but encountered the opposition of the estates, which he cruelly suppressed. In the agreements of Worms (1521) and Brussels (1522) Charles V formally handed over the Austrian lands to his brother. The subsequent years of Ferdinand's reign were troubled by peasant risings in the Tirol and Salzburg and were followed by similar upheavals in Innerösterreich.

Summary of developments in the late Middle Ages

In the late medieval period the Alpine lands were assembled by the Habsburgs into a monarchical union comprising about the extent of the present Austrian state. The process of union was at times intercepted and hindered by the partitions among the dynasty. When the process was finished, however, the territories still preserved their individuality and their own legal codes. During this period the towns developed and prospered, but in the rural settlements a backward tendency had set in. Many settlements were abandoned, especially in Lower Austria. The leading classes lost their interest in rural colonization as they found other and more lucrative sources of income. Mining developed, but trade was impaired by political instability. To about 1450 the University of Vienna enjoyed some fame in the fields of theology and science. The literary culture of Austria was characterized by remarkable works, among them the rhyming chronicle of the Styrian Otakar aus der Geul, the work of the Carinthian abbot John of Viktring, the poetry of Oswald of Wolkenstein, and the works of the theologian and historian Thomas Ebendorfer. From the middle of the 15th century onward Austria came under the influence of Italian Humanism.

REFORMATION AND COUNTER-REFORMATION

The acquisition of Bohemia. The year 1526 saw the defeat and death of the Jagiellon king of Hungary and Bohemia, Louis II, who fell in the Battle of Mohács against the Turks. In view of the treaties of 1491 and 1515, Ferdinand I and the Vienna court envisaged Hungary and Bohemia plus the adjoining countries falling to the Habsburgs. Thus, the union of Austria, Bohemia, and Hungary became the leading concept of Habsburg politics. After clever diplomatic overtures, Ferdinand was elected king of Bohemia (October 23, 1526). In Hungary, however, there was a split election; János (John) Zápolya, *voivode* (governor) of Transylvania, was chosen by an opposition party, whereupon war broke out between the two candidates.

Ferdinand's troops in Hungary would have been in a

stronger position had Zápolya not been assisted by the Turks under Süleyman I. In 1529 the Turks advanced as far as Vienna, which they besieged in vain. Another Turkish offensive came to a halt at Güns in western Hungary in 1532. Ferdinand, on the other hand, failed in his attempt to take Ofen (Hungarian Buda), where the Turks had entrenched themselves. By around the middle of the century the frontiers had become fixed. Hungary happened to be divided into three parts: the west and the north remained with the Habsburgs, the central part came under Turkish rule, and Transylvania and adjoining territory were kept by Zápolya and his successors. This situation was anticipated in the truce of 1547 and became formalized in the Peace of Constantinople (1562).

Ferdinand I's administrative reforms

During a short truce in the fighting against Zápolya and the Turks, Ferdinand started to reorganize Austrian administration. In 1527 he created new central organs: the Privy Council (Geheimer Rat) for foreign affairs and dynastic matters; the Court Council (Hofrat) as the supreme legal authority; the Court Chancery (Hofkanzlei), which served as the central office and only later on was to deal with internal affairs; and the Court Treasury (Hofkammer) for finance and budgeting. As the Court Treasury proved inefficient in the financing of the Turkish war, the Court Council of War (Hofkriegsrat) was established in 1556 to take care of the pay, equipment, and supplies of the troops, acquiring some influence on military operations as well.

The advance of Protestantism. The Protestant movement gained ground in Austria very fast. The nobility especially turned toward the Lutheran creed. For generations eminent families provided the protagonists of Protestantism in the Lower and Inner Austrian territories. The sons of the nobility were often sent to the north German universities to expose them more fully to Protestant influence. From 1521 Protestant pamphlets were produced by Austrian printers. Bans on them, issued from 1523 onward, remained ineffective, however.

Among the peasant population the Anabaptists had a stronger appeal than the Lutherans. As they had no support from the estates and because of their radicalism, however, the Anabaptists were persecuted from the start. In 1528 Balthasar Hubmaier, their leader in the Danube countries and southern Moravia, was burned at the stake in Vienna, and in 1536 another Anabaptist, the Tirolian Jakob Hutter, was put to death in the same way in Innsbruck after he had led many of his followers into Moravia. Ferdinand, for his part, advocated religious reconciliation and looked for means to achieve it; but the dogmatic viewpoints proved irreconcilable. The Peace of Augsburg (1555) finally brought some respite in the religious struggles.

When Charles V abdicated, Ferdinand I became emperor (1558), and thus the leadership of the empire was taken over by the Austrian (German) line of the Habsburgs. Maximilian II, the eldest son, followed his father in Bohemia, Hungary, and the Austrian Danube territories (1564). The next son, Ferdinand, was endowed with Tirol and the Vorlande; Charles, the youngest of the brothers, received the Inner Austrian lands, and took up residence in Graz. Maximilian was known for his Protestant leanings but was bound by a promise he had given his father to remain true to the Catholic religion. The Protestants were therefore granted fewer concessions from him than they might have expected.

Catholic reaction and the Counter-Reformation

Meanwhile, Catholic counteractivity began, with the Jesuits particularly prominent in Vienna, Graz, and Innsbruck. A new generation of energetic bishops took part and proved a great asset to the cause. It was also of some importance that the monasteries, though they had been deserted by many of their members and were struggling for existence, had not been secularized. On the Protestant side, it proved impossible to reconcile the various reforming movements. Social differences between them, especially between the nobility and the peasants, also stood in the way of a united Protestant front. The Counter-Reformation scored its first successes in Gorizia and Carniola, where Protestantism had remained insignificant. And in other parts, official religious commissions started to replace the Protestant preachers with Catholic clergymen.

Rudolf II and Matthias. Maximilian's successor, Rudolf II (reigned 1576–1612), had been educated in Spain strictly in the Catholic faith. He had all Protestants dismissed from court service. The conversion of the cities and market centres of Lower Austria to Catholicism was conducted by Melchior Klesl, at that time administrator of the Vienna see but later to become bishop and cardinal. In Upper Austria, where the Protestants had their strongest hold, the situation remained undecided, with the Catholic governor, Hans Jakob Löbl of Greinburg, and the Calvinist Georg Erasmus of Tschernembl leading the opposing religious parties. When Charles's son, Ferdinand II, took over in Styria, he proved to be the most resolute advocate of the Counter-Reformation. It was he who eventually succeeded in uprooting Protestantism, first in Inner Austria and then in the other Habsburg countries, with the exception of Hungary and Silesia.

From local skirmishes along the frontier, a long, drawn-out war with the Turks developed (1592–1606). In 1598 Raab (Hungarian Győr), which served as a bastion of Vienna, was temporarily lost; Gran, Veszprém, and Stuhlweissenburg (Hungarian Székes-fehérvár) passed several times from one side to the other. The introduction of the Counter-Reformation in Hungary, moreover, resulted in a rising of Protestant elements under István Bocskay. But in 1606 at Vienna a peace was concluded between Austria and the Hungarian estates. At Zsitvatorok another peace was negotiated with the Turks, who for the first time recognized Austria and the emperor as an equal partner.

Conflict between Rudolf and Matthias

Political disagreements between Emperor Rudolf, who to an increasing degree showed signs of mental derangement, and the rest of the family led to the "Habsburg Brothers Conflict." Cardinal Klesl in 1607 brought about an agreement among the younger relatives of the Emperor to recognize the Emperor's brother Matthias as the head of the family. As the conflicts with Rudolf persisted, Matthias strove also to come to an understanding with the estates, which were mainly Protestant. The formation of opposing religious leagues in Germany, the Protestant Union and the Catholic League, also added to the general confusion.

Matthias advanced into Bohemia, and, in the Treaty of Lieben (1608), Rudolf conceded to him the rule of Hungary, the Austrian Danube countries, and Moravia, while Matthias had to give up the Tirol and the Vorlande to the Emperor. In 1609 the estates received a confirmation of the concessions Maximilian II had made to them. The cities were guaranteed only in general terms that their old privileges should not be interfered with. At the same time, Rudolf II was forced to grant to Bohemia the so-called Letter of Majesty, which contained far-reaching concessions to the Protestants. After a final defeat of Rudolf in Bohemia in 1611, Matthias was crowned king of Bohemia. Rudolf's death in 1612 finally ended the conflict.

After Matthias had been elected emperor, his principal councillor, Cardinal Klesl, tried in vain to arrange an agreement with the Protestants in Germany. The ensuing years were filled with wars in Transylvania, where Gábor Bethlen came to power. In the Peace of Tyrnau (1615) the Emperor had to recognize Bethlen as prince of Transylvania, and in the same year he extended the truce with the Turks for another 25 years. In the meantime, war had broken out with Venice (1615–17) because of the pirating activities of the Serb refugees (Uskoken) established on the Croatian coast. A settlement was reached in the Peace of Madrid. The situation in Bohemia then reached a critical point, the religious tensions in the country finding a vent in the "Defenestration of Prague" (May 23, 1618), in which two of the Emperor's regents were thrown from the windows of the Hradčany Palace.

The Bohemian rising and the victory of the Counter-Reformation. War became inevitable when Emperor Matthias died in 1619. Not that he had been master of the situation, but his death brought Ferdinand II, the

most uncompromising Counter-Reformer, to the head of the House of Habsburg. Ferdinand was hard pressed at first, as Bohemian and Moravian troops invaded Austria. A deputation of the estates of Lower Austria tried to make him renounce Bohemia in a peace treaty and demanded religious concessions for themselves, unsuccessfully, however. The Bohemians were forced to retreat, and imperial troops advanced into their country. The Bohemians deposed Ferdinand from the throne of Bohemia and elected Frederick V in his stead. But two days later Ferdinand II was elected German emperor at Frankfurt (August 28, 1619).

War over the Bohemian crown

War was the only means of resolving the issue. The conflict for the Bohemian crown developed into a European war when Spain, the Bavarian duke Maximilian I, and the Protestant elector of Saxony entered the struggle on the side of the Emperor. The Upper Austrian estates rashly joined Frederick, with the result that their country was occupied by the army of the Catholic League and afterward pledged to Bavaria. At the Battle of the White Mountain, Ferdinand became master of Bohemia, Moravia, and Silesia, while Lusatia was pledged to Saxony. King Frederick fled to the Netherlands. The leaders of the Bohemian rising were executed, and other nobles who had compromised themselves lost their property. Many Protestants left the country. In the new constitution of 1627 Bohemia and its associated lands became a hereditary kingdom. The diets were not dissolved entirely, as the government wanted to make use of their administration, but their influence was restricted to financial matters.

After the death of Matthias, Ferdinand had also inherited the Danubian territories. Tirol, however, retained a special status under a new Habsburg secundogeniture (inheritance by a second branch of the house). Upper Austria, pledged to Bavaria, was disturbed by a great peasant rising. The Protestant peasants were defeated after heavy fighting, and in 1628 the country passed into the hands of the Emperor again.

The Counter-Reformation was vigorously enforced in the Austrian domains. This led to the mass emigration of Protestants, including many members of the nobility. Most went to the Protestant states and to the imperial cities of southern Germany. After the Bohemian victory the war went favourably for the Emperor, and the Peace of Lübeck (1629) seemed to secure the hegemony in Germany for the Habsburgs. But in 1629 Ferdinand's attempt in the Edict of Restitution (Restitutionsedikt) to establish religious unity by force throughout the empire provoked the violent opposition of the Protestants.

The struggle with Sweden and France. July 1630 saw intervention in Germany's religious strife from a different quarter—Sweden. In that month the Protestant Swedish king, Gustavus II Adolphus, landed on the Baltic coast of Pomerania. His purpose was to defend the Protestants against further oppression, to restore the dukes of Mecklenburg, his relatives, who had been driven from their lands by Ferdinand's forces, and perhaps to strengthen Sweden's strategic position in the Baltic. In the ensuing conflict the city of Magdeburg was destroyed by fire after it had been taken by the troops of the Emperor under Gen. Johann Tserclaes, Graf von Tilly (1631). The north German Protestants, who had so far remained undecided, consequently went over to the Swedes. After victories near Breitenfeld and on the Lech, the Swedish troops entered Bavaria.

During the subsequent period of the Thirty Years' War (*q.v.*), Ferdinand adopted a rigorous and often unrelenting attitude, though he yielded a little when the Peace of Prague was being negotiated (1635). His successor, Ferdinand III (1637–57), was as loyal to Catholicism as the father had been but showed himself more of a realist. He was not able, however, to prevent the war from again dragging into Habsburg territory, so that in 1645 even Vienna was threatened. The extremist party that had rejected all concessions lost its influence at the Vienna court, and two able diplomats, Maximilian, Graf von Trauttmansdorf, and Isaac Volmar, were entrusted with the representation of a weakened Austria at Münster and Osnabrück, where extended negotiations were conducted until acceptable terms could be settled for Austria. In the Peace of Westphalia (1648) Austria lost its possessions in Alsace, and Lusatia had to be ceded for good to Saxony. The peace in many respects marked the beginning of a new epoch. The Holy Roman Empire from then on was reduced to a loose union of otherwise independent states, and Habsburg politics shifted its emphasis, falling back entirely on the political, military, and financial resources of the hereditary Habsburg lands, now including also Bohemia. The new central organs and the administrative bodies of the territories took on much greater importance than the remaining institutions of the Holy Roman Empire. The Emperor came to rely on a standing army rather than upon troops provided by the German princes.

Economic and cultural consequences of the religious struggle

The heavy drain the religious wars had made on the population of the Austrian territories was compensated for by immigrants from the Catholic parts of the empire and by Croatian refugees from the southeast. The economic position of the peasants on the whole deteriorated. Many members of the nobility, as well as the church, acquired new property. In mining, boom and depression followed quickly upon each other. The loss of many experienced miners during the Counter-Reformation resulted in difficulties, but the government took several steps toward improving and extending the salt mines. In 1625 it founded the Innerberg Union, under which the Styrian iron industry was reorganized. The Emperor also tried to interfere with the trade organizations of the towns, though without much success. Trade and finance in the Austrian territories was dominated by foreign capital.

The cultural life of the period was also dominated by the religious struggle. In the field of education the schools of the denominational parties rivalled each other. In 1585 a Jesuit university was founded at Graz, while at Salzburg a Benedictine university was established (1623). Austrian humanists produced some outstanding works of poetry and historical writings, and the sovereigns were great patrons of the arts, but on the whole this was an epoch dominated by Italian and Western influences.

AUSTRIA AS A GREAT POWER

After the Thirty Years' War, Austrian politicians were understandably reluctant to enter into another military conflict. In 1654 Ferdinand IV, the eldest son of the Emperor, died. His brother Leopold, who had been destined for a church career, then was considered as heir to the throne and was recognized as such by Austria, Bohemia, and Hungary. In Germany, however, difficulties arose when France declared itself against Leopold. Nevertheless, after the death of Emperor Ferdinand, Leopold was finally elected (1658), after having conceded constitutional limitations that restricted his liberty of action in foreign politics. West German princes under Johann Philipp von Schönborn, archbishop of Mainz, formed the French-oriented League of the Rhine. At the same time, Austria was engaged in the northeast, when it intervened in the war between Sweden and Poland (1658) in order to prevent the collapse of Poland. There were some military successes, but the Treaty of Oliva (1660) brought no territorial gains for Austria, though it stopped the advance of the Swedes in Germany.

During the Thirty Years' War the Turkish front had been quiet, but in the 1660s a new war broke out with the Turks (1663–64) because of a conflict over Transylvania, where a successor had to be appointed for György II Rákóczi, who had been killed fighting against the Turks. The Turks conquered the fortress of Neuhäusel in Slovakia, but the imperial troops succeeded in throwing them back. The Austrian military success was not, however, reflected in the terms of the Treaty of Vasvár: Transylvania was given to Mihály Apafi, a ruler of pro-Turkish sympathies. A minor territorial concession was also made to the Turks. The year after the Turkish peace, Tirol and the Vorlande reverted to Leopold I (1665), and the second period of the Habsburg partition (1564–1665) came to an end.

In Hungary dissatisfaction with the results of the Turkish war spread. Not only the Protestants, who were threatened by the Counter-Reformation, but also many Catholic nobles were alarmed by Habsburg absolutism. A group of Hungarian nobles and the Styrian count Hans Erasmus of Tattenbach entered into a conspiracy. The Austrian government, informed of their activities, had four of the ringleaders executed—an action that led to a rising by rebels known as Kuruzen (Crusaders).

In the meantime, the position of the Habsburgs in the west had again deteriorated. At first Leopold I's leading statesmen, Johann Weikhard, Fürst Auersperg (dismissed in 1669), and the president of the Court Council of War, Wenzel Eusebius, Fürst von Lobkowitz, remained rather passive in view of the expansionist policies of Louis XIV of France. They also stayed outside the Triple Alliance of Holland, England, and Sweden that was concluded in order to ward off the attacks of Louis against the Spanish Netherlands. When Louis actually invaded Holland, the Emperor finally entered the war, but in the ensuing Treaty of Nijmegen (1679) he had to cede Freiburg im Breisgau to France.

The threat to Vienna by the Turks

Another and still more menacing danger appeared in the southeast. After some deliberation, the leader of the Hungarian rebels, Imre Thököli, had asked the Turks for help, whereupon the grand vizier Kara Mustafa organized a large Turkish army and marched it toward Vienna. Habsburg diplomats succeeded in concluding an alliance between Austria and Poland. Meanwhile, imperial troops under Duke Charles of Lorraine tried to hold the enemy but had to retreat. From July 17 to September 12, 1683, Vienna was besieged by the Turks. Deciding against a direct assault, the Turks began to drill tunnels underneath the bastions of the city, when relief columns arrived from Bavaria, Saxony, Franconia, and Poland. King John III of Poland took over the command of the relieving army, which descended upon the Turks and dispersed them. The Emperor concluded a pact with Poland and the Venetian republic—the Holy League. In 1685 Neuhäusel was won back, and in September of 1686 Ofen was captured, despite fierce Turkish resistance.

In 1687 the Hungarian diet recognized the hereditary rights of the male line of the Habsburgs to the Hungarian throne. In 1688 Belgrade was conquered and Transylvania was secured by imperial troops. In the meantime, Louis XIV had begun an offensive against the German Palatinate. This meant that no further troops could be spared for the Turkish war, and in 1690 all recent conquests in the south, including Belgrade, were lost again. A victory of the imperial and the allied German troops under Margrave Louis of Baden near Slankamen (1691) prevented the Turks from advancing farther, but then the Margrave was ordered to the Rhine front. Eventually Prince Eugene of Savoy took over the command and gained a decisive victory over the Turks near Zenta (1697). After another offensive against Bosnia, the Turks finally decided to negotiate a peace. In the Treaty of Carlowitz (1699), Hungary, Transylvania, and large parts of Slavonia fell to the Habsburg emperor. In the meantime, the war in the west had come to an end (Treaty of Rijswijk, 1697), overshadowed already by the question of the Spanish succession.

The War of the Spanish Succession. From 1701 to 1714 Austria was involved in hostilities with France over the issue of the Spanish succession. The childless King Charles II of Spain, a Habsburg, had willed his entire possessions to a Bourbon prince—a grandson of Louis XIV of France. All those who disliked the idea of a French hegemony in Europe consequently united against the French. The Emperor declared war (1701) and was immediately supported by Brandenburg-Prussia and Hanover. In the spring of 1702 England and Holland entered the war in the Grand Alliance against France. Louis XIV, on the other hand, was able to win the electoral princes of Bavaria and Cologne as his allies. At this critical juncture another Hungarian rising, led by Ferenc II Rákóczi, occurred. The rebels were prepared to join forces with the enemies of Austria and for years engaged Austrian troops. The rebels even threatened Vienna, whose suburbs had to be fortified. In the war with France, imperial troops fought on four fronts: in Italy, on the Rhine, in the Spanish Netherlands, and in Spain. Much larger forces were mobilized than had been customary during the 17th century, with the result that the financial drain on the imperial treasury was so heavy that the Emperor had to resort to Dutch and English loans. When Bavaria entered the war on the side of the French, Austria was in further danger, until the Battle of Blenheim (1704), in which a joint English and Austrian army under the Duke of Marlborough and Prince Eugene defeated the French and Bavarian forces.

Scale of the Spanish war

After a reign of 48 years filled with almost endless troubles, Emperor Leopold died in 1705. He was succeeded by his son, Joseph I (1705–11). In the religious quarrels the new emperor, an ally of Protestant states, showed great restraint and allowed himself to be guided mainly by political motives.

In 1703 the Duke of Savoy, who had left the French to go over to the Habsburgs, found himself in a critical situation; his capital, Turin, had come under French siege. An imperial army under Prince Eugene and reinforced by a Prussian contingent was sent to his aid and succeeded in uniting with the Savoyan forces and relieving Turin after a victorious battle (1706). At the beginning of the next year an agreement was reached under which the French evacuated northern Italy. The same year a smaller imperial army under Wirich, Graf von Daun, conquered Spanish-ruled southern Italy; but an invasion of southern France, which the sea powers had instigated, failed. A quick success, however, fell to the Austrians in a campaign against the Vatican state over a conflict between the Emperor and the Curia over mutual feudal rights and because of Pope Clement XI's rather pro-French leanings.

The allies were victorious in the Netherlands, winning the Battle of Oudenaarde and conquering Lille (1708). Paris seemed within easy reach. The Battle of Malplaquet (1709) was another victory for the allies, but they had to pay dearly for it. In the meantime, peace negotiations had foundered. After reverses in Spain and a political change in England, the alliance itself was in danger of falling apart. The situation was further aggravated by the death (1711) of Emperor Joseph I, who left daughters only.

At this juncture, liquidation of the Hungarian rising became possible. Rákóczi, who in 1707 had declared the deposition of the Habsburgs, began to meet with growing opposition among his followers. Imperial troops forced Rákóczi to flee to Poland; and the rebels, who had been promised an amnesty and who were guaranteed religious liberty, made their peace in 1711. From then on the Vienna government tried to be more considerate of Hungary and its aristocracy.

The Peace of Utrecht

The election of Charles VI as emperor was effected without any difficulties. The English left the coalition, and after a military reverse most of the Habsburg's allies joined the Treaty of Utrecht (1713). In the peace negotiations between Austria and France that were begun at Rastatt, Prince Eugene showed himself an unyielding and successful agent of Habsburg interests. Of the Spanish heritage, Austria gained the Spanish Netherlands, a territory corresponding approximately to modern Belgium and Luxembourg. These gains were somewhat impaired, however, by the Dutch privilege of stationing garrisons in a number of fortresses. In Italy, Austria received Milan, Mantua, Mirandola, the continental part of the kingdom of Naples, and the isle of Sardinia. The Wittelsbachs of Bavaria regained their country, but the treaty contained an appendix that provided for the eventuality of Bavaria being exchanged for the Spanish Netherlands. Of its gains, the north Italian territories were of the greatest value to Austria; the possession of Naples and the Netherlands, on the other hand, posed considerable military and political risks.

The problem of the Austrian succession. The extinction of the Spanish line of the Habsburgs and the fact that the emperor Charles VI was the last male member

of that house posed serious problems for the Habsburg territories, which at the beginning of the 18th century were held together mainly by the person of the sovereign, notwithstanding the fact that there were some institutions of central administration. A settlement was made in the form of a family ordinance. On April 19, 1713, Charles VI issued a decree according to which the Habsburg lands should remain an integral, undivided whole. In the event of the Habsburgs becoming extinct in the male line, the daughters of Charles or their descendants and, in default of any descendants of Charles, the daughters of Joseph I and their descendants and, after them, all other female members of the house should be eligible for the succession. As the son that was born to the Emperor in 1716 died after a few months, and only daughters were born to him after that (Maria Theresa, 1717; Maria Anna, 1718; Maria Amalia, 1724), this Pragmatic Sanction (a term used to characterize a pronouncement by a sovereign on a matter of prime importance) became of great significance. Austrian diplomacy in the last decades of Charles's reign was directed toward securing acceptance of the Pragmatic Sanction from all the European powers. It was published in 1720 and by 1722 had been recognized by the estates of all the Habsburg countries. Even the unanimous consent of the Hungarian diet was eventually obtained.

The Pragmatic Sanction of Charles VI

New conflicts with Turkey and the Bourbons. During the War of the Spanish Succession, Turkey had remained neutral toward Austria. But the Turks had attacked the possessions of the Venetians on the Pelopónnisos and the Ionian Isles. Austria tried to intervene and finally declared war. Prince Eugene defeated the Turks near the fortress of Peterwardein and conquered the strong bastion of Temesvár (1716). In the summer campaign of 1717 Belgrade again came into the hands of the imperial troops after a battle had been won against a Turkish relief army. In the Treaty of Passarowitz (1718) a frontier line was agreed upon that corresponded to the de facto situation. The Turks had to cede to the Austrians the Banat, the Turkish part of Syrmia, Walachia Minor as far as the Aluta, northern Serbia, Belgrade, and a strip of land along the frontier in northern Bosnia. A favourable trade agreement was also concluded.

During the Turkish war another crisis emerged. The Spanish minister Giulio Alberoni tried to initiate a policy of expansion in Italy. When Spanish troops landed in Sardinia and Sicily, the Emperor formed an alliance with Great Britain and France, later joined by the Netherlands (the Quadruple Alliance). After the English defeated the Spanish fleet, Madrid recalled its troops from the disputed territories. Austria received the more prosperous Sicily in exchange for Sardinia, which fell to Savoy. Charles then agreed to recognize the Spanish Bourbons. The gains from the Quadruple Alliance plus those of the Treaty of Passarowitz gave the Habsburgs the largest territory they were ever to rule. Their domains were far from unified, however, with the individual provinces showing a wide national, economic, cultural, and constitutional diversity.

Trading interests soon interfered with the alliance with the maritime powers. At first the attempts of the Ostend Company, which was backed by Charles VI, to enter into trade with India were quite successful. Because of the antipathy of the maritime powers, however, it seemed advisable to find an alternative to trade with Dutch and English colonial markets in the vast transatlantic empire of Spain. In 1725 Charles entered into an alliance with Spain, whereupon France, Great Britain, and Prussia formed a rival alliance. But soon after Russia was won over to the Habsburg cause, Prussia changed sides. As the outbreak of a European war seemed imminent, attempts were made at the Congress of Soissons to relax political tensions. Spain abruptly changed its alliances and concluded a treaty (1729) with England and France, the Netherlands joining in later. When Russia also began to waver, Prince Eugene tried to fall back on the traditional alliance with the maritime powers. After prolonged and difficult negotiations, England in 1731 accepted the Pragmatic Sanction, the Emperor in return giving a promise not to marry off his daughter Maria Theresa, the Habsburg heiress, to a prince who was himself heir to important domains. Austria finally dissolved the Ostend Company, having already suspended its charter in 1727. Charles VI then invested a great deal of energy in his endeavours to secure the recognition and the guarantee of the Pragmatic Sanction in the German diet. In this he was opposed by Bavaria and the elector of Saxony, but Austria finally obtained the guarantee of the Pragmatic Sanction at the Regensburg Diet (1732).

The question of the Polish succession led to a revival of the Austrian conflict with the Bourbon countries. Austria, with Prussia and Russia, favoured Augustus III of Saxony, the son of the deceased king, whereas France backed Stanisław I (Stanisław Leszczyński). On the military intervention of Russia in Poland, the Bourbons attacked Austria. The issue came to be mixed up with the problem of Lorraine, France dreading that on the impending marriage of Maria Theresa to Francis Stephen, duke of Lorraine, the latter's domains would be united with Austria's, so that French plans for the acquisition of Lorraine would be thwarted. France, Sardinia, and Spain simultaneously opened the war against Austria (1733). Prince Eugene, who was now aged, was able only to prevent a major success of the enemy on the Rhine. On the Italian front the Habsburgs fared even worse. The Battle of Parma ended undecided, but the Austrians were finally beaten near Guastalla. The small Austrian force that was stationed in southern Italy was unable to resist the Spanish attack, and Sicily and Naples were occupied by the Spaniards. In 1735 a Russian relieving corps reinforced the Habsburg front on the Rhine, and in northern Italy also there were a few successful operations of some local importance.

The question of the Polish succession

Direct contacts between Austria and France eventually led to the preliminary Peace of Vienna (October 3, 1735). Austria lost Naples and Sicily, which fell to a secondary branch of the Bourbons, and had to cede a tract of Lombard territory to Sardinia. As some compensation, Austria received Parma and Piacenza. Francis Stephen of Lorraine was promised Tuscany but had to renounce his hereditary duchy. On these conditions, France agreed to recognize the Pragmatic Sanction. The final peace was then concluded at Vienna in 1738.

Prince Eugene had died during the War of the Polish Succession. It soon proved disastrous that a successor of similar capacity of the prince was not found. During the second Turkish war of Charles VI (1737–39), Austria had joined in the Turkish–Russian conflict but without coordination of military operations. The Austrians, furthermore, underrated the Turkish forces and were themselves reduced by epidemics. The fortress of Niš was taken but was lost again soon thereafter. Peace negotiations conducted at Nemirov were broken off, and the war went on. The Austrians lost another battle at Grocka. Again peace negotiations were launched, in the course of which the larger part of the gains of the Peace of Passarowitz were lost. More disquieting even than the territorial losses was the loss in prestige. The epoch that had been the rise of Austria to a great power thus ended with reverses.

Social, economic, and cultural trends in the Baroque age. The Thirty Years' War and the Turkish wars had resulted in the devastation of large parts of the country and in great losses among the population, which suffered further reduction during the plague years of 1679 and 1713. The territories that had been wrested from the Turks had to be resettled systematically by German and other immigrants. The initiative for resettlement projects came from the official bureaucracy, the settlements being concentrated mainly in the south of Hungary. During the period of religious conflicts many Protestants had been exiled, but in the 18th century transportation to the various underpopulated parts of the empire was often resorted to.

In the industrial and commercial field, mercantilist ideas, encouraged by the government, were prominent from the 1660s on. The situation of the peasantry was a thoroughly unfavourable one. Tentative measures in the

Mercantilist policies after the 1660s

reigns of Leopold I and Charles VI to protect the peasants had little effect. Certain "model industries" (mostly textile factories) were established but were only partly successful. The economic policy of the absolutist state also resulted in strong interference with trade organizations. The guilds were suppressed or at least debarred from the new manufactures.

Trade was encouraged but yielded only small gains for the state. Industrial and commercial undertakings were managed in part directly by the state but largely through privileged corporations or private persons. Of some importance were the first (1667) and the second (1719) Oriental trading companies and the Ostend Company (1722). Trade in the Mediterranean was also intensified. Promising colonial ventures in India were discontinued for political reasons, however, in the middle of the 18th century. Under Charles VI new roads came to be planned and built on a large scale.

The state was in permanent want of money. This was a period of perpetual war as well as great economic investments, both entailing an excessive strain on state finances. At first the government resorted to the rich bankers such as Samuel Oppenheimer and his successor Samson Wertheimer for funds. Soon, however, it attempted to establish banking firms that were state controlled. The Banco del Giro, founded in Vienna in 1703, quickly failed, but the Vienna Stadtbanco of 1705 managed to survive; the Universalbancalität of 1715 was liquidated after a short period of operation.

After the victory of the Counter-Reformation, education was almost exclusively in the hands of the Catholic Church. The grammar schools of the religious orders, especially of the Jesuits and the Benedictines, set a very high standard for the most part. In 1677 another university was established at Innsbruck, the theological school of which was to acquire some fame. Historical writing flourished, the most outstanding works being those of two Benedictine brothers, Bernard and Hieronymus Pez; Gottfried Bessel, abbot of Göttweig; and Leopold I's official historiographer, the Jesuit Franz Wagner. The Austrian Jesuits were famous for their scientific and geographic researches, taking part in exploring China.

Baroque poetry, theatre, and music

Among the achievements of Baroque poetry, mention should be made of Wolf Helmhart of Hohberg, whose works offer interesting insights into the life of the nobility, and of Katharina of Greiffenberg. The theatre of the Baroque was of great appeal, being remarkable for the splendour of its decorations and the ingenuity of stage machinery. The plays produced ranked from the elaborate Italian opera to the blunt humour of the popular play. Music attained an especially high standard, encouraged by three emperors who were composers themselves (Ferdinand III, Leopold I, and Joseph I). Charles VI was also a skillful musician, and he engaged the services of Johann Joseph Fux, who came from eastern Styria and developed into an important composer and teacher.

Austrian Baroque culture is, however, most clearly revealed by the splendours of its architecture. At first the field was dominated by the Italians, but soon native architects stepped forth. Preeminent was Johann Bernhard Fischer von Erlach (first plan of Schönbrunn Palace, Karlskirche in Vienna, Kollegienkirche in Salzburg) and his son Josef Emanuel (Hofbibliothek). They were rivalled by Jakob Prandtauer (Herzogenburg, Melk, and part of Sankt Florian monasteries) and especially by Johann Lucas von Hildebrandt (Schwarzenberg Palace, Belvedere, Peterskirche in Vienna, monastery of Göttweig). Among native sculptors Georg Raphael Donner was the first in rank and quality of work. Fresco painting was represented by Johann Michael Rottmayr from Salzburg, Daniel Gran from Vienna, and Paul Troger from the Tirolian Pustertal. (E.Zo.)

II. The period 1740–1866

FROM THE ACCESSION OF MARIA THERESA TO THE CONGRESS OF VIENNA

The war period, 1740–63. In October 1740 the Holy Roman emperor Charles VI, the last male Habsburg ruler, died and was succeeded by his daughter Maria Theresa, the wife of the grand duke of Tuscany, Francis Stephen of Lorraine. Until the election of her husband as emperor in 1745, Maria Theresa was referred to only as queen of Hungary and Bohemia. Her descendants represented the House of Habsburg-Lorraine.

Charles VI had established a reasonably unified order of succession for all of the lands under the Habsburg sceptre (the so-called Pragmatic Sanction). By making broad concessions to foreign powers, he had secured their recognition of this act, and he died expecting a smooth succession for Maria Theresa. It was her misfortune that the poor state of Austria's military defenses during the last years of Charles's reign had vitiated his careful diplomatic manoeuvres, and it was of particular importance that four months prior to the Emperor's death another young ruler, Frederick II the Great, had succeeded to the throne of Prussia, which he wanted to raise to great power status. Thus it was that a major German state, which previously had been consistently loyal to the Austrian and imperial cause, became throughout Maria Theresa's entire reign the most determined foe of the Habsburg Empire. The specific issue in the conflict over supremacy in the German orbit was Frederick's intent to wrest the rich province of Silesia from the Habsburgs. The kings of Spain and of Piedmont-Sardinia and the electors of Bavaria and Saxony in full or in part challenged Maria Theresa's claims to succession, despite the fact that they had previously all acknowledged the Austrian heiress' right to rule. Frederick, on the other hand, cared less about the succession than about Silesia.

Conflict with Prussia over Silesia

By October of 1741 Frederick's army, then the best trained in Europe, had occupied Lower Silesia, and Maria Theresa in that month concluded a treaty in which she ceded this major and richest part of the province to Prussia under threats from other quarters. France, the hereditary foe of Austria and main inspiration of the anti-Habsburg coalition, had, in an alliance of Nymphenburg (May 1741), pledged to support Spanish and Bavarian claims on Maria Theresa's inheritance. Charles Albert, the elector of Bavaria, was promised part of the Alpine Hereditary Lands and Bohemia, and, with French support, was elected emperor as Charles VII. On the day of his coronation, Austrian forces occupied his own capital, Munich.

Maria Theresa was helped by the fact that two major European powers, Great Britain and Russia, did not wish to see the Habsburg Empire dismembered. The British and the Dutch soon gave Austria active support, and Saxony and Sardinia dropped out of the anti-Habsburg coalition to support Maria Theresa, whose chances of consolidating herself on the throne thus became more promising.

But the situation remained serious. Habsburg forces still had to face Spanish troops in northern Italy, and in the spring of 1744 France declared war on Austria. One year later, in May, French troops defeated British and Dutch forces at Fontenoy in the Austrian Netherlands (the major part of present-day Belgium).

Frederick II of Prussia, who had watched developments closely after the definitive peace with Austria (Treaty of Berlin, July 1742), was afraid that the Austro–British–Dutch coalition might eventually be victorious and that Maria Theresa might be able to turn her main forces against him and regain Silesia. Stealing a march on the Habsburgs, he invaded Bohemia in August 1744. This time Austrian resistance was more determined, and though Frederick failed in his designs on Bohemian territory, he succeeded in confirming the victory of his first campaign by a new peace treaty, the Treaty of Dresden, December 1745. Having thus secured his Silesian spoils, he could afford to support the election of Francis Stephen of Lorraine as Holy Roman emperor in succession to Charles VII (died January 1745).

Francis Stephen becomes Holy Roman emperor

The war over the Austrian succession continued. As far as the Habsburg power was concerned, the results of the fighting in Italy, Belgium, and Holland were on the whole indecisive. A defensive alliance with Russia (1746) protected Austria from the danger of a new Prussian attack.

During these latter stages of the conflict, the question of the preservation of the Habsburg Empire was no longer an issue. The problem was merely the price that had to be paid for survival. In the long, drawn-out peace negotiations of Aix-la-Chapelle, Wenzel Anton, Graf von Kaunitz (subsequently Prince von Kaunitz-Rietberg, from 1753–92 Austria's state chancellor) showed for the first time his mettle as a diplomat of consummate skill. Austria had to return some minor principalities in Italy to Spanish Bourbons until such time as the Bourbon lines there became extinct. A small frontier rectification in favour of Piedmont-Sardinia also had to be made, but neither of these adjustments was of great consequence. Far more important and painful was, of course, the loss of the major part of Silesia to Prussia, which opened the way to the rise of a new European great power as the most serious rival of the Habsburgs in Germany. It also meant a considerable drop in the number of Germans living within Habsburg lands, with important consequences in the rise of the national problem in the following century. On the other hand, Maria Theresa, a determined woman of courage, moderation, and charm, had managed to establish good relations with the frequently rebellious Magyars and had secured at least their nominal support at the height of the succession crisis.

The Habsburg Empire was not dismembered. Nor did it become a satellite state under the tutelage of other great powers. The outcome of the War of the Austrian Succession, except for the loss of Silesia, was a genuine defensive victory and proved to the world that Austria represented more than an agglomeration of lands under the same rule, acquired by wars and marriage contracts. In the two centuries since Ferdinand I, regent in the so-called Hereditary Lands, had become king in Bohemia, Hungary, and Croatia, a certain cohesion between the major historic units of the empire had clearly, after all, been established.

As far as the worldwide colonial aspects of the struggle were concerned, the results of the war were indecisive; certainly they were not to the advantage of Austria's traditional ally, Great Britain. A more permanent settlement of the conflict was reached only at the Treaty of Paris between Britain, France, Spain, and Portugal in February 1763—by and large to the disadvantage of the French, by then Austria's nominal ally.

During the brief era of peace—the eight years (1748–56) between the end of the War of the Austrian Succession and the Seven Years' War—Austrian military organization was revamped, and a state-wide system of conscription was introduced. The artillery in particular was greatly improved, and at the end of the period the Empress was ready once more to take up the struggle with Prussia. The new state chancellor, Kaunitz, had set an entirely new diplomatic stage for this difficult enterprise. The diplomatic actions taken at that time are generally referred to as the "reversal of alliances," actually a treaty system intended to isolate Prussia. It was in the interests of both Austria and France, hereditary enemies for two centuries, to become allies, since both were concerned about the rapid rise of an aggressive and unpredictable Prussia in the north. In the event of an Austrian reconquest of Silesia, the Austrian Netherlands were to be ceded to France. Russia, worried about Prussia's future designs in the east in regard to Poland, joined the coalition in January 1757, as did Sweden.

Cooperation with France against Prussia

Prussia forestalled the Austrian diplomatic and military preparations by means of a surprise preventive attack in 1756. But it was able to counterbalance the weight of the formidable coalition rallied against it only by a subsidy treaty agreement with Britain, the former traditional ally of the Habsburg Empire. The tremendous superiority of the great coalition in territory and population figures was, however, in part offset by divisions among its members, in whose success Austria had by far the major stake. In a purely military sense, Frederick II had the full advantage of an inner line of defense. His brilliance as a military leader compared to that of the careful but too cautious Austrian commander in chief, Leopold Joseph, Graf von Daun, also counted heavily in his favour. The French army was in full decline, and the forces from the Holy Roman Empire outside of Austria, convoked by the emperor Francis of Lorraine against the Prussian aggressor, failed lamentably.

Though Austrian and Russian victories were sparse compared to a string of Prussian successes, the superior power of the coalition would have inevitably resulted in victory if the new tsar, Peter III, a great admirer of the Prussian King, had not withdrawn in 1762 from the war. Further designs to reverse Russia's position and to side openly with Frederick were foiled by Peter's overthrow a few weeks later. The initiator of the plot, his former consort and now ruling empress, Catherine II, did, however, sign a separate peace with Prussia on the basis of the status quo. Only a few weeks later the French withdrew from the war as well, since the obvious inability of the Austrian troops to regain Silesia killed France's hope for the acquisition of Belgium. In consequence of this, Maria Theresa, in the hardest decision of her reign, was forced to give in. Thus it was that the Treaty of Hubertusberg, concluded with Prussia in February of 1763, merely confirmed the outcome of the two previous Silesian wars. The only minor concession made by Frederick was a pledge to cast the electoral vote of Brandenburg (Prussia) in the next imperial election in favour of Maria Theresa's oldest son, Joseph.

The most decisive result of the Austro-Prussian Seven Years' War was the rise of Prussia to great power status. Austria, though weakened, remained a great power, and compensatory acquisitions for the loss of Silesia were impending. But, taking a long-range view, the Prussian victory represented a decision in the first round of the struggle for supremacy in Germany between the Habsburg Empire and Prussia, a conflict that the Habsburg Empire was to lose decisively within a century.

Foreign policy, 1763–92. In 1772 Austria participated in the first partition of Poland and acquired Galicia. The initiative for the partition came from Frederick II. Catherine II the Great of Russia would have preferred to have an undivided satellite Poland as her neighbour, but Maria Theresa, anxious to prevent a further shift of the balance of power to Austria's disadvantage, participated in the partition, though she regretted the breach of all traditions of international order. In 1774 the Habsburg Empire was given the Bukovina to the southeast of Galicia from the Ottoman Empire as reward for Austrian mediation in a Russo-Turkish conflict. These enterprises were due in part to the influence of the young Joseph II, who, after the death of his father, Francis, in 1765, succeeded as shadow emperor of the Holy Roman Empire and became co-regent with his mother in the Habsburg lands.

Austria and the first partition of Poland

Joseph's ambitions went much further. In 1778, after the older line of the House of Wittelsbach had expired, he came to an understanding with the head of the younger Palatine line, according to which the Habsburgs would become heirs to the rule of Bavaria. Frederick II quite naturally opposed this agreement, which would much more than offset the loss of Silesia and would have given the Habsburgs renewed predominance in Germany. Joseph refused to yield, even though he was only lamely supported by his mother, and a new confrontation became inevitable. Military operations initiated in Bohemia in the summer of 1778 remained indecisive, however, and in May 1779 the Treaty of Teschen was negotiated between Maria Theresa and Frederick, both then in their old age and reluctant to fight another major war. Thus, Joseph had to put off his ambitious scheme, and the cession of the Innviertel by Bavaria, now incorporated into Upper Austria, had to serve as meagre consolation. Though Joseph's original plan would, in fact, never have been tolerated by the European great powers, in 1785, five years after the death of the great Empress, her intemperate son and successor reverted to his old scheme, this time proposing the exchange of Bavaria against the Austrian Netherlands. Again Frederick thwarted the plan, and Joseph's designs to undo the balance established by the Silesian wars were put to rest.

Joseph's foreign policy lacked success in other respects,

too. His eagerness to barter the noncontiguous Austrian Netherlands for Bavaria resulted in part from the fact that he was frustrated in his understandable designs to undo the restrictions imposed on the Austrian rule there by the peace treaties of Utrecht and Rastatt of 1713 and 1714. These restrictions included the closing of the Scheldt River by the Dutch and Dutch rights to garrison the Austrian border fortresses against France at Austrian expense. But Dutch and French objections blocked Joseph's plan.

Failing thus in the west, Joseph hoped, as Russia's ally, to make at least some gains in a new Austrian war against the Turks. This struggle, started in 1788, ended the year after Joseph's death (1791), again in a meagre compromise. Thus the Emperor, whose great gifts included skill neither in diplomacy nor in military strategy, was in his conduct of foreign affairs far more unfortunate than most of his predecessors, who were not in other respects his intellectual peers.

Accession of Leopold II, 1790

His brother and immediate successor, Leopold II, heretofore Grand Duke of Tuscany, certainly was Joseph's intellectual peer, particularly in his ability as diplomat. He inherited from his brother a domestic situation in which Hungary and Belgium were in full revolt. In international relations he had to carry the mortgage of the sterile Turkish War begun by his brother, and he was faced as well by the possibility of a new partition of Poland, which might exclude Austria as beneficiary. But above all he had to deal with the spectre of an ever more serious revolutionary situation in France, which might well involve Austria in a long war of unpredictable outcome.

In domestic matters, Leopold, an enlightened ruler in Tuscany, had to retreat cautiously and regretfully from some of the reform legislation in the Habsburg Empire. In foreign affairs he had to end the Turkish War by the best possible compromise. As to the Polish question, encouraged by the spirit of reform in truncated Poland, he wanted to avoid a new partition altogether, but at the same time he wished to keep relations with Russia and Prussia on an even keel. This included, of course, an understanding in regard to the foremost international problem of his reign—the relationship to revolutionary France. Though naturally opposed to the revolutionary spirit, Leopold's course was remarkably free from considerations arising from close family ties, specifically the fate of his brother-in-law, King Louis XVI, and sister, Queen Marie-Antoinette. Leopold approved of the concept of a French constitutional monarchy, but to be prepared for all contingencies, in July 1790, he secured an understanding with Frederick William II, the new king of Prussia, concerning common interests of both countries in the east. At this time relations with France were aggravated further by the French seizure of the estates of great nobles in the Alsace, since they could be considered subjects of the Holy Roman Empire as well. The establishment of the headquarters of anti-revolutionary French political refugees in the German Rhineland created additional tension. In a second meeting with Frederick William II at Pillnitz in Saxony in August 1791, the two rulers publicly expressed their concern with the French situation. But joint intervention would depend on British and Russian support. In February 1792 the Emperor considered it opportune to go one step further and concluded a defensive alliance with Prussia. Whether he would eventually have taken the final step and gone to war with France is conjectural; on March 1, 1792, he died unexpectedly. Less than two months later Austria did find itself at war, and while the declaration to that effect was made by France, the new emperor, Francis II, Leopold's son, a young man of modest abilities, had done little to prevent it.

The struggle with France, 1792–1815. In the ensuing era of almost continuous warfare that lasted for nearly a quarter of a century, the Habsburg Empire was involved more heavily than any other continental European power. This was partly because of its geographic location in the centre of Europe, partly because of Francis' position as Holy Roman emperor until 1806. The gradual transition from enlightened regimes of Joseph II and Leopold II to an increasingly conservative spirit under his rule was of additional significance. At the beginning of the war period Austria fought the spirit of the French Revolution. Supported by Spain, Portugal, and, above all, Prussia, it was engaged in the War of the First Coalition from beginning to end (1792–97). Yet Prussia dropped out of the war in 1795 to prepare for the third partition of Poland, after Prussia and Russia had jointly excluded

Expansion of the Austrian Habsburg domains until 1795.

Austria from the second partition. The Austrians fought against the French revolutionary armies in Belgium, Holland, and the Rhinelands with indifferent success. While the emperor Francis' far abler younger brother Archduke Charles checked the French in southern Germany, the young Bonaparte routed the Austrians in Italy, crossed the Alps, and invaded Carinthia and Styria. In April 1797 Austria had to agree to the armistice and Preliminary Peace of Leoben and in October of the same year to the permanent one of Campo Formio. The Habsburg Empire was let off relatively lightly. While the Austrian Netherlands (an indefensible province anyway) and Lombardy had to be ceded, territories of the Republic of Venice to the east of the Adige were gained. This forced participation in the destruction of the ancient Venetian republic put Austria in no better light than Prussia and Russia in the second partition of Poland. On behalf of the Holy Roman Empire, Francis also had to cede the left bank of the Rhine to France and accept a scheme by which the German ecclesiastical princes were deprived of their secular powers (Congress of Rastatt, 1797–99). This action further weakened Francis as Holy Roman emperor, although his position as ruler of the Austrian lands was strengthened somewhat by the third and final partition of Poland in 1795, in which Austria gained West Galicia as far as the Bug River.

Gains and losses at the Peace of Campo Formio, 1797

In the War of the Second Coalition (1798–1802), three major European powers—Prussia, England, and Austria—supported by Portugal, Naples, and the Ottoman Empire, represented the anti-French alliance. The theatres of war were again southern Germany and Italy, and, this time, Switzerland. When, in 1800, the Russian armies withdrew, the Austrian position became precarious. French advances in northern Italy and southern Germany were followed by the Armistice of Steyr in December 1800 and by the Treaty of Lunéville in February 1801. According to the terms of the latter, the provisions of the Treaty of Campo Formio of 1797 and the cession of the left bank of the Rhine to France were confirmed. The system of French satellite republics in Holland and Italy had to be recognized. Thus the main Habsburg territories were left intact, but Austria's position in Germany was further weakened.

Austria's chances in the War of the Third Coalition (1805–07) at first seemed promising. There was genuine military cooperation with Russia, and the coalition was able to count on the naval and financial support of Britain. Prussia, however, delayed a decision concerning its participation. The Austrians were defeated in Germany and the critical situation thus created forced their retreat from Italy as well. In November 1805 French troops occupied Vienna for the first time. On December 2 the Austrians and Russians were badly defeated by Napoleon at Austerlitz in Moravia, and the harsh Treaty of Pressburg was imposed on Austria hardly three weeks later. According to its principal provisions the Venetian territories gained in 1797 had to be ceded together with Tirol, Vorarlberg, Brixen, and the Trentino. The confirmation of Austria's incorporation of Salzburg and Berchtesgaden (1803) could not serve as adequate compensation for these severe losses. The Habsburg Empire had ceased to be a great power, and the Holy Roman Empire, in the face of French advances toward the east, was doomed.

Battle of Austerlitz, 1805

It had not been difficult to foresee these developments when Bonaparte proclaimed himself emperor of the French in 1804. To maintain Austria's position as best he could, and anxious to preserve the imperial title for his house, Emperor Francis proclaimed himself emperor of Austria on August 14, 1804. This purely declaratory manifesto, never submitted for the consent of the Estates of his lands as the Pragmatic Sanction had been a century before, pertained to all the Habsburg realms and might well therefore have been challenged, above all by Hungary. Yet this was not a major issue in the turmoil of the times. A month after Napoleon established the Confederation of the Rhine, Francis accordingly abdicated the empty title of Holy Roman emperor (August 1806). Invested only with an imperial title devoid of a great historical tradition, he ruled henceforward as Emperor Francis I of Austria.

The period from 1805 to 1809, when Austria was compelled to join the French continental blockade system, was one that saw the rise of feelings that were truly national, even though they were largely confined to the Austro-German orbit. A new, energetic, and idealistic foreign minister—Johann Philipp, Graf von Stadion—attempted to prepare the diplomatic ground for a renewed struggle against French expansion, and the archduke Charles organized a national militia. Encouraged by continued British resistance and by the guerrilla warfare of the Spanish people against the French occupation, Austria, on April 9, 1809, declared war on France. In contrast to a prostrate Prussia and to the German princes who catered to the whims of the foreign conqueror, the Habsburg Empire—bravely and vainly—tried to redress the balance in Europe. By mid-May 1809 Vienna was in French hands, though this time only after an artillery bombardment. The Austrians fought on, and a week later, at Aspern, on the left bank of the Danube opposite Vienna, Archduke Charles administered the first defeat to a French army commanded personally by Napoleon. He failed, however, to take advantage of this victory, and six weeks later the Austrians were decisively defeated at Wagram. Peace was dictated by the victors at the imperial castle of Schönbrunn in October 1809. This time Salzburg, a part of Upper Austria, and northern Tirol became parts of Bavaria; southern Tirol became part of the satellite kingdom of Italy, and West Galicia part of a new puppet Grand Duchy of Warsaw. The western parts of the Austrian southern Slav territories were ceded to France, and a heavy indemnity had to be paid.

A by-product of the defeat was the crushing of the heroic rising of the Tirolean peasants and the execution of their brave leader, Andreas Hofer. A far-reaching economic consequence of the war period was the state bankruptcy of 1811, which reduced the Austrian currency to one-fifth of its previous value.

Now a remarkable change in Austrian foreign policy took place. Shortly before the conclusion of the Treaty of Schönbrunn, Count (later Prince) Clemens Metternich, formerly ambassador to Napoleon's court, was appointed minister of foreign affairs in place of Stadion, whose anti-French policy had failed. Metternich conducted foreign policy for almost 40 years, until the outbreak of the Revolution of 1848. His first task was to shift from an anti-French policy, based partly on ideological grounds, to one of expedient cooperation until the day when new opportunities to restore Austria to its former rank as a great power would present themselves. He pursued this policy with great skill. One of his first moves was to persuade his imperial master to agree to Napoleon's request for the hand of Francis' eldest daughter, Marie-Louise (1810). Humiliating as acceptance of this demand by an upstart ruler was to an ancient dynasty, Metternich considered it conducive to Austrian interests.

Metternich becomes minister of foreign affairs

In the War of 1812, Austria—France's new ally by marriage—was forced to put up an auxiliary corps under Karl Philipp, Prince zu Schwarzenberg, but Metternich's instructions were that any significant encounter with the Russian forces should be avoided. After the annihilation of the great French army in Russia and the continuation of the war in Germany by Russia and Prussia with the support of England and Sweden, the Habsburg Empire managed to stay neutral, thus raising the price for its subsequent intervention. It was clear that such intervention could only be on the side of the anti-French alliance, but Austria first offered Napoleon its "armed mediation," provided Napoleon would give up his overlordship of the German territories on the right bank of the Rhine and dissolve the Grand Duchy of Warsaw. The demand for the return of all Austrian territories ceded to France in the Treaty of Schönbrunn was raised. Napoleon, as expected, rejected the offer, and in August 1813 Austria became a partner in the War of Liberation, although the national issues previously raised by Stadion were played down by the conservative Metternich.

By its belated entry into the grand coalition, Austria had secured particularly favourable terms. Even though the Habsburg forces were smaller in number than those of Russia and Prussia, Prince zu Schwarzenberg was appointed commander in chief of the allied armies. Although a strategist of no better than average ability, he proved to be a skillful moderator among the ambitious generals of the coalition. His much abler chief of staff, Joseph, Graf Radetzky, must be credited with drawing up the plans for the great Battle of Leipzig (October 16–19), which broke the back of the French operations in Germany. Napoleon rejected an offer on the part of the allies that would have conceded the Rhine and Alp frontiers including Belgium and Holland to France. It is probable that Metternich at this time would have liked to keep a greatly weakened Napoleon in power as the best bulwark against the danger of a new French revolution.

On New Year's Eve, 1813, the war was carried into France. Had it not been for the tremendous superiority of the allies and the exhaustion of the French people, Schwarzenberg's indifferent strategy would hardly have secured victory. At it was, the allies were able to take Paris by the end of March 1814, force Napoleon's abdication, and secure the restoration of the Bourbons. The Treaty of Paris of May 30, 1814, gave France the relatively favourable frontiers of 1792. The reorganization of Europe was to be arranged at a congress that was to meet in Vienna in September 1814 under Metternich's chairmanship.

Austria and the Vienna Settlement, 1815

In the negotiations, which lasted until June 1815, Austria sided in general with Bourbon France and with England. Austria regained most of the territories that it had lost in the Treaty of Schönbrunn. Its former rule in the Austrian Netherlands and in southwest Germany was not restored, since Metternich saw little advantage in the control of noncontiguous areas. The Habsburg Empire was compensated in Italy: not only were Lombardy and the Venetia recovered; Tuscany, Modena, and —for the lifetime of Marie-Louise—Parma and Piacenza, also, were established as Habsburg semi-independent appendages in Italy. Napoleon's consort, now separated from him, was to rule in these two last-mentioned principalities. It is questionable whether the restoration of the Holy Roman Empire might not have served Austria's interests better than the establishment of the German Confederation (June 1815) under Austria's presidency.

In line with Emperor Francis' and Metternich's wishes, the confederation gave Austria, though only jointly with Prussia, far-reaching control over German affairs. This control was aimed in particular at preventing the establishment of representative constitutional governments and liberal institutions in any of the 50 German states. Reestablishment of the Holy Roman Empire would have struck a strong chord in the heart of the Austro-German peoples but this was precisely what Metternich, fearful of any expression of the popular will, did not want. Following the same line of thought, he believed that the dismemberment of Italy would prevent the future unification of the country under liberal national banners.

Metternich's skill restored Austria to great power status and even resulted in his diplomatic leadership as the so-called coachman of Europe. But the two major issues that were to severely weaken the position of the Habsburg Empire within the next half-century—the German and the Italian problems—were accentuated rather than solved by the settlement of 1815.

Reforms and their reversal, 1740–1815. The enlightened era in the Habsburg Empire comprises the reigns of Maria Theresa (1740–80) and those of her two brilliant sons, Joseph II (as co-regent from 1765 to 1780 and in his own right from 1780 to 1790) and Leopold II (1790–92). Maria Theresa, much better adjusted to reality than her immediate successor, drew chiefly on pragmatic experience. She wanted to secure the well-being of her subjects and to affirm the control of the state as far as compatible with traditions and customs. Joseph II intended to move faster and more in line with abstract, enlightened principles. He had little patience with references to tradition and was in some respects less prejudiced than his mother. Leopold II was, in his basic views, closer to his brother than to his mother, whom he resembled in his judicial temperament. While he would presumably have liked to expand Joseph's reforms, it was the main task of his all-too-short reign to quell the revolts in Hungary and the Austrian Netherlands and to settle the unrest in the Hereditary Lands and Bohemia. Thus he was forced to retreat in essence from the reforms of Joseph II to those of Maria Theresa. Under his son, Francis (1792–1835), the trend gradually became one of extreme conservatism and outright reaction, in part because of the preferences of this mediocre ruler but largely as a result of the counter-revolutionary spirit of the times.

Administrative reforms

The basic idea of the administrative reforms was to transform the estates system into a partially bureaucratic administration based on civil service rules, although Maria Theresa considered it expedient to preserve at least the external, but by then rather hollow, shell of the estates structure. Thus, on the provincial level, the speakers of the crownland Estates presided over most of the agenda of the provincial administration. On the top level of administration for the whole empire, the state chancellery of old was divided into a court chancellery entrusted with domestic agenda and a state chancellery proper for foreign affairs. An advisory state council was composed in part of great nobles and in part of high bureaucratic officials. A directory on public affairs for the Bohemian and Hereditary Lands was subsequently converted into the United Austrian and Bohemian Court Chancellery. A new commerce directory for the whole empire was established.

Maria Theresa introduced restrictions on the largely arbitrary patrimonial jurisdiction of the lords on their estates and transferred venue in matters of capital offenses to fewer and better courts. She steadfastly opposed the abolition of torture, though not on account of any basic cruelty of her character. She simply could not imagine how sufficient evidence could be gathered without forced confession. It was not until 1776 that she was finally persuaded to abolish torture. In this respect, Austria had lagged behind France, Prussia, and even Russia.

Joseph, who had much more understanding of judicial questions than did his mother, did much to improve civil and criminal procedure. He provided free legal counsel for peasants in litigation with lords. Although criminal justice administered on the basis of the strictly utilitarian philosophy of the Emperor was still extremely harsh, Joseph did much to improve civil law. The superb code of civil law of 1811, initiated in substance under Joseph, came to fruition only under Emperor Francis.

Economic policy

As to public finance, both the nobles and the church lost various privileges in regard to exemption from taxation. Craft guild restrictions, particularly those concerning the admission of apprentices, were loosened. Much was done to help the peasants in the newly gained trans-Carpathian territories (Galicia and Bukovina) by direct and indirect government assistance, the abolition of customs duties for exports to other crownlands, and by the granting of various privileges for new settlers. The basically mercantilist economic policy of Charles VI's reign was somewhat changed in line with the influence of physiocratic and so-called populationist theories. Henceforth, skilled human labour, and not precious metal, was gradually to become the yardstick of national wealth. This led, on the one hand, to restrictions on emigration, and, on the other, to improvements in vocational training. Severe import restrictions on so-called luxury goods, which frequently had killed demand rather than encouraged the rise of competitive domestic industries, were somewhat modified. Joseph II went further. In regard to industrial and commercial enterprise, he was, much in contrast to his overall political philosophy, a strong supporter of private initiative.

Maria Theresa went a long way toward alleviating the

lot of the unfree peasants. For the first time in Austrian history, the service obligations of the peasants were strictly defined. Above all, the ambiguous double role of the lord as landowner and official of local government was put under government supervision.

Joseph expanded the reforms of Maria Theresa. He further reduced the governmental functions of the lord and by legislation of 1781 abolished serfdom altogether outside of Hungary. Similar legislation was introduced in Hungary between 1784 and 1786. The mistaken belief of the Hungarian peasants that abolition of serfdom made them free owners of the land was, however, a major cause of the revolutionary situation at the time of the Emperor's death. The full conversion of the peasant's personal services outside of Hungary into obligations to be paid off in cash was somewhat precipitate, for money, in an agricultural economy still largely based on barter, was lacking. Leopold II reversed Joseph's peasant legislation so that things stood much as they had been at the time of the death of Maria Theresa. There was little further change until 1848.

Educational reforms of Maria Theresa

The greatest single achievement of Maria Theresa's reign was her educational reform at the elementary and intermediate levels. Three types of schools were introduced: (1) elementary schools in all but the smallest villages, in which reading, writing, and arithmetic were taught, with attendance being compulsory; (2) district schools in every administrative district, in which history, more advanced study of the vernacular language, geometry, drawing, and some vocational training were offered; and (3) so-called normal schools, established in the crownland capitals. Meant to be terminal schools for the urban middle class, they served also as teacher-training institutions. As for higher education, reforms under Maria Theresa were handicapped by her mistrust of—as she perceived them—radical enlightened ideas. She was, however, persuaded to transfer censorship from Jesuit control to a new and somewhat more liberal state agency. Some new chairs in the natural sciences and law were established at the University of Vienna, but progress in this respect was limited, and non-Catholics were altogether barred from graduating. Maria Theresa also founded some outstanding special schools. One of them was meant to train young nobles for public service, another, officers for the armed forces.

Joseph's reign proved to be disappointing as far as education was concerned. Censorship, it is true, was eliminated—at least as far as criticism of the government was concerned. But the Emperor's utilitarian objectives precluded practically any purpose in higher education other than the training of civil servants. The publication of literature that could not serve as a textbook for disciplines of immediate practical use was not encouraged. Under Emperor Francis, censorship was reintroduced in full force.

Radical church reforms are usually associated with Joseph's reign, but here also Joseph followed in the footsteps of his mother. Both rulers were devoutly religious, but both believed in firm state control of ecclesiastical matters outside of the strictly religious sphere. Following populationist doctrines, the Empress ordered restrictions of religious holidays and the prohibition of ecclesiastic vows prior to the 24th birthday. She insisted that clerics were subject to the jurisdiction of the state in nonecclesiastical matters. The acquisition of land by the church was to be controlled by the government. She took action against the Society of Jesus (Jesuits), but only in 1774, after the Pope had ordered its suppression.

Joseph's most radical measures were the issue of the Edict of Tolerance of 1781 and his monastic reforms. The edict and the legislation attached to it gave Protestants near equality and gave Jews the right to enter various trades, as well as permission to study at universities. In this respect the difference between the Emperor and his mother was fundamental. While Maria Theresa viewed Protestants as heretics and Jews as the embodiment of the Antichrist, Joseph fully respected other Christian denominations and entertained secret plans to establish an Austrian state church independent of Rome.

As to the monasteries, Joseph held that institutions not engaged in useful work for the community, above all agriculture, care of the sick, and education, should be dissolved. Consequently, about a third of the Austrian monasteries ceased to exist, their former members being ordered to learn skills adapted to secular life. The property of the dissolved institutions was used to pay for the upkeep of parishes and to finance the establishment of new parishes.

Control of church discipline and church property were further tightened by Joseph; seminaries for the training of the clergy were secularized. He even tried, without success, to simplify radically the Catholic liturgy. Many of his religious policies were discontinued in the reaction that followed, but the Edict of Tolerance and the monastic reform were maintained.

Joseph was unsuccessful in his efforts to achieve empire-wide administrative centralization. In particular, his attempt to enforce the use of German as the language of administration in Hungary was a failure and certainly accelerated the growth of Magyar nationalism and anti-German feeling there. On his accession, Leopold II was forced once more to recognize Hungary as a separate unit of the Habsburg lands.

THE AGE OF METTERNICH, 1815–48

Foreign and domestic policy. Austria's leading diplomatic position after the conclusion of the second peace treaty of Paris in November 1815 was never anchored primarily in the power potential of the Habsburg Empire but in the skill of Metternich and his adviser, Friedrich von Gentz, in establishing a common conservative platform acceptable to east and west. Its ideological foundation was meant to be the Holy Alliance of the European powers of September 1815, as proposed by Tsar Alexander I and as opposed by the British government. It was meant to organize Europe on the basis of Christian authoritarian principles, implying the possibility of intervention by foreign powers in revolutionary or even merely liberal movements abroad.

The Concert of Europe

In the ensuing period of the Concert of Europe (an attempt to establish a directorate of the great powers over European affairs), which saw limited cooperation among the great powers at the conferences of Aix-la-Chapelle (1818), Troppau (1820), Laibach (1821), and Verona (1822), France was commissioned to put down a revolutionary rising in Spain and Austria was to suppress a revolt against the brutal oppression by the Bourbon regime in the Kingdom of the Two Sicilies. These actions caused Britain to withdraw from the concert of the five great powers. The shattering blow to Metternich's concept of the anti-revolutionary unity of the European powers, however, was Russia's support of the Greek independence movement between 1821 and 1830. Therewith his system in international relations had for all practical purposes broken down and could not be restored but merely patched up.

Two immediate problems for Metternich were the maintenance of Austria's hold in Italy and the struggle with Prussia for supremacy in Germany. As to Italy, the secret Carbonari Movement and the liberal Young Italy promoted by Giuseppe Mazzini were in full swing throughout the whole Restoration period. The French July Revolution of 1830, another defeat of the Metternich system, encouraged open revolt in the Austrian appendages of Parma and Piacenza and in the Papal states. Austrian troops had to restore the old order by force of arms.

The handling of the Italian question, while it did not really undermine Austria's great power position, gave Austria the image of a tyrannical oppressor of a freedom-loving, highly cultured people. That the Austrian administration in Lombardy-Venetia was neither corrupt nor by contemporary standards particularly inefficient counted little in Austria's favour.

Even more serious was the German problem, which involved issues of real power for the whole Habsburg Empire. Such issues had great emotional impact on the Austro-Germans in general and in particular on the liberal

intelligentsia. In their rejection of liberal, potentially revolutionary trends as dangerous to their rule, the German princes saw eye to eye, but the Emperor of Austria and the King of Prussia were deeply divided as regards the issue of supremacy in Germany.

The Wartburg Festival (1817) of German academic youth celebrating the tercentenary of the beginning of the Reformation had worried the princes deeply. The assassination of the playwright August von Kotzebue as an alleged Russian spy by a radical German student gave the conservative powers the opportunity for which they had been waiting. Under the leadership of Metternich and with the active cooperation of the increasingly reactionary Tsar Alexander, the Carlsbad Decrees were passed in August 1819. These put the German and Austrian universities under strict government control. Student associations were forbidden, censorship was strengthened. An investigatory commission was set up in Mainz, and teachers, writers, and students suspected of liberal views were blacklisted throughout Germany and Austria. In 1824 the German Confederal Assembly in Frankfurt renewed these provisions at the instigation of Metternich for an indefinite period. New oppressive measures on an even larger scale were again introduced at Metternich's behest by the German Confederation as answer to republican demonstrations at Hambach (Palatinate) in 1832 and at Frankfurt in 1833. The restrictions were in essence still in force at the time of the outbreak of the Revolution of 1848.

The Carlsbad Decrees, 1819

In the conflict between the two leading powers in the confederation, Prussia took the lead first in the economic field. In 1819 Prussia and its largely noncontiguous domains were merged into one customs association. Treaties of adherence by small neighbour states followed. By 1829 most German states had joined the association. There were some major exceptions—most notably Austria. The whole plan was indeed directed primarily against Austria. Counter movements such as a south German customs union and a more limited central German one collapsed. When, on January 1, 1834, the German customs union (the Zollverein) was completed, Frankfurt, Baden, and the Hansa cities stayed outside with Austria. Prussia had however won an important political as well as economic victory. It made the German north and west (the Rhineland) the centres of gravity of further industrial development.

At this time Metternich's power was not only externally but also internally in decline. In 1824 Franz Anton, Graf von Kolowrat, a great noble of Czech origin, was appointed minister of state. Somewhat more enlightened than Metternich, particularly in regard to the Austrian Slavs, he carried great weight in matters of domestic administration. The situation changed further when in 1835 the emperor Francis died and was succeeded by his eldest son, the feeble-minded crown prince Ferdinand. Metternich believed that even a feeble-minded prince could not be bypassed, but the actual power of the government was transferred to a state conference consisting of two archdukes (both of limited intelligence) and Kolowrat and Metternich as permanent members.

Metternich's decline

Metternich's last success occurred in 1846 when a revolt, initiated by Polish nobles in Galicia, was suppressed after the peasants, indirectly supported by the government, had turned against their oppressive masters. Because the revolutionary ferment had been fed from the city republic of Cracow, Russia and Prussia agreed that Austria should incorporate the ancient Polish coronation city into Galicia.

REVOLUTION AND COUNTER-REVOLUTION, 1848–59

The revolutions of 1848–49. Metternich's victory was short-lived. Early in March 1848 a revolution began in Austria as soon as news about the success of the revolution in France had spread. In Vienna, crowds of people led by students and young academicians asked for liberalization of the regime. A clash with the military led to bloodshed. The riots, in which workers participated, thereupon spread further. The demand for the aged Metternich's resignation was met by the crown at once, for it was expected that after this symbol of reaction was overthrown, order would quickly be restored. But encouraged by this first and unexpected quick success, the revolution spread across the empire.

Three main aspects of the Austrian Revolution may be distinguished: social, democratic liberal, and national or multi-national.

As to the social revolution, the Habsburg Empire was less industrialized than any major European state west of Russia. Thus, while workers participated courageously in the risings in Vienna, the impact of their intervention was small and had little effect on governmental policies. There existed a far stronger movement for the full emancipation of the peasants, which meant giving them clear title to the lands without any further obligation of service to the lords. The newly elected constituent assembly in Vienna, in September 1849, passed legislation to this effect. It was sanctioned by the Emperor, but the actual enforcement of this sweeping reform, in particular in regard to the financial indemnity to be paid by the peasants, was left to the postrevolutionary regime. Still, the influence of peasant emancipation on the revolution was a powerful one. The largest and basically most conservative social class appeared satisfied and by the autumn of 1848 was no longer a major factor in the revolution.

Concerning the liberal democratic revolution, a moderately conservative new cabinet had by April 1848 drawn up a new constitution usually referred to as the Pillersdorf Constitution, after the name of the minister of the interior. This document was, on the whole, fairly democratic. At about the same time, a liberal government under Count Lajos Batthyány was formed in Hungary, in which some of the great leaders of the nation and the dominant figure of the more radical reform policy, Lajos Kossuth, participated. These men drew up a new constitution for Hungary. It provided far-reaching home rule for the country and, except for two provisions, was agreed to by the Emperor. The unresolved provisions were a demand for a separate budget and a more important demand that Hungarian troops not be called to action without the approval of the Hungarian government.

Developments in Hungary

In the meantime František Palacký, the great Czech historian and recognized intellectual leader of his people, had in a public letter rejected the participation of Czech representatives in the first freely elected German national assembly, which was to convene in May 1848 in Frankfurt. While the lands of the Bohemian crown were legally a portion of the territory of the Habsburg Empire that belonged to the German Confederation, Palacký held that the Czechs, who strongly affirmed the existence of a multi-national Austria as a bulwark against Russian advances to the west, could never be part of Germany.

German Austrian liberals and enlightened conservatives participated gladly in the National Assembly in Frankfurt. One of the few enlightened, though not liberal, members of the imperial house, Archduke John, was elected temporary regent of the new Germany, while a moderate Austrian liberal, Anton Ritter von Schmerling, was appointed prime minister in September 1848. Inasmuch as the Frankfurt assembly had no executive power, these positions meant little in practical terms. The assembly immediately began to work on the draft of a constitution, and here the Austrian question represented one of the foremost divisive issues. The Grossdeutsch (Large German) faction wanted to include the Austrian Germans but was opposed to any overall association with the non-German majority of the Habsburg Empire. The Kleindeutsch (Small German) faction thought the only way to avoid this difficulty was to exclude Austria altogether. The solution adopted in the German federal constitution in May 1849 affirmed the incorporation of the German Austrian lands as long as they had a constitution and administration separated from that of the non-Germanic parts of the Habsburg Empire. But the practical effect of these provisions was nil, because by the time the constitution was adopted the counter-revolution was in full swing. Hardly a month later the Austrian deputies at Frankfurt were recalled. The Prussian government fol-

lowed suit and about a month later the remainder of the parliament, which had been transferred to Stuttgart, was dissolved by simple police action. In essence this meant the end of the revolution in Germany, but not the end of the Austro-Prussian conflict as it had developed during the revolution.

The Prussian government wanted to exclude Austria in a roundabout way from the confederation. A union scheme was therefore proposed by Prussia and put before a new, no longer revolutionary, assembly at Erfurt. Austria did not participate in these proceedings. According to the Erfurt plan, supported for a time by Saxony and Hanover, the German Confederation should be divided into two sections, an inner German section under the leadership of Prussia and a second, purely nominal, section consisting only of Austria in alliance with the inner section. The Austrian government, under its energetic prime minister, Felix, prince zu Schwarzenberg, rejected this plan and forced the states that supported Prussia to withdraw from the scheme. Finally, the old confederation was again called into session at Frankfurt. Schwarzenberg would in fact have liked to create a central European union including the whole of the Habsburg Empire. But this goal, which would have made Austria supreme in the whole of central Europe, was unobtainable.

Provisions of the Erfurt plan

In deciding to take his stand on a relatively minor issue, the question of the right of Prussia or Austria to intervene in a revolutionary situation in Electoral Hesse, Schwarzenberg forced Prussia to withdraw and hence to recognize the restoration of the Confederation of 1815 under Austria's presidency (the Punctation of Olmütz, November 1850). This was the last, and a merely diplomatic, victory of Austria over Prussia. It was achieved only because Tsar Nicholas I backed the Habsburg Empire, which seemed to him the more reliable conservative power. The Austrian triumph proved to be short-lived. It merely strengthened the Prussian resolve to undo the humiliation as soon as an opportunity offered itself.

Such an opportunity was not long in coming, since the lack of cohesion within the Habsburg Empire had become painfully obvious during the course of the revolution. While riots in Prague, Lwów, and Cracow could be quelled, events in Hungary took a collision course. The new government there, though eagerly introducing educational and social reforms, was at the same time set on a policy of rapid Magyarization. The result was risings among non-Magyar Hungarian national groups—Croats, Serbs, Slovaks, and Romanians. The conflict with the government in Vienna stiffened when the diplomatic Batthyány was replaced by the far more radical Kossuth, in September 1848.

A further aspect to be considered was Austria's involvement in a war with Piedmont-Sardinia, whose king, Charles Albert, intended to drive the Austrians out of northern Italy. His army invaded Lombardy in March 1848. By August, however, the Sardinians were decisively defeated in the Battle of Custoza. An armistice was concluded in late summer of 1848, but the war, because of violation of its provisions, was resumed by Sardinia in March 1849. After the new attack was repelled, peace was restored on the basis of the status quo in August 1849. Although the Sardinians were no match for the Austrian army, the Italian campaigns made it impossible for Austria to deal with the Hungarian revolution effectively.

The Slav problem

In the meantime, the Slavic question had become a major issue in the western part of the empire as well. In June 1848 a Slav congress was convoked in Prague, in which Czechs, Croats, Poles, Ruthenians, Serbs, Slovaks, and Slovenes were represented. Before the congress could terminate its deliberations, street riots offered the government a pretext to terminate the proceedings. Even though a final program of action could not be agreed upon, the results of the Prague Congress were of great importance in the history of Pan-Slavism. Beyond this, various plans for federalization and local autonomy within the empire were discussed.

By September 1848 the Hungarian situation had deteriorated further. Troops led by the ban (viceroy) of Croatia, Josip von Jelačić, entered the country under orders to restore royal authority. The action created general indignation in Magyar Hungary, and the imperial commander in Budapest was lynched during a riot. Thereupon the Hungarian Reichstag was dissolved by royal decree.

The situation in Hungary encouraged a new revolutionary rising in Vienna, in early October 1848. It was the last major attempt in the German-speaking orbit to regain the revolutionary initiative. The imperial minister of war, Theodor, Graf Latour, was lynched by a mob, and an imperial army under the command of the arch-reactionary Prince Alfred Windischgrätz occupied Vienna, meting out harsh retribution to the revolutionary leaders.

A momentous change took place on December 2, 1848. The feeble-minded Emperor Ferdinand, dubbed by official historiography "the Benign," abdicated in favour of his 18-year-old nephew, Francis Joseph, from whom a more energetic stand against the revolution could be expected. The first prime minister of the young Emperor was Schwarzenberg, a gifted conservative and an utterly ruthless and shrewd statesman, whose advice Francis Joseph accepted more indiscriminately than he did that of any other of his ministers.

Schwarzenberg was even less inclined to compromise in the internal affairs of the Habsburg Empire than in those concerning the German Confederation. Thus, an open break with Hungary occurred in mid-December 1848, and Windischgrätz's army marched into the country on a full wartime footing. Under this mediocre commander, the Austrians did poorly against the effective tactics of the insurgents. The Hungarian Reichstag, encouraged by this turn of events, in April 1849 declared that the Habsburgs had forfeited their right to rule. Hungary was accordingly proclaimed a republic under the presidency of Kossuth.

One factor in the Hungarian decision was the changed situation in Austria. By early March of 1849 the constitutional committee of the Reichstag, after prolonged and thorough discussion on a high intellectual level, had adopted the draft of an Austrian constitution (the Kremsier draft, after the Moravian town in which the Reichstag was reconvened). The draft provided for a constitutional monarchy, giving the sovereign only a suspensive veto against parliamentary legislation. Administrative organization along national lines was provided on the district level, yet crownland administration, the old historic boundaries, and the essence of the centralistic structure of the empire remained intact. A weakness of the draft was that it did not deal with the Hungarian problem. But, all things considered, the bill represented a reasonable compromise between the federalist and centralistic concepts, the former promoted mostly by Slavs, the latter primarily by German liberals.

The Kremsier constitution

The Kremsier constitution was the first reform plan drawn up by genuine representatives of the Austrian peoples, and it was precisely for this reason that the cunning Schwarzenberg decided to foil it. He had the Reichstag dissolved by police and warrants issued for the arrest of some of the reformers. At the same time he had the minister of the interior, Stadion, issue by decree a new, strictly unitary and centralistic constitution for the empire as a whole, including Hungary. The Stadion constitution was more conservative than the Kremsier draft, but it still subscribed to representative government. Enactment was, however, held in abeyance. Thus not only the Austrian peoples felt deceived but Stadion and other members of the Cabinet as well, since the constitution was never put into force and was even formally rescinded in December 1851. In the long history of Austrian government, the dissolution of the Reichstag of Kremsier was one of the most fatal governmental mistakes.

In March 1849 Piedmont-Sardinia had resumed military operations against Austria. This fact and the tense political situation in Germany caused Hungary's military situation to deteriorate rapidly. In April 1848 Windischgrätz was replaced as commander, and after an interim the cruel and ruthless Julius, Freiherr von Haynau, was

appointed as his successor. By mid-May 1849 the Hungarian revolutionary army had reconquered Budapest, presenting the young Francis Joseph with the painful alternative of risking his throne or asking the Tsar for help. Nicholas I, afraid of the possibility of the spread of the revolution to Russian Poland, complied with the Austrian Emperor's request. Russian armies entered Hungary and cooperated with Austrian forces. Budapest was reconquered by mid-July, and on August 13, 1849, the Hungarian troops capitulated. Kossuth and some of his followers managed to flee to Turkey. Even Tsar Nicholas recommended mercy for the gallant Hungarian military commanders. The answer of the Schwarzenberg-Haynau regime was the execution of 14 Hungarian generals—those who had surrendered to the Russians rather than to the Austrians—by hanging. About a hundred other executions, including that of Kossuth's moderate predecessor, Count Lajos Batthyány, followed. These actions as well as many long prison sentences and property confiscations imposed on minor rebels had only a limited deterrent effect, but they revolted public opinion across Europe. Hungary was dismembered and Transylvania, Croatia, and other areas were organized as separate crownlands under strictly authoritarian rule. The prostrate country was divided into five military districts and put under the administration of the stern Archduke Albrecht, whose intervention in the March 1848 Revolution in Vienna had made him hated by all liberals.

Defeat of the revolt in Hungary

All things considered, the revolution across the empire had not accomplished very much. Absolutism was seemingly more firmly entrenched than before, and the political clock had been put back beyond the regime of Maria Theresa. And yet a regime so badly shaken as Austria's could not hope to rule unchallenged in the future. The unresolved social, constitutional, and national issues became more intense, and new changes were soon in the offing.

The neoabsolutist era, 1849–60. The neoabsolutist era in Austria from the breakdown of the revolution in 1849 to 1860 must be judged from the point of view of the domestic policies of the regime—which were controversial but not entirely negative—and of a foreign policy that proved to be of disastrous consequence.

Positive domestic achievements were the establishment of a unified customs territory for the whole empire, distinct progress in industrialization, the promulgation of a code for trades and crafts, and some rudimentary beginnings of social legislation. Enactment of the full emancipation of the peasants, initiated by the revolutionary legislation, worked well. One-third of the cost was to be carried by the former owners of the land, one-third by the peasants themselves, and one-third by the government. This was, on the whole, a solution more equitable than that adopted in Prussia, and in Russia in the 1860s. Some improvements in standards were made in the universities and in the curricula of the Gymnasia. Overall credit for the reform policies belonged largely to Alexander Bach, the successor of Schwarzenberg, who had died in April 1852, lamented by few but the young Emperor.

Emancipation of the peasants

The regime's policies on other matters were more typically reactionary. Freedom of the press and jury and public trials were abandoned; corporal punishment by police orders was reintroduced. Informers flourished: the observation of the liberal reformer Adolf Fischhof that the regime rested on the support of a standing army of soldiers, a kneeling army of worshippers, and a crawling army of informers was exaggerated but not entirely unfounded. One of the most unwholesome developments was the conclusion in 1855 of a concordat with the Holy See that gave the church more power than it had possessed since the middle of the 18th century. Jurisdiction in marriage questions was handed over to the church, as well as control of censorship and elementary education. Church control extended indirectly to secondary education, also, because the priests, who were entrusted with compulsory religious education, had the right to see to it that instruction in any other field, be it physics or history, did not conflict with their teachings. In the second half of the 19th century, a regime of this type could possibly have stayed in power if it had been successful in the conduct of foreign affairs. But this was not to be the case.

Exclusion from Germany and Italy. In the protracted Crimean War crisis (1853–56) the Habsburg Empire took a stand against the Russian occupation of the Danube principalities (Moldavia and Walachia). By threatening military intervention on the side of the Western allies, Austria forced their evacuation by Russian troops and from 1854 occupied the territories itself for the duration of the war. In December 1854, Austria joined the Western alliance but refrained from a declaration of war on Russia and from active military participation. The continuing threat of such action forced Russia to accept the humiliating Treaty of Paris in March 1856.

The consequences for the Habsburg monarchy were grave. Russia, Austria's ally for well over a century, moved into the camp of its enemies. The tsars, Nicholas I and his son Alexander II, never forgave the alleged ingratitude for the Russian intervention in Hungary in 1849. The Western powers, on the other hand, were highly dissatisfied that the Habsburg Empire had refused to take the last decisive step and become a combatant in the war. In retaliation, and in payment of political debts, they supported the cause of Italian unification, skillfully engineered by the Sardinian prime minister, Count Cavour.

The end of Austria's alliance with Russia

Though Karl Ferdinand, Graf von Buol-Schauenstein, Metternich's successor as minister of foreign affairs, was blamed for allowing Austria to fall between two chairs, the fact is that the Habsburg Empire simply had been caught in an insoluble dilemma. By the nature of its own absolutist regime, it was drawn to tsarist despotism; but in justified fear of encirclement and of the effect of Russian-inspired Pan-Slavism on Austria's Slav population, the empire had to look for the support of the West with its alien political values. This was the basic contradiction in the policy of the Habsburg power.

Napoleon III, largely to distract attention from his own semidictatorial regime and to assuage the Liberals, deemed it advisable to support the cause of Italian independence. In the secret agreement of Plombières of July 1858, he pledged French military support for the liberation of Lombardy and Venetia. This was technically a defensive pact, but in face of a political situation in which three major European powers—France, Great Britain, and Russia—sided with the Italian cause, the Austrians would have been well advised to ignore any Piedmontese provocations. But Buol blundered Austria into an ultimatum by which in April 1859 it demanded Piedmont-Sardinia's demobilization within three days. This was all the justification Cavour and Napoleon III needed to start the Austro-French Piedmontese War. French and Italian military leadership and preparations were far from satisfactory, and conditions on the Austrian side were even worse. Under an inferior commander, Franz, Graf von Gyulai, the Austrians hesitated to take the offensive. In the Battle of Magenta on June 4, they were defeated and Milan had to be evacuated. Gyulai was discharged and the inexperienced emperor Francis Joseph took over the supreme command. On June 24, 1859, the Austrians were decisively beaten in the Battle of Solferino, and two weeks later Napoleon III and Francis Joseph, who was deeply shocked by the carnage of the encounter, concluded the preliminary Peace of Villafranca, followed in November 1859 by the permanent Peace of Zürich. According to its terms Austria had to cede Lombardy—except for Mantua and Peschiera—to Napoleon III, who in turn would give it to Piedmont-Sardinia. The rulers in the Austrian appendages, Modena and Tuscany, who had been driven out by their subjects in the course of the war, were to be restored. These terms represented a kind of compromise. Napoleon III was not anxious to continue a war that might have brought about Prussian intervention on the side of Austria.

The underlying conflict between Austria and Prussia over supremacy in Germany erupted into a crisis as a result of the involvement of the two powers in Danish affairs. When in 1863 the King of Denmark decreed a union of Schleswig and Holstein under one constitution

The Schleswig-Holstein crisis

Austrian Empire, 1815–59.
Adapted from *Westermann Grosser Atlas zur Weltgeschichte;* Georg Westermann Verlag, Braunschweig

and finally incorporated Schleswig into Denmark, he thereby violated international agreements and the charter of the German Confederation, to which Holstein belonged. Protests by Austria and Prussia on behalf of the Confederation were of no avail, nor were they meant to be. Consequently it came in 1864 to war between the two major German powers and Denmark.

The Habsburg Empire's interest in this conflict was not as peripheral as it seemed, for the government was afraid that if action was left to Prussia alone the war would end with unilateral Prussian aggrandizement. Secondly, and perhaps equally important, the issue of Schleswig-Holstein was of major concern to German nationalists. After a brief war, Denmark was forced, by the Peace of Vienna of October 1864, to cede Schleswig, Holstein, and the small duchy of Lauenburg to the Austrian and Prussian sovereigns. But it became increasingly clear that Bismarck did not want to establish the principalities as states within the German Confederation under a sovereign prince. He worked instead in an underhand way for annexation by Prussia. A temporary arrangement was, however, reached at the Convention of Gastein (August 1865), according to which Holstein was put under Austrian military administration, Schleswig under Prussian. Lauenburg was sold outright to Prussia.

The real reason behind this temporary arrangement was the desire of both sides to gain time to make military preparations for the showdown that Bismarck considered inevitable and the Austrian government likely. Further efforts to settle the status of the duchies on a permanent basis by compromise failed, chiefly because this issue served Bismarck with a useful pretext for war. In further preparation Bismarck in April 1866 concluded an alliance treaty with Italy, which promised Italy Prussia's support for the conquest of the Austrian-held Venetian province. The treaty was to lapse if Italy did not open hostilities against Austria within three months. Thus a time limit was set for the beginning of the war.

The pretext for the openings of hostilities was a minor one. When Austria convoked the Estates of Holstein in early June 1866, Prussia declared the Convention of Gastein violated and occupied the duchy by military force. Thereupon Austria asked for mobilization of the confederal armies against the aggressor, Prussia. All member states agreed. Prussia in turn declared the charter of the confederation void and invaded Saxony, Hanover, and Electoral Hesse. The great war for supremacy in Germany, sometimes also referred to as the war between brethren or the Seven Weeks' War, began on June 16, 1866. Four days later Italy joined in the hostilities.

Francis Joseph's initial and grave error was his selection of the commander in the northern theatre of war. Gen. Ludwig August, Ritter von Benedek, a subcommander with many years of experience in the Italian theatre, was against his will put in charge of the main forces against Prussia. Archduke Albrecht, cousin of the Emperor, was given the far less risky command in the south against Italy, so that a member of the dynasty would not be compromised in case of defeat.

The Prussian forces, in accordance with the superior strategy of the chief of staff, Helmuth von Moltke, started a three-pronged attack on Bohemia. Austrian army units were defeated in most of the preliminary engagements in Bohemia. Benedek wanted to withdraw to Moravia, but when the Emperor appealed by implication to his sense of honour, he accepted battle on July 3 at Sadowa (Königgrätz) against three converging Prussian armies. The Austrians, their brave resistance notwithstanding, were defeated and withdrew in disarray. Before the Prussian offensive could be carried to the gates of Vienna, a temporary truce was arranged at Nikolsburg, followed by the preliminary peace concluded there on July 26. Bismarck, concerned with the possibility of immediate French intervention and with long-range plans for future friendly relations with Austria, wanted to avoid unnecessary humiliation of the Habsburg power. The terms confirmed by the permanent Treaty of Prague of August 23 were therefore moderate. Austria would have to recognize the dissolution of the German Confederation and the reorganization of Germany without its participation. Austria's rights in Schleswig-Holstein were transferred to Prussia and it had to pay a relatively minor indemnity. Yet no territorial cessions were demanded, and as a point of honour it was allowed to secure the preservation of the territorial integrity of its most faithful ally, Saxony.

Defeat by Prussia at Sadowa

Before evaluating the peace, the outcome of the war against Italy must be considered. By 1866 the Emperor and most Austrian statesmen had belatedly realized that Austrian rule in Venetia in the face of the opposition of the overwhelming majority of the population there made little sense. Nonetheless, a secret semi-official Italian offer to buy the province was rejected as dishonourable. A conditional offer to cede Venetia outright to Italy came too late in view of the Prusso-Italian alliance. Instead Emperor Francis Joseph concluded on June 12, 1866, a strange agreement with Napoleon III. According to its main provisions in regard to Italy, Austria would cede Venetia, win or lose, to Napoleon, who in turn would give the province to the new Italian kingdom. This meant in effect that the Habsburg power would fight a regular war for the sake of prestige and medieval chivalry, although the outcome was settled before the fighting started. The Italians in turn refused to accept a gift from Napoleon and preferred to fight. The Austrians defeated the Italians at Custoza in Lombardy as well as in the naval Battle of Lissa (Vis) off the Dalmatian coast. But this was of no consequence because of Italy's partnership with Prussia and the latter's victory at Sadowa. By the Peace of Vienna with Italy on October 3, 1866, the cession of Venice, this time to Italy directly, was confirmed.

Significance of the defeat

Of all the wars in the long history of the Habsburg monarchy prior to World War I, the brief Seven Weeks' War of 1866 had probably the most far-reaching effect. Its outcome banished Austria from the rank of the genuine first-rate powers. Beleaguered German nationalism within the empire increasingly assumed a belligerent tone, quite different from the moderate German-directed centralism that had been dominant for many generations. This spirit was challenged not only by a proud Magyarism but also by the combined force of the empire's Slavs —about half the population. This in turn made the Habsburg power increasingly vulnerable to Russian pressure from the east and within 13 years forced it into a German alliance, not as an equal but as a junior partner. Equally important were the internal changes brought by military defeat in two wars within seven years.

THE TRANSITION TO CONSTITUTIONAL GOVERNMENT, 1860–66

In March 1860 Francis Joseph ordered that the Reichsrat, a kind of empire-wide, purely advisory council of

state, should be enlarged by the addition of 38 members proposed by the diets and selected by the crown itself. Only in matters of public finance was this body given a share in legislation, yet it was entrusted with the formidable task of advising the emperor concerning the promulgation of a new imperial constitution. No agreement, however, could be reached. The moderately liberal centralists, represented largely by the Germans, demanded a strong empire-wide legislature and restriction of the agenda of the old Estates diets. They were faced by conservative federalists, largely Magyar, Czech, and Polish nobles, who wanted to strengthen the diets' position. Magyar influence was again on the rise. The Emperor himself sided naturally enough with the conservative forces, which were federalist mainly on the strength of historic and not ethnic claims. The result was the October Diploma of 1860, a constitution proclaimed by decree. It enlarged the diet to 100 representatives and broadened the legislative functions of the Reichsrat in matters of finance, commerce, and industry. Foreign and military agenda remained the exclusive domain of the emperor. Hungary's constitutional status within the empire was restored as it had existed prior to the revolution of 1848, but the concessions agreed to in March 1848 were not recognized. The federalists, particularly the Magyars, objected because their demands had been met only halfway. The centralists rejected the constitution just as strongly, as fully at variance with their claims. In effect, the whole unfortunate legislation had to be abandoned, and on the advice of the new German centralist cabinet, a new one, technically a revision of the October Diploma, was decreed (the so-called February Patent of February 26, 1861).

Constitutional changes

The October Diploma was really no constitution at all in the representative sense; the February Patent was at least an inadequate one. It provided for a bicameral system, an empire-wide house of representatives composed of dietal delegates, and a house of lords, consisting partly of hereditary members and partly of men of special distinction appointed for life. Furthermore, a parliamentary body for the Habsburg lands exclusive of Hungary was established. Opposition of the national groups rendered the constitution unworkable, and in 1865 it had to be suspended. Absolutism was, for all practical purposes, restored under a new prime minister, Richard, Graf Belcredi. The crown could hardly expect that this renewed elimination of constitutional government would be permanent, and the outcome of the war of 1866 made this assumption a certainty. In the meantime, negotiations with the Magyars, who were under the leadership of the highly respected moderate liberal Ferenc Deák and Count Gyula Andrássy, continued. (R.A.K.)

III. Austria-Hungary and the republics of Austria, since 1867

AUSTRIA-HUNGARY, 1867–1918

The liberal ascendancy. *The Ausgleich of 1867.* The economic consequences resulting from the defeat in the war of 1866 (Seven Weeks' War) made it imperative that the constitutional reorganization of the Habsburg monarchy, under discussion since 1859, be brought to an early and successful conclusion. Personnel changes facilitated the solution of the Hungarian crisis. Friedrich Ferdinand, Freiherr (later Graf) von Beust, who had been prime minister of Saxony, took charge of Habsburg affairs, first as foreign minister (from October 1866) and then as chancellor (from February 1867). By abandoning the claim that Hungary be simply an Austrian province, he induced Francis Joseph I to recognize the negotiations with the Hungarian politicians (Déak and Andrássy) as a purely dynastic affair, excluding non-Hungarians from the discussion. On February 17, 1867, Francis Joseph I restored the Hungarian constitution; a ministry responsible to the Hungarian parliament was formed under Count Gyula Andrássy; and in May 1867 Law XII was approved by parliament, legalizing what became known as the *Ausgleich* ("compromise"). This agreement was a compromise between the Hungarian nation and the dynasty, not between Hungary and the rest of the empire; and it is symptomatic of the Hungarian attitude that Hungarians referred to Francis Joseph and his successor as their king and never called him emperor.

Beust becomes chancellor

In addition to regulating the constitutional relations between the king and the nation, Law XII accepted the unity of the Habsburg lands for purposes of conducting certain economic and foreign affairs in common. The compromise was thus the logical result of an attempt to blend traditional constitutional rights with the demands of modern administration. In December 1867, the *engerer* Reichsrat, the section of parliament representing the non-Hungarian lands of the Habsburg monarchy, approved the compromise. Though, after 1867, the Habsburg monarchy was popularly referred to as the Dual Monarchy, the constitutional framework actually was tripartite, comprising the common agencies for economics and foreign affairs, the agencies of the kingdom of Hungary, and the agencies of the rest of the Habsburg lands—commonly but incorrectly called "Austria." (The official title for these provinces remained "the kingdoms and lands represented in the Reichsrat" until 1915, when the term "Austria" was officially adopted for them.)

Under the Compromise of 1867, both parts of the Habsburg monarchy were constitutionally autonomous, each having its government and its parliament composed of an appointed upper and an elected lower house. The "common monarchy" consisted of the emperor and his court, the minister for foreign affairs, and the minister of war. There was no common prime minister and no common cabinet. The common affairs were to be considered at the "delegations," annual meetings composed of representatives from the two parliaments. For economic and financial cooperation, there was to be a customs union and a sharing of accounts, which was to be revised every ten years. (This decennial discussion of financial quotas became one of the the main sources of conflict between the Hungarian and Austrian governments.) There would be no common citizenship, but such matters as weights, measures, coinage, and postal service were to be uniform in both areas.

Although there was no common prime minister or cabinet, there soon developed the so-called *gemeinsamer* Ministerrat, a kind of crown council in which the common ministers of foreign affairs and war and the prime ministers of both governments met under the presidency of the monarch. The common ministers were responsible to the crown only, but they reported annually to the delegations representing both parliaments.

The December constitution

The Compromise of 1867 for all practical purposes set up a personal union between the lands of the Hungarian crown and the western lands of the Habsburgs. The Hungarian success inspired similar movements for the restoration of states' rights in Bohemia and Galicia. But the monarch who only reluctantly had given in to Hungarian demands was unwilling to discontinue the centralist policy in the rest of his empire. Public opinion and parliament in Austria were dominated by German bourgeois liberals who opposed federalization of Austria. As a prize for their cooperation in compromising with the Hungarians, the German liberals were allowed to amend the February constitution of 1861; the Fundamental Laws, which were subsequently adopted in December 1867 and became known as the December consitution, lasted until 1918. They granted equality before the law and freedom of press, speech, and assembly and protected the interests of the various nationalities, stating that

> all nationalities in the state enjoy equal rights, and each one has an Inalienable right to the preservation and cultivation of its nationality and language. The equal rights of all languages in local use are guaranteed by the state in schools, administration, and public life.

The authority of parliament was also recognized. Such provisions, however, were more a promise than a reality. Although parliament, for instance, did theoretically have the power to deal with all varieties of matters, it was, in any case, not a fully representative parliament (suffrage was restricted, and it was tied to property provisions until 1907); and the king was authorized to govern without

parliament in the event that the assembly should prove unable to work. Austrian affairs from 1867 to 1918 were, in fact, determined more by bureaucratic measures than by political initiative; Josephinistic traditions (see above *Foreign Policy, 1763–92*) rather than capitalist interests characterized the Austrian liberals.

Domestic affairs. After the December constitution had been sanctioned, Emperor Francis Joseph appointed a new Cabinet, named the "bourgeois ministry" by the press, because most of its members came from the German middle class (though the prime minister belonged to the Austrian high aristocracy). In 1868 and 1869, this ministry was able to enact several liberal reforms, undoing parts of the Concordat of 1855. Civil marriage was restored; compulsory secular education was established; and interconfessional relations were regulated, in spite of a strong protest from the Catholic Church. In 1870, the Austrian government used the promulgation of the dogma of papal infallibility as pretext for the total abrogation of the concordat.

The progressive legislation of the bourgeois Cabinet stood in sharp contrast to its inability to cope with the demands of the non-German nationalities. In 1868 the Czechs and the Poles issued declarations demanding a constitutional status analogous to that of the Hungarians. The government in Vienna did give the Poles in Galicia a considerable amount of self-government, which was later used to Polonize the Ruthenian minority. In 1871 a ministry for Galician affairs was set up, and the Poles remained the staunchest supporters of the Austrian government well into World War I.

Czech demands for autonomy

The bourgeois ministry was split into a liberal-centralist and a conservative-federalist faction; its members could not reach an agreement among themselves on policies to be adopted. The liberal members of the Cabinet opposed Czech demands; the conservatives showed themselves willing to consider them. Francis Joseph, indignant because of the anti-clerical policy of the liberals, dismissed the prime minister, Fürst Carlos Auersperg, in 1868, replacing him with the conservative Eduard, Graf von Taaffe, his boyhood friend. A period of indecision nevertheless persisted. The Emperor wavered between the liberals, whose anti-clericalism and parliamentarianism he disliked but with whom he sympathized in their centralist, German-oriented policy, and the conservatives, who had his favour in political legislation but aroused his fears by their demands for federalization. Neither Taaffe nor his successors, Leopold Hasner (from December 1868) and Potocki (from April 1870), could solve the Czech problem. The Franco-German War of 1870–71 temporarily diverted public attention from the Czech demands, though public opinion was divided strictly along lines of nationality: Austro-Germans celebrated the victories of the Prussian army, whereas the Slavs were decidedly pro-French. The Austrian government remained neutral because conflicting international interests had blocked the Austro-French negotiations that had culminated in a meeting of Francis Joseph and Napoleon III at Salzburg in 1867. The victory of Chancellor Otto von Bismarck and the establishment of the Second German Empire under the leadership of the Prussian king gave finality to the military decision of 1866. Austria was definitely excluded from the German scene, and a reorientation of dynastic interests seemed a logical consequence. Francis Joseph decided to explore the possibilities of satisfying the Czechs with some measure of federalism. On February 5, 1871, he appointed as prime minister Karl Siegmund, Graf von Hohenwart, a staunch clericalist. The driving mind in Hohenwart's Cabinet, however, was the minister of commerce, Albert Schäffle, an economist whose socialism may not have appealed to the Emperor but whose federalism did.

Failure to satisfy Czech demands

As a first step toward conciliation with the Czechs, the Hohenwart Cabinet dissolved parliament and the provincial diets. When the Bohemian elections improved the federalist position, Hohenwart proceeded to deal directly with the Czechs, copying in certain measure the method used to conclude the compromise with Hungary. Secret talks with Czech leaders František Ladislav Rieger and František Palacký led to the issuance of an imperial rescript by Francis Joseph on September 12, 1871, promising the Czechs recognition of their ancient rights and showing his willingness to take the coronation oath. The Czechs answered this rescript on October 10, 1871, by submitting a constitutional program of 18 articles, called the Fundamental Articles. According to this program, Bohemian affairs should be regulated along the principles of the Hungarian compromise, raising Bohemia to a status equal to Hungary. With this, Hohenwart, who had been up against violent German opposition from the very first day of his appointment, aroused Hungarian resistance, too. Andrássy, fearing that the Czech program could incite minority groups in Hungary, succeeded in convincing Francis Joseph that the stability of the Habsburg monarchy was endangered by the Czech program. On October 27, 1871, Hohenwart was dismissed and Francis Joseph returned the government to the hands of the German liberals.

The new prime minister, Prince Adolf Auersperg, entrusted the key ministries of his Cabinet to university professors and lawyers. The "ministry of doctors," as it was nicknamed by the people, concentrated on legal and administrative reform and endeavoured to strengthen the German control in parliament. After the dismissal of Hohenwart, the Czechs turned to passive resistance, withdrawing from the Bohemian diet and again abstaining from attendance at the parliament in Vienna. This attitude gave the government the chance to weaken the federalist position by introducing a bill for electoral reform. Instead of the existing modus, whereby the diets selected the deputies that were sent to parliament, the new bill set up electoral districts, each of which was to elect one deputy directly to the Reichsrat. The new system, however, preserved the old division of the electorate into *curiae* (socio-economic classes), making parliament in this way a representation of German bourgeois interests.

The economic crisis of 1873

By a strange coincidence, the political victory of German capitalism took place at the very moment of a severe economic crisis. In April 1873, the opening of the Vienna International Exhibition had been thought of as a manifestation of the material progress and economic achievements of the Habsburg monarchy. The so-called *Gründerjahre*, or years of expansive commercial enterprise during the late 1860s and early 1870s, however, were characterized not only by railroad and industrial expansion and the growth of the capital cities of Vienna and Budapest but also by reckless speculation. Warning signs of an imminent crisis were disregarded, and in May, soon after the opening of the exhibition, the stock market collapsed.

The ensuing depression forced the government to abandon liberal bourgeois principles. The state took over the railroads and instituted public-works projects in an attempt to alleviate popular distress. A far-reaching consequence of the stock-market crash of 1873 was the permeation of anti-Semitism into Austrian politics. Jews were accused of being responsible for the speculative stock-market activities, even though official investigations proved that many elements of the population, including some ministers and high aristocracy, had participated in the *Gründungsfieber*, or "speculative fever," and the attendant scandals. The government survived the crisis, however, and German liberal political rule continued for five more years. German liberalism passed into eclipse not because of economic or domestic crisis but as a consequence of its opposition to foreign expansion.

International relations: the Balkan orientation. After his appointment as foreign minister, on November 14, 1871, Count Gyula Andrássy conducted the foreign affairs of Austria-Hungary with the intention of preserving the status quo. Discarding the anti-Bismarck bias of his predecessor, Beust, he sought the friendship of the German *Reich* with the intention of strengthening his position in the unavoidable confrontation with Russia over Balkan problems. The Three Emperors' League (*Dreikaiserbund*) of 1873, by which Francis Joseph and the German and Russian emperors agreed to work together

The Three Emperors' League of 1873

for peace, gave expression to this policy. It also represented Andrássy's intention to strengthen Austria's position in a possible confrontation with Russia over Balkan problems, because the league made a change of the status quo in the Balkans dependent on German consent.

The continuing decline of Ottoman power encouraged the Balkan nations in their opposition to Turkish rule, and in 1875 there were revolts and upheavals. Andrássy failed to induce the Turkish government to adopt a reform program, and by 1876 Russian intervention seemed to be imminent. Russia offered to join with Austria-Hungary in partitioning the Balkans between them, but Andrássy was convinced that Austria-Hungary was a "saturated state" unable to cope with more nationalities and lands, and thus he temporarily resisted the offer. He was aware, however, that Russia could not be restrained altogether; and thus, through Bismarck's mediation, there were concluded two secret agreements, at Reichstadt (Zákupy) in July 1876 and at Budapest in January 1877, whereby Russia gave up its plans for a "great partition" and settled for the territory of Bessarabia and, in return, acquiesced in Austria-Hungary's acquiring Bosnia and Hercegovina. Austria-Hungary and Russia further agreed, however, to refrain from intervention for the time being, and it was only when great-power mediation proved unable to settle the conflict between Serbia and Turkey that Russia declared war on Turkey, in April of 1877, after having once more secured Austro-Hungarian neutrality. In February 1878, with the war won, the Russians did not content themselves with Bessarabia, but, in the Treaty of San Stefano, violated Austria-Hungary's Balkan interests by creating a Great Bulgaria. Having Great Britain as an ally in his opposition to the Russian advance in southeastern Europe and Bismarck as an "honest broker," Andrássy managed at the Congress of Berlin in July 1878 to force Russia into retreating from its excessive demands. Bulgaria was broken up again, Serbian independence was guaranteed, Russia retained Bessarabia, and Austria-Hungary was allowed to occupy Bosnia and Hercegovina. Military occupation of the two provinces turned out to be more than the expected mere formality. It took 150,000 Habsburg troops and several weeks of fighting before the lands were under Habsburg authority. Since no agreement could be reached on whether the newly acquired lands should aggrandize the Hungarian or the Austrian part of the monarchy, an ingenious solution placed them under the jurisdiction of the common Habsburg ministry of finance.

Decisions of the Congress of Berlin, 1878

National conflict and reform. *Taaffe's ministry.* The German liberals had opposed the Balkan policy of Andrássy; and, out of fear that the Slav element in the monarchy would be strengthened by the addition of new Slav population, they voted against the occupation of Bosnia and Hercegovina, in this way withdrawing support from the government. When Prime Minister Auersperg resigned, the era of German liberal predominance came to an end. In 1879, the same year in which the Dual Alliance with the German *Reich* bound the Habsburg monarchy to Germany's foreign policy, the appointment of Taaffe as prime minister signified a reorientation in domestic affairs. From 1879 onward, the German element in the Habsburg monarchy was on the defensive, fighting stubborn and senseless rearguard actions against the Slav drive for political and national equality.

For the elections of 1879, a coalition had formed, consisting of clericals, German aristocrats, and Slavs, which gave itself the name of the Iron Ring. Taaffe had first tried to form a cabinet above parties. It was to include even the liberal Karl, Edler von Stremayr, who had presided over a caretaker government after Auersperg's resignation. The situation in parliament had decisively changed when the Czechs were persuaded by Taaffe, in 1879, to give up their boycott. In April 1880, as a first step, language ordinances were issued that made Czech and German equal languages in the "outer [public] services" in Bohemia and Moravia. In 1882 the University of Prague was divided, giving to the Czechs a national university. In the same year, an electoral reform reduced the tax requirement for the right to vote from ten to five florins, thus enfranchising the more prosperous Czech peasants and weakening the hold of the German middle class. The Taaffe government is also remembered for social-reform legislation; the laws of 1884 fixed the maximum working day (at 11 hours), outlawed the employment of children under 12, required a Sunday rest day for workers, and set up compulsory insurance against accidents and sickness.

Reforms of the 1880s

Despite the conservative character of the government, political life in the Habsburg monarchy underwent a decisive change during the Taaffe period. In the 1880s, the traditional party lineup decomposed, and new alignments and parties formed that were essentially radical and aggressive. The Slav orientation of the Taaffe Cabinet did not satisfy the Czechs but rather encouraged a mood of belligerence; because the moderate Old Czechs failed to live up to radical demands, the nationalistic Young Czechs were able to gain support from the electorate. Similarly, in German Austria and, especially, in Vienna, the moderate liberals were increasingly challenged by extremist groups—notably, German nationalists. In 1882 their "Linz program" proposed the restoration of German dominance in Austrian affairs by detaching Galicia, Bukovina, and Dalmatia from the monarchy, reducing relations with Hungary to a purely personal union under the monarch, and establishing a customs union and other close ties with the German *Reich*. This Pan-Germanic program found its chief protagonist in Georg, Ritter von Schönerer, a deputy to the Reichsrat, who also introduced, for the first time, a note of anti-Semitism into German nationalism. Although his version of extreme chauvinism and racialism never attracted more than a small number of followers, in a modified and moderate way Pan-Germanism and anti-Semitism became the ideological support of the bureaucracy and officer corps; though these elements did not favour union with Germany, they did feel that the Habsburg monarchy had the task of bringing German culture to the "inferior" non-German nationalities. The period also witnessed the founding of parties for the masses. While Schönerer and Pan-Germanism appealed to the educated classes, Karl Lueger transformed the Christian Socialism of Karl, Freiherr von Voegelsang, into a political organization which appealed to small shopkeepers, artisans, tradesmen, and lower bourgeois circles of Vienna and the surrounding countryside. The 1880s finally saw the transition of the workers' movement from the welfare and adult education societies into a political party. Although workers' movements had been weakened in Austria by personal rivalries and government persecution, Victor Adler in 1889, at a conference in Hainfeld, managed to unite the competing Marxist groups into the Social Democratic Party. Political life in Austria from 1890 well into the 1920s was dominated by these three movements originating in the 1880s: Pan-Germanism, Christian Socialism, and Democratic Socialism.

Reaction of the German nationalists

Taaffe continued to probe for compromises between nationalities that were becoming increasingly radical in their demands. In 1890 he tried to negotiate an agreement between the Old Czechs and the German liberals whereby Bohemia would have been divided for administrative and judicial purposes along lines of nationality, but he was balked by the more chauvinistic Young Czechs and German nationalists, and his efforts led to riots in Prague in 1893. When Emil Steinbach joined Taaffe's Cabinet as minister of finance in 1891, he encouraged Taaffe and the Emperor to try electoral reform as an instrument of breaking nationalist opposition. It was hoped that, by extending the franchise, nationalistic antagonism could be allayed and the growing unrest among urban workers could be placated. On October 10, 1893, a suffrage bill was introduced, giving the vote to virtually every literate adult male (though preserving the traditional system of voting in *curiae*). The conservative groups of all nationalities joined forces against this bill, and, under pressure from the Hungarian government, Taaffe had to resign on November 11, 1893. Though failing in political matters, the Cabinet had been successful

Taaffe's later attempts to lessen national tensions

in introducing some economic and social reforms: between 1888 and 1892 a system of cooperative banks for farmers was organized; the taxation system was revised; Austrian currency was stabilized by a return to the gold standard; and the florin was replaced by the crown, which remained the Austrian currency until 1924.

Badeni's ministry. The franchise question continued to dominate Austrian domestic affairs and became closely welded to the nationality conflicts. Alfred, Fürst zu Windischgrätz, sought to win the support of parliament by forming a cabinet in which the clerical conservatives, the Poles, and the German liberals were represented. They were united, however, only in opposition to universal suffrage. Each minister defended his national cause, and the ministry was torn by ceaseless conflict. The end came in June 1895, when the government fulfilled an old promise and introduced Slovene classes into the grammar school at Cilli (Celje), in Styria. Because the school had been exclusively German, this was regarded as a grave blow to the German cause, and the German liberals resigned, forcing Windischgrätz himself to resign.

Deeply embittered by the conduct of the German liberals, Francis Joseph on October 2 entrusted the task of solving the country's problems to a Polish aristocrat, Kazimierz Felix, Graf Badeni, known as a "strong man" for the high-handed way in which he had acted as governor of Galicia. Little noticed at the time, the appointment of Badeni symbolized the breakdown of German control over the Habsburg monarchy. For the first time in Habsburg history, the Germans controlled none of the key positions of government. Not only the Prime Minister (Badeni) but also the Finance Minister (Leo, Ritter von Biliński) and the Foreign Minister (Gołuchowski, who had succeeded Count Gusztáv Kálnoky von Köröspatak the year before) came from the Polish part of the empire. Badeni managed to induce parliament to accept a compromise franchise bill that introduced qualified universal male suffrage but preserved the system of class voting (a fifth *curia* was even added).

Significance of Badeni's appointment

The shortcomings of the new system enraged the parties representing the masses of the population. In the 1870s and 1880s, decisive economic changes with far-reaching social consequences had occurred in the Habsburg lands. Though remaining primarily agrarian, the Habsburg lands had undergone an industrialization that had resulted in an unprecedented growth of urban centres. Vienna, which had about 430,000 inhabitants in 1851, found itself a metropolis of 1,800,000 at the turn of the century; and this phenomenon was paralleled in other areas, especially in Bohemia, which had become the industrial centre of the western part of the Habsburg lands. The socio-economic development naturally began to affect politics. From 1890 on, the advance of the Social Democrats and Christian Socialists caused considerable tension in Vienna. In October 1894, the Social Democrats were able to organize their first impressive, orderly mass demonstration in the capital, and the communal elections of 1895 had made the Christian Socialists the strongest party in Vienna, ending the long liberal rule. When the Emperor refused to confirm Karl Lueger, the popular leader of the Christian Socialists, as mayor of Vienna, there were demonstrations and protests. Not until Lueger was elected mayor the fifth time did Francis Joseph agree to confirm him, in April 1897. Furthermore, a few weeks earlier, the elections held on the basis of the new suffrage had strengthened the radical elements in the Reichsrat; the Young Czechs, for instance, had completely overwhelmed the conservative Old Czechs.

Growing strength of socialist parties in the 1890s

Counting on support from the Slav and conservative parties in parliament, Badeni dared to take up the Bohemian language question again. In April 1897, he issued a famous language ordinance that introduced Czech as a language equal to German even in the "inner service"—that is, for communications within government departments. This decision would have meant that civil servants in Bohemia and Moravia would have to be able to speak and write Czech as well as German. Since the Germans refused to learn Czech, this would have put them in a definite disadvantage in Bohemia's administration. The publication of the ordinance thus provoked violent German reactions: university professors signed resolutions of protest; mass meetings incited the public; and German deputies in the Reichsrat began to obstruct all legislative activities. The protest reached its climax in November 1897, when parliamentary sessions turned into bedlam, and popular protests against Badeni led to street demonstrations. The mass protest was not restricted to Vienna; it was even worse in some German towns in Bohemia; in Graz, clashes between soldiers and the masses ended in the death of one demonstrator. For a moment it seemed as if 1848 was about to return. To pacify the public, Francis Joseph gave in; on November 28, 1897, he dismissed Badeni, and asked Paul, Freiherr Gautsch von Frankenthurn, a former minister of education, to form a government out of the German parties of parliament. Gautsch's attempts to appease the Germans ran into obstruction from the Czechs. The stage of violence was shifted from Vienna to Prague and from the Reichsrat to the Bohemian diet. In March 1898 Gautsch was replaced by the former governor of Bohemia, Franz Anton, Fürst von Thun und Hohenstein, who in turn failed within a year. Neither Manfred, Graf Clary und Aldringen, who formally revoked the Badeni language ordinance, nor his successor, Wittek, who headed a short-lived cabinet of a few weeks, managed to solve the nationality problem.

Koerber's ministry. Finally, on January 18, 1900, Francis Joseph asked Ernst von Koerber, a former minister of the interior, to form a new Cabinet. Koerber was the first and only commoner to be appointed prime minister by Francis Joseph; as a leading bureaucrat, he formed his ministry from the ranks of other bureaucrats, concentrating, in the subsequent years, on the administration of public affairs and economic programs rather than trying to deal with political problems. First by imperial decree and then, after some political bargaining, by consent of parliament, Koerber carried through a program of economic expansion, social legislation, and administrative reform, liberating the press from government and police control. By devious politicking, Koerber managed to keep government activities free from national strife, but he could not prevent national emotions from becoming more and more extremist. The national conflict came to be fought over educational matters, and in the final years of Koerber's government the desire for national universities aroused the sentiment of the Italians, Slovenes, and Ruthenians, turning the traditional Czech–German conflict into a multi-national one. In December 1904, Koerber's various manoeuvrings faltered, and he was driven from office by a combination of parties.

Nationalism and electoral reform. The political climate in Austria was further complicated by the worsening of relations between the Emperor and the Hungarian government. Magyar separatists had agitated for the separation of the Habsburg army, and when Francis Joseph used an address to the troops at Chlopy in 1903 for an unequivocal reaffirmation of the common and unified character of his army, a controversy developed that had repercussions in the Austrian half of the Dual Monarchy. The plan to use universal suffrage to break the opposition in Hungary furthered the cause of political democracy in Austria. The demand for universal and equal suffrage had increased since the Russian revolution in the winter of 1905; after Koerber's Cabinet had run aground over a minor financial matter toward the end of 1904, Gautsch was chosen by the Emperor to introduce universal franchise in Austria. Though the first bill, introduced to parliament by Gautsch in February 1906, ran into the opposition of the middle-class and conservative parties that still controlled parliament, the realization of this program could no longer be blocked. Imperial interest and popular pressure—the Social Democrats had organized mass rallies to support the bill—combined to overcome parliamentarian opposition. After Gautsch had resigned in March 1906 and Prince Conrad von Hohenlohe-Schillingsfürst had failed to master the situation, Max Wladimir, Freiherr von Beck (prime minister from June 1906), managed to carry the bill through

Universal suffrage

parliament. In January 1907 Francis Joseph sanctioned the law giving the vote to every male of 24 or over, and abolished the *curiae*. Membership of the Reichsrat was increased from 425 to 516; the returns of the election of 1907 made the Germans now inescapably a minority, with 233 members, though certainly the strongest national group. The Czechs could count on 107 seats, the Poles 82, the Ruthenians 33, the Slovenes 24, the Italians 19, the Serbo-Croats 13, and the Romanians 5.

Universal suffrage brought the expected decline of the chauvinistic parties. The Young Czechs as well as the Pan-Germans were reduced to small factions without parliamentarian influence, whereas the Christian Socialists and the Social Democrats returned as the two strongest parties out of more than 30 represented in parliament; the Socialist delegation in the Austrian parliament was, in fact, larger than in any other country. The Austrian constitution, however, did not force the emperor to form his government according to the composition of the parliament. Neither the Social Democrats nor the Christian Socialists were able to acquire any significant influence on the shaping of Austrian government affairs.

Beck remained in office and satisfied the Christian Socialists with some concessions but for the most part based his policy on the support of the conservative parties. In 1905 the diet of Moravia had succeeded in finding a compromise between German and Czech national demands, and it was hoped a similar compromise could be achieved for Bohemia. But, within a short time, national conflicts got the upper hand again, and parliamentary debate and public opinion were once more excited by national strife. In 1908, however, international complications diverted attention from domestic affairs.

Foreign policy, 1878–1908. *The alliances.* The occupation of Bosnia and Hercegovina in 1878 had reasserted Habsburg interests in Balkan affairs. Facing the possibility of conflict with Russia in this area, Austria-Hungary looked for an ally, with the result that in 1879 Austria-Hungary and the German Reich had joined in the Dual Alliance, by which the two sovereigns promised each other mutual support in the case of Russian aggression. The signing of the Dual Alliance was Andrássy's last act as foreign minister, for he resigned shortly afterward, but the alliance survived as the main element in the international position of the Habsburg monarchy until the very last day of the empire. Under Andrássy's successors—Heinrich, Freiherr von Haymerle, and Kálnoky—Habsburg foreign policy continued its conservative course.

The Three Emperors' Alliance of 1881

In 1881 an alliance with Serbia, which after the Congress of Berlin turned to Austria-Hungary for protection, made this Balkan state a satellite of the Habsburg monarchy. The Three Emperors' Alliance (Russia, Germany, Austria-Hungary) of the same year brought Russian recognition of Habsburg predominance in the western part of the Balkan peninsula. The signatories of this alliance promised to consult one another on any changes in the status quo in the Ottoman Empire, and, while Russia was given assurances that its position regarding the Straits and Bulgaria would be recognized, Austria-Hungary received from Russia the promise that there would be no objection to a possible annexation of Bosnia-Hercegovina in the future.

The Three Emperors' Alliance was an important element in the structure of alliances that Bismarck set up to stabilize the European continent. Having decided to rely on Austria-Hungary as the fundamental partner in international affairs, Bismarck had to endeavour to neutralize all the areas in which the Habsburg monarchy might possibly be drawn into a conflict. It was essential to avoid being involved in a controversy at an inopportune moment and in a region of little interest to Germany. Bismarck therefore attempted to lessen the possibility of a conflict between Austria-Hungary and Russia by making them partners in the Three Emperors' Alliance. And when, in 1882, Italy approached Germany to find a partner in its anti-French policy, Bismarck used the opportunity to neutralize another European trouble spot. He informed the Italian foreign minister that the road to Berlin led through Vienna, with the result that the Triple Alliance (Italy, Germany, Austria-Hungary) was signed in May 1882. It was primarily a defensive treaty against a French attack on Italy or Germany. It further stated that, in the event of any signatory coming to war with another power, the partners of the alliance would remain neutral. The treaty did not settle the problems still existing between the Habsburg monarchy and the Italian kingdom, but for Bismarck it sufficed that they were neutralized.

The Triple Alliance

In 1883 Bismarck acted once more to reduce the danger of war in "Europe's backyard" by arranging a defensive agreement between Austria-Hungary and Romania. The Triple Alliance and the Romanian Alliance not only strengthened the international status quo but also gave security to the internal order of the Habsburg monarchy by weakening the irredentist movements in Transylvania and the Italian parts of Austria-Hungary.

The deterioration of German–French relations in the following years convinced Bismarck of the indispensability of the Triple Alliance, and he made every effort to force Vienna to renew the alliance in 1887. By threatening to withdraw protection against Russian aggression, Bismarck forced Kálnoky to consent to his demands, but there can be no doubt that Austria-Hungary was clearly impeded in its national interests by having to adapt its foreign policy to the German and Italian demand for the isolation of France. Although Kálnoky succeeded during the negotiations in avoiding any new obligation in western Europe, he was less successful in defending more immediate Austrian interests. He managed to evade the Italian request for the support of an active Italian colonial policy, but he was unable to keep Italy out of involvement in Balkan affairs. It might be that in view of his own conservative and defensive policy he saw an advantage in having Italy as a third partner in the maintenance of the status quo against possible Russian expansion. At any rate, it was on Kálnoky's initiative that the original Italian demand for a declaration in favour of the status quo along the Ottoman coasts and the Adriatic and Aegean seas was extended to the interior of the Balkan peninsula.

Kálnoky's Balkan policy

On top of this Kálnoky granted the Italians the right to ask for compensation in case of any change in the territorial status quo without defining this term. In a certain way, all the differences and clashes between Austrian and Italian Balkan policy in the first decade of the 20th century can be traced to the introduction of this clause (later formulated in article VII of the treaty) at the renewal of 1887. In the same year, Bismarck built around the Triple Alliance a system of alliances and agreements which amounted to complete isolation of France and obliged the major European powers to guarantee the status quo along the borders of the Ottoman Empire. The First and Second Mediterranean Agreements of 1887 joined Great Britain to the powers (Austria and Italy) interested in blocking Russia from the Straits, and enabled Kálnoky to abandon direct agreements with Russia. The Three Emperors' Alliance of 1881 was allowed to expire, and Austria-Hungary was thus left without any formal understanding with Russia. Count Agenor Gołuchowski, who followed Kálnoky as foreign minister in 1895, decided, however, that direct relations with St. Petersburg should be renewed. In April 1897, Francis Joseph and Gołuchowski visited St. Petersburg. The agreements signed as a result of this initiative aimed at excluding Italy from Balkan affairs and sought to entrust preservation of the Balkan order to the bilateral cooperation of the two eastern monarchies rather than to a multilateral alliance system. The final years of the 19th century were marked by a change from static continental policy to a more dynamic world policy, and the ensuing mobility in international relations reduced the value of the Triple Alliance.

The Bosnian crisis. The Austro-Russian agreements of 1897 came to bear when, in 1903, a major revolt occurred in Macedonia. Following a meeting of Tsar Nicholas II and Francis Joseph in October 1903, their foreign ministers drafted a reform program for the Otto-

man Empire. A mutual neutrality agreement was added the following year, leaving Austria-Hungary a free hand in the event of a conflict with Italy and enabling Russia to turn and face Japan. Explicitly excluded from the agreement with Russia were Balkan conflicts. When King Alexander of Serbia was assassinated in a military revolt in 1903 and the Obrenović dynasty was replaced by the Karageorgević, Serbian relations with the Habsburg monarchy deteriorated. The Serbs adopted an expansionist policy of unifying all southern Slavs in the Serbian kingdom, and, in order to block a Serbian advance, the Habsburg monarchy applied economic pressure. In 1906 all livestock imports from Serbia into the Habsburg monarchy were prohibited. This conflict, the so-called Pig War, did not crush Serbia but rather pushed it into the Russian camp.

When, in 1906, Count Gołuchowski was replaced as foreign minister by the former ambassador to St. Petersburg, Alois, Freiherr Lexa von Aehrenthal, a turning point in Austrian foreign policy was signalled. Aehrenthal made a belated effort to free Austria-Hungary from its submission to German interests and to engage in a dynamic Balkan policy. A first step in this direction was his proposal for the construction of a railroad through the Sandjak of Novi Pazar. The combined Russian and Serbian opposition forced Aehrenthal to abandon the project temporarily and made it clear that any advance in the Balkans would probably result in war with Serbia and perhaps with Russia as well. The danger of such a conflict arose within a short time. In July 1908, following a revolution in Turkey, the Young Turk movement announced the reform of the Turkish constitution. Afraid that this constitutional change could undermine the Habsburg position in Bosnia and Hercegovina, two provinces that nominally were still under Ottoman suzerainty, Aehrenthal decided to use the opportunity to fortify the Austro-Hungarian position in the Balkan peninsula. In September 1908, he met with the Russian foreign minister, Count A.P. Izvolsky, and secured, so he thought, Russian approval of the proposed annexation in return for Austria's support in having the Straits opened to Russian warships. On October 6, 1908, the annexation was announced, immediately bringing a violent reaction from Serbia. When Izvolsky found that his plans for the Straits were opposed by Great Britain and France, he retracted his tentative support of Austria and supported the Serbian position. The situation became serious, and for a while war seemed imminent. Franz, Freiherr Conrad von Hötzendorf, the chief of the general staff of the Habsburg monarchy, who had long advocated preventive war, pushed for an aggressive move, but Aehrenthal had apparently never planned more than going to the brink of war. In March 1909, a German ultimatum forced the Russians to withdraw their support from Serbia, and, since the Turkish government had agreed to the annexation of the two provinces in return for a monetary compensation, Serbia also had to come to terms with the Habsburg monarchy. The Bosnian crisis was settled, but the Serbians felt their national pride deeply wounded and continued to stir unrest in the southern Slav provinces of the Habsburg monarchy.

Annexation of Bosnia and Hercegovina

The last years of peace. *Conflicts of nationality.* The annexation crisis had repercussions among the other Slav nationalities in the monarchy. For several years, Czechs had been attracted by the Pan-Slav movement, and in July 1908 a Pan-Slav congress was held in Prague. During the diplomatic crisis of the following winter, the Czechs unabashedly took the side of the Serbs, and, on the day of the 60th anniversary of Francis Joseph's accession to the throne, martial law had to be declared in Prague. National strife broke out once more all over the monarchy, and parliamentary activities were all but blocked by filibustering and the riotous activities of the deputies. Prime Minister Beck had resigned in November 1908; and his successor, Richard, Freiherr von Bienerth, after having accomplished little with a cabinet of civil servants, tried to appease the nationalities by including *Landsmannminister* (national representatives) into his Cabinet (February 1909).

Obstruction in parliament continued. The Germans, in control of the government and the central administration, continued to assign to the monarchy the role of an outpost of German culture; the Slavs, however, increasingly wanted to make Austria the home of Slav national aspirations. The Czech agrarian leader František Udržal stated in parliament: "We wish to save the Austrian parliament but we wish to save it for the Slavs of Austria who form two-thirds of the population." A population census taken in 1910 confirmed the Slav claim: out of the 28,324,940 inhabitants of the western half of the Austro-Hungarian Empire, only 35.58 percent regarded themselves as German; 17.77 percent Poles; 12.58 percent Ruthenians; 23.02 percent Czechs and Slovaks; 4.48 percent Slovenes; 2.8 percent Serbs and Croats; and 2.75 percent Italians. The Slav predominance was weakened by the attitude of the Poles, who remained loyal to the central government, thus allowing the national conflict to assume the character of a primarily Czech–German quarrel. Even the Social Democratic Party could not overcome nationalist antagonism. In 1899, at the party congress at Brünn, the Social Democrats had presented a national reform program based on democratic federalism, granting the right of national decisions to territorial units formed on a basis of nationality. Karl Renner and Otto Bauer, who later became leaders of German–Austrian Socialism, drafted various programs for the solution of the nationality problem in books published between 1900 and 1910. But these efforts could not prevent the Socialists from splitting along national lines, too, and in 1910 the Czech Socialists declared themselves independent of the Austro-German Socialist Party.

National composition of the empire in 1910

Party rivalries. Such national differences weakened the Socialist position in the elections of 1911. Over 50 parties had competed in the campaign, and, since the German nationalist parties had allied in the Deutscher Nationalverband, they managed to return to parliament as the strongest single party, gaining 104 seats out of 516. The Christian Socialists, weakened by personal rivalry, suffered heavy losses, winning only 76 seats. The German Social Democrats received 44 seats and the Czech Socialists 24. The Czech parties were badly divided, those representing the Czech middle class gaining 64 seats. Bienerth found himself unable to form a workable ministry, and he was replaced by Gautsch, who tried to reconcile the Germans and the Czechs. For a while negotiations seemed quite successful, but extremist incidents deadlocked the talks, and the Gautsch Cabinet was replaced by a new ministry headed by Karl, Graf von Stürgkh (November 1911). Unable to deal with the nationality problem in a parliamentarian fashion, Stürgkh repeatedly suspended the Reichsrat. It was characteristic of the general political climate in Europe that Stürgkh had to concentrate his legislative program on the improvement of Austrian armament, for international crises overshadowed the nationality conflict.

Stürgkh's suspensions of the Reichsrat

Conflict with Serbia. Ever since the Bosnian crisis of 1909, Austrian diplomats had been convinced that war with Serbia was bound to come. Aehrenthal had fallen sick soon after the annexation of Bosnia and Hercegovina, and after a long illness he died (February 1912), at a moment when an Italian–Turkish conflict over Tripoli had provoked anti-Turkish sentiment in the Balkan states. Leopold, Graf Berchtold, who directed Austro-Hungarian foreign policy from 1912 on, did not possess the qualities required in such a critical period. Aehrenthal had been able to silence the warmongering activities of Conrad, who continued to advocate preventive war against Italy and Serbia, but Berchtold yielded to the aggressive policies of the military and the younger members of his ministry. During the Balkan Wars (1912–13), fought by the Balkan states over the remnants of the Ottoman Empire, Austria-Hungary twice tried to force Serbia to retract from positions gained by threatening it with an ultimatum. In February and October 1913, military action against Serbia was contemplated, but in both instances neither Italy nor Germany was willing to guarantee support. Austria-Hungary had to acquiesce in the territorial changes in the Balkan peninsula, changes that

eliminated the Turks from Europe. By supporting Bulgaria against Serbia, Austria-Hungary alienated Romania, which country had shown resentment against the Habsburg monarchy because of the treatment of non-Magyar nationalities in Hungary. Romania thus joined Italy and Serbia in support of irredentist movements inside the Habsburg monarchy. By 1914, leading government circles in Vienna were convinced that offensive action against the foreign protagonists of irredentist claims was essential to the integrity of the empire.

The assassination of Francis Ferdinand

In June 1914, Archduke Francis Ferdinand, the heir of Francis Joseph, participated in army manoeuvres in the provinces of Bosnia-Hercegovina, disregarding warnings that his visit would arouse considerable hostility. When Francis Ferdinand and his wife were assassinated by a Bosnian nationalist at Sarajevo on June 28, 1914, the Austro-Hungarian foreign office decided to use the opportunity for a final reckoning with the Serbian danger. The support of Germany was sought and received, and the Austro-Hungarian foreign office proceeded to draft an ultimatum putting the responsibility for the assassination on the Serbian government and demanding full satisfaction. The attitude of the foreign office was shared by Conrad and by Stürgkh but was opposed by the Hungarian prime minister, Count István Tisza, who wanted an assurance that a military move against Serbia would not result in territorial acquisitions and thus increase the Serb element in the monarchy. His demand satisfied, Tisza joined the advocates of war. In ministerial meetings on July 15 and 19, a deliberately provocative ultimatum was drafted in words that supposedly excluded the possibility of acceptance by Serbia. The ultimatum was handed to the Serbian government on July 23. The Serbian answer, handed in on time on July 25, was declared as being insufficient, though Serbia had agreed to practically all Austro-Hungarian demands with the exception of two that, in effect, entailed constitutional changes in the Serbian government. These were that certain unnamed Serbian officials be dismissed at the whim of Austria-Hungary and that Austro-Hungarian officials participate, on Serbian soil, in the suppression of organizations hostile to Austria-Hungary and in the judicial proceedings against their members. In its reply, the Serbian government pointed out that such demands were unprecedented in relations between sovereign states but nevertheless agreed to submit the matter to the Permanent Court of Arbitration or to the arbitration of the great powers. On receiving this reply, the Austro-Hungarian ambassador immediately left Belgrade, severing diplomatic relations between the two countries. Berchtold and his government were clearly determined to make war on Serbia, regardless of the fact that such action might result in war between the great powers. While the European governments frantically tried to offer compromise solutions, Austria decided on a *fait accompli*. On July 28, 1914, Berchtold asked Emperor Francis Joseph to sign the declaration of war, informing him that

> it cannot be excluded that the [Triple] Entente powers [Russia, France, Great Britain] might make another move to bring about a peaceful settlement of the conflict unless a declaration of war establishes a fait accompli [*eine klare Situation geschaffen*].

In the meantime the German government had taken control of the situation and, placing German strategic and national plans over Austro-Hungarian interests, had changed the Balkan conflict into a Continental war.

World War I. *Subordination to Germany.* The German declaration of war against France and Russia subordinated the Austro-Serbian conflict to the German aim of settling its own rivalries with France and Russia. According to the terms of the military agreement between Germany and Austria-Hungary, the Austro-Hungarian army had to abandon plans to conquer Serbia and instead protect the German invasion of France against Russian intervention. The setbacks that the Austrian army suffered in 1914 and 1915 can be attributed, to a large extent, to the fact that Austria-Hungary became a military satellite of Germany from the very first day of the war, though it cannot be denied that the Austrian high command proved to be quite incompetent. Conrad had clamoured for preventive war since 1906, but, when he received his chance, in July 1914, it turned out that the

Peoples of Austria–Hungary in 1914.

Austrian army had no plans for an expeditious offensive. Similarly, after Italy entered the war on the side of the Allies in May 1915, Conrad was unprepared. The fact that only after the Germans had taken command could the Russian front be stabilized and that Serbia and Romania were not defeated until 1915 and 1916, respectively, did little to enhance the prestige of the Austrian government.

Internal disintegration. In July 1914, parliament had been out of session, and Stürgkh had refused to convene it. This and the military censorship that was established immediately after the outbreak of the war concealed the discontent of the non-German population. While German public opinion in Austria had welcomed the war enthusiastically, and while some Polish leaders supported the war out of their anti-Russian resentment, the Czech population openly showed its animosity. The Czech leader Tomáš Garrigue Masaryk, who had acted as one of the most prominent spokesmen for the Czech cause, emigrated to western Europe. Karel Kramář, who had supported the Pan-Slav idea, was put on trial for high treason and declared guilty on the basis of shaky evidence. German nationalism was riding high, but in reality the German Austrians had little influence left. In military matters, they were practically reduced to executing German orders; in economic affairs, the Hungarians, who controlled the food supply, had the decisive influence. Count Tisza, who had opposed the war in July 1914, became the strong man of the empire. On his advice, Berchtold was dismissed in January 1915, and the foreign office was once again entrusted to a Magyar. But Count István Burián, who was in charge of foreign affairs until December 1916, failed to keep Italy and Romania out of the war. German attempts to pacify the two states by concessions were unsuccessful, because Francis Joseph was unwilling to cede any territory in response to the irredentist demands of the two nations. How little the outward calm in the Habsburg lands corresponded to the sentiment of the population became apparent when Stürgkh was assassinated by Friedrich Adler, the pacifist son of the leader of Austrian Socialism, in October 1916. Francis Joseph made Ernst Koerber prime minister, but Koerber had no chance to develop a program of his own. On November 21, 1916, Francis Joseph died, at the age of 86, leaving the throne and the shaky empire to his 29-year-old grandnephew, Charles, who had had little preparation for his task until the death of Francis Ferdinand had made him the heir apparent. Full of the best intentions, Charles set out to save the monarchy by searching for peace in foreign affairs and by recognizing the rights of the non-German and non-Magyar nationalities of his empire. Charles relied heavily on the advice of politicians who had had the confidence of Francis Ferdinand. He dismissed Koerber in December 1916 and made Count Heinrich Clam-Martinic, a Czech aristocrat, prime minister. At the foreign office, he replaced Burián with Ottokar, Graf Czernin.

Assassination of Stürgkh

When parliament was reconvened in May 1917, it became manifest how far internal disintegration of the Habsburg monarchy had progressed. Parliament once again became the stage of unrelenting national conflicts. Finding so little support from the Czech side, Charles turned back to the German element, and in June 1917 made Ernst von Seidler, once his tutor in administrative and international law, prime minister. But, even though he tried to appease the Czechs, the stubborn insistence of the Germans not to yield any of their prerogatives made reform of the empire impossible.

Early peace feelers

At the same time, various moves to get Austria-Hungary out of the war ended in failure. After a U.S. offer of general mediation had miscarried in December 1916, Charles tried through secret channels to deal directly with the Entente powers. In the spring of 1917, an exchange of peace feelers took place through the mediation of his brother-in-law, Sixtus of Bourbon-Parma, but Italy's unwillingness to abandon some of the concessions granted to it in the Treaty of London (1915) made these talks abortive. Similarly, negotiations with Allied representatives carried on in Switzerland brought no results.

Since the Austro-Hungarian government was unable to extricate itself from the ties of the Dual Alliance, France and England ceased to have regard for the integrity of the Habsburg monarchy. Furthermore, the revolutionary events in Russia in 1917 and the entry of the United States into the war introduced a new, ideological element into Allied policy toward the Central Powers. The German-directed governments represented an authoritarian system of government, and national agitation in the Habsburg monarchy henceforth assumed the character of a democratic liberation movement, winning the sympathies of west European and American public opinion. From early 1918 on, the Allied governments began officially to promote the activities of the emigrés from Austria, foremost among them Tomáš Masaryk, the Czech leader, and in April 1918 a Congress of Oppressed Nationalities was organized in Rome. But the collapse of the Habsburg monarchy cannot be ascribed to the new Allied policy of supporting the independence claims of the Habsburg nationalities, which was only a belated adjustment to the changed conditions within Austria-Hungary. From the summer of 1917, the activities of the nationalist movements within the empire made the situation increasingly untenable, and, two days before U.S. Pres. Woodrow Wilson proclaimed his Fourteen Points, one of which demanded the reorganization of the Habsburg monarchy in accordance with the principles of national autonomy, the Czechs demanded outright independence (January 6, 1918). Within a month, Polish and South Slav deputies, together with the Czechs, presented to the Reichsrat a program demanding the establishment of independent constituent assemblies for nationally homogeneous areas.

The end of the Habsburg Empire. During the same period in which the national-independence movement reached its final stage, another dangerous development manifested itself. From 1915 on, the supply situation had worsened increasingly, and by January 1918 there were dangerous shortages, especially of food. Prompted by the difficult food situation and inspired by the Bolshevik victory in Russia, a strike movement developed. Demands for more bread and a demand for peace were combined with nationalist claims into open opposition to the government. The strikes among the civilian population were followed by mutinies in the army and navy. In January and February 1918, however, the army and the government succeeded in suppressing social unrest and antiwar demonstrations. But, from the same date, the national opposition movement gathered momentum.

Strikes, mutinies, and demonstrations

The hopes that the government had placed in peace settlements with the eastern states were not fulfilled, either. The peace treaty with the Ukraine (signed in February 1918), the Treaty of Brest-Litovsk with Soviet Russia (March 3, 1918), and the Treaty of Bucharest, which settled the peace with Romania (May 7, 1918), did not alleviate the supply situation and irritated the Poles because of certain provisions of the Ukrainian settlement.

In April 1918, Czernin was replaced as foreign minister by Burián. This change was the result of a conflict between Czernin and Charles over the desirability and possibility of Austria concluding a separate peace with the Allies. Unknown to Czernin, Charles had in 1917 made certain secret overtures to the Allies, which were revealed by French premier Georges Clemenceau. The Germans were outraged, and Czernin was dismissed on their orders. Burián returned to the foreign office on April 16 and immediately reported to the German high command at Spa, where Emperor Charles and Burián had to assure the German Emperor of their unchanging loyalty. While this act of submission satisfied the German Austrians, it further incensed the Slav opposition. In May 1918 a Slav national celebration in Prague demonstrated the strength of the independence movements. But the Emperor and the German elements in the central government were still not aware of the extent of the disintegration. In July 1918, Prime Minister Seidler resigned, and his successor, Max Hussarek von Heinlein, began a belated effort to reorganize the Habsburg monarchy. Hussarek's efforts to federalize the empire in the moment of imminent military defeat unintentionally turned out to provide

Belated attempts at reform

the basis for the formal liquidation of the Habsburg monarchy. On October 16, 1918, Emperor Charles issued a manifesto announcing the transformation of Austria into a federal union of four components (German, Czech, South Slav, and Ukrainian). The Poles were to be free to join a Polish state, and Trieste was to be given a special status. The lands of the Hungarian crown were to be excepted from this program. Within a few days, national councils were established in all the provinces of the empire and for all practical purposes acted as national governments. The Poles proclaimed the union of all Poles in a unified state and declared their independence at Warsaw on October 7, 1918. The South Slavs advocated union with Serbia, and on October 28, 1918, the Czechs proclaimed the establishment of an independent republic. The dissolution of the Habsburg monarchy was thus consummated by the end of October 1918—that is, before the war actually ended.

It was impossible for the country to survive another winter of hostilities, and on September 14, 1918, Burián published an appeal to all belligerents to discuss the possibilities of ending the war. When this move was opposed by the Germans as well as by the Allied powers, Burián tried for a separate peace settlement for Austria-Hungary. On October 14, 1918, he sent a note to President Wilson asking for an armistice on the basis of the Fourteen Points. On October 18, 1918, U.S. Secretary of State Robert Lansing replied that, in view of the political development of the preceding months and, especially, in view of the fact that Czechoslovakia had been recognized as being at war with the Central Powers, the U.S. government was unable to deal on the basis of the Fourteen Points anymore. On October 27, 1918, Count Gyula Andrássy, who had replaced Burián three days before as foreign minister, sent a new note to President Wilson; in asking for an armistice, he declared full adherence to the statements set forth in the U.S. note of October 18, thus explicitly recognizing the existence of an independent Czechoslovak state. From this moment on, it remained only to liquidate the war. On October 22, 1918, Heinrich Lammasch, a renowned authority in the field of international law and a respected pacifist, formed a new Cabinet. He hoped to save the Habsburg monarchy by drawing up a federative structure. But instead of saving the state, he found himself charged with the task of supervising the dissolution of the empire and bringing about an orderly transfer of power. The government could not influence events outside of Vienna anymore and from October 30, 1918, was even challenged in the central agencies by the German–Austrian state council. The hostilities were ended by an armistice signed on November 3, 1918. The Austro-Hungarian high command, which had blundered into the war unprepared in 1914, did little better at its conclusion. Due to inaccuracies in the wording of the documents, more than 300,000 soldiers were taken prisoner by the Italian army. For some days the government hoped that, in spite of the secession of the Slav areas, the Habsburg dynasty could survive in the remaining lands. But even the German Austrians had lost faith in the Habsburgs, and, with revolutionary agitation on the rise and republican passion widespread, Charles adhered to the advice of Lammasch and decided to waive his rights to exercise political authority. On November 11, 1918, he issued a proclamation acknowledging "in advance the decision to be taken by German Austria" and stating that he relinquished all part in the administration of the state. The declaration of November 11, 1918, marks the formal act of dissolution of the Habsburg monarchy.

THE FIRST REPUBLIC AND THE ANSCHLUSS

The war's aftermath. On October 21, 1918, the 210 German members of the imperial parliament (Reichsrat) of Austria formed themselves into a national assembly for Deutschösterreich, or German-Austria; and on October 30 they proclaimed this an independent state under the direction of a State Council (Staatsrat) composed of the leaders of the three main parties and other elected members. Revolutionary disturbances in Vienna and, more important, the news of the German revolution forced the State Council on the republican path. On November 12, the day after the emperor Charles's abdication, the National Assembly resolved unanimously that "German-Austria is a democratic republic" and "German-Austria is a component part of the German republic." Karl Renner, a leading Socialist, became head of a coalition government, with Otto Bauer, the acknowledged spokesman of the left wing of the Social Democrats, as foreign secretary. On November 22, the territory of the republic was further defined: the National Assembly claimed for the new state all the Habsburg lands in which a majority of the population was German. It also claimed the German areas of Bohemia and Moravia.

Dangers of a Communist revolution

From the first day, the republic was faced with the disastrous heritage of the war. Four years of war effort and the breakup of the Habsburg Empire had brought economic exhaustion and chaos. The resulting social distress and poverty inspired revolutionary activities, thus making Bolshevism appear the greatest danger to the new republic, especially after a Soviet republic was established in Hungary at the end of March 1919. The Austrian Social Democrats were determined to resist Bolshevism with their own forces without making an alliance (as the German Social Democrats did) with the old order. A Volkswehr (People's Guard) was organized and was twice effective (April 17 and June 15) against Communist attempts at a *Putsch*. Otto Bauer and Friedrich Adler staked their popularity on defeating the Communist agitation in the workers' and soldiers' councils, which had been set up on the Soviet model. By mid-1919, political and social order was restored on parliamentary lines, the Communist Party relapsing into insignificance. More dangerous was the tendency of the *Länder* (provinces, or states) to break away from Vienna or to claim almost complete independence. Though the principal motive of this was reluctance to send food supplies to Vienna, it also represented a genuine social, political, and ideological conflict: the administration of the industrialized capital was Socialist controlled, while the *Länder*, being predominantly agrarian, remained conservative and faithful to the Catholic tradition. This difference was aggravated by the fact that the monarchy had been the only bond between the German Austrian lands; with the abdication of the Emperor, no symbol of loyalty common to all *Länder* remained. Vorarlberg voted for union with Switzerland in May 1919, and Tirol also attempted to secede.

The constitutional settlement. In February 1919, elections for a constitutional assembly were held. The Social Democrats were returned as the largest single party, with 69 seats. Sixty-three were won by the Christian Socialists and 26 by the German Nationalists. When this assembly met (March 4), it had to make wide concessions to federalism in order to appease the provinces. In exchange, Vienna was also elevated to the rank of a state and the mayor made the equivalent of a state governor. This proviso subsequently enabled "Red Vienna" to pursue an autonomous policy, despite the fact that the *Bundesregierung* ("federal government") was controlled by the conservative parties from 1920 to 1934.

Autonomy of Vienna

The constituent assembly also settled the constitution of the federal republic (October 1, 1920). The State Council was abolished, and a bicameral legislative assembly, the Bundesversammlung, was established. The Bundesrat (upper house) was to exercise only a suspensive veto and was to be elected roughly in proportion to the population in each state. This represented a defeat for the federal elements in the states, which had wanted the Bundesrat to exercise an absolute veto and to be composed of equal numbers of members from each state. The lower house, or Nationalrat, was to be elected by universal suffrage on a basis of proportional representation. The Bundesversammlung in full session elected the president of the republic for a four-year term, but the federal government, with the chancellor at its head, was elected in the Nationalrat on a motion submitted by its principal committee; this committee was itself representative of the proportions of the parties in the house.

The foreign policy of Otto Bauer and representatives of

the major political parties had insisted firmly on *Anschluss* ("union") with Germany, and as late as 1921 unauthorized plebiscites held in the western provinces returned overwhelming majorities in favour of union with Germany. But article 88 of the peace treaty of Saint-Germain, signed on September 10, 1919, forbade *Anschluss* without the consent of the League of Nations and also stipulated that the republic should cease to call itself Deutschösterreich (German-Austria); it became the Republik Österreich. The Austrian claim for the German-speaking areas of Bohemia and Moravia was denied by the peace conference, and Austria had to recognize the frontiers of Czechoslovakia along slightly rectified historical administrative lines. The southern frontier with Yugoslavia was threatened by Yugoslav armed invasion, and it was finally decided that the question should be settled by a plebiscite, which, on October 10, 1920, returned a majority of 59 percent in favour of Austria. The German-speaking districts of western Hungary were to be ceded to Austria outright; but Austria, in the face of Hungarian resistance, was obliged to hold a plebiscite. The area of Sopron was finally restored to Hungary.

After the elections of February 1919, Renner formed another coalition government, but after a government crisis in the summer of 1920 a caretaker cabinet under the Christian Socialist Michael Mayr was formed. This government prepared the draft of the constitution and introduced it into parliament. After its approval, new elections were held, on October 17, 1920. The Christian Socialists were returned as the strongest party, gaining 82 seats, while the Social Democrats were reduced to 66 and the German Nationalists to 20. Mayr formed a new cabinet composed of Christian Socialists; the Social Democrats went into opposition and never returned to the government throughout the First Republic. This political division hardened, and no decisive change took place during the following years. The system of proportional representation combined with the ideological background of Austrian parties made oscillations of political allegiance unlikely. Of the two mass parties, the Social Democrats had an unshakable majority in Vienna (in which about a third of all the inhabitants of the republic lived), while the Christian Socialists had an equally secure majority among the Catholic peasants and the conservative classes, the latter consisting largely of army officers, landowners, and big business. The urban middle classes, hostile to both workers and peasants, became German nationalists. But German nationalism was not limited to the middle classes. The workers and even the peasants felt themselves to be Germans and also responded to the national appeal.

Christian Socialist electoral victory (1920)

Economic reconstruction. The main task of the non-Socialist governments in power in Austria from the autumn of 1920 on was to restore financial and economic stability. Between 1919 and 1921, the urban population of Austria lived largely on relief from the United States and Great Britain, and, although production improved, distress was heightened by inflation that threatened financial collapse in 1922. In October 1922, the chancellor, Ignaz Seipel, secured a large loan through the instrumentality of the League of Nations, enabling Austrian finances to be stabilized. In return, Austria had to undertake to remain independent for at least 20 years. The controller general appointed by the League of Nations reported in December 1925 that the Austrian budget had been balanced satisfactorily, and in March 1926 international financial supervision was withdrawn.

Seipel's success in October 1922 gave Austria some years of stability and made economic reconstruction and relative prosperity possible. In Socialist-controlled Vienna, an ambitious program of working class housing, health schemes, and adult education was carried out under the leadership of Karl Seitz, Hugo Breitner, and Julius Tandler. "Red Vienna" thus acquired a unique reputation in Europe.

Political strife. In 1920 all three major parties spoke in democratic terms. Despite democratic phrases, however, preparations for possible civil war had never been abandoned. The Christian Socialists, led by Seipel, a believer in strong government, were convinced that they had to protect the existing social order against a Marxist revolution. In the provinces, reactionary forces (the *Heimwehr*, or "home defense forces"), originally formed for defense against the Yugoslavs or merely against international disorder, gradually acquired Fascist tendencies. The Social Democrats felt that their social-reform program was endangered by reaction. They possessed their own armed force, the *Schutzbund* (Defense League), descended from the People's Guard of 1918, and they and the reactionary forces regularly demonstrated against each other. In 1927, in the course of a clash between members of the Schutzbund and certain reactionary forces at Schattendorf, an old man and a child were accidentally shot by the reactionaries. When the latter were acquitted by a Vienna jury on July 14, the Social Democrats called for a mass demonstration, which got out of hand and ended in the burning down of the ministry of justice. In street fighting between the police and the demonstrators, almost 100 persons were killed. The Social Democrats then launched a general strike, but this had to be called off after four days. Seipel had used the opportunity for a violent assertion of government authority. The balance between Socialist and non-Socialist forces in Austria was never secure after this decisive date.

Emergence of Fascist groups

The Christian Socialists, pressed increasingly by the *Heimwehr*, now began to take the offensive against the Social Democrats. Wilhelm Miklas, a leading Christian Socialist, was elected president as successor to the non-party Michael Hainisch, who had been in office since December 1920. There were repeated attempts to revise the constitution, principally with the object of strengthening the power of the executive. After protracted negotiations, a compromise was reached late in 1929. On December 7, 1929, a series of constitutional amendments gave increased powers to the president. Of particular importance were the rights to appoint ministers and issue emergency decrees. But Vienna preserved its autonomy, and the democratic principle was preserved against the far-reaching authoritarian demands of the *Heimwehr*. In the elections of November 1930, the Social Democrats were returned as the largest single party, with 72 seats. The Christian Socialists held 66, the German Nationalists 19, and the *Heimwehr*, now posing as a Fascist party on the Italian model, 8.

These political events were overshadowed by the great world economic crisis. Though the Social Democratic leaders believed that the crisis should be met by the orthodox means of deflation and spending cuts, they were resolved not to be compromised by supporting these measures and refused to enter a coalition government. On the other hand, in October 1931 they acquiesced in suspending the election of the president by direct popular vote, as had been provided by the constitution of 1929, and agreed to the re-election of Miklas by parliament for a further four years. The government, meanwhile, led by Otto Ender and Johann Schober, was driven to desperate devices in order to stave off collapse. Schober, leader of the middle class German Nationalists, launched the project for a customs union with Germany in March 1931; this provoked violent opposition from France and the alliance of the Little Entente (Czechoslovakia, Yugoslavia, and Romania) and was subsequently condemned by a majority of the International Court at The Hague. The bankruptcy in May 1931 of the Creditanstalt, the most influential banking house in Austria, brought Austria close to financial and economic disaster. This, together with the rise of the National Socialists in Germany, resulted in considerable support being given to the Nazis in Austria; and the provincial elections in 1932 showed that they were draining off votes from the conservative parties. The Nationalists began to demand a general election, and this demand was taken up by the Social Democrats, who saw a chance of winning a majority in parliament.

Proposed customs union with Germany (1931)

Authoritarianism: Dollfuss and Schuschnigg. After the election, when Engelbert Dollfuss came to form a Christian Socialist government on May 20, 1932, he could count on a majority of only one vote. Dollfuss be-

longed to a new generation that had been educated in the conservative conviction that the Western form of parliamentary government had been forced upon the central Europeans as a result of military defeat and Socialist revolution and that the political and social order could be restored only by the establishment of some kind of strong authority. The leaders of the Christian Socialist Party found themselves under attack from two ideological enemies, the Marxists and the Nazis, who apparently threatened the very basis of the conservative order. In reaction, Dollfuss thus determined to replace parliamentary government by an authoritarian system. The opportunity to do this came in March 1933, when, during a debate on a minor bill, an argument arose over alleged irregularities in the voting procedure. The president of the Nationalrat resigned; the two vice-presidents followed his example; and Dollfuss declared that parliament had proved unworkable. It never met again in full, and Dollfuss governed thenceforth by emergency decree.

The end of parliamentary government

By this time (spring of 1933), Adolf Hitler was in power in Germany, and Nazi propaganda for the incorporation of Austria was greatly increased. In this situation, Dollfuss turned to Italy for help, convinced that British and French aid would be ineffective. This shift in foreign policy can also be attributed to the fact that Dollfuss had to rely on the help of the *Heimwehr* to stay in power: the anti-Marxist *Heimwehr* had been in close contact with the Italian Fascist Party for a number of years, and when Dollfuss visited Benito Mussolini at Riccione in August 1933, he secured Mussolini's promise to protect Austria's independence only on the condition that he would give the *Heimwehr* a free hand in the destruction of the Social Democratic Party in Austria.

The Social Democrats were subjected to increasing provocation and on February 12, 1934, took to arms. Civil war followed. After four days of fighting, Dollfuss and the *Heimwehr* were victorious. The Social Democratic Party was declared illegal and driven underground. In the course of the same year, all political parties were abolished except the Vaterländische Front (Fatherland Front), which Dollfuss had founded in 1933 to unite all conservative groups. In April 1934, the rump of the parliament was brought together and accepted an authoritarian constitution. The executive was given complete control over the legislative branch of government; the elected assemblies disappeared and were replaced by advisory bodies, appointed in a complicated and futile fashion. The rights of man guaranteed under the democratic constitution were also swept away. "Republic" was removed from the official name of the state, which became merely the Federal State of Austria.

Dollfuss murdered by Nazis

On July 25, 1934, a group of Nazis seized the chancellery and attempted to proclaim a Nazi government. Dollfuss, whom they had taken prisoner, was murdered. The plan, however, miscarried: the Nazi party in the chancellery was compelled to surrender, and its leaders were executed; a Nazi rising in Styria was suppressed; and, faced with the mobilization of an Italian army on the Brenner Pass, Hitler repudiated his Austrian followers. Franz von Papen was sent as German ambassador to reduce Austria by other means. Kurt von Schuschnigg, who became chancellor on the death of Dollfuss, was a man of gentler personality and of less violent political passions. The administration of the authoritarian constitution was in the easygoing Austrian fashion, less oppressive than in Italy and Germany. Schuschnigg had a mild preference for restoring the Habsburgs, but he shrank from the international complications that this would involve. The regime drifted on without popular favour, weakened by the personal rivalries and ambitions of its leaders and sustained only by a guarantee from Italy. The temporary accord of Great Britain, France, and Italy in the "Stresa front" (April 1935) seemed to promise new security, but the Ethiopian crisis soon destroyed the unity of the Western powers, and Austria's isolation was complete when Hitler and Mussolini allied themselves in 1936. Schuschnigg had to negotiate a compromise with Germany, which was signed on July 11, 1936; Germany promised to respect Austrian sovereignty, and in return Austria acknowledged itself "a German state." Schuschnigg promised amnesty to the Nazis and held out a prospect of including some "nationally minded" Austrian in his ministry in the future. The agreement of July 1936 left Austria open to Nazi infiltration. In January 1938, the Austrian police discovered a new Nazi conspiracy. Schuschnigg hoped to defeat this by a meeting with Hitler, but at Berchtesgaden, where Hitler received Schuschnigg on February 12, 1938, Schuschnigg was faced with threats of massive military intervention in support of the Austrian Nazis. He had to agree to give a general amnesty to the Austrian Nazis and to include some leading Nazis in his cabinet; the ministry of the interior had to be entrusted to Arthur Seyss-Inquart, the spokesman of Austrian Nazis. The open agitation of the Nazis threatened to destroy the government's authority, and confidential contacts in the European capitals brought Schuschnigg to realize that he could not count on the support of the great powers. He therefore resolved to challenge Hitler alone. On March 9 he announced that a plebiscite would be held on March 13, 1938, to decide in favour of Austrian independence.

Anschluss and World War II. Hitler could not allow Schuschnigg's plebiscite to be held. Though the Austrian crisis had taken him unaware, he acted with energy and speed. Mussolini's neutrality was assured, there was a ministerial crisis in France, and the British government had made it known for some time that it would not oppose union of Austria with Germany. On March 11, 1938, two peremptory demands were made for the postponement of the plebiscite and for the resignation of Schuschnigg. Schuschnigg gave way, and German troops, accompanied by Hitler himself, entered Austria on March 12. A Nazi government in Austria, headed by Arthur Seyss-Inquart, was established and collaborated with Hitler in proclaiming the *Anschluss* on March 13. France and Great Britain protested against the methods used by Hitler but accepted the *fait accompli*, as did all other governments. A plebiscite on April 10, held throughout greater Germany, recorded a vote of more than 99 percent in favour of Hitler.

Hitler marches into Austria (March 1938)

Austria was absorbed into Germany for all purposes. Immediately after the invasion, the Nazis arrested the leaders of the Austrian political parties. Many Austrians, especially those of Jewish origin, went into exile, but the political antagonism that had previously weakened the status of the republic continued to block cooperation among the emigrés, as well as among the resistance groups that formed inside Austria.

The possibility of re-establishing an independent Austria was, however, far from dead, and, after the outbreak of World War II, the Allied governments began to reconsider their attitude toward the *Anschluss*. In December 1941, Stalin informed the British that the Soviet Union would regard the restoration of an independent Austrian republic as an essential part of the postwar order in central Europe, and, at the meeting of the foreign ministers of Great Britain, the U.S.S.R., and the United States in Moscow (October 1943), a declaration was published that declared the union with Germany null and void and pledged the Allies to restore Austrian independence. Though British Prime Minister Winston Churchill continued to make various proposals for setting up a central European federation comprising the former Habsburg lands and even southern Germany, the European Advisory Commission in London prepared its plans for the liberation and occupation of Austria on the assumption that Austria would return to sovereignty within the borders of 1937. When Soviet troops liberated Vienna on April 13, 1945, representatives from the resistance movement and the former political parties were allowed to organize.

THE SECOND REPUBLIC

The Allied occupation. On April 27, 1945, Karl Renner set up a provisional government composed of Social Democrats, Christian Socialists, and Communists and proclaimed the re-establishment of Austria as a democratic republic. The Western powers, afraid that the Renner government might be an instrument of Communist

expansion, withheld full recognition until the autumn of 1945. Because of similar suspicions, agreement on the division of Austrian zones of occupation was delayed until July 1945. Shortly before the Potsdam Conference (which stipulated that Austria would not have to pay reparations but assigned the German foreign assets of eastern Austria to the Soviet Union), control machinery was set up for the administration of Austria, giving supreme political and administrative powers to the military commanders of the four occupation armies. In September 1945, a Länderkonferenz of representatives of all provinces extended the authority of the Renner government to all parts of Austria. A general election held in November 1945, in which former Nazis were excluded from voting, returned 85 members of the Austrian People's Party (corresponding to the Christian Socialists of the prewar period), 76 Socialists (corresponding to the Social Democrats and Revolutionary Socialists), and 4 Communists. Renner was elected president of the republic; Leopold Figl, leader of the Austrian People's Party, became chancellor of a coalition cabinet. The government decided not to draft a new constitution but to return to the constitution of 1920, as amended by the laws of 1929. In June 1946, the control agreement of July 1945 regulating the machinery of Allied political supervision was modified by restricting Allied interference essentially to constitutional matters. Denazification laws passed in 1946 and 1947 eliminated Nazi influence in the public life of Austria. In the postwar years, the Austrian People's Party and the Socialists were the sole partners in a coalition government that was formed in proportion to the parties' strength in parliament. This principle of proportional representation, originally introduced in 1919, was to be an important factor in Austrian political life after 1945.

General elections of November 1945

From 1945 to 1952, Austria had to struggle for survival. After liberation from Nazi rule, the country faced complete economic chaos. Aid provided by the United Nations Relief and Rehabilitation Administration (UNRRA) and, from 1948, support given by the United States under the Marshall Plan made survival possible. Heavy industry and banking were nationalized in 1946, and, by a series of wage–price agreements, the government tried to control inflation. Reconstruction was especially difficult in the Soviet zone of occupation, where military commanders continuously interfered in political and economic affairs. The result was a migration of capital and industry from Vienna and Lower Austria to the formerly purely agricultural western provinces. This brought about a far-reaching transformation of the economic and social structure of the country. Austria remained occupied by U.S., British, French, and Soviet forces until 1955. A treaty restoring Austrian sovereignty was expected early, but the atmosphere of the Cold War made agreement among the former Allied powers impossible. In 1953, however, a heavy burden was removed from the Austrian economy when the Soviet government declared that it would pay its own occupation costs (as the United States had done since 1947). Thereupon, the British and the French followed suit.

Party alignments

In 1949 former Nazis were allowed to participate in the general election. The Union of Independents (later renamed as the Freedom Party), corresponding to the former German Nationalist group but free from ideological ties, won 16 seats in parliament. In the subsequent elections (1953, 1956, 1959, 1962), the relationship of the three parties remained stable.

When Renner died (December 31, 1950) Theodor Körner, the Socialist mayor of Vienna, was elected president of the republic by direct popular vote. On his death (January 4, 1957) the leader of the Socialist Party, Adolf Schärf, was elected president. After being re-elected in 1962, Schärf died in office in 1965. He was succeeded by Franz Jonas, former mayor of Vienna, who began a second term in April 1971.

The influence of the Socialists in the coalition government, which had been relatively strong under Leopold Figl's chancellorship, was reduced when the Austrian People's Party replaced Figl with Julius Raab in the spring of 1953 and had Reinhard Kamitz appointed minister of finance. The subsequent economic reconstruction and the advance to a prosperity unknown to Austrians since the years before World War I is generally identified with the so-called Raab–Kamitz course, based on a modified free-market economy. The nationalized steel industry, electrical-power plants, and oil fields, together with the privately owned lumber and textile industries and the tourist traffic, were the major economic assets.

The Berlin conference of the foreign ministers of the Big Four (France, Great Britain, the Soviet Union, and the United States; January 1954) raised Austrian hopes for the conclusion of a peace treaty. For the first time, Austria was admitted as an equal conference partner, but the failure of the foreign ministers to agree on the future of Germany again prejudiced Austria's chances. It appeared that the Soviet government was not prepared to forego its strategic advantages in Austria so long as Germany was not "neutralized." In February 1955 the Soviet government suddenly contacted the Austrian government and extended an invitation to bilateral negotiations in Moscow. An Austrian delegation visited Moscow in April 1955, and a memorandum was agreed on, according to which the Soviet government declared itself ready to restore full Austrian sovereignty and to evacuate its occupation troops in return for an Austrian promise to declare the country permanently neutral.

Restoration of sovereignty. The treaty was signed in Vienna on May 15, 1955, by the representatives of the four powers and Austria. It formally re-established the Austrian republic in its pre-1938 frontiers as a "sovereign, independent and democratic state." It prohibited *Anschluss* between Austria and Germany as well as the restoration of the Habsburgs. It guaranteed the rights of the Slovene and Croatian minorities in Carinthia, Styria, and Burgenland. The United Kingdom, the United States, and France relinquished to Austria all property, rights, and interests held or claimed by them as former German assets or war booty. The U.S.S.R., however, obtained tangible payment for the restoration of Austrian freedom. This included $150,000,000 for the confiscated former German enterprises which Austria had to buy back from the Administration of Soviet Property in Austria; $2,000,000 for the confiscated German assets of the First Danube Steamshipping Company; and 10,000,000 metric tons of crude oil as the price of Austrian oil fields and refineries which had been Soviet war booty. The state treaty came into force on July 27, 1955. By October 25 all occupation forces were withdrawn, and Austria recovered its freedom and sovereignty, lost on March 13, 1938. On October 26, 1955, a constitutional law of perpetual Austrian neutrality was promulgated. The Austrian government had never left any doubts that the pledge to neutrality could be interpreted only as a military one and never as an ideological one. Throughout the Soviet occupation, the Austrians had proved their anti-Communist attitude, and the spontaneous reaction of the Austrian people during the suppression of the Hungarian Revolution in 1956 demonstrated their sympathy with Western democratic ideas. Austria preserved political stability; changes in the personal and ideological structure of the government and political parties were effected without major political crisis.

Austria becomes a formal neutral

From 1962 disagreement over economic problems generated friction between the coalition parties. The annual budget led to grave disunity in the coalition, and in the autumn of 1965 the government resigned and called new elections. The election, held on March 6, 1966, brought a setback for the Socialist Party, and the People's Party was returned to parliament with an absolute majority. Negotiations for a new coalition government failed. The Socialists, led by former foreign minister Bruno Kreisky, went into opposition, and Josef Klaus formed the first one-party cabinet of the Second Republic. Contrary to widespread misgivings, the political stability of the country was not disturbed, and parliament was given new vigour and influence. In ensuing provincial elections, the Socialist Party demonstrated recovery from the setback of 1966, and in the national elections of 1970 the So-

cialist Party managed to win a plurality of votes, becoming the strongest party in parliament, with 81 seats, but falling short of a majority. After negotiations for a new coalition cabinet failed, in May 1970 Bruno Kreisky was appointed chancellor; he formed the first Austrian all-Socialist cabinet. Sensing increased support for the Socialists he called for new elections in October 1971. Now the Socialists won a clear majority of 93 seats.

Participation in European organizations

Austria became a member of the United Nations in 1955 and of the European Council in Strasbourg in 1956. Major problems of Austrian foreign relations were the conflict with Italy over South Tirol (Alto Adige) and the problem of association with the European Economic Community (EEC). During the Paris Peace Conference of 1946 an agreement was signed guaranteeing the rights of the German-speaking population of South Tirol. The Austrian government, claiming that the Italians had not lived up to their obligations, initiated bilateral talks. In the early 1960s, acts of terrorism committed by German-speaking chauvinists blocked the progress of the negotiations, but in 1969 agreement was finally reached on implementation of the guarantees provided in the 1946 agreement. In 1958 Austria joined the European Free Trade Association, but a special arrangement with the EEC was regarded as essential to the Austrian economy. Membership in the EEC would, however, present special difficulties, as Austria's neutral status might be compromised. Negotiations to resolve this problem were continuing in the early 1970s. (F.Fe.)

Austro-Asiatic Languages

Austro-Asiatic languages are spoken by approximately 40,000,000 people scattered throughout Southeast Asia and eastern India. The family comprises about 150 languages, most of them having numerous dialects. Khmer, Mon, and Vietnamese are culturally the most important and have the longest recorded history. The rest are languages of non-urban minority groups written, if at all, only recently. The family is of great importance as a linguistic substratum for all Southeast Asian languages.

Superficially, there seems to be little in common between a monosyllabic tone language like Vietnamese and a polysyllabic toneless Munda language like Mundari of India; every recent study, however, confirms the underlying unity of the family. The date of separation of the three main Austro-Asiatic subfamilies—Munda, Nicobarese, and Mon-Khmer—has never been estimated and must be placed well into prehistory. Within the Mon-Khmer subfamily itself, 12 main branches are distinguished; glottochronological estimates of the time during which specific languages have evolved separately from a common source (derived from a comparison of similarities in selected vocabulary items) indicate that these 12 branches all separated at approximately 1000 to 2000 BC.

Munda, Nicobarese, and Mon-Khmer subfamilies

Relationships with other language families have been proposed, but, because of the considerable time depths involved and the scarcity of reliable data, it is very difficult to present a solid demonstration of their validity. In 1906 Wilhelm Schmidt, a German priest and anthropologist, classified Austro-Asiatic together with the Austronesian family (formerly called Malayo-Polynesian) to form a larger family called Austric. More recently, Paul K. Benedict, a U.S. scholar, accepting the Austric theory, extended it to include the Tai-Kadai family of Indochina and Burma and the Miao-Yao family of China, together forming an "Austro-Tai" superfamily.

Regarding subclassification within Austro-Asiatic, there have been several controversies. Schmidt, who first attempted a systematic comparison, included in Austro-Asiatic a "mixed group" of languages containing "Malay" borrowings and did not consider Vietnamese to be a member of the family. On the other hand, some of his critics contested the membership of the Munda group of eastern India. The "mixed group," recently called Chamic, is now considered to be Austronesian. It includes Cham, Jarai, Rhade, Chru, Roglai, and Hroy, and repre-

sents an ancient migration of Indonesian peoples into southern Indochina. As for Munda and Vietnamese, the recent works of the German linguist Heinz-Jürgen Pinnow on Kharia and of the French linguist André Haudricourt on Vietnamese tones have shown that both language groups are Austro-Asiatic.

Classification of the Austro-Asiatic languages. The work of classifying and comparing the Austro-Asiatic languages is still in the initial stages. In the past, classification has been done mainly according to geographic location. For instance, Khmer, Pear, and Stieng, all spoken on Cambodian territory, were all lumped together, although they actually belong to three different branches of the Mon-Khmer subfamily.

The main lines of the following classifications have been established by the glottochronological method, which involves the statistical comparison of similarities.

Munda subfamily (East India, *c.* 6,000,000 speakers)
- A. North Munda:
  - 1. Korku
  - 2. Kherwarian:
    - a. Santali
    - b. Mundaric
      - i. Mundari
      - ii. Asuri
      - iii. Bhumij
      - iv. Birhor
      - v. Ho
      - vi. Koda
      - vii. Korwa
      - viii. Turi
- B. South Munda:
  - 1. Central Munda:
    - a. Kharia
    - b. Juang
  - 2. Koraput Munda:
    - a. Sora, Gorum
    - b. Geta, Gutob, Remo
- C. (?) West Munda: Nahali

Nicobarese subfamily (Nicobar Islands, *c.* 7,000 speakers)
- A. North Nicobar:
  - 1. Car
  - 2. Chowra
  - 3. Teressa, Bompaka
- B. Central Nicobar:
  - 1. Camorta
  - 2. Nancowry
  - 3. Trinkut, Katchall
- C. South Nicobar:
  - 1. Coastal Great Nicobar
  - 2. Little Nicobar
- D. Inland Great Nicobar: Shompe

Mon-Khmer subfamily (continental Southeast Asia, *c.* 35,000,000 speakers)
- A. Khasi branch (Assam, *c.* 200,000 speakers)
  - 1. Standard Khasi
  - 2. Lyngngam
  - 3. Synteng
  - 4. War
- B. Palaungic branch (Burma, Thailand, Yunnan Province, over 1,000,000 speakers)
  - 1. Palaung
  - 2. Wa
  - 3. Riang-Lang
  - 4. Danaw
  - 5. Lawa
  - 6. Kawa
  - 7. (?) Khamet
  - 8. (?) Mang
  - 9. Bulan
  - 10. Angku
- C. Monic branch (Burma, Thailand, *c.* 500,000 speakers)
  - 1. Mon
  - 2. Niakuol
- D. Khmuic branch (Laos, Thailand, number unknown)
  - 1. Khmu'
  - 2. Mal
  - 3. Mrabri
  - 4. Yumbri
  - 5. Khao
  - 6. Tayhat
  - 7. (?) Puôc
  - 8. (?) Lamet
  - 9. Tin
  - 10. (?) Kha Kon Ku'
  - 11. Kha Kwang Lim
  - 12. (?) Kha Doi Luang
- E. Viet-Muong branch (Vietnam, [?] 23,000,000 speakers)
  - 1. Vietnamese:
    - a. North upland
    - b. Lowland (several major dialects)
  - 2. Muong: Pi, Thàng, Tông, Wang
  - 3. Mày
  - 4. Arem
  - 5. Tày Pong
  - 6. (?) Sach
  - 7. (?) Nguôn
  - 8. (?) Hung Khong Khêng
- F. Katuic branch: (Vietnam, Laos, Cambodia, over 200,000 speakers)
  - 1. Katu
  - 2. Kantu, High Katu
  - 3. Phuâng
  - 4. Brũ
  - 5. Pacoh
  - 6. Taoih
  - 7. Ngeq, Nkriang
  - 8. Kataang
  - 9. Kuy
  - 10. Lor
  - 11. Leu
  - 12. Ir
  - 13. Tong
  - 14. Souei
  - 15. So
  - 16. Alak
  - 17. (?) Kasseng
  - 18. (?) Tiari
- G. Bahnaric branch (mostly South Vietnam, over 550,000 speakers)
  - 1. South Bahnaric:
    - a. Stieng
    - b. Chrau
    - c. Srê
    - d. Mnong: South Central, East,
  - 2. West Bahnaric:
    - a. Loven
    - b. Nyahöñ, Prouac
    - c. Oi, The
    - d. Lave
    - e. (?) Brao, Kru'ng, Kravet
    - f. Sok
    - g. Sapuan
    - h. Cheng
    - i. (?) Suq
  - 3. North Bahnaric:
    - a. Bahnar
    - b. Rengao
    - c. Sedang
    - d. Jeh, Halăng
    - e. Mo'no'm
    - f. Kayo'ng
    - g. Hrê
    - h. Cua
    - i. Takua
    - j. To'drah
    - k. (?) Duan
- H. Pearic Branch (Cambodia, [?] 5,000 speakers)
  - 1. Pear
  - 2. Chong
  - 3. Samre
  - 4. Angrak
  - 5. Sa'och

I. Khmer (Cambodia, Thailand, South Vietnam, [?] 5,500,000 speakers)
J. Jahaic branch (Malaya and Thailand, *c.* 2,000 speakers)
1. Tonga
2. Kensiu, Kintak
3. Jahai
4. Menriq
5. Mintil, Batek
6. Che Wong
K. Senoic branch (Malaya, *c.* 30,000 speakers)
1. Temiar, Lanoh, Semnam
2. Semai
3. Jah Hut
L. Semelaic branch (Malaya, *c.* 5,000 speakers)
1. Mah Meri
2. Semelai, Temoq, Semaq Bri

Khmer and Vietnamese: national languages

Numerically the most important, the Khmer and Vietnamese languages are also the only national languages of the Austro-Asiatic group and are regularly taught in schools and used in the mass media and on official occasions. Speakers of most other Austro-Asiatic languages are under strong social and political pressure to become bilingual in the official languages of the national unit in which they live. Most groups are too small or too scattered to win recognition, and, for many, the only chance of cultural survival lies in retreating to a mountain or jungle fastness, an old Austro-Asiatic tradition.

Alternate Names of Languages and Dialects

Alakong	Bahnar
Amok	Angku (Palaungic)
Attouat	Katu
Boda	Gutob
Bahr	Pear
Besisi	Mah Meri (Semelaic)
Be	Wa
Biat	C Mnong (S Bahnaric)
Bodo, Bondo	Gutob (Munda)
Bondo	Remo
Boloven	Loven (W Bahnaric)
Bo'nâm	Mo'no'm (N Bahnaric)
Cambodian	Khmer
Câu	Khmu'
Chaoban	Niakuol (Monic)
Chau Ma	Srê (S Bahnaric)
Chawng, Chong	Pear
Central Sakai	Semai (Senoic)
Davak, Davach	Hrê (N Bahnaric)
Darang	Palaung
Dedang	Rengao (N Bahnaric)
Didey	Geta' (Munda)
Dié	Jeh (N Bahnaric)
Eastern Sakai	Jah Hut (Senoic)
Ernga	Korwa (Munda)
En	Wa (Palaungic)
Gadaba	Gutob (Munda)
Galler	Brũ (Katuic)
Gar	East Mnong (S Bahnaric)
Hasada	Mundari (Munda)

Phonological characteristics. In order to make general statements about the phonology (sound systems) of Austro-Asiatic languages, it is necessary to exclude Munda and Vietnamese, which, having been under the influence of Indian and Chinese languages, respectively, have acquired very divergent characteristics. The usual Austro-Asiatic word structure consists of a major syllable sometimes preceded by one or more minor syllables. A minor syllable has one consonant and one minor vowel. Most languages have only one type of minor vowel or, sometimes, three (*e.g.*, *a*, *i*, or *u*); others may also have vocalic nasal sounds, which are produced by releasing the breathstream through the nose, or liquids (*l* and *r* sounds) as minor vowels. Major syllables are composed of one or two consonants, followed by one major vowel and usually one final consonant.

Consonants. A typical consonant system for an Austro-Asiatic language would be the following (the symbols used are from the International Phonetic Alphabet):

p	t	c	k	ʔ
b	d	j	g	
ɓ	ɗ			
m	n	ɲ	ŋ	
w	r	l	s	y h

Some languages (*e.g.*, Pearic, Semelaic) have an aspirated series of consonants, p^h, t^h, c^h, k^h, in which the sounds have an accompanying audible small puff of air, and many have no voiced stops at all (Monic, Khmer, Pearic). (Stops are consonants made with complete stoppage of the breathstream at some point in the vocal tract; voiced stops such as *b*, *d*, and *g* are produced with vocal cord vibration, as opposed to voiceless sounds produced without vocal cord vibration.) The imploded ɓ and ɗ are sounds pronounced by briefly drawing the air inward, causing suction, and are not truly voiced; they have sometimes been called preglottalized sounds or "semivoiceless" sounds. These imploded stops are found only in a few branches of Mon-Khmer (*e.g.*, Mon, Khmer, Bahnaric), but it is possible that they existed in the ancestral language, called Proto-Mon-Khmer. Pre-glottalized nasals and liquids (*i.e.*, nasal and liquid sounds preceded by a glottal stop) are also found, sometimes as single distinctive sounds (unit phonemes) and sometimes as consonant clusters. In final position, all consonants except voiced stops can be found, but in several languages (*e.g.*, Mon, Sedang, Palaung) the number of possibilities is more reduced. Final stops are pronounced without release, nasals are often decomposed (*e.g.*, a final *m* becomes pronounced as b^m), and *s* sounds usually tend toward *h* sounds. Palatal consonants (*č* and *ñ*), produced with the blade of the tongue touching the hard palate, are commonly found at the end of words, a feature that sets Austro-Asiatic languages apart from the other languages of South Asia.

Vowels. Also characteristic of the Austro-Asiatic languages is an extraordinary variety of major vowels: systems of 30 to 35 different vowels are not uncommon (Bru has 41 distinctive vowel sounds [phonemes]). Four degrees of height are often distinguished in front and back vowels as well as in the central area. Diphthongs are not rare. Vowel length is usually distinctive: a normal vowel may contrast with an extra-short vowel of the same quality. Nasal vowels are found in several branches of the family, but, in any one language, they do not occur very frequently. A few dialects of Palaung, Wa, and North Bahnaric have a simple tone system, usually high versus low tone, but this is not typical of the Austro-Asiatic family. The Viet-Muong branch is the only one to have developed complex tone systems, probably influenced by non-Austro-Asiatic languages.

Registers, or voice qualities

Much more typical of the Austro-Asiatic family is a contrast between two series of vowels pronounced with different voice qualities, which are called registers. The voice may have a "creaky" register, a "breathy" register, or a normal one. Mon, Khmer, Jeh, Sedang, and some Palaung dialects have a two-way distinction of this sort. There is a controversy regarding the historical origin of the registers. Some believe that they were found in the original Proto-Mon-Khmer language; others, who seem to hold the more likely theory, propose that they are independent innovations in each branch, representing a transitional state from toneless to tonal languages.

Grammatical characteristics. *Morphology.* In morphology (word formation), Munda and Vietnamese again show the greatest deviations from the norm. Munda

languages have an extremely complex system of prefixes, infixes (elements inserted within the body of a word), and suffixes. Verbs, for instance, are inflected for person, number, tense, negation, mood (intensive, durative, repetitive), definiteness, location, and agreement with the object. Furthermore, derivational processes indicate intransitive, causative, reciprocal, and reflexive forms. On the other hand, Vietnamese has practically no morphology.

Between these two extremes, the other Austro-Asiatic languages have many common features. (1) Except in Nicobarese, there are no suffixes. A few languages have enclitics, certain elements attached to the end of noun phrases (possessives in Semai, demonstratives in Mnong), but these do not constitute word suffixes. (2) Infixes and prefixes are common, so that only the final vowel and consonant of a word root remain untouched. It is rare to find more than one or two affixes (*i.e.*, prefixes or infixes) attached to one root; thus, because roots are mostly monosyllabic, the number of syllables per word remains very small. (3) The same prefix (or infix) may have a wide number of functions, depending on the noun or verb class to which it is added. For instance, the same nasal infix may turn verbs into nouns and mass nouns into count nouns. Sometimes, these different functions have similar meanings: for instance, reduplication, the repetition of a word or word element, may indicate plurality in nouns and repetition in verbs. This phenomenon may be widespread enough to make the distinction between basic word classes very unclear and questionable. (4) Many affixes are found only in a few fossilized forms and have often lost their meaning. (5) Expressive language and wordplay are embodied in a special word class called "expressives." These are sentence adverbials that describe noises, colours, light patterns, shapes, movements, sensations, emotions, aesthetic feelings, and so on. Some sort of symbolism, perhaps based on synaesthesia, is often observable in these words and serves as a guide for individual coinage of new words. The forms of the expressives are thus quite unstable, and the additional effect of wordplay can create subtle and endless, sometimes apparently empty, structural variations. For example, in Bahnar one can say /pha:m lɛč həmrɔ:ŋ həmra:ŋ "blood flows həmrɔ:ŋ həmra:ŋ (like a torrent, irregularly)." (The slash marks indicate that the symbols enclosed are phonetic, standing for speech sounds rather than letters of the alphabet. Many Austro-Asiatic languages do not have their own writing systems and are thus recorded here in phonetic transcription.) In Semai /slɯ:č, səslɯ:č, səralɯ:č, səralĭ:č, srlĭ:č, shu:č, səsrhu:č, səralĭ:m/ and many other forms describe "a massage on oily skin, a snake's creeps, shiny fur, noodles in Chinese soup," and so on. The Semai forms /ɲəɲ pəlayə:ɲ, lɛɲ kəlayɯ:ɲ, pəɲ pəlayã:ɲ, puɲ pəlayõ:ɲ/ all describe "oversize hat, opening of parachute, flying disc, ridiculously large ears" and are based on wordplay with the borrowed Malay noun /payuŋ/, meaning "umbrella." Spontaneous expression rather than rational communication seems to be the dominant function of these expressives.

Use of "expressives"

Syntax. In syntax, possessive and demonstrative forms and relative clauses follow the head noun; if particles are found, they will be prepositions, not postpositions (elements placed after the word to which they are primarily related), and the normal word order is subject–verb–object. There is usually no copula equivalent to the English verb "be." Thus, an equational sentence will consist of two nouns or noun phrases, separated by a pause; *e.g.*, in Rengao, /klan, bəs kən/, literally "python, snake large," means "a python (is) a large snake" or "pythons (are) large snakes." Predicates corresponding to the English "be + adjective" usually consist of a single intransitive (stative) verb; *e.g.*, in Khmer, /srəy nuh, lᵖɔ:/, literally "girl that, pretty," means "that girl (is) pretty." Ergative constructions (in which the agent of the action is expressed not as the subject but as the instrumental complement of the verb) are quite common; *e.g.*, in Semai, the ergative sentence /tlɛy ʔadɛh ʔɲ-caaʔya ʔɛɲ/, literally, "banana this I-ate by me," means "I ate this banana" as does the active sentence: /ʔɛɲ ʔɲ-caaʔ tlɛy ʔadɛh/ "I I-ate banana this." Also noteworthy are sentence final particles that indicate the opinion, the expectations, the degree of respect or familiarity, and the intentions of the speaker. Munda syntax, here again, is radically different, having a basic subject–object–verb word order, like the Dravidian languages of India. It is quite conceivable that the complexity of Munda verb morphology is a result of the historical change from an older subject–verb–object to the present subject–object–verb basic structure.

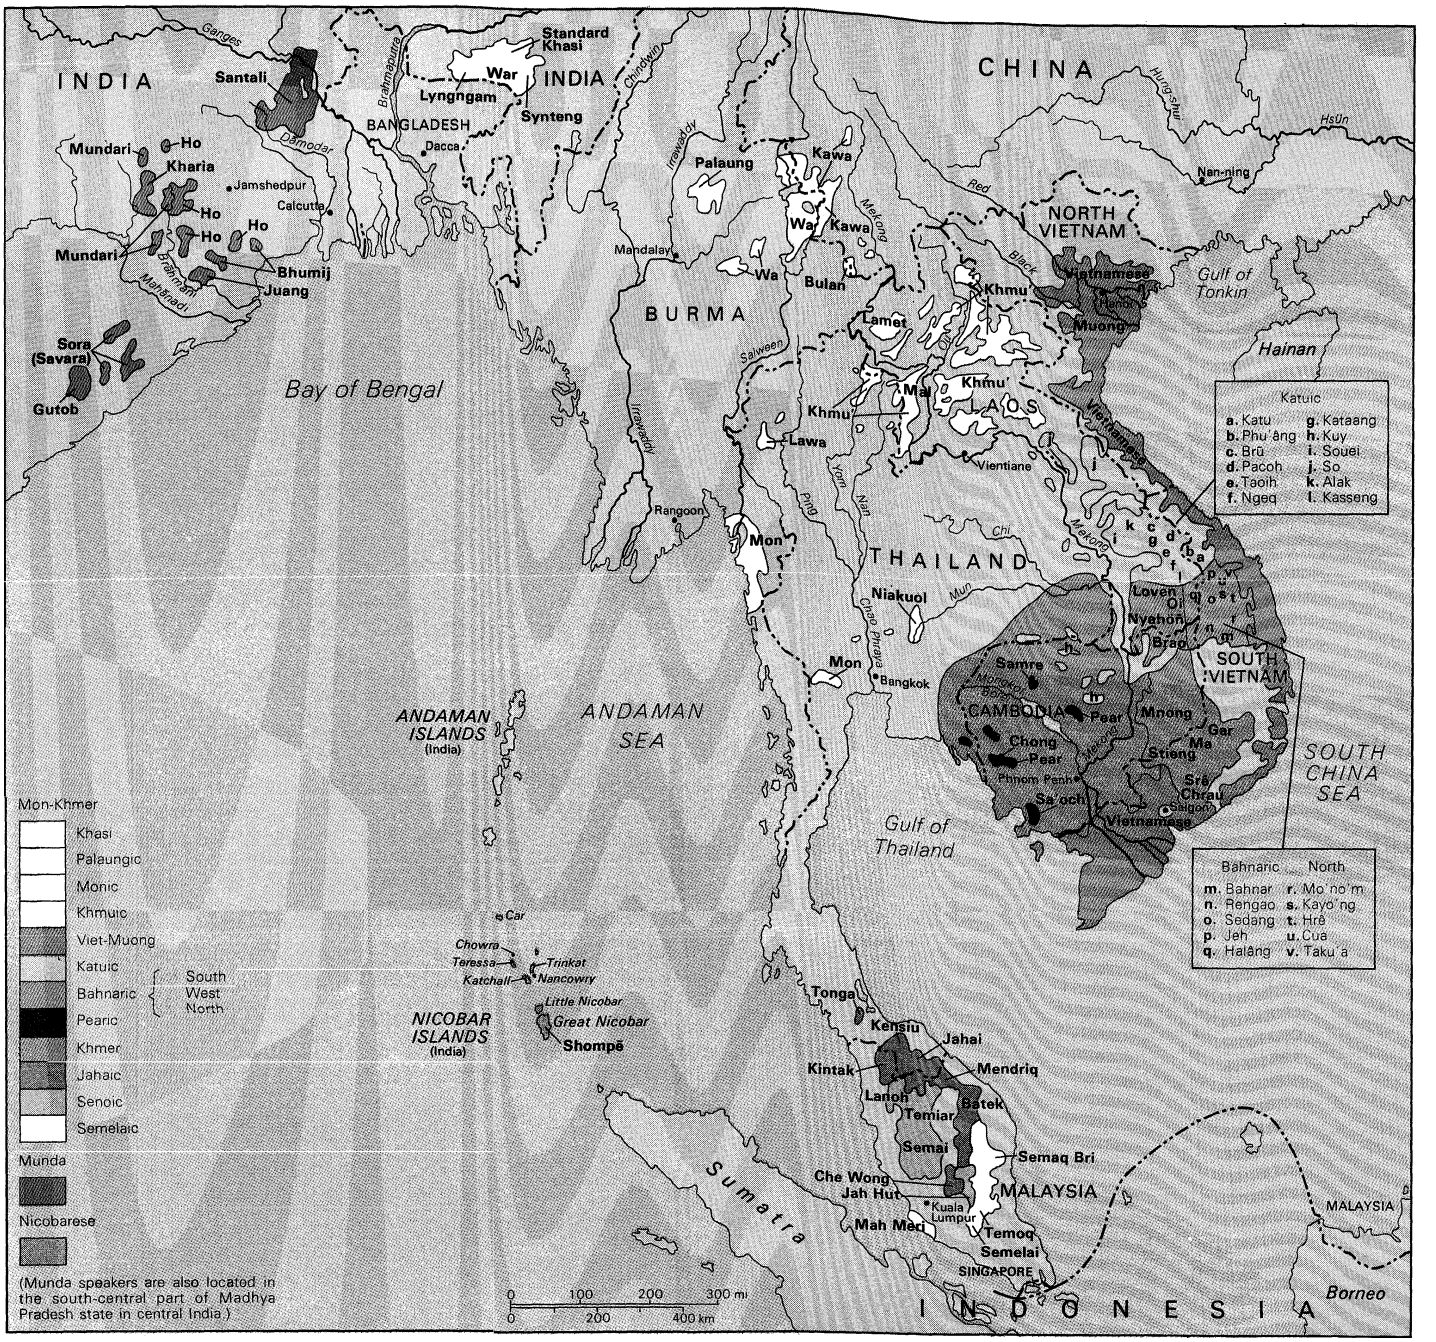
Vocabulary. The composition of the vocabulary of the Austro-Asiatic languages reflects their history. Vietnamese, Mon, and Khmer, the best known languages of the family, came within the orbit of larger civilizations and borrowed without restraint—Vietnamese from Chinese, Mon and Khmer from Sanskrit and Pāli. At the same time, they have lost a large amount of their original Austro-Asiatic vocabulary. It is among isolated mountain and jungle groups that this vocabulary is best preserved. But there, other disruptive forces are at work. For instance, animal names are subject to numerous taboos; and the normal name is avoided in certain circumstances (*e.g.*, hunting, cooking, eating, and so on). A nickname is then invented, often by using a kinship term ("uncle," "Grandfather") followed by a pun or an expressive adverb describing the animal. In the course of time, the kinship term is abbreviated (thus many animal names begin with the same letter), the normal name is forgotten, and the nickname becomes standard. It is then again avoided, and the process is repeated. There are also taboos on proper names; *e.g.*, after a person's death, his name and all words resembling it are avoided and replaced by metaphors or circumlocutions. This may explain why, for instance, the Nicobarese languages, which seem closely related, have few vocabulary items in common. In general, new words and fine shades of meanings can always be introduced by wordplay and from the open-ended set of expressive forms. Borrowings from the nearest majority languages are also common.

Word taboos

Writing systems and texts. Two Austro-Asiatic languages have developed their own orthographic systems and use them to this day. For both scripts, the letter shapes and principles of writing were borrowed from Indian alphabets (perhaps those of the Pallava kingdom in South India) that were in use in Southeast Asia at the time. Both Austro-Asiatic groups modified these alphabets in their own way, to suit the complex phonology of their languages. The most ancient inscriptions extant are in Old Mon (6th century AD), soon followed by Old Khmer in the early 7th century. The monuments of Burma, Thailand, and Cambodia have preserved a large number of official inscriptions in these two languages. Both alphabets were in turn used as models by other peoples for writing their own languages, the Thais using Khmer letters and the Burmese using Mon letters. The religious literature in Old and Middle Mon played a very important role in the spreading of Theravāda Buddhism to the rest of Southeast Asia.

Because Vietnam was a Chinese province for a thousand years, the Chinese language was used and written there for official purposes. In the course of time (perhaps as early as 8th century AD), a system called Chunom (popular writing) was developed for writing the Vietnamese language with partly modified Chinese characters. About 1650, a French missionary, Alexandre de Rhodes, devised a systematic spelling for Vietnamese, based on its distinctive sounds (phonemes). It uses the Latin (Roman) alphabet with some additional signs and several accents to mark tones. In this alphabet, tone was, for the first time in the world, recognized as a functional element and was systematically noted. At first, and for a long time, the use of this script was limited to Christian contexts, but it spread gradually, and in 1910 the French colonial administration made its use official. Now called Quoc-ngu (national language), it is learned and used by all Vietnamese.

Most other Austro-Asiatic languages have been written for less than a century; the literacy rate remains very low



Distribution of the Austro-Asiatic languages.

with a few exceptions (*e.g.*, Khasi). Dictionaries and grammars have been written only for the most prominent languages, with traditional and often insufficient methods. Many languages (*e.g.*, Wa, Kuy, Stieng, Pacoh, Katu, Muong) have only been described briefly in a few articles, and many more (Semelai, Puman, Sa'och, Riang, Lawa, Mrabri) are little more than names on the map.

BIBLIOGRAPHY. H.L. SHORTO, J.M. JACOB, and E.H.S. SIMMONDS (comps.), *Bibliographies of Mon-Khmer and Tai Linguistics* (1963), is an unannotated bibliography of linguistic books and articles from the beginning (1790) to 1960, which does not include the Munda subfamily or the Viet-Muong branch but incorporates the (Austronesian) Cham languages into Mon-Khmer. See W. SCHMIDT, *Grundzüge einer Lautlehre der Mon-Khmer-Sprachen* (1906); *Die Mon-Khmer-Völker: Ein Bindeglied zwischen Völkern Zentralasiens und Austronesiens* (1906; French trans., "Les Peuples Mon-Khmer: trait-d'union entre les peuples de l'Asie Centrale et de l'Austronésie," in *Bulletin de l'École française d'Extrême-Orient*, 7: 213–263 and 8:1–35, 1907–08); and W.W. SKEAT and C.O. BLAGDEN, *Pagan Races of the Malay Peninsula*, 2 vol. (1906). Schmidt's articles for the first time supported the Austro-Asiatic hypothesis with lexical, phonological, and morphological evidence. They remain until today the basic work of Austro-Asiatic studies. Blagden compiled a very large comparative vocabulary but did not attempt any analysis. H.J. PINNOW, *Versuch einer historischen Lautlehre der Kharia-Sprache* (1959), an ambitious project with somewhat uncertain results, contains an analysis and systematic comparison of the phonologies of Munda languages and establishes connections with the rest of the Austro-Asiatic group. The *Mon-Khmer Studies* (Linguistic Circle of Saigon), 4 vol. (1964–), are collections of short technical articles mostly on the Montagnard languages of South Vietnam, with topics varying from basic vocabulary to phonology, morphology, syntax, folk taxonomies, and oral literature.

(G.Di.)

Austronesian Languages

The Austronesian language family, also called Malayo-Polynesian, consists of languages spoken in almost the whole of Malaysia and the Indonesian Archipelago, all of the Philippines, parts of Vietnam, Cambodia, and Taiwan (Formosa), Madagascar, and on all of the main island

groups of the South and Central Pacific (except for Australia and a large part of New Guinea, which contain languages belonging to other stocks). In terms of the number of its languages and of their geographic spread, the Austronesian language family is among the world's largest.

Austronesian languages are generally divided into two primary subgroups: a Western, or Indonesian, branch contains perhaps 200 languages, including such well-known tongues as Malay, Indonesian, Javanese, and Pilipino, the national language of the Philippines (based on Tagalog); and an Eastern branch, more commonly termed Oceanic, comprises about 300 small languages, scattered throughout the South and Central Pacific, the best known of which are the Polynesian group and Fijian. The classification of a small residue of languages is uncertain. While around 150,000,000 people speak languages belonging to the Western Austronesian branch, only about 1,000,000 speak Oceanic languages.

The challenge of piecing together the complex history of a family of languages with such an enormous distribution, and with speakers of such great cultural and physical diversity, has attracted scholars to the study of Austronesian languages. Recently, the Austronesian languages have also received attention because of their structural characteristics and, in addition, have served as a testing ground for subgrouping methods and theories of linguistic change.

HISTORY AND CLASSIFICATION

Resemblances between the languages of Madagascar, the East Indies, and Polynesia were first pointed out in 1706 by Hadrian Reland, a Dutch scholar. It was not until the second half of the 19th century, however, that the languages of the intervening island groups of Melanesia and Micronesia were recognized as belonging to the same family. At that point it became customary to divide Austronesian languages into four groups coinciding with the geographic regions known as Indonesia, Melanesia, Micronesia, and Polynesia. More recently, it has become clear that such a classification is not linguistically valid. Though arguments continue over the position of certain languages, it is generally agreed that most Austronesian languages fall into only two groups. The majority of the languages formerly assigned to the Melanesian and Micronesian divisions, together with the Polynesian group, form a single, although internally very diverse, subgroup: Eastern Austronesian (more often called Oceanic). The Western division coincides fairly closely with the old Indonesian grouping, comprising most, and possibly all, Austronesian languages spoken west of New Guinea, together with two found in Micronesia.

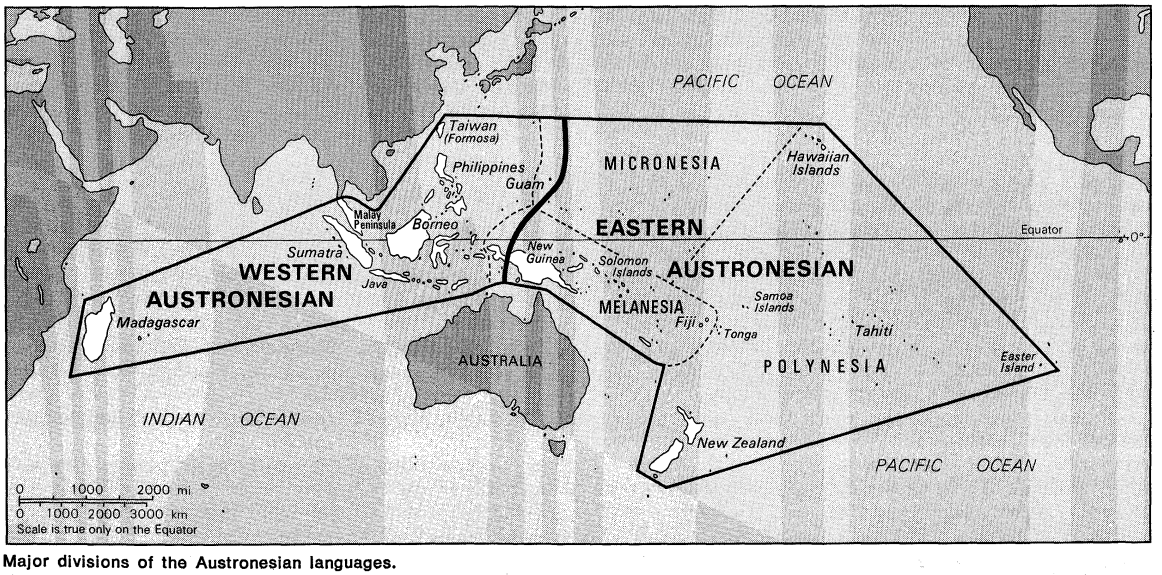
Eastern and Western Austronesian groups

The main areas of disagreement in classification concern the position of the Formosan languages, of certain languages located in eastern Indonesia and on or near the western tip of New Guinea, and of the more divergent languages in Melanesia. The Formosan languages are usually treated as Western Austronesian, though some scholars have suggested that they represent a third primary branch of Austronesian. The languages of east Indonesia, including the western end of New Guinea, more diverse than those of west Indonesia and the Philippines, are sometimes treated as a single subgroup of Western Austronesian, and sometimes regarded as composed of a number of primary branches, each coordinate with Oceanic and with a group comprising the remaining members of Western Austronesian. Similarly troublesome are a number of languages of the north coast of New Guinea and certain regions of insular Melanesia. These languages share very few related words with each other and with other languages in the family, although in grammar they usually show quite strong resemblances to members of the Oceanic subgroup. They are generally regarded as aberrant Oceanic languages, but other theories have been advanced to explain their divergent character.

Proto-Austronesian. A protolanguage is a parent language, or early form of a language or group of languages. It can either be a hypothetical reconstruction or may actually exist in written records, as does Latin, the protolanguage of the Romance tongues. There are no actual records of Proto-Austronesian, but it has been the subject of research and reconstruction by linguists. Because it is clear that the Proto-Austronesian speech community possessed agriculture and may have been responsible for its introduction—along with that of several other important cultural innovations—into the Pacific, the reconstruction of Proto-Austronesian and the history of the dispersal of Austronesian languages has been of considerable concern to culture historians as well as linguists.

Location. The location of Proto-Austronesian has been the subject of much speculation but little systematic investigation. At various times in the past the parent tongue has been placed somewhere in the Southeast Asian mainland, South China, and even in India and Mesopotamia. There is increasing evidence of an archaeological, geographic, and linguistic nature, however, that the homeland lay in the region of Indonesia and New Guinea.

Chronology. The best evidence for dating and determining the directions of the dispersal of Austronesian languages comes from Oceania, where it is easier to correlate linguistic and archaeological findings than in the west. It is clear that Austronesian languages were already in Fiji and Tonga, near the eastern margin of Austronesian territory, by 1000 BC. Archaeological excavations indicate that the coastal area of Fiji was widely settled by that date, that by then Tonga also had been settled by a people with a material culture essentially iden-



Major divisions of the Austronesian languages.

tical to that of the first inhabitants of Fiji, and that Samoa was inhabited a few centuries later. In each place there is continuity of material culture—and, one may assume, continuity of language—right through to the period of European contact. The first Europeans found Fiji and Polynesia (and indeed the whole of the neighbouring island groups—the New Hebrides, New Caledonia, and Micronesia) to be occupied exclusively by Austronesian-speaking peoples. Glottochronology, a technique for dating the division between languages (known as linguistic splits) based on the assumption that there is a stable rate of basic vocabulary replacement in languages, places the separation of the Fijian and Polynesian subgroups at between 3,000 and 4,000 years ago. The divergence of Proto-Polynesian into separate branches is dated at between 1,800 and 2,500 years ago.

These are relatively recent branchings, far down on the Oceanic limb of the Austronesian family tree, and it follows that the separation of the common ancestor of Fijian and Polynesian from more distant branches of Oceanic must have occurred somewhat earlier. Glottochronological estimates indicate that diversification of Austronesian languages began around 4,000 to 5,000 years ago in the New Hebrides, in New Caledonia, and in the Solomons, and earlier still in the region of New Guinea. Very little archaeological work has been done in these areas, but assemblages of artifacts similar to those found in early Fijian and Tongan sites have been unearthed in New Caledonia and the central New Hebrides and dated at 800 BC and 600 BC respectively. The general trend, at least, is clear. The dispersal of Austronesian languages in Oceania cannot have begun later than around 2000 BC, with 3000 BC appearing to be a more realistic estimate.

Glottochronological computations suggest that the differentiation of the Western Austronesian languages was well advanced by 1000 BC.

Relationships to other families. Many different proposals have been made to link Austronesian with other language groups—Mon-Khmer, Munda, and Vietnamese of the Austroasiatic language family, Tai-Kadai, Sino-Tibetan, and Indo-European, among others. None has been convincing. Ultimately, no doubt, Austronesian languages, like every other family in Oceania, must derive from ancestral stages spoken in Asia at some remote period. Discovery of such distant connections, however, will have little bearing on the question of where the ancestral Austronesian language itself developed.

Reconstruction. Many scholars have worked to reconstruct the Proto-Austronesian sound system and word stock. The reconstructions of Otto Dempwolff, a German ethnologist and linguist, published between 1920 and 1938, have remained the point of departure for all subsequent comparative studies. Dempwolff attributed to Proto-Austronesian a four-vowel system, consisting of a low vowel *a* and three higher vowels—*i* (front), *e* (central), and *u* (back). The reconstructed consonants are the voiced stops *b, d, D, j, g* (a stop is a sound made with complete stoppage of the breath from the lungs); the matching voiceless stops *p, t, T, c, k* and the glottal stop *q;* the nasal consonants *m, n, ñ,* ŋ (nasals are pronounced with the breath going through the nose); the semivowels *w* and *y;* plus *l, r, R, h, s, z,* and *Z.* (Phonetic value of phonemes represented by capital letters, and that of certain other reconstructed symbols, cannot be precisely determined.) Most word bases consisted of two syllables, the commonest shape being consonant-vowel-consonant-vowel-consonant or consonant-vowel-consonant-consonant-vowel-consonant. Clusters of consonants were restricted to a few types and occurred only in the middle of words and possibly in initial position. Words with initial vowels or final vowels or both were probably more common than Dempwolff's reconstructions allow.

Reconstructions of Otto Dempwolff

Although some languages, particularly certain members of the Oceanic group, have changed this sound system drastically, it is still reflected fairly faithfully by many Western Austronesian languages. Indeed, in both Western Austronesian and Oceanic languages, many words seem to have persisted in almost unchanged form, a condition unparalleled in the Indo-European languages, for example. Table 1 compares the forms of some Proto-Austronesian words with the cognate terms in four modern languages.

Table 1: Some Proto-Austronesian Terms and Their Related Forms in Several Modern Languages

	Proto-Austronesian	Tagalog	Malay	Fijian	Samoan
two	*Duwa	dalawa	dua	rua	lua
four	*e(m)pat	apat	empat	vā	fā
five	*lima	lima	lima	lima	lima
six	*enem	anim	enam	ono	ono
bird	*manuk	manok	manu	manu-manu	manu
eye	*mata	mata	mata	mata	mata
road	*Zalan	daan	jalan	sala	ala
pandanus	*panDan	pandan	pandan	vadra	fala
coconut	*niuR	niyog	nior	niu	niu

*Form that is not actually found in any document or living dialect; it is a reconstructed, hypothetical form.

Systematic reconstruction of Proto-Austronesian grammar has scarcely begun. Structural features retained by a majority of languages in both major branches include a fairly constant form for each grammatical and vocabulary element, with boundaries between elements in words being clearly definable, and a relatively simple morphology of verbs and nouns. In addition, in the verb phrase, a number of elements indicating tense, aspect, and voice are present; they were evidently prefixes and infixes (particles inserted within the body of a word) in Proto-Austronesian. Reduplication, the repetition of a word or a portion thereof, occurs in the case of the verb root and has several functions. Most roots are capable of being used either as nouns or verbs. Adjectives, numerals, and markers indicating negatives can act as verbs. Noun subclasses include personal names, marked by a personal article; common nouns, marked by a common article; locatives, place names, and directionals, marked by a locative particle; and temporals, which are not marked. Personal pronouns include distinct forms for 1st person including the hearer and 1st person excluding the hearer; pronouns marking subject or possessor differ in form from those marking object or focus.

Current research. Since World War II the descriptive and comparative study of Austronesian languages has expanded considerably, with centres at universities in the Philippines, Indonesia, Australia, New Zealand, the United States, and Europe. Reasonably good dictionaries and grammars are now available for most of the better known Western Austronesian languages and many of the Polynesian languages. Several large areas remain poorly known, however, including most of Melanesia and much of Borneo and east Indonesia. A good deal of recent research has concentrated on classification and associated problems in the methodology of subgrouping and the theory of linguistic change. A major work has been a lexicostatistical classification of over 200 Austronesian languages prepared by the American linguist Isidore Dyen (1965). A lexicostatistical classification uses statistics to compare the vocabularies of two or more related languages; the method is similar to glottochronology (see above) but assumes a constant rate of change only within a given language family.

Lexicostatistical classification

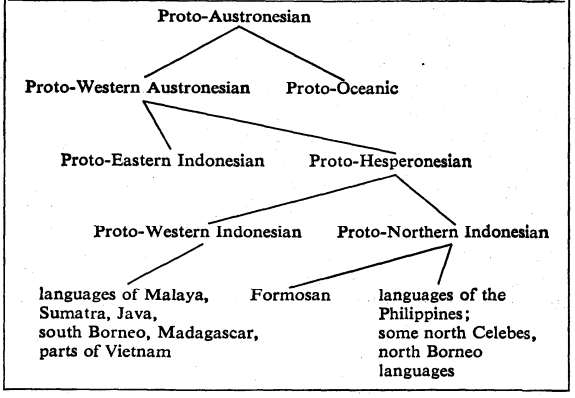
WESTERN AUSTRONESIAN (INDONESIAN)

The Austronesian languages lying west of New Guinea, together with the Chamorro and Palauan tongues of Micronesia, are often called Indonesian. The term is unfortunate in that it does not do justice to the wide geographic distribution of the languages concerned and can be confused with the name of Indonesia's national language. The commonly used alternative, Western Austronesian, is, therefore, employed here.

The classification of Western Austronesian languages is not completely agreed upon. There is, however, fairly general recognition of one very large grouping containing most of the languages of west Indonesia and of Malaysia, all the languages of the Philippines and Madagascar, some languages of the northern Celebes, and the Chamic group of Vietnam and Cambodia. The name Hesperone-

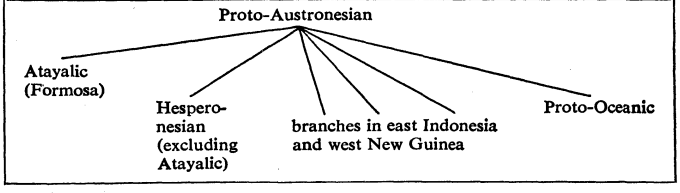
sian has recently achieved some acceptance as a convenient label for this grouping. Disagreement centres around the place of the Austronesian languages of Formosa and east Indonesia, including the western end of New Guinea. Many regard these as most closely related to Hesperonesian, and, in particular, treat the Formosan languages as a branch of Hesperonesian with closest relatives in the Philippines. In this view, Western Austronesian refers to a primary subgroup of Austronesian, contrasting with Oceanic, as indicated in the family tree in Table 2.

Table 2: Austronesian Family Tree (Theory 1)



Other scholars regard the east Indonesian–west New Guinea languages as forming a number of primary subgroups, each coordinate with Hesperonesian and Oceanic. Similarly, a case recently has been made for treating the Atayalic group in Formosa as a primary branch of Austronesian. The Atayalic languages share a very low percentage of basic vocabulary with all other members of the family, including other Formosan languages. There is, then, some support for an alternative family tree, with several primary branchings, representable roughly as in Table 3.

Table 3: Austronesian Family Tree (Theory 2)



Branches of the Hesperonesian group

The Hesperonesian group is generally regarded as dividing into two main branches (see Table 2). One, Western Indonesian, includes the languages of Malaya, Sumatra, Java, Madura, Bali, and Lombok, south Borneo, Madagascar, and probably the Chamic group of Vietnam and Cambodia. The other, Northern Indonesian, encompasses the Philippine languages, some of the languages of north Borneo and the northern Celebes, and possibly the Formosan languages.

Regional division of Western Austronesian languages. In the following sections, the main Western Austronesian languages are discussed in more detail under the appropriate regional headings.

Western Indonesia and Malaysia, Madagascar, Vietnam. The west Indonesian–Malaysian region includes the islands of Sumatra, Java, Madura, Bali, Lombok, and Borneo, and the Malay Peninsula. Except for a few Mon-Khmer languages in the interior of Malaya, its indigenous languages are all Austronesian. There have been important influences on the languages and cultures from mainland Asia, however, and, more recently, from Europe. Hindu culture reached Java and Sumatra in the 1st century AD, and from the 4th century diffused to Borneo and the Celebes. Many languages of western Indonesia contain extensive borrowings from Sanskrit. Islāmic influence began in the 7th century and spread over much of Indonesia and the Philippines. European colonization, beginning in the 16th century, added a third layer of borrowings to the Sanskrit and Arabic.

Malay in its several dialects is the native language of some 6,000,000 people occupying both sides of the Strait of Malacca. Its expansion throughout Malaya is apparently recent; until the 13th century it was confined to east and south Sumatra and the facing coastline of the Malay Peninsula. For some centuries prior to European contact, a simplified form of Malay, Bazaar Malay, had been the lingua franca in coastal regions of the whole Indonesian Archipelago. This status was attained because of the strategic position of Malacca on the trade routes and its function as a dispersal centre of Islām, and also because of the seafaring and trading skills of the Malay speakers. Malay was in turn adopted by the Dutch and British administrations as their lingua franca. In the present century, the language, now the national tongue of the Indonesian state, is called Bahasa Indonesia, or Indonesian. The choice of Malay as a politically acceptable national language was facilitated by the fact that it was the first tongue of only a small minority of Indonesians (in contrast to such languages as Javanese and Sundanese) but was, at the same time, widely used in Indonesia as a second language. The Indonesian variant of Malay has undergone spelling reforms, and a large new vocabulary has been coined to cover modern technical concepts. Many words have also been borrowed from European languages and Javanese.

Bahasa Indonesia

Malay is closely related to most of the other languages of Sumatra, including Minangkabau, Kerintji (Kinchai), Rejang, and Achinese, and to Madurese of Madura Island. Other well-known Sumatran languages are Gajo and Toba-Batak, spoken in the north and somewhat less closely related to Malay. In all, Sumatra contains between 12 and 15 languages (the boundaries between dialects and languages not being clear-cut) spoken by about 9,000,000 people. Engganese, used on a small island off southeast Sumatra, is an extremely divergent Indonesian language that shares only about 10 percent of basic vocabulary with the rest.

Java, the most populous island of Indonesia, is linguistically one of the most uniform, with only three indigenous languages. Javanese, with about 45,000,000 speakers, is numerically the largest Austronesian language after Indonesian (which is known by over 80,000,000 people, but mainly as a second language). Javanese dialects are spoken throughout central and east Java and in sections of western Java. Old Javanese is known from inscriptions dating back to the 9th century AD. The language was extensively influenced by Sanskrit between the 9th and 15th centuries, during the time of the Indianized kingdoms of east Java. Thoroughly documented by Dutch linguists in a series of grammars and dictionaries produced over the last 250 years, Javanese is now generally written in the roman (Latin) alphabet and continues to flourish alongside Indonesian as a literary language and as the daily medium of communication of many Javanese newspapers, magazines, and radio stations. Several registers, or styles, distinguishing degrees of respect and marked by vocabulary differences, have arisen out of the elaborate stratification of Javanese society.

Styles, or registers, of Javanese

Sundanese, with about 13,000,000 speakers, is found throughout west Java, with the exception of small islands of Javanese speakers along the north coast of Banten and in the region of Indramaju. The language has been written in various scripts since the 14th century, roman now being in general use. The dialect spoken around Bandung is considered to be the most prestigious, or the standard form. Madurese is the language of Madura Island and smaller offshore islands, but about half of its 6,000,000 speakers now reside in east Java. There are two principal variants of Madurese—Eastern and Western; an Eastern dialect, Sumenep, has been adopted for educational purposes as the standard dialect. Madurese shows greater similarities to the Malay–Sumatran group than to Javanese or Sundanese. Balinese, with about 2,000,000 speakers, is spoken on Bali and the western part of Lombok; Sasak is the language of eastern Lombok.

Linguistically the most diverse of the islands of the western Indonesian region, Borneo is also the least known. It is sparsely populated, and most coastal areas have been occupied in relatively recent times by speakers of Malay-type languages, such as Iban (Sea Dayak), Brunei Malay, Kutai Malay, Banjarese, and Sambas Malay, all of which are closely related dialects or languages. The most important Bornean language is Ngadju (Ngaju), spoken as the native language in southwest Borneo in the region of the Barito, Kapuas, Kahayan, Kaitingan, and Sampit (Mentaya) rivers; it is more widely used as the lingua franca of most of south Borneo. In northeast Borneo there are a number of languages with close relatives in the Philippines, including Illanum (Lanum), Bajau, Sulu, and the various Murut dialects. Maanyan and closely related languages spoken in south Borneo are apparently the closest relatives of the Malagasy dialects of Madagascar.

The Malagasy dialects

The Malagasy dialects probably derive from Bornean traders who journeyed to Indian, Arabian, and East African ports and settled the previously uninhabited island of Madagascar. A quite close correspondence in basic vocabulary (45 percent agreement) between Maanyan and Malagasy indicates separation around 2,000 years ago. The Malagasy dialects show sufficient internal diversity to justify classification into two or three different languages. The Merina dialect, now official in the Malagasy Republic, has around 5,000,000 speakers. A small group of Austronesian languages spoken in Vietnam and Cambodia—the Chamic languages—probably falls into the Western Indonesian subgroup. Cham, with 150,000 speakers in Vietnam and Cambodia, has been the subject of several studies. Rade, Curu (Chru, Cru), and Jarai, spoken in Vietnam, may be closely related to Cham.

The Philippines and Formosa. At least 70 languages are spoken in the Philippines in a land area a little larger than that of Great Britain. There are two main subgroups. A Central (Mesophilippine) division includes many of the languages of central and southern Luzon, Mindoro, Palawan, and the Visayan Islands. The most important is Tagalog, the first language of about 5,000,000 people in central and southwest Luzon, including the region of the capital city, Manila, and, parts of coastal Mindoro. A standardized form of Tagalog was selected as the national language after the Philippines gained independence in 1946. This language, officially called Pilipino, is now spoken as a first or second language by a considerable proportion of the 38,000,000 Filipinos. Although it faces competition from English and other important local languages, it is increasingly used in education and government and in the popular press, radio, and literature of the Philippines. Closely related to Tagalog are Bikol or Bicol (over 2,000,000 speakers in southeast Luzon and smaller adjacent islands) and Subanon (western Mindanao, southern Philippines). Also in the Central branch are Cebuano, or Sugbuhanon, with 6,000,000 speakers, and Hiligaynon, or Ilongo, with 2,000,000 speakers, the two main members of the Bisayan subgroup. Spoken primarily in Cebu, Bohol, west Leyte, and the eastern third of Negros, Cebuano is used as a trade language throughout Mindanao and Hiligaynon in Panay and on smaller adjacent islands and in Negros. Pampangan (Kapampangan) is another important language, spoken in Luzon on the northwest flank of the Tagalog speech area.

Northern Philippine subgroup

The second major Philippine group, called Northern or Cordilleran, contains most of the languages of northern Luzon. Chief among them is Ilocano (Iloko), the lingua franca in northern Luzon, which has some 3,000,000 speakers in much of northwest and northern Luzon. Other members of this branch include the languages of the Igorot mountain tribes, including Bontoc, Ifugao, and Tinggian, the Gaddang group, Isneg, Isinay, and Kalinga. Pangasinan, spoken by 750,000 in the province of the same name, probably belongs to the Northern subgroup.

A number of Philippine languages fall outside the two large subgroups. Maranao, Tiruray, Bilaan, and Tagabili are languages of important groups in the southern Philippines, while Luzon contains several unclassified tongues—Ilongot, Casiguran, and others. These languages share around 30 percent of basic vocabulary and many structural characteristics with other Philippine languages but are not closely related to any large subgroup. The Sulu Archipelago has Tau Sug and Samal; both are also spoken on Borneo, where Tau Sug is known as Sulu. The major Philippine languages—Tagalog, Cebuano, and Ilocano—have extensive literatures, and together with other important languages, are widely used in broadcasts and newspapers.

Prior to the arrival of the Chinese, Austronesian languages were probably spoken over most of Formosa. The surviving languages are now confined to small communities in less accessible regions. The Formosan languages are internally fairly diverse, but there is some evidence for treating them as a single subgroup of Western Austronesian. The Atayalic or Northern group contains the Atayal dialects, Seedik, and probably Saisiyat. Although some central, eastern, and southern languages share less than 25 percent of basic vocabulary with each other, most of them are generally assigned to a single group (Central or East Formosan). Its members include Ami, Paiwan, Bunun, and Thao. Tsou, Saaroa, and Kanabu (central Formosa), though they may form a third subgroup, are usually treated as members of the Central division.

Two languages of Micronesia, Chamorro (Mariana Islands) and Palauan (Palau, western Carolines), are generally regarded as deriving from the Philippines or Indonesia.

The Celebes, eastern Indonesia, west New Guinea. Eastern Indonesia is centred in the Lesser Sunda Islands and the Moluccas. The large island of the Celebes occupies a position intermediate between Borneo, the Philippines, and eastern Indonesia. Approximately 100 different Austronesian languages are spoken in eastern Indonesia, in places on the coast of west New Guinea, and on Aru Island south of the Doberai (Vogelkop) Peninsula, west New Guinea. Papuan languages (*q.v.*) are spoken in parts of Timor in the Lesser Sundas and Halmahera in the Moluccas.

Austronesian tongues in eastern Indonesia and west New Guinea

Dutch and Indonesian linguists have long recognized that this region contains many disparate Austronesian groups but have generally assigned them to a relatively small number of divisions: Bima–Sumba, Ambon–Timor, Sula–Batjan, south Halmahera–west New Guinea, and several Celebes groups. Very thorough lexicostatistical comparisons provide little support for most of these larger groupings and indicate instead that east Indonesia–west New Guinea harbours many small, genetically diverse subgroups, most of which are members of or have their closest relationships with the Hesperonesian group and with each other, with a residue not at present assignable to any large subgroup of Austronesian.

The Celebes, with more than 40 languages, is the most diverse area. Buginese, with about 2,500,000 speakers, is the most important language of the group. Gorontalo and Suwawa, in the north Celebes, and Sangir (Sangir Islands, north of the Celebes) show closer agreement with Philippine languages than with other Celebes tongues. Other numerically large speech communities in or near the Celebes are the Sidjai, Duri, and Mandar (Andian), Kendari, Muna (Muna Island), and Butung (Butung Island). Sikka of Flores Island and Solor of nearby Solor Island appear to be quite closely related to each other, with a 37 percent common basic vocabulary. Endeh of Flores is more distant. Havunese, spoken on Sawu and Raidjua, between Flores and Timor, and Sumba (Sumba Island) appear to be fairly distant from all other eastern Indonesian languages. A large number of similar isolated languages exists on smaller islands in this region; one such small group includes Ambonese of Ambon Island and the adjacent coastal area of Ceram. Buli and Minyafuin, of Halmahera, may belong to a group that also includes As, spoken on the western tip of New Guinea, and Biga, from Wakde Island in northwest New Guinea. The Bomberai Peninsula group in west New Guinea has close relatives on east Ceram. Most of the Austronesian

languages on the north coast of west New Guinea, as far east as Sarera (Geelvink) Bay, however, show no close relationship to the Hesperonesian, eastern Indonesian, or Oceanic languages.

Great internal diversity of western Austronesian

Characteristics of Western Austronesian. The Western Austronesian languages are so diverse internally that little can be said about their common characteristics apart from what has already been said of Proto-Austronesian. Most of the members of this division maintain distinctions in the Proto-Austronesian sound system that are lost in Oceanic; *e.g.*, the distinction between **b* and**p*. (An asterisk indicates an unattested, hypothetical, reconstructed form.) The original verb morphology is also generally retained more completely than in the Oceanic division, but it is difficult to isolate common innovations that mark off Western Austronesian languages in the absence of detailed reconstructions of Proto-Austronesian grammar.

The Philippine languages, typologically the most uniform of the large subgroups of Western Austronesian, have been the best described. No doubt owing to their long coexistence in a single region, as well as to their relatively close relationship, members of this subgroup of Hesperonesian are more alike in their sound systems (though not in vocabulary) than the languages of the West Indonesian subgroup. Consonants usually include three voiceless stops, *p*, *t*, *k*, and the glottal stop *q*; three voiced stops, *b*, *d*, and *g*, and the nasals *m*, *n*, and ŋ; plus *l*, *r*, *h*, *s*, *w*, and *y*. In many languages, borrowings from Spanish have resulted in the addition of two new vowels, *e* and *o*, to the original four (*a*, *i*, *u*, and ɨ or ə) retained from Proto-Austronesian. The morphology of the verb and, to a lesser extent, of the noun is fairly complex. The use of affixes and reduplication distinguishes several tenses (past, future, and present or general), various aspects (progressive, distributive, causative, etc.), and two modes (obligatory and indicative).

Philippine voice and case systems

The grammar of Philippine languages is most famous for its complex voice and case systems. (Voice, in grammar, indicates the relationship of the subject of the verb to the action that the verb expresses. A grammatical case is a form of a word that shows the relationship of the word to other words.) Besides distinguishing so-called active (*e.g.*, "John washed the dishes") and passive (*e.g.*, "The dishes were washed by John") constructions, Philippine languages possess at least three kinds of passive. The noun phrase occurring as "topic" or "focus" in the sentence can represent the actor (subjective or active constructions), the goal or object (goal or object-focus passives), the referent (benefactive or location-focus passives), or the instrument (instrumental-focus passives). The distinctions are expressed by three devices. One uses affixes to mark voice in the verb: subjective voice is usually indicated by an infix *-um-* and the prefixes *ma-*, *mag-*, *maka-* (the actual choice varies with the different verb classes); objective voice is shown by the suffix *-in* or *-en*; referential voice by *-an*; and instrumental voice by the prefix *i-*. The other methods of distinguishing passives include the marking of case with nominal (noun) particles and transposing phrases and changing stress. An example from Tagalog is: "The child bought the mango," *b-um-ili, ang bata, n-ang mangga*; *bili* is the verb "buy" with the subjective infix *-um-*, *bata* is "child," and *mangga* is "mango"; *ang* marks the focus common-noun phrase ("the child"), and *n-ang* indicates the nonfocus common-noun phrase ("the mango"). To say "The mango was bought by the child," the sentence construction is rearranged to *b-in-ili nang bata ang mangga*, which in actual Tagalog order is "buy-objective voice, the child, the mango." A number of other arrangements of the sentence elements are possible to cover the instrumental and referential voices.

Members of the Western Indonesian and Formosan groups share a great deal of morphological and syntactic structure with the Philippine languages, although they are typologically less homogeneous. Most of the Indonesian languages have developed more elaborate vowel systems than that of Proto-Austronesian, with five (Havunese), six (Malay, Balinese, Buginese), seven (Sundanese), eight (Javanese, in one analysis), or nine (Cham) contrasting vowels. Maanyan and the Malagasy dialects retain the four original vowels. Most Western Indonesian languages preserve the distinction between four voiced and four voiceless stops (the voiced *b*, *d*, *j*, *g*, and the voiceless *p*, *t*, *c*, *k*) and four nasals (*m*, *n*, *ñ*, ŋ), plus *l*, *r*, *w*, *y*, *s*, and *h*. Only Javanese, however, also distinguishes retroflex stops and alveolar stops (made with the tip of the tongue touching the ridge behind the upper teeth). This distinction seems likely to have arisen from the later influence of Sanskrit, which possessed retroflex consonants, on Javanese. As in all branches of Austronesian, most word bases may be used in the function of nouns or verbs. There are numerous transformative and formative affixes in Western Indonesian that derive adverbs, adjectives, nouns, comparative forms, ordinal forms, and various verb constructions, in addition to several kinds of verb reduplication; these features also appear in the Philippine languages.

Possible influence of Sanskrit on Javanese

The large Hesperonesian group, in general, appears to be the most conservative branch of Austronesian. A high proportion of the 2,207 words attributed to Proto-Austronesian, for example, are retained by Tagalog (1,125), Toba–Batak (1,299), Javanese (1,446), Malay (1,627), and Ngaju (1,170). Much lower proportions are present in Oceanic languages (Bauan Fijian 461, Tongan 328, Samoan 385).

Eastern Indonesian languages in general appear to be morphologically simpler than members of the Hesperonesian group, in which regard they resemble Oceanic languages. They have, however, retained several distinctions in sound that have been lost in the Oceanic group.

Although books and articles on Western Austronesian languages run into several thousands, documentation of the speech traditions of many of the smaller, minority communities is still poor, and many gaps remain in the understanding of the history of the group as a whole. Indonesian and Filipino linguists are now working extensively on their own languages, while several Dutch and American universities, and the Summer Institute of Linguistics in the Philippines (an association of Protestant missionary linguists that specializes in studying unrecorded languages) are active in both descriptive and comparative studies.

European languages contain a number of words borrowed from the better known languages of the Indonesian region. From Malay derive such English words as sarong, (to run) amuck, mandarin (through Portugese), the kris (or creese) dagger, and the names of several animals (orang-utan, pangolin, dugong, kalong) and plants or plant products (kapok, paddy, nipa). Javanese contributions include junk (sailing vessel) and batik. The American English word boondocks is from Tagalog *bundok* "mountain."

EASTERN AUSTRONESIAN (OCEANIC)

Roughly 300 Austronesian languages are spoken east of Sarera (Geelvink) Bay in New Guinea and on the islands of Melanesia, Micronesia, and Polynesia.

Classification. The classification of these languages remains somewhat controversial. Dempwolff found evidence to indicate that all known Austronesian languages in the Oceanic region, apart from Chamorro and Palauan, belong to a subgroup that excludes Western Austronesian languages. The names Oceanic and, less commonly, Eastern Austronesian are now applied to this grouping. The evidence consists of a number of common innovations in the treatment of Proto-Austronesian sounds. All Oceanic languages agree in having lost the original final consonants of most word bases in most contexts, and in simplifying the initial and medial consonants as shown in Table 4. In addition, Oceanic languages reflect a five-vowel system in which Proto-Austronesian *a*, *i*, *u* were retained, *ay* became *e*, and *e* and *aw* became *o* in Proto-Oceanic.

Though the evidence cited above is not challenged, the conclusions drawn from it have been. Scholars remain puzzled by the great differences among Oceanic languages, especially in vocabulary items. Comparisons of

Puzzling differences among Oceanic languages

basic vocabulary show that several New Guinea–West Melanesian groups share less than 15 percent of a common basic vocabulary with all other members of Austronesian, indicating a divergence from the parent language at least 5,000 years ago. It has been suggested that the Oceanic languages may not constitute a single subgroup but may divide into several primary divisions within the Austronesian family, and indeed that West Melanesia may be the primary dispersal centre for Austronesian. A quite different theory, with a few modern adherents, explains the diversity among the languages of Melanesia by deriving them from relatively recent mixtures of Indonesian and Papuan languages, which results in disparate varieties of pidginized Indonesian with Papuan substrata in each island group.

There are increasing grounds for accepting Dempwolff's theory of the Western Austronesian–Oceanic division as correct, while still allowing for a more dramatic time depth. It is also evident that, after a period of development as a single language, most of the descendants of Proto-Oceanic that dispersed in the New Guinea–West Melanesian area were influenced by nearby Papuan languages; this, together with other factors, such as the small size of the speech communities, word taboos, and several millenia of separate development, probably account for the extreme diversity found in this part of Oceania. It is not clear whether the New Guinea–West Melanesia region was the primary dispersal centre for Austronesian languages, but it is certain that it was a very early one. From there Oceanic-speaking groups moved fairly rapidly into the unoccupied islands of East Melanesia, Micronesia, and Polynesia. As has been noted, both Fiji and Tonga were inhabited by 1000 BC, almost certainly by speakers of the branch of Oceanic ancestral to Fijian and Polynesian, while the Solomons, New Hebrides–Banks Islands, and New Caledonia were probably settled by 2000 BC or earlier. In New Guinea and the western Melanesian islands, Oceanic-speaking peoples encountered Papuan populations and in many places intermarried with them and borrowed from their languages. One result of this contact is that many Austronesian languages in that region have changed faster than those situated further east.

Austronesian encounter with Papuan languages

Characteristics of Proto-Oceanic. Among the additional evidence for Dempwolff's hypothesis that has come to light in recent years is the sharing by the Oceanic languages of many words and grammatical features that are not characteristic of Western Austronesian languages. More than 30 percent of Proto-Oceanic words from a standard list of 215 "basic vocabulary" meanings are not represented at all in Western Austronesian. Oceanic languages also agree in having peculiar forms for certain common Austronesian words; *e.g.*, the Proto-Oceanic forms are **au* "I," **mai* "come," **suRi* "bone horn," **pati* "four," **moze* "sleep," **katoluR* "egg," where Western Austronesian languages reflect **aku*, **maRi*, *duRi or **DuRi*, **e(m)pat*, **peZem*, **teluR*. In grammar, a number of common simplifications and elaborations are observable. The general features of the following discussion of Proto-Oceanic grammar apply generally to present-day Oceanic languages, although some languages retain the parent system more completely than others. Most languages of the central and eastern Solomons, some languages of the central and northern New Hebrides and Banks Island, the Fijian dialects, the Polynesian group, and certain languages in New Guinea–West Melanesia appear to have preserved the Proto-Oceanic system more completely than others.

Some morphological simplifications occurred in Proto-Oceanic: many verb and noun affixes were lost, some prefixes lost their prefix quality and were assimilated as nonproductive elements into the word base, and some affixes normally appended to a word became reinterpreted as free-form particles. On the other hand, Proto-Oceanic developed several new prefixes and changed the shape or function of certain old ones.

Whereas tense, aspect, mode, and probably person and number of the verb were marked in Proto-Western Austronesian by affixes (*e.g.*, as in English "walk," "walked"), in Proto-Oceanic they were indicated by separate particles. Many verb bases also functioned as postverbal particles indicating direction or tense-aspect—*e.g.*, Proto-Oceanic **zake* "ascend," **zipo* "descend," **mai* "come," **nopo* "stay" also occurred as modifiers meaning "upward," "downward," "toward," and "progressive aspect," respectively.

Nominal (noun) phrases were of at least four types. Common nouns were marked by the "common article" **na*, personal pronouns and possibly personal names were indicated by personal articles (**i*, probably **a* or zero—unmarked—in certain contexts), locative nouns were shown by **(q)i* immediately preceding the base word, and temporal nouns were marked by a temporal prefix or zero (the lack of a prefix). One subclass of locatives, called relationals, used personal suffixes, as **(q)i lalo-na* "at inside-his" (*i.e.*, "inside him").

Pronouns in Oceanic

As in Proto-Austronesian, personal pronouns fell into two sets of variants: subjective and possessive forms, and focus and objective forms. Examples from the Wayan dialect of Fijian that preserve the Proto-Oceanic forms are: "I go," *qu laka* (*qu* is the subjective pronoun "I," *laka* is "go"); "my arm," *qu-lima* (*qu* is the possessive pronoun "my," *lima* is "arm"); "It is I," *o au* (*o* is the personal article, *au* is the focal or emphatic pronoun "I"); "give (it to) me," *vaganī au* (*vaganī* is "give," *au* is the objective pronoun "me"). Several new distinctions appeared in Proto-Oceanic, however. One was the development of dual (two-person) and trial (three-or-more-person) suffixes. The forms **ru(a)* "two" and **tolu* "three" were suffixed when two or a few people, rather than an unlimited plurality, were referred to. Plurals were indicated by the simple nonsingular base, as Fijian *keda* "we plural (including hearer)" contrasting with *keda-ru* "we two (including hearer)" and *keda-tou* "we three (including hearer)."

It was in possessive constructions that Proto-Oceanic underwent some of the most distinctive elaborations. Common nouns in such structures fell into at least three "genders": edible (foods, drinks, etc.), familiar or inalienable (kinship terms, parts of a whole), and neutral. The possessor was linked to the possessed noun by a particle of variable form. When the possessed noun was of edible gender, the consonant of the possessive particle was **k-*; in instances of neutral gender it was **n-*; and when of familiar gender, the consonant was omitted. The vowel or vowels of the possessive particle varied according to whether the possessor was a personal pronoun, a common noun, or a proper noun. Similarly, word order depended on the class of the possessed and possessor nouns: the particle plus possessor normally followed the head noun, as in Fijian *na uvi kei Manu* "Manu's yam," *na vosa nei Manu* "Manu's speech," *na tina i Manu* "Manu's mother," but, when the possessor was a pronoun and the possessed noun was of other than familiar gender, then the particle and pronoun preceded, as Fijian *na ke-mu uvi* "your yam," *na no-mu vosa* "your speech" (but *na tina-mu* "your mother," *na mata-mu* "your eye").

Proto-Oceanic interrogative pronouns included several retained from Proto-Austronesian: **zapa* "what?", **zai* "who?", **piza* "how much? how many?", and **kuya* "how? in what state?" together with **pai* "where?", and **ŋ(a)iza* "when?". Demonstratives distinguished three positions or persons: **[i,e]ni* "this, here, near me, now," **ina* "that, there (by hearer), then," and a form marking remote position in space and time.

Oceanic words functioning as nouns and verbs

As in Proto-Austronesian, most word bases, other than proper nouns, functioned as both verbs and nouns, and adjectives, numerals, and negatives played the role of verbs in sentences.

Subgroups of Oceanic languages. Many aspects of the subgrouping of Oceanic languages are still obscure. In the west, many small divisions are evident, but no large subgroup has been attested. In the east, there is some evidence for a wider subgroup—Eastern Oceanic—comprising the languages of the southeast Solomons, much of the New Hebrides–Banks Islands, Rotuma, Fiji, and Polynesia, and possibly also most of the Micronesian languages. Within Eastern Oceanic, there is fairly clear support for a subgroup consisting of Fijian and Polynesian, whose closest immediate relatives may lie in the central New Hebrides. Table 5 presents a classification that has some degree of general acceptance.

LANGUAGES OF MELANESIA

At a conservative estimate, 250 different Austronesian languages (not counting dialectal variants) are found in Melanesia. Most of them are spoken by communities of a few hundred to a few thousand people; with several exceptions they remain documented only by brief word lists and sketches. The term Melanesian is often applied to the Austronesian languages of Melanesia but has validity only as a geographical label, for these languages are not a linguistic unity comparable to the Polynesian and Nuclear Micronesian groups. Rather, Polynesian and Micronesian are each branches of particular Oceanic subgroups whose other members are in Melanesia (see Table 5).

Papuan and Austronesian languages in New Guinea

In New Guinea, Austronesian languages occur on the Doberai (Vogelkop) Peninsula, extending southwest as far as Kaimana, and in patches along the north coast, and along the southeast coast of Papua as far west as Cape Possession (100 miles west of Port Moresby). Only in the Markham Valley and parts of the Central District of Papua are Austronesian languages found any distance inland. The interior and large stretches of the coast of New Guinea are occupied by Papuan languages. Apart from those tongues situated around Sarera (Geelvink) Bay and on the Doberai (Vogelkop) Peninsula, all the New Guinea Austronesian languages appear to belong to the Oceanic division. The best known of them is Motu, spoken by about 10,000 people who occupy the coastal strip around Port Moresby. Police Motu, a simplified form of Motu, is used as a lingua franca throughout Papua. Motu is quite closely related to the eight other languages of Papua's Central District. This group, in turn, appears to form a larger grouping with many of the languages spoken around the southeast tip of Papua and the offshore islands, including Suau (Suau Island and adjacent coastal area) and Dobu (Dobu and Normanby Islands). These two languages, together with Kiriwina from the Trobriand Islands and Wedau spoken around Dogura, have some currency as lingua francas in their respective regions of the Milne Bay District.

Austronesian languages are found in coastal pockets in the Northern District of Papua, in the Morobe, Madang, and Sepik Districts of New Guinea, and on many offshore islands in these regions. Most of them have been strongly influenced by Papuan languages; *e.g.*, Yabêm and several closely related languages in the Morobe District have developed tone, like their Papuan neighbours. Yabêm and Graged (Gedaged) of Kranket Island, in the Madang District, have gained wider currency as the lingua francas of the Lutheran Mission in their regions. Some of the Morobe and Madang languages appear to fall into a subgroup with Kove (Kombe) and certain other languages of southwest New Britain.

Austronesian tongues of New Britain

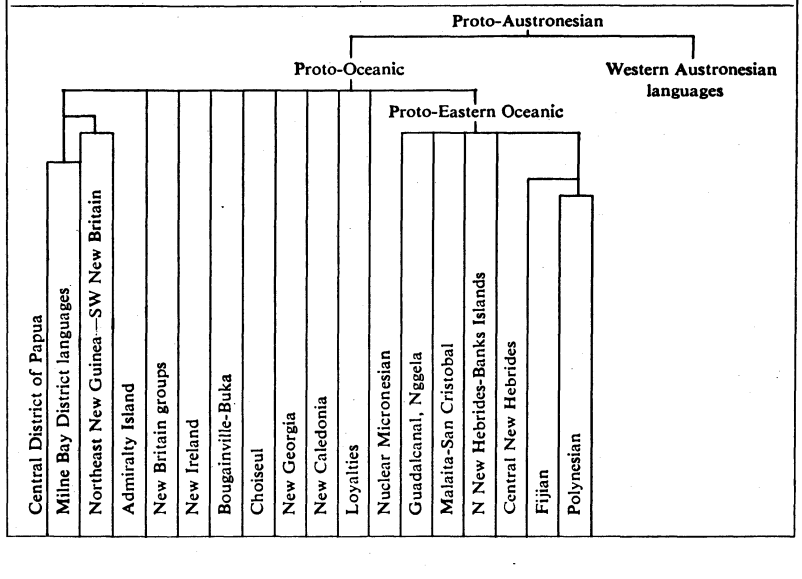
The large island of New Britain contains around 25 extremely diverse Austronesian languages, the most important being Tolai (Kuanua, Tuna, Raluana), spoken around Rabaul on the Gazelle Peninsula and used extensively by missions in New Britain and New Ireland. New Ireland's languages are poorly known but appear to be of only moderate diversity. On the small Admiralty Islands group at least 20 (in some estimates as many as 50) different languages are found.

The Solomon Islands contain more than 60 languages that belong to several divergent groups. Bougainville is predominantly Papuan speaking, but several Austronesian languages are present on the north coast, and a few in the south and on offshore islands. The adjoining island of Buka contains several more, most of them closely related to the Bougainville languages.

On Choiseul Island are found an indeterminate number of languages and dialects closely related to each other but not to any outside group. Babatana is the literary language of a Methodist Mission there. Santa Isabel (Ysabel Island) is sparsely peopled by communities speaking perhaps 10 languages; Kia in the northwest and Bugotu in the southeast are the best known. Bugotu, the lingua franca of the Melanesian mission on Santa Isabel, is closely related to the Guadalcanal and Nggela languages. The New Georgia group contains more than a dozen languages—*e.g.*, Roviana (southwest New Georgia) and Marovo (east New Georgia and Vangunu Island)—most of which belong to a single division. Roviana is used by the Methodist Mission everywhere in the British Solomons except on Vella Lavella. The languages of the southeast Solomons divide into two subgroups. Almost all those on Malaita and San Cristóbal belong to a single group whose best documented members are Sa'a, Kwara'ae (Fiu), Lau (all of Malaita), and Arosi (of San Cristóbal). The other group includes most of the Guadalcanal languages, together with Bugotu and Nggela, of Florida Island.

Polynesian languages spoken on several islands near the main Solomons group include: Nukuria, Nukumanu, Taku, Luangiua (Ontong Java), and Sikaiana to the

Table 5: Classification of the Oceanic Languages



north; Rennell–Bellona to the south; and Tikopia, Anuta, and Pileni–Taumako (Duff Islands) to the east. The latter is spoken in the Santa Cruz group, which also contains one Papuan and several little-known Austronesian languages.

Languages of the New Hebrides–Banks–Torres archipelago

Approximately 60 different languages, many of them dialectally very diverse, are spoken in the New Hebrides–Banks–Torres archipelago. The best known are Mota (of Mota or Sugarloaf Island, in the Banks group), used in the 19th century throughout the northern islands and in the Solomons as the lingua franca and literary language of the Melanesian Mission, and the Nguna–Tongoa dialects, spoken on north Efate and adjacent islands in the central New Hebrides. Many of the central and northern languages are closely related to Fijian and Polynesian. Further south, Eromanga, Tana, and Aneityum harbour three languages that show no very close relationship to other members of the Oceanic group. Polynesian languages are spoken on Emae, Futuna, and Aniwa and on Mele and Vila islands in the New Hebrides.

Both New Caledonia and the Loyalty Islands are internally fairly diverse. New Caledonian languages appear to form a subgroup characterized by far-reaching sound changes. Languages of the central and far southern regions of the island are tonal. A Polynesian language, West Uvean, is spoken on Heo Island in the Loyalties.

Easily the best described, and politically the most important, language in Melanesia is Fijian, or Bauan Fijian, spoken as a first or second language by over 200,000 Fijians and also by other ethnic groups in the Fiji group. The Fijian dialects are sharply differentiated into Western and Eastern Divisions. Bauan, an Eastern dialect, became Fiji's lingua franca in the 19th century and is now widely used in the popular press, broadcasting, and administration. Rotuman, spoken on Rotuma Island, 200 miles north of Fiji, has borrowed heavily from Polynesian, but its classification as a language closely related to Fijian and Polynesian has been disputed.

LANGUAGES OF POLYNESIA

A triangle-shaped area, the apexes of which are Hawaii, Easter Island, and New Zealand, embraces almost all the islands of the central and eastern Pacific. Early European explorers found the inhabited islands in this region occupied by culturally homogeneous peoples speaking some 16 closely related languages. The name Polynesian was first applied to them by 19th-century scholars, who also observed that another 12 to 14 languages belonging to the Polynesian group are situated to the west of the Polynesian Triangle, on islands in Melanesia, and on the southern fringes of Micronesia; these are the Polynesian "Outliers."

Origins of the Polynesians

The question of Polynesian origins has been the subject of much romantic speculation. Various writers have pictured the ancestral Polynesians as migrating from such far-flung homelands as India, Egypt, Mesopotamia, and the Americas. It is now quite clear that, linguistically at least, the Polynesians developed their distinctive characteristics within Polynesia itself. Their languages form a subgroup of the Oceanic branch of Austronesian, whose immediate relatives lie in eastern Melanesia (see Table 5). Fijian, Polynesian, and certain languages of the New Hebrides were a single language until approximately 1000 BC, when some speakers of this early eastern Oceanic language appear to have moved from the New Hebrides into Fiji. There a dialect developed that subsequently split into Fijian and Polynesian branches. During several centuries of isolation somewhere in west Polynesia, probably in Tonga, the Polynesian branch underwent those further modifications that characterize all present-day Polynesian languages.

Characteristics of Proto-Polynesian. The general features of the following sketch of Proto-Polynesian are applicable to all its descendants. Each has changed some of the details for the Polynesian languages show an internal diversity comparable to the Romance or Germanic subfamilies of the Indo-European language family.

Phonology. Proto-Polynesian retained the five-vowel system of Proto-Oceanic but added a contrast between long, or geminate (double), vowels and short vowels. Several simplifications occurred in the consonant system, with the loss of the nasal element in stops (Proto-Oceanic *p* and *mp* both became *p*; *t* and *nt* became *t*; *k* and *ŋk* became *k*) and the loss of retroflex *R*. Proto-Polynesian consonants thus comprised four stops, *p*, *t*, *k*, and ʔ (the glottal stop); three nasal sounds, *m*, *n*, *ŋ*; three fricatives, *f*, *s*, *h*; plus *l*, *r*, and *w*. No consonant clusters or final consonants were permitted, but vowel sequences were common. Most word bases had two syllables, but longer forms were not uncommon, while some prebasic particles were monosyllabic—*e.g.*, **fale* "house," **waka* "canoe," **wai* "water," **uaua* "vein," **fafine* "woman," **tuakana* "older sibling of same sex," **maanifinifi* "thin," **ki* "to," **ma* "and," and **o* "of."

Grammar. Proto-Polynesian retained most features of the Proto-Oceanic grammar, the main changes being in possessive constructions and in the development of distinctive passive and nominal (*i.e.*, verbless) sentence structures. The smallest natural phonological or pause unit was the phrase rather than the word, a phrase consisting of a head word flanked by affixes and particles. The verb phrase contained several classes of preposed particles: (1) tense-aspect particles (marking past, prospective, subjunctive, imperative, negative subjunctive, hypothetical, nonpast, and progressive); (2) subject-marking personal pronouns occurring between tense-aspect particle and verb; (3) manner particles, indicating the "manner" of the action; and (4) negatives. Verbal prefixes included **fe-* reciprocal, **faka-* causative, **ma-* abilitative (*i.e.*, "able to," "capable of"), **tua-* ordinal, **taki-* distributive, **toko-* human number. Verbal suffixes included a passive **-(C)ia*, instrumental **-aki*, and derivative or transformative **-(C)i*, **-(C)aki*.

Significance of the phrase in Polynesian

Noun phrases divided into common, personal, locative and temporal, each class of noun being marked by a distinctive article or other syntactic marker. Proto-Polynesian probably distinguished only two common articles, a definite **(t)e* and an indefinite **ha*, but several of its descendants have more elaborate series. Most interrogative pronouns were retained from Proto-Oceanic, but manner and temporal interrogatives were innovations. In personal pronouns the distinction between trial (three) and plural was lost, the old trial forms becoming the new plurals. Demonstratives included **eni* "this, these, here," **ena* "that, those, there (near hearer)," and **ia* "that, those (particular ones)."

In possessive constructions the three-way gender distinction of Proto-Oceanic was replaced by a two-way distinction between nouns subordinate to the possessor and nouns not subordinate to the possessor.

Case relations between noun phrases and the verb were indicated by particles placed at the beginning of the phrase. Active sentence structures normally consisted of verb phrase plus subject noun phrase plus complement, and contrasted with passive, nominal, and topicalized structures.

Samoan, Tahitian, and Hawai'ian

Languages and subgroups. The best known Polynesian languages are Samoan, spoken by about 200,000 people in Western and American Samoa and by sizable migrant communities in New Zealand and the United States; Tongan, with about 80,000 speakers; Tahitian, spoken as the native language in the Society Islands and as a second language by Marquesans, Tuamotuans, Magarevans, Austral Islanders (Îles Tubuai), and other ethnic groups in French Polynesia; New Zealand Maori, with about 100,000 speakers; and Hawai'ian, once the language of perhaps 100,000 people, but now used as a daily medium of communication by only a few hundred Hawai'ians. Samoan and Tongan are the national tongues of Western Samoa and the Kingdom of Tonga. Hawai'ian, Maori, and Tahitian, together with the languages of the Marquesas, Tubuai (Austral), Tuamotuan, and Cook island groups, and Magareva and Easter Island, form a well-marked subgroup known as Eastern Polynesian. Samoan with Futunan, Uvean, Tokelauan, Ellice, Pukapukan (in the northern Cooks), and all the Outlier languages spoken in Melanesia and Micronesia form a second division known as the Samoic-Outlier group. A third subgroup

consists of Tongan and Niuean. Eastern Polynesian and Samoic-Outlier languages possess certain innovations that suggest they shared a period of common development after separating from the language ancestral to Tongan and Niuean. This wider grouping is known as Nuclear Polynesian.

The numerous subgroupings and language divisions in Polynesia are the result of the geography of this region. Around 2,000 years ago, following the breakup of Proto-Polynesian and the build-up of populations on the main islands in the west Polynesia area, there was a fairly rapid settlement of all the main uninhabited islands to the immediate east and west. Distances between most of the island groups were such that regular contact between them was impossible, and a distinct language evolved for each group. The last islands to be settled appear to have been the marginal east Polynesian islands, such as Hawaii, New Zealand, Mangareva (all settled about AD 1000), and some of the Outliers. Surprisingly, Easter Island was one of the first eastern islands to be settled, a fact attested by archaeological remains and by the considerable differences between the Easter Island language and those of other members of the Eastern Polynesian group.

The oral literature of Polynesia

The oral literature of Polynesia is extremely rich. Much of it has been recorded by Polynesian and European scholars and by missionaries, who in the 19th century developed excellent orthographies—using the roman alphabet—for Polynesian languages. In the precontact period, Easter Island was the only community to have developed a script of its own; it was an ideographic form of writing with very restricted uses. Missionary scholars also produced many excellent grammars and dictionaries, and intensive linguistic research continues, chiefly at universities in Hawaii and New Zealand.

European languages have borrowed many words from Polynesian. Among the English borrowings are taboo (Polynesian *tapu*), tattoo (Tahitian *tatau* "to mark"), mana, ukulele, hula, Kanaka (South Sea Islander), tapa cloth, kava (drink and plant), and the names of many plants and animals native to Pacific regions; *e.g.*, the New Zealand birds kiwi, moa, tui, huia, kaka, and takahe, the tuatara lizard, the kauri family of trees, and many others.

LANGUAGES OF MICRONESIA

The widely dispersed groups of small islands comprising Micronesia lie to the north of Melanesia, between the Philippines and the Polynesian Triangle. Micronesia has received linguistic infusions from each of the surrounding regions. Of the 13 or so languages native to Micronesia, two are intruders from the Philippines–Indonesia region, and two are Polynesian. The rest have probably been there longer but almost certainly derive ultimately from some part of Melanesia. Most or all of this last group fall into a single subgroup of Oceanic that has been called Nuclear Micronesian.

The two Indonesian-type languages are Chamorro, spoken in the Mariana Islands, and Palauan, spoken on Palau in the western Carolines. Chamorro, with about 50,000 speakers, most of them living on Guam, shows close resemblances to Philippine languages. The Palauan-speaking community numbers about 12,000. Palauan is Hesperonesian, but its immediate affiliations are uncertain. The two Polynesian languages in Micronesia are Nukuoro and Kapingamarangi; they are spoken on atolls lying south of Truk and Ponape by about 400 and 700 people respectively.

Nuclear Micronesian languages

Nuclear Micronesian languages include Marshallese (Marshall Islands, 19,000 speakers), Gilbertese (Gilbert Islands, 44,000 speakers), Trukese (Hall Islands, Truk, Mortlock Islands, 26,000 speakers), Ponapean (15,000 speakers on Ponape, Ngatik, Mokil, and Pingelap), Kusaiean (Kusaie Island, 3,600 speakers), Carolinean (4,000 speakers, with a migrant community on Saipan in the Marianas and a source community in the eastern Carolines speaking a number of fairly diversified dialects), and Ulithian (originally applied to the dialect of Ulithi Island, but now used for the language or dialect continuum that extends from Tobi and Sonsoral through Ulithi and Woleai to Lamotrek, in the western Carolines). In addition, there are two languages that are possibly Nuclear Micronesian but their divergent structure and vocabulary make their membership doubtful at present. Yapese, spoken on Yap Island by more than 4,000 speakers, is one of them, and Nauruan, with about 3,000 speakers on Nauru Island, is the other.

Nuclear Micronesian languages show a variability in vocabulary and structure exceeding that of the Polynesian group, thus indicating that their immediate common ancestor began to divide into several languages at least 3,000 years ago. Gilbertese and Marshallese, for instance, share only about 21 percent of related words in their basic vocabularies, while Kusaiean and its neighbouring languages, Ponapean and Marshallese, share only about 26 percent and 24 percent, respectively. The figures for Yapese and Nauruan and other languages are still lower.

The greatest diversity lies in east Micronesia, suggesting that the homeland of Proto-Nuclear Micronesian may have been in that region. Further west, the languages are more alike; a continuum of mutually intelligible dialects or very closely related languages extends from Truk through the main body of the Caroline Islands southwest to Tobi Island, and includes the Trukese, Carolinean, and Ulithian languages.

The following features appear to be characteristic of Nuclear Micronesian languages (with the partial exception of Gilbertese): velarized consonants (made with movement of the tongue toward the soft palate), long or geminate consonants, the assimilation of vowel pronunciations to neighbouring sounds, and a number of other fairly complex phenomena that modify the pronunciation of particular sounds in particular contexts. Grammatical features include verb phrases introduced by subject prefixes marking person and number, attachable to the verb or to one of the many preverbal tense-aspect particles; many subclasses of nouns distinguished in numerical and possessive constructions; elaborate sets of demonstrative pronouns paralleling many of the meaning distinctions found in personal pronouns; complex numeral and classifier systems; and several kinds of reduplication of base words carrying several grammatical–semantic functions.

In general, the Nuclear Micronesian languages have been among the most innovative of the Oceanic languages. They have considerably modified the original Oceanic sound system and lost a number of grammatical distinctions made in Proto-Oceanic, while elaborating others and developing several new features. Grammatical sketches exist for most of the languages, but as yet few dictionaries have been published. Micronesian communities are almost 100 percent literate. Because of the phonological complexity of many of the languages, however, few of the orthographic systems, all of which are in roman script, are as uniform or satisfactory as those for the Polynesian or Indonesian languages.

BIBLIOGRAPHY. The classic comparative work is OTTO DEMPWOLFF, *Vergleichende Lautlehre des austronesischen Wortschatzes*, 3 vol. (1934–37), in German, which followed a series of important earlier essays by RENWARD BRANDSTETTER, some of which appear in *An Introduction to Indonesian Linguistics*, trans. by C.O. BLAGDEN, (1916). ISIDORE DYEN, *The Proto-Malayo-Polynesian Laryngeals* (1953), modifies some of Dempwolff's reconstructions, while the same author's *A Lexicostatistical Classification of the Austronesian Languages* (1963), presents a subgrouping of 214 languages. G.W. GRACE, *The Position of the Polynesian Languages Within the Austronesian (Malayo-Polynesian) Language Family* (1959), also contains an excellent discussion of previous comparative work. R.H. CODRINGTON, *The Melanesian Languages* (1885), and S.H. RAY, *A Comparative Study of the Melanesian Island Languages* (1926), are now important chiefly for the many grammatical sketches they contain. A. CAPELL, "Oceanic Linguistics Today," *Current Anthropology* 3:371–396, 422–428 (1962), reviews comparative work up to 1960. *A Pacific Bibliography*, 2nd ed. by C.R.H. TAYLOR (1965), and H.R. KLIENEBERGER (comp.), *Bibliography of Oceanic Linguistics* (1957), contain excellent bibliographies of earlier works. More-up-to-date information may be found in *Oceanic Linguistics* (semi-annual), chief among the several journals that

publish work on Austronesian; in T.A. SEBEOK (ed.), *Current Trends in Linguistics*, vol. 8, *Oceania* (1971); and in C.F. and F.M. VOEGELIN, *Languages of the World: Indo-Pacific Fascicles* (1964–).

(A.K.Pa.)

Automata

Usually designed to be decorative or amusing or both, automata are mechanical objects that are relatively self-operating once they have been set in motion. They often imitate natural phenomena, both in form and in movement. An automaton may be large enough to be watched by a concourse of people or small enough to be carried in the pocket. Although some automata, such as robots, are functional and utilitarian, this article is concerned only with automata as art objects, that is, with those that delight the aesthetic sense and fancy.

Aesthetic considerations. Automata are designed to arouse interest through their visual appeal and then to inspire surprise and awe through the apparent magic of their seemingly spontaneous movement. In ancient and medieval times, this ability to stimulate wonder was used in magico-religious ceremonies. Most automata, however, were made either for ornamentation of functional objects and architecture or as gifts and items of personal whimsy. As decorative objects their appeal lay not only in their realism but also in the beauty of their precision craftsmanship and technology. The more ingenious and involved the action of their concealed power source and mechanisms, the greater was their ability to intrigue the spectator. Elaborate movements demand thought and skill on the part of both designer and craftsman. Design limitations are imposed by the materials available and the level of technological knowledge. Complex actions involve many precisely moving parts, some of delicate construction; by nature, therefore, automata are generally fragile and require frequent repair.

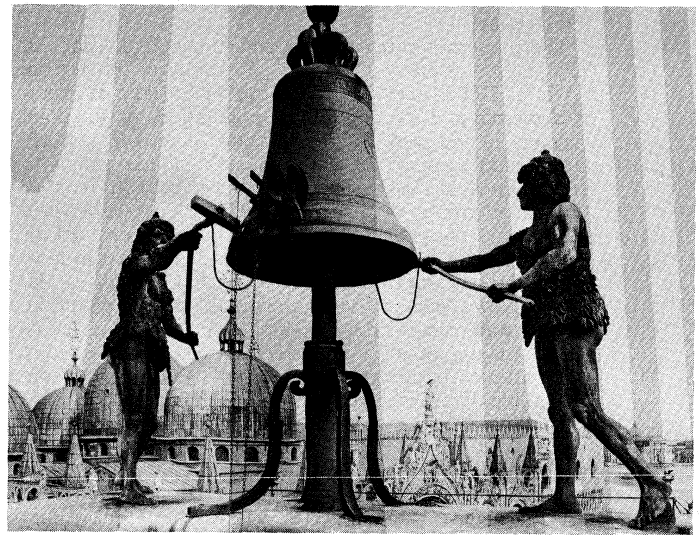
The majority of automata are direct representations of creatures and plants or of kinetic aspects of natural phenomena. Imitations of such natural phenomena as the moving water of streams and waterfalls, for instance, can be simulated with twisted rods of glass. A mechanical device can be used to make a flower open its petals to imitate blooming or to make a figure walk. Some purely capricious automata consist of complete scenes in which caricature personages perform in a humourous manner. Not all automata, however, are mimetic. Some offer only visual fascination, such as spinning roundels set with gems to make flashing patterns of color and light.

Automata classified

Automata can be generally classified into two groups: those that are ancillary to a functional article and those that in themselves are fanciful objects, solely for decoration and pleasure. Clocks and watches, which lend themselves to displays of motion, are the most common type of functional object with automata. With or without the accompanying music of bells or other instruments, clock automata can take a variety of forms. In 1599, for example, Queen Elizabeth I of England sent to the Turkish Sultan a 16-foot-high (4.877-metre) clock that included not only an organ and bells but also mechanical figures of trumpeters and a holly bush with blackbirds and thrushes that sang and moved.

Early mechanical clocks, dating from the 14th century, were set up in public places and equipped with human-looking figures that marked the hours by striking bells with hammers. Known as jaquemarts or jacks, these figures replaced live watchmen or bell ringers who had performed this task. Increased mechanical knowledge and technical skill resulted in more complicated displays. Public clocks showed joustings, processions, or religious scenes, such as the scene of the adoration of the Magi begun in 1352 for the Cathedral of Strasbourg in France and the famed procession of puppets made in 1356–61 for the clock of the Frauenkirche at Nürnberg in Germany. One of the most famous public clocks with automata is located in Venice's Piazza di S. Marco. A three-level clock with jacks, it was built in 1496–99 from the designs of the Renaissance architect Mauro Coducci (1440–1504). Clocks for the home performed comparably to these elaborate works, but on a smaller scale. From *c.* 1775 automata, especially tiny jacks that beat out the time, became increasingly popular for watches.

Alinari



The two "Mori" or jacks by Mauro Coducci, 1496–99. The figures strike the hour on the Torre dell'Orologio in the Piazza di S. Marco, Venice.

Frequently, functional objects became overburdened with decorative mechanisms, and the objects' primary utilitarian function was subordinated. The simple snuff box, for example, eventually became so encumbered with clockwork mechanisms for telling time, providing music, and operating moving figures that only a tiny space remained for holding snuff. Thus, the automaton itself became the centre of interest, and the container was often designed around it, rather than vice versa. The majority of automata have been objects of fancy that are purely decorative in concept and function. The most complicated are the androids: figures in human form that can be made to walk about, play music, write, or draw. They are mostly of fairly large size and intended for public display. At the other end of the scale are exquisitely finished, pocket-sized objects such as trick pistols that were the speciality of the Rochat brothers, Ami-Napoléon and Louis, both of whom were among the finest automata designers and craftsmen of the early 19th century. These pistols are made of gold or gilded silver, enamelled, and set with pearls and precious stones. When the trigger is pressed, a tiny bird appears at the end of the barrel and proceeds to sing, simultaneously moving its wings and turning its head from side to side, or a flower shoots forth in full bloom and sprays perfume.

Automata as decorative objects

Historical development. Few examples of automata made prior to the 16th century remain, but numerous documents record their one-time existence. Among the earliest references is one to a wooden model of a pigeon constructed by Archytas of Tarentum (flourished 400–350 BC), a Greek friend of Plato. The bird was apparently suspended from the end of a pivoted bar, and the whole apparatus revolved by means of a jet of steam or of compressed air. More complete information about other devices is found in the writings of Hero of Alexandria (flourished 1st century AD), who described devices actuated by water, falling weights, and steam.

Some of the most elaborate examples of medieval automata were designed by the early Byzantines. Most renowned of these was a great clock erected in about 500 AD at Gaza, Syria. It was operated by water and centred on a figure of Hercules that struck the hours with its club. Later in date was a gold throne made *c.* 835 for the Byzantine emperor Theophilus (reigned 829–842), who is said to have employed it to impress foreigners. When required, figures of lions supporting the royal seat roared realistically, while mechanical birds sang in imitation trees at either side.

During the Middle Ages in the Islāmic world, there were a number of inventors active from about the 9th century. Best documented are the water-operated automata, many of moving peacocks, invented and made by al-Jazarī, who worked in the 13th century for princes of the Urtugid dynasty in Mesopotamia.

References to automata devised by Western Europeans in the Middle Ages cite such distinguished names as Roger Bacon (*c.* 1220–*c.* 1292) and Albertus Magnus (*c.* 1200–1280), both of whom are credited with constructing androids—Bacon, a talking head, and Albertus, an iron man. Decorative mechanical objects for ecclesiastical use are illustrated by the Gothic architect Villard de Honnecourt in his famed sketchbook (1235). He drew, for example, a movable eagle to be operated when scripture was read. A sensational medieval automaton was a "magic fountain" designed in 1242 by Guillaume Boucher, a Parisian goldsmith, for the Mongol Möngke Khan (1208–1259), who held Boucher captive in Belgrade. Late Gothic examples included the flying iron eagle and fly of the German astronomer and mathematician Johann Müller (1436–76), known as Regiomontanus. When demonstrated for the emperor Maximilian, the fly was said to have alighted on the imperial arm. Perhaps the inspiration for this construction was the legendary mechanical fly of the medieval magician Vergil, which was reputed to have kept the Neapolitan meat market free of other flies.

In the early 16th century there was renewed interest in the manufacture of automata, largely stemming from the influence of Eastern examples brought to Europe through trade with the Orient and the translation from the ancient Greek of the 1st century AD writings on mechanical objects by Hero of Alexandria. Intricate fountains emphasizing spectacular and trick effects became highly fashionable among the wealthy. Notable among them were the mid-16th century fountains and waterworks built for the gardens of the Villa d'Este at Tivoli, Italy.

With the use of coiled tempered steel spring from the mid-15th century, a truly portable source of motion became available in the Renaissance. It was used, for instance, in some of the nefs, table ornaments in the form of sailing ships. Largely dating from the second half of the 16th century, nefs probably originated in the gold and silversmithing centres of Germany, namely, Augsburg and Nürnberg, with such important masters of mechanical construction and the jeweler's craft as Hans Schlottheim (1547–1625). Among the most celebrated nefs is the "Ship of Charles V" (Musée de Cluny, Paris). When the hour strikes, a miniature organ plays, and the approximately 2½-foot-long by 3¼-foot-high (.7620-metre by 1-metre) boat rocks, with musicians playing instruments on the deck and sailors moving in the rigging; ten courtiers pay their respects to Charles, who bows in acknowledgment.

Androids were also popular in the Renaissance. One of the best preserved examples is a mandolin-playing lady (*c.* 1540; Kunsthistorisches Museum, Vienna) attributed to Giannello Torriano of Cremona (*c.* 1500–85), clockmaker to Charles V (of the Holy Roman Empire).

It was in the later 18th and early 19th centuries that the most intricate automata made their appearance. Typical are the objects made by the Rochat brothers, who specialized in the manufacture of miniature singing birds. The mechanical songbirds were devised to appear suddenly from beneath hinged panels in snuffbox tops or to operate in cages that were suspended so that a clock under the base was visible. Such birds might even be concealed in a bracelet or a pocket watch. Perhaps the most intriguing of small-size automata were the so-called magician boxes. A disk engraved with a question is inserted in a slot in the box, upon which the tiny figure of a magician comes to life and points with his wand at a space where the answer appears.

Among the more elaborate mechanical devices popularized in the 18th century were *tableaux mecaniques*, or mechanical pictures. These framed painted landscapes, in which figures, windmills, and so forth spring to life by means of hidden clockwork, remained popular through the 19th century. A tableau designed for Mme de Pompadour (1759; Conservatoire National des Arts et Métiers, Paris) is a prime example of this type of automaton. Closely related to the *tableaux mécaniques* are mechanical theatres, the most extravagant of these having been built in the gardens of Hellbrunn near Salzburg. Consisting of 113 hydraulically operated figures, it was assembled between 1748 and 1752.

The most intricate mechanisms of all were those employed for the androids. The first famed maker of them was a Frenchman, Jacques de Vaucanson (1709–82), who in 1738 created a flute player capable of playing a dozen songs. His most distinguished followers were the Swiss Jaquet-Droz, father and son: Pierre (1721–90), who worked in conjunction with Jean-Frédéric Leschot (1746–1824), and Henri-Louis (1752–91). They constructed figures to write and draw and others to play musical instruments. Later came the Maillardet family, who worked on into the 19th century, when simplified versions of clockwork-operated automata began to be produced in tin and cardboard.

From the late 16th century onwards, automata featured among exports from West to East. Ambassadors and representatives of trading companies were agreeably received upon presenting such objects. Invariably complex in action and sumptuously cased, they were displayed with pride in the palaces of the Far East and India. The most prominent European supplier was James Cox (died 1788), of London, whose 18th-century clients included the East India Company. Turkey was another profitable market for English-made clocks with automata. Markwick Markham of London supplied (*c.* 1750–75) many clocks for sale. All have Turkish numerals on their faces, and some are embellished with automata.

Automata in China and India

Accounts of automata in China date from as early as the 3rd century BC, during the Han dynasty, when a mechanical orchestra was made for the emperor. By the Sui dynasty, in the 6th and 7th centuries AD, automata had become widespread, and a book entitled the *Shui shih t'u Ching* ("Book of Hydraulic Elegancies") was published. In the T'ang period, from the 7th to the 10th centuries AD, automata continued to be popular with imperial circles. There are records of flying birds, an otter which caught fish, and figures engaged in numerous activities ranging from a monk begging to girls singing. After the Yüan period (1279–1368), the creation of automata seems to have waned. In the 18th and 19th centuries during the Ch'ing period, however, automata were again made and were often inspired by those in clocks imported from Europe. The imperial Summer Palace in Peking was the principal repository of the great collection of automata formed by the emperor Ch'ien-lung in the second half of the 18th century. Much of the contents of the palace was destroyed or looted by European soldiers in 1860 and again in the Boxer Rebellion of 1900, leaving little evidence of the artistic and mechanical merit of Chinese automata.

In India there is little more than references in legends and myths to mechanical flying chariots, animals, and dancing figures. With the exception of a few brief entries in various treatises, most of the knowledge of construction seems to have been kept secret and passed orally from one craftsman to another. There are no examples, therefore, of automata before the Mughal period of the 16th to the 18th centuries. Most extant automata in India were imported from the Near and Far East and Europe, especially England and France.

20th century

With the exception of a few works by Peter Carl Fabergé (1846–1920), the production of costly artistic automata virtually ceased in the late 19th and early 20th centuries because of the diminishing number of skilled craftsmen, as well as rich patrons to support them. Collecting, therefore, is reserved for only the most wealthy. This expensive hobby is still served by the dealer who locates increasingly rare examples of historic automata and by a small corps of highly skilled craftsmen whose dearly priced services keep the objects in working order.

BIBLIOGRAPHY. Splendidly illustrated monographs on this subject include: A. CHAPUIS and E. GÉLIS, *Le Monde des Automates,* 2 vol. (1928), with an extensive bibliography; A. CHAPUIS and E. DROZ, *Les Automates* (1949; Eng. trans., *Automata: A Historical and Technological Study,* 1958), a re-assessment of the earlier work by Chapuis and Gélis; and E. MAINGOT, *Les Automates* (1959). A description with illustrations of some examples of 13th- to 18th-century automata may be found in W. BORN, "Early European Automatons," *Connoisseur,* vol. 100, pt. 1–2, pp. 123–129, 246–252 (1937).

(G.Wi.)

Automata Theory

In simple terms an automaton represents a formalization of a set of rules for a computation, and automata theory, studied as part of the foundations of mathematics, is used in the building of such machines as all-purpose computers. An example of a typical automaton is a pendulum clock. In such a mechanism the gears can assume only one of a finite number of positions, or states, with each swing of the pendulum. Each state, through the operation of the escapement, determines the next succeeding state, as well as a discrete output, displayed as the discrete positions of the hands of the clock. As long as such a clock is wound and its operation is not interfered with, it will continue to operate unaffected by outside influences except the effect of gravity on the pendulum.

More general automata are designed to respond to changes in external conditions or to other inputs. For example, thermostats, automatic pilots of aircraft, missile guidance systems, telephone networks, and controls of certain kinds of automatic elevators are all forms of automata.

The internal states of such devices are not determined solely by their initial state, as is the case of the pendulum clock, but may be determined by an input from a human operator, from another automaton, or by an event or series of events in the environment. A thermostat, for instance, has an "on" or "off" state that depends on the temperature. Perhaps the most widely known example of a general automaton is the modern electronic computer, the internal states of which are determined by the data input and which operates to produce a certain output.

The components of automata consist of specific materials and devices, such as wires, transistors, levers, relays, gears, and so forth, and their operation is based on the mechanics and electronics of these parts. The principles of their operation as a sequence of discrete states can, however, be understood independently of the nature or arrangement of their components. In this way, an automaton may be considered, abstractly, as a set of physically unspecified states, inputs, outputs, and rules of operation, and the study of automata as the investigation of what can be accomplished with these. This mode of abstraction yields mathematical systems that in certain respects resemble logical systems. Thus, an automaton can be described as a logically defined entity that can be embodied in the form of a machine, with the term automaton designating both the physical and the logical constructions.

The Turing machine

In 1936 an English mathematician, Alan Mathison Turing, in a paper published in the *Proceedings of the London Mathematical Society* ("On Computable Numbers with an Application to the Entscheidungsproblem"), conceived a logical machine the output of which could be used to define a computable number. For the machine, time was considered to be discrete and its internal structure, at a given moment, was described simply as one of a finite set of "states." It performed its functions by scanning an unbounded tape divided into squares, each of which either contained specific information in the form of one of a finite number of symbols or was blank. It could scan only one square at a time, and, if in any internal state except one called "passive," it was capable of moving the tape forward or backward one square at a time, erasing a symbol, printing a new symbol if the square was blank, and altering its own internal state. The number it computed was determined by symbols (the "program") provided on a finite portion of the tape and the rules of operation, which included stopping when the passive state was reached. The output number was then interpreted from the symbols remaining on the tape after the machine stopped.

Automata theory since the middle of the present century has been extensively refined and has often found practical application in civilian and military machines. The memory banks of modern computers can store large (though finite) amounts of information. The original Turing machine had no limit to the memory bank because each square on the unbounded tape could hold information. The Turing machine continues to be a standard reference point in basic discussions of automata theory, and many mathematical theorems concerning computability have been proved within the framework of Turing's original proposal.

Part of automata theory lying within the area of pure mathematical study is often based on a model of a portion of the nervous system in a living creature and on how that system with its complex of neurons, nerve endings, and synapses (separating gap between neurons) can generate, codify, store, and use information. The "all or none" nature of the threshold of neurons is often referred to in formulating purely logical schemata or in constructing the practical electronic gates of computers. Any physical neuron can be sufficiently excited by an oncoming impulse to fire another impulse into the network of which it forms a part, or else the threshold will not be reached because the stimulus is absent or inadequate. In the latter case, the neuron fails to fire and remains quiescent. When several neurons are connected together, an impulse travelling in a particular part of the network may have several effects. It can inhibit another neuron's ability to release an impulse; it can combine with several other incoming impulses each of which is incapable of exciting a neuron to fire but that, in combination, may provide the threshold stimulus; or the impulse might be confined within a section of the nerve net and travel in a closed loop, in what is called "feedback." Mathematical reasoning about how nerve nets work has been applied to the problem of how feedback in a computing machine can result in an essential ingredient in the calculational process.

Original work on the neurophysiological aspect of automata theory was done by Warren S. McCulloch and Walter Pitts at the Research Laboratory of Electronics at the Massachusetts Institute of Technology starting in the 1940s.

While the automata themselves are prototypes of deterministic machines, the U.S. mathematician Norbert Wiener (*q.v.*) showed that they may be programmed in such a way as to extrapolate certain types of random data that are introduced as input. A prediction of data that are not yet received as input can be accomplished, provided the data are what will later be defined to constitute a stationary time series and provided the prediction is restricted according to a well-defined optimization procedure. In this way a logically defined robot, or automaton, may be placed in an environment that evolves according to both deterministic and random processes (the bifurcation of the environment into deterministic and random processes being mathematically postulated by the designer of the robot) and may be seen to respond to the advantage of its designer: The robot can control a ship's rudder, guide an airplane to its landing, reorient a rocket on its course, predict weather, and so forth. The programming of an automaton so that it will react in a suitable way when placed in a naturalistic environment falls under the heading of prediction theory. (B.R./R.J.Ne)

Use of automata for prediction

NEURAL NETS AND AUTOMATA

The finite automata of McCulloch and Pitts. The definitions of various automata as used here are based on the work of two mathematicians, John von Neumann (*q.v.*) and Stephan Cole Kleene, and the earlier neurophysiological researches of McCulloch and Pitts, which offer a mathematical description of some essential features of a living organism. The neurological model is suggested from studies of the sensory receptor organs, internal neural structure, and effector organs of animals. Certain responses of an animal to stimuli are known by controlled observation, and, since the pioneering work of a Spanish histologist, Santiago Ramón y Cajal, in the latter part of the 19th and early part of the 20th century, many neural structures have been well-known. For the purposes of this article, the mathematical description of neural structure, following the neurophysiological description, will be called a "neural net." The net alone and its response to input data are describable in purely mathematical terms.

The neural net

A neural net may be conveniently described in terms of the kind of geometric configuration that suggests the physical structure of a portion of the brain. The component parts in the geometric form of a neural net are named (after the physically observed structures) neurons. Diagrammatically they could be represented by a circle and a line (together representing the body, or soma, of a physiological neuron) leading to an arrowhead or a solid dot (suggesting an endbulb of a neuron). A neuron may be assumed to have either an excitatory or an inhibitory effect on a succeeding one; and it may possess a threshold, or minimum number of unit messages, so to speak, that must be received from other neurons before it can be activated to fire an impulse. The process of transmission of excitation mimics that which is observed to occur in the nervous system of an animal. Messages of unit excitation are transmitted from one neuron to the next, and excitation is passed along the neural net in quantized form, a neuron either becoming excited or remaining non-excited, depending on the states (excitatory or quiescent) of neurons whose endbulbs impinge upon it. Specifically, neuron N, with threshold h, will be excited at time t, if and only if h or more neurons whose excitatory endbulbs impinge upon it are excited at time $t - 1$ and no neuron whose inhibitory endbulb impinges upon it is excited at time $t - 1$. A consistent picture can be made of these conditions only if time and excitation are quantized (or pulsed). It is assumed conventionally that a unit of time is required for the transmission of a message by any neuron.

Certain neurons in the configuration mathematically represent the physiological receptors that are excited or left quiescent by the exterior environment. These are called input neurons. Other neurons called output neurons record the logical value, excited or quiescent, of the whole configuration after time delay t and transmit an effect to an exterior environment. All the rest stimulate inner neurons.

Any geometric or logical description of the neural structure of an organism formulated as the basis of physical construction must be sufficiently simple to permit mechanical, electric, or electronic simulation of the neurons and their interconnections.

The basic logical organs. The types of events that can excite the automaton and the kinds of responses that it can make must next be considered. By stripping the description down to the most simple cases, the basic organs from which more complicated robots can be constructed may be discovered. Three basic organs (or elementary automata) are necessary, each corresponding to one of the three logical operations of language: the binary operations of disjunction and conjunction, leading to such proposition as $A \cup B$ (read "A or B"), $A \cap B$ (read "A and B"), and the unary operation of negation or complementation, leading to such propositions as A^c (read "not A" or "complement of A"). First to be considered are the stimulus–response pattern of these elementary automata.

Binary operations of disjunction and conjunction

Assuming that a neuron can be in only one of two possible states—*i.e.*, excited or quiescent—an input neuron at a given instant of time $t - 1$ must be either excited or nonexcited by its environment. An environmental message transmitted to two input neurons N_1 and N_2 at time $t - 1$ can then be represented numerically in any one of the four following ways, in which binary digit 1 represents excitation and binary digit 0 represents quiescence: (0, 0), (0, 1), (1, 0), (1, 1). The disjunction automaton must be such that a single output neuron M correspondingly registers at time t the response: 0, 1, 1, 1. The conjunction automaton must be such that a single output neuron M correspondingly registers at time t the response: 0, 0, 0, 1. The negation automaton considered as having two input neurons N_1 and N_2, of which N_1 is always excited, must respond to the environmental messages (1, 0) and (1, 1) with 1, 0, respectively, at the output neuron M.

The generalized automaton and Turing's machine. The construction of more complicated robots from these basic building blocks constitutes a large part of the theory of automata. The first step in the direction of generalization is to define the neural nets that correspond to formal expressions in n variables of the propositional calculus—that is, the formal system that concerns "or," "and," "not," and "implies." A single output automaton (of which the above three are simple examples) is a neural net with n input neurons, one output neuron, and with interconnections between neurons that conform to the rule that no neuron stimulated at time t can impinge upon a neuron that could have experienced its first stimulation at the same or an earlier time. The latter rule is the requirement of no feedback. Given this concept of a single output automaton, it is possible to examine the output response at time $t + s$, considered as a function of the configuration of stimuli at the n input neurons at time t. This response can be compared with the truth value of a logical statement (polynomial) from the propositional calculus. A logical statement is formed from n component propositions, each of which can assume the truth value either true or false. The comparison between automaton and logical statement is accomplished by matching response at the output neuron at time $t + s$ with truth value of the statement for every one of the 2^n cases in which the configuration of stimuli conforms to the configuration of truth values of the component propositions. If, in this sense of comparison, the functional response of the automaton is identical to the functional value of the logical statement (polynomial), the automaton is then said to compute the statement (polynomial) or the statement is said to be computable. A wider class of computable statements is introduced with the general automaton, yet to be defined, as with the more general Turing machine.

Response of automata and truth value of statements

The important distinction between the logical statement and the automaton that computes it is that the first is free of any time ingredient while the second is defined only with reference to a time delay of length s.

A basic theorem states that for any polynomial P of the propositional calculus, there exists a time delay s and a single output automaton A, such that A computes P with time delay s. The proof of the theorem rests on the fact from the propositional calculus that all statements are composed from component propositions with the operations of disjunction, conjunction, and negation and the fact from the automata theory that all single output automata can be composed by interconnecting elementary automata of the disjunctive, conjunctive, and negative types.

A second step of generalization in the construction of robots proceeds from the single output automata to the neural net that possesses more than one output neuron and in which the internal connections may include feedback. Such a construction is called a "general automaton." The class of general automata includes all-purpose, electronic digital computers the memory-storage units of which are of fixed, though possibly of very considerable, size. It is within the context of the general automaton that the purely automated decision-making, computing, controlling, and other sophisticated neural functions so suggestive of the mental ability of man may appropriately be discussed.

The Turing machine can be defined not only as it was in the introduction (following roughly Turing's approach) but as a general automaton to which an unbounded memory unit (such as an unbounded tape) is added. Thus, the general automaton and the Turing machine differ in logical design only with respect to the extent of memory storage.

Extent of memory in a Turing machine

The distinction is critical, however, for Turing proposed that the class of numbers computable on his machine (a wider class than can be obtained by general automata) coincide with those that are effectively computable in the sense of constructive logics (see MATHEMATICS, FOUNDATIONS OF). A simple convention also makes it possible to interpret the output of a Turing machine as the computation of a function. The class of functions so computed, called "Turing computable" or "computable," are of basic importance at the foundations of mathematics and elsewhere. It can also be stated that a useful class of functions that are definable without

reference to machines, namely, the so-called partial recursive functions, has the same membership as the class of computable functions. For the present purposes, then, no effort need be made to define the partial recursive functions.

Turing's approach admitted mathematical formalization to the extent that a finite list of symbols q_1, q_2, q_3, $\cdots$, q_n could be used to denote internal states and a finite list of symbols a, b, c, $\cdots$, λ could designate abstractly what is called "the alphabet"—that is, the list from which individual members could be chosen and printed into the squares of the machine's tape. If the symbols R and L, respectively, designate a move of the tape one square to the right and one square to the left, it remains only to list in some orderly fashion the alternative possible steps in the machine's operation in order to define it completely. Turing himself chose to list alternate steps, or instructions, in the form of quintuples of the above symbols. It is also possible to use quadruples to define a machine. Such a list, then, of, say, quadruples of instructions is equivalent to a Turing machine, and it is significant that the list is finite.

The finiteness of the list of quadruples of instructions leads to the idea that all Turing machines can be listed —that is, they are at most countable in number. This being the case, it can be proved that there is what Turing called a "universal" machine capable of operating like any given Turing machine. For a given partial recursive function of a single argument, there is a corresponding integer, called the "Gödel number," that identifies the Turing machine capable of computing the given function. The Gödel number and the argument value of the function to be computed can be given as input data on the tape of the universal machine. From the Gödel number, the list of instructions, defined in the form of quadruples, that are necessary for the computation of the given recursive function at the specific argument value can be encoded by the universal machine on its own tape, and, from that point on, the universal machine will duplicate the required Turing machine.

The "universal" machine

Input: events that affect an automaton. Once having reached the definition of the general automaton and the more general universal Turing machine, a general definition of the events in the environment that stimulate it may be introduced. The automaton, which computes logical statements, is not defined without reference to time, a characteristic that distinguishes the machine itself from the logic. In the same way, stimuli are not definable, in general, without reference to time. These facts are indicative of the simulation features that the computing machine bears with respect to man.

For an automaton with n input neurons, $N_1, N_2, \cdots, N_n$, an individual history of stimulation, starting with the present moment, $t = 0$, and continuing to the remote past, can be recorded as a sequence of n-tuples, $(\beta_1, \beta_2, \cdots, \beta_n)$, in which each binary digit, β_k, is either a 0 or a 1. Thus, the beginning of one such individual history for an automaton of four neurons might be recorded in tabular form as an unending list of quadruples of the type (1, 0, 1, 1) (see Box, display 1).

Events as collections of individual histories

An event is a collection of individual histories. This is a generalization of the idea already used to characterize an environmental message transmitted to the two input neurons of an elementary automaton at time $t - 1$. As an example, the stimulus (0, 1) is the same as the collection of all individual histories in which neuron N_2 was stimulated at time $t - 1$ and neuron N_1 was not. As another example, the event that neuron N_2 (of a two-neuron automaton) is presently stimulated and has always been stimulated on alternate second can be represented as the collection of two individual histories (see 2). While some events require an infinite tabulation, others that specify the states of each neuron over a finite past (allowing that anything might have occurred before) permit a finite tabulation. Events of the second kind are called definite events, or stimuli.

The construction (either actual or theoretical) of a general automaton with the help of the logical components and interconnections of a neural net results in an entity that responds in reproducible ways to stimuli. A response becomes recorded as a configuration of binary digits, corresponding to the states of the finite number of output neurons at a specified time t in the future, while a stimulus is a collection of individual histories extending over the past and including the present. The logical construction implies a behaviour in the guise of a listing of responses to all possible stimuli. Reciprocally, for a given behaviour of the type defined, the possible structure of a machine that could produce such behaviour can be investigated.

PROBABILISTIC QUESTIONS

It was traditional in the early treatment of automata theory to identify an automaton with an algorithm, or rule of computation, in which the output of the automaton was a logically determined function of the explicitly expressed input. From the time of the invention of the all-mechanical escapement clock in Europe toward the end of the 13th century, through the mechanistic period of philosophy that culminated in the work of the French mathematician Pierre-Simon Laplace (*q.v.*), and into the modern era of the logically defined Turing machine of 1936, an automaton was a mechanical or logical construction that was free of probabilistic components. It was also understood to be immersed in an environment (that is, activated or supplied with input data) that could be logically specified without the concept of chance. The strength of the mechanistic philosophy as it influenced science prior to the 20th century is illustrated in a quotation from Laplace in PROBABILITY, THEORY OF: *Foundations of 20th-century probability theory*.

Automata and the idea of chance

After the middle of the 20th century, mathematicians explicitly investigated questions concerning automata that included in their formulation the idea of chance, and in doing so they drew upon earlier applicable mathematical results.

Of the types of probabilistic questions considered, four (which will be listed in arbitrary order) were predominant. The first, that of Norbert Wiener, was broached in 1948. It concerned the use of mathematically expressed algorithms or physically constructed computers to predict the future of a system, such as the weather, that includes random components—*i.e.*, an automaton in Turing's logical sense immersed in a random environment. The second, of von Neumann, was concerned with the reliability of large computing machines with many components and sought methods of design, called "multiplexing," that would reduce the chance for unwanted error during the machine calculation of a problem. In this context, the automaton was interpreted as a randomly operating device that in practice approximates the operation of a Turing machine under the influence of better and better design. The third, considered by various researchers, concerned the possibility of computing a wider class of sets than are accessible to Turing machines by adding a random component to the machine itself. In this context, the automaton was being interpreted as a Turing machine modified with the potentiality for injecting the output of a random number generating device into one or more of its operational steps. The fourth concerned the logical possibility of an automaton, such as a Turing machine, actually yielding as output a sequence of random numbers. In this context, the automaton was considered to be simultaneously a Turing machine and a generator of numbers that are indistinguishable from measurements on random phenomena.

Some results that have been achieved from examination of each of these four types of questions will constitute the remainder of this section.

The automaton and its environment. It must first be observed that, just as an automaton is an acceptable description (or model) of a neural structure, an automaton, though frequently thought of as a computing machine, is in general a response mechanism that produces output (or behaviour) as a consequence of the input (or environmental stimuli). "Environment" is then another

name for the input and output of an automaton. Some poetic license in identifying automata with living things may justify the use of the term.

During his researches on cybernetics, Wiener recognized that, if computers could be programmed to solve certain mathematical equations, then the data read from physically generated time series (or numerical values indexed consecutively in time and related through a transformation) could be extrapolated. He saw that, if this process could be accomplished with sufficient speed, as would be possible with modern electronic circuits, then the extrapolated values would be obtained faster than the actual physically evolving process that produced the time series, and a prediction of the future would result. Errors would be inevitable because a complete history of data and adequate measurements would be unobtainable. For this reason, the mathematical equations that would be at the heart of such an extrapolation could be deduced, in part, from the objective of minimizing the errors. Thus, the matching of an automaton, or computer, with a real physical environment could result in the anticipation of the future, if certain mathematical equations were derived that minimized prediction error.

Matching an automaton with an environment

Control and single-series prediction. A derivation of the mathematical equations of prediction had been accomplished in a limited sense some years before Wiener's work on cybernetics. In 1931 Wiener had collaborated with an Austrian-born U.S. mathematician, Eberhard Hopf, to solve what is now called the Wiener–Hopf integral equation, an equation that had been suggested in a study of the structure of stars but later recurred in many contexts, including electrical-communication theory, and was seen to involve an extrapolation of continuously distributed numerical values. During World War II, gun- and aircraft-control problems stimulated further research in extrapolation, and Wiener composed a purely mathematical treatise, *Extrapolation, Interpolation, and Smoothing of Stationary Time Series*, which was later published in 1949. As early as 1939, a note on extrapolation by a Russian mathematician, A.N. Kolmogorov (*q.v.*), had appeared in the French journal *Comptes Rendus*. Although the Wiener–Hopf work was concerned exclusively with astronomy and done without the guiding influence of computers, it was recognized in World War II that high-speed computations could involve input information from a moving object and, through prediction or extrapolation, provide output data to correct its path. This recognition was the seed of the concept of the guided missile and radar-controlled aircraft. Weather prediction was also possible, as was computerized research on brain waves whose traces on the electroencephalograph offered another physical realization of the time series that are predictable. The mathematics that was necessary for a complete understanding of prediction included the concept of a stochastic process, as described in the article PROBABILITY, THEORY OF.

The Wiener and Kolmogorov research on extrapolation of time series became known as single-series prediction and owed much to the studies (1938) of a Swedish mathematician named H. Wold, whose work was predicated on the assumption that, if $X_1, X_2, X_3 \cdots$ are successive values of a series identified with discrete points in time $t = 1$, $t = 2$, $t = 3, \cdots$, then the successive values are not entirely unrelated (for if they were, there would be no way for an algorithm or an automaton to generate information about later members of the sequence—that is, to predict). It was assumed, with anticipation that there is frequently such a thing in nature, that a transformation T relates members of the series by successively transforming an underlying space of points ω according to a rule. The rule states that the kth member of the time series is a function of an initial point ω that has migrated in the underlying space $X_k = X(T^k\omega)$. It was also assumed that, if sets of points $\{\omega\}$ constituted a region (of sufficient simplicity called "measurable") in space, then when the set was transformed under the influence of T its volume would not be changed. The last assumption had, in fact, been proved by a French mathematician, Joseph Liouville, a century earlier for a wide class of physical processes whose behaviour is correctly described by the so-called Hamiltonian equations. The clearly stated assumptions of Wiener and Kolmogorov, referred to as the stationarity of the time series, were supplemented with the idea (the linearity restriction) that a solution $S_k(\omega)$ for the predicted value of the series, displaced in time k steps into the future, should be restricted to a linear combination of present and past values of the series (see 3).

With the help of one other mathematical assumption, it was then possible to solve the single-series prediction problem by specifying an algorithm that would determine the coefficients in the linear combination for $S_k(\omega)$, in which k is a positive integer (see 4). It was possible also to solve for the error of prediction (see 5)—that is,

The assumptions of prediction theory

(1)
$$\begin{array}{l}(1,0,1,0)\\(1,0,1,1)\\(0,0,0,1)\\(1,0,1,0)\\\cdots\\\cdots\\\cdots\end{array}$$

(2)
$$\begin{array}{ll}(0,1) & (1,1)\\(0,0) & (1,0)\\(0,1) & (1,1)\\(0,0) & (1,0)\\\cdots & \cdots\\\cdots & \cdots\\\cdots & \cdots\end{array}$$

(3) $$S_k(\omega) = \sum_{n=0}^{\infty} X(T^{-n}\omega)\, P_n^{(k)},$$
with convergence defined in the L_2-metric.

(4) An algorithm for computing the coefficients $P_n^{(k)}$ in the prediction $S_k(\omega)$ is the following:

From the auto-correlation (X_{-n}, X_0) of the time series compute $|\psi(\theta)|$:
$$\frac{1}{2\pi}\int_{-\pi}^{\pi} |\psi(\theta)|^2 e^{in\theta}\, d\theta = (X_{-n}, X_0).$$

From $|\psi(\theta)|$ compute $\psi(r, \theta)$:
$$\log \psi(r,\theta) = \frac{1}{2\pi}\left\{\sum_{n=1}^{\infty} r^n e^{in\theta}\int_{-\pi}^{\pi} \log|\psi(x)|^2 e^{-inx}\, dx + \int_{-\pi}^{\pi} \log|\psi(x)|\, dx\right\}.$$

From $\psi(r, \theta)$ compute (X, h_{-n}):
$$\psi(r,\theta) = \sum_{n=0}^{\infty} r^n e^{in\theta}(X, h_{-n}), \qquad 0 \leq r < 1.$$

From (X, h_{-n}) compute a_n:
$$(X, h)a_0 = 1$$
$$\sum_{n=0}^{m} (X, h_{n-m})a_n = 0; \qquad m > 0.$$

From a_n and (X, h_{-n}) compute $P_n^{(k)}$:
$$P_n^{(k)} = \sum_{m=0}^{n} a_{n-m}(X, h_{-m-k}), \qquad k > 0.$$

(5) $$\sigma_k^2 = \sum_{n=0}^{k-1} |(X, h_{-n})|^2$$

a measure of the discrepancy between the value predicted and the true value of the series that would occur at time k in the future. This meant that for a variety of circumstances, such as the prediction of atmospheric pressure measured at one weather station, or the prediction of a single parameter in the position specification of a particle (such as a particle of smoke) moving according to the laws of diffusion, an automaton could be designed that could sense and predict the chance behaviour of a sufficiently simple component of its environment.

Multiple-prediction theory. Generalizations of the above limited accomplishments are tantalizing to mathematicians. If animals, and man in particular, are viewed, even in part, as automata with varying degrees of accomplishment and success that depend on their abilities to cope with their environment, then man himself could be better understood and his potentialities could be further realized by exploring a generalized version of an automaton's ability to predict. Success in generalizations of this kind have already been achieved under the heading of what is called multiple-prediction theory. A reference to the problem of multiple prediction without a complete solution was made as early as 1941 by a Russian mathematician, V. Zasuhin. The first major step forward, after Zasuhin, was taken by Wiener in 1955 under the title "On the Factorization of Matrices." Many significant results soon followed.

If multiple-prediction theory is identified with part of automata theory (which is not always done), it is possible to consider the construction of a computing machine, or automaton, capable of sensing many interdependent elements of its environment at once and, from a long history of such data, of predicting a future that is a function of the same interdependent elements. It is recognized that multiple prediction is the most general approach to the study of the automaton and its environment in the sense that it is a formulation of prediction free of the linearity restriction earlier mentioned with reference to single series (see 3). To express a future point $S_k(\omega)$, for example, as a linear function of its present and past values as well as first derivatives, or rates of change, of its present and past values is to perform a double prediction or prediction based on the two time series $X_1, X_2, X_3, \cdots; X'_1, X'_2, X'_3, \cdots$, in which primes indicate derivatives with respect to time. Such double prediction is a first step toward nonlinear prediction.

Automata with unreliable components. In 1956 with the continuing development of faster and more complex computing machines, a realistic study of component misfiring in computers was made. Von Neumann recognized that there was a discrepancy between the theory of automata and the practice of building and operating computing machines because the theory did not take into account the realistic probability of component failure. The number of component parts of a modern all-purpose digital computer was in the mid-20th century already being counted in millions. If a component performing the logical disjunction (A or B) misfired, the total output of a complex operation could be incorrect. The basic problem was then one of probability: whether given a positive number δ and a logical operation to be performed, a corresponding automaton could be constructed from given organs to perform the desired operation and commit an error in the output with probability less than or equal to δ. Affirmative results have been obtained for this problem by mimicking the redundant structure of parallel channels of communication that is frequently found in nature—*i.e.*, rather than having a single line convey a pulse of information, a bundle of lines in parallel are interpreted as conveying a pulse if a sufficient number of members in the bundle do so. Neumann was able to show that with this redundancy technique (multiplexing) "the number of lines deviating from the correctly functioning majorities of their bundles" could with sufficiently high probability be kept below a critical level.

Discrepancy between automata theory and practice

Automata with random elements. The term algorithm has been defined to mean a rule of calculation that guides an intelligent being or a logical mechanism to arrive at numerical or symbolic results. As discussed above under *Neural nets and automata*, a formalization of the intuitive idea of algorithm has led to what is now called an automaton. Thus, a feature of an automaton is the predictability, or the logical certainty, that the same output would be obtained for successive operations of an automaton that is provided with the same input data. If, as a substitute for the usual input data, random numbers (or results due to chance) are provided, the combination of input data and automaton is no longer completely predictable. It is notable, however, that unpredictable results that might be obtained with the use of uncertain input are not without their practical application. Such a method of combining the operation of a computer with the intentional injection of random data is called the "Monte Carlo method" of calculation and in certain instances (such as in the numerical integration of functions in many dimensions) has been found to be more efficient in arriving at correct answers than the purely deterministic methods (see MATHEMATICS AS A CALCULATORY SCIENCE).

Quite apart from the questions of efficiency that might bear upon the addition of an element in a computing machine (automaton) that could produce numbers due to chance, the purely logical question has been asked: "Is there anything that can be done by a machine with a random element that cannot be done by a deterministic machine?" A number of questions of this type have been investigated, but the first clear enunciation and study of such a question was accomplished in 1956 by the U.S. engineer Claude E. Shannon and others. If the random element in the machine is to produce a sequence of digits 0 and 1 in a random order so that the probability is p for a digit 1 to occur, then (assuming that the number p is, itself, obtainable from a Turing machine as a computable number) the machine can do nothing new, so to speak, as compared to the unmodified Turing machine. This result is precisely expressed in the language of automata theory by saying that the sets enumerated by the automaton with random elements can be enumerated also by the unmodified automaton. The computability of p, however, is critical and is necessary for the result. It is also important to emphasize, in order to distinguish this result from what follows, that the computability of p is under discussion, not the computability of the sequence of random digits.

The computability condition for random elements

Computable probability spaces. Finally, it is to be observed that the concept of chance or random number, wherever it has occurred in the above discussion, submits to the interpretation of result of observation of an experiment or physical phenomenon. The chance ingredients in the weather data to which prediction theory applies could be due to molecular disturbances in the atmosphere that are of diverse and minute origin. The chance failure that might cause a component breakdown in a computing machine is due to the physical structure and environment of the defaulting part. The source of chance that could be used to augment the input of a computer for the purposes of the Monte Carlo method of calculation may be chosen as the erratic emission of electrons from the cathode of an electronic tube, and is frequently so chosen.

An entirely distinct question is involved in relating chance and computers. It would be important to know whether an automaton in the sense defined by Turing can generate random numbers. The question is tantamount to asking whether a Turing machine can logically describe the behaviour of those sources of chance that are found in nature and are the subject of the study of probability theory. Because there are many points of view—too many to consider here—more tightly phrased questions may serve as an introduction to the subject, and a few conclusions that can be brought as answers will be mentioned. At the outset, one limited question can be affirmatively answered: Can a computable sequence of numbers, $S = (a_1, a_2, a_3, \cdots)$, serve as the basic ingredient of a probability theory by providing all of the necessary points in a probability space? In this question the term computable sequence is defined to mean that the

numbers a_k are real and there is a Turing machine that, for any pair of positive integers A, B, will print out in order the first A digits of all a_k, for k ranging from 1 to B, in a finite number of steps. The term probability space is precisely defined in the article PROBABILITY, THEORY OF. It might appear that an affirmative answer to the above question is not striking if simple probability theory alone is considered—that is, a theory of events in which the number of possible outcomes is finite, as in the theory of dice, coins, roulette, and the like. On the other hand, it was shown in 1960 that, although a computable sequence can serve as a set of points in a simple probability space, the mathematical expectations of all random variables X defined on the space can be computed according to an explicit algorithm (see 6) that makes use of the sample values, $X(a_1)$, $X(a_2)$, $X(a_3)$, $\cdots$, which themselves are computable if X is computable. In this algorithm it is evident that the potential number of values to be calculated is infinite, though the number of possible outcomes (distinct values of X) might be finite.

Random numbers that a Turing machine can compute

In the language of the limited question considered, a listing of all sample values (random numbers) of an infinite sequence of statistically independent random variables can be printed out by a Turing machine, at least in the simple case, with strict adherence to the definition of all probabilistic terms as based on measure theory, the theory that generalizes the concept of length.

Extension of such constructions beyond the simple case has also been shown to be possible, provided the concept of a random variable can be extended to a class of functions that are more general than the measure–theoretic class. The most explicit formulation of a suitable generalization was given in 1966, and on the basis of this work it is possible to answer affirmatively a second question: For any sequence of probability distributions, is there a sequence of statistically independent random variables with these respective distributions, each of whose sample values can be computed on a Turing machine and whose mathematical expectations are also attainable by algorithm? The implications are discussed in PROBABILITY, THEORY OF: *The additivity assumption.*

Such results would seem to affront the intuition that tends to divide phenomena into deterministic (or computable) and random (or uncomputable) parts. It is to be observed, however, that in probabilistic matters, passage to the limit and infinite collections are essential ingredients, and such entities are unfamiliar objects in the world in which intuitions are formed. (B.R.)

CLASSIFICATION OF AUTOMATA

All automata referred to from this point on may be understood to be essentially Turing machines classified in terms of the number, length, and movement of tapes and of the reading and writing operations used. The term discrete state automaton is sometimes used to emphasize the discrete nature of the internal states. The principal classes are transducers and acceptors. In automata theory, a transducer is an automaton with input and output; any Turing machine for computing a partial recursive function, as previously described, can stand as an example. An acceptor is an automaton without output that, in a special sense, recognizes or accepts words on the machine alphabet. The input of an acceptor is written on tape in the usual way, but the tape is blank at the end of the computation, and acceptance of the input word is represented by a special state called a final state. Thus, a word x, or sequence of symbols from an alphabet denoted by the letter S, is said to be accepted by an acceptor A if A computes, beginning in an initial state q_0 with x on tape, and halts in a final state with tape being entirely blank. A subset designated U of the set of words S^* on an alphabet S is called an accepted set if there is an automaton A that accepts any word $x \in U$.

Acceptors. An elementary result of automata theory is that every recursively enumerable set, or range of a partial recursive function, is an accepted set. In general the acceptors are two-way unbounded tape automata.

A useful classification of acceptors has been introduced in conjunction with a theory of generative grammars developed in the United States by a linguist, Noam Chomsky. A generative grammar is a system of analysis usually identified with linguistics. By its means a language can be viewed as a set of rules, finite in number, that can produce sentences. The use of a generative grammar, in the context of either linguistics or automata theory, is to generate and demarcate the totality of grammatical constructions of a language, natural or automata oriented. A simple grammar for a fragment of English, determined by 12 rules (see 7), can serve to introduce the main ideas.

Generative grammars

(6) $$EX = \lim_{N \to \infty} \frac{1}{N} \sum_{k=1}^{N} X(a_k)$$

(7)

1st rule:	$\overline{\text{S}} \rightarrow \overline{\text{Pr}}\ \overline{\text{VP}}$
2nd rule:	$\overline{\text{NP}} \rightarrow \overline{\text{Art}}\ \overline{\text{Adj}}\ \overline{\text{N}}$
3rd rule:	$\overline{\text{Adj}} \rightarrow \overline{\text{Adv}}\ \overline{\text{Adj}}$
4th rule:	$\overline{\text{VP}} \rightarrow \overline{\text{V}}\ \overline{\text{NP}}$
5th rule:	$\overline{\text{Pr}} \rightarrow$ she
6th rule:	$\overline{\text{Art}} \rightarrow$ a
7th rule:	$\overline{\text{N}} \rightarrow \overline{\text{Adj}}\ \overline{\text{N}}$
8th rule:	$\overline{\text{Adj}} \rightarrow$ pretty
9th rule:	$\overline{\text{Adj}} \rightarrow$ little
10th rule:	$\overline{\text{Adv}} \rightarrow$ pretty
11th rule:	$\overline{\text{N}} \rightarrow$ girl
12th rule:	$\overline{\text{V}} \rightarrow$ is

(8)

Step (i):	$\overline{\text{S}}$, initial symbol
Step (ii):	$\overline{\text{Pr}}\ \overline{\text{VP}}$, using 1st rule
Step (iii):	$\overline{\text{Pr}}\ \overline{\text{V}}\ \overline{\text{NP}}$, using 4th rule
Step (iv):	$\overline{\text{Pr}}\ \overline{\text{V}}\ \overline{\text{Art}}\ \overline{\text{Adj}}\ \overline{\text{N}}$, using 2nd rule
Step (v):	$\overline{\text{Pr}}\ \overline{\text{V}}\ \overline{\text{Art}}\ \overline{\text{Adj}}\ \overline{\text{Adj}}$ N, using 7th rule
Step (vi):	she $\overline{\text{V}}\ \overline{\text{Art}}\ \overline{\text{Adj}}\ \overline{\text{Adj}}\ \overline{\text{N}}$, using 5th rule
Step (vii):	she is a pretty little girl, using rules: 12, 6, 8, 9, 11

In this simple grammar, each rule is of the form $g \rightarrow g'$ (read, "g' replaces g") and has the meaning that g' may be rewritten for g within strings of symbols. The symbol $\overline{\text{S}}$ that appears in the rules may be understood as standing for the grammatical category "sentence," $\overline{\text{Pr}}$ for "pronoun," $\overline{\text{VP}}$ for "verb phrase," $\overline{\text{NP}}$ for "noun phrase," and so forth. Symbols marked with a vinculum ($\bar{}$) constitute the set V_N of nonterminal symbols. The English expressions "she," etc., occurring in the rules constitute the set V_T of terminal symbols. $\overline{\text{S}}$ is the initial symbol.

Beginning with $\overline{\text{S}}$, sentences of English may be derived by applications of the rules. The derivation begins with $\overline{\text{S}}$; the first rule allows $\overline{\text{Pr}}\ \overline{\text{VP}}$ to be rewritten for $\overline{\text{S}}$, yielding $\overline{\text{Pr}}\ \overline{\text{VP}}$; the fourth rule allows $\overline{\text{V}}\ \overline{\text{NP}}$ to be rewritten for $\overline{\text{VP}}$, yielding $\overline{\text{Pr}}\ \overline{\text{V}}\ \overline{\text{NP}}$; and so forth (see 8). A last step yields a terminal string or sentence; it consists solely of elements of the terminal vocabulary V_T. None of the rules apply to it; so no further steps are possible.

The set of sentences thus generated by a grammar is called a language. Aside from trivial examples, grammars generate denumerably infinite languages.

Recursively enumerable grammars and Turing acceptors. An elementary result of automata theory is that every recursively enumerable set, or range of a partial recursive function, is an accepted set. In general, the acceptors are two-way unbounded tape automata. On the other hand, a grammar consisting of rules $g \rightarrow g'$, in which g and g' are arbitrary words of $(V_T \cup V_N)^*$ is an unrestricted rewriting system and any recursively enumerable set of words—*i.e.*, language in the present sense—is generated by some such system. These very general grammars thus correspond to two-way ac-

ceptors, called Turing acceptors, that accept precisely the recursively enumerable sets.

Finite-state grammars and finite-state acceptors. Acceptors that move tape left only, reading symbol by symbol and erasing the while, are the simplest possible, the finite-state acceptors. These automata have exactly the same capability as McCulloch-Pitts automata and accept sets called regular sets. The corresponding grammars in the classification being discussed are the finite-state grammars. In these systems the rules $g \rightarrow g'$ are restricted so that g is a nonterminal v of V_N (as exemplified above) and g' is of the form us, $u \in V_N$ and $s \in V_T$. The languages generated by finite-state grammars, owing to this correspondence, are called regular languages. 09

Comparison with McCulloch-Pitts automata

Although these simple grammars and acceptors are of some interest in information theory and in neural network modelling, they are not descriptively adequate for English or for such standard computer languages as Algol (see COMPUTERS) because they are not able to account for phrase structure. In particular, finite-state grammars cannot generate self-embedded sentences such as "the man the dog bit ran away," nor can they produce sentences with several readings such as "she is a pretty little girl."

Context-free grammars and pushdown acceptors. Context-free, or phrase-structure, grammars, although apparently not affording completely adequate descriptions of vernacular languages, do have the desirable properties just noted. For this family, the rules $g \rightarrow g'$ contain single nonterminals on the left, as in the finite-state grammars, but allow g' to be any word of $(V_T \cup V_N)^*$. The example discussed above is a context-free grammar.

These grammars can account for phrase structure and ambiguity (see 9). For further discussion, see LINGUISTICS; *Methods of synchronic linguistic analysis.*

Pushdown acceptors, which play a key role in computer-programming theory, are automata corresponding to context-free grammars. A pushdown acceptor is a finite-state acceptor equipped with an added two-way storage tape, the so-called pushdown store. At the beginning of operation this tape is blank. As the automaton computes, the store is used to analyze the syntactical structure of the sentence being read. The store moves left when printed, and only the last symbol printed may be read, then the next to the last, and so forth. The input is accepted if both the (one-way) input and storage tapes are blank when the automaton halts in a final state.

The representation of Turing machines in quadruple form may be replaced here by a somewhat clearer list of rules that simulate tape action in their application. Rules can be formulated for a pushdown acceptor P for a context-free language L of items xcx^{-1}, in which x is a word on an abstract alphabet $\{a, b\}$ and x^{-1} is x written in reverse. A first such rule can be formulated to mean that, if P is in state q_0 scanning a on input and any (defined) symbol on the pushdown store, it moves tape left, erases a from the input, prints a on the store, and goes into state q_1. A symbolic expression for the rule might be: $q_0a \rightarrow aq_1$. Another rule might be of the form: if P is in state q_1 scanning c on input and anything on store, it moves input left, erases c, and does nothing with respect to the store—briefly, $q_1c \rightarrow q_2$. Another requires that, if P is in q_2 scanning a on input and a on store, then it moves input left, erases a, moves store right, and erases a (see 10). An example is easily constructed to show that under certain rules a set, say, *abcba* is accepted (see 11). If q_0abcba indicates the outset of a computation with P in the initial state q_0 scanning the first a in *abcba* on input tape and blank on store tape, and if q_2 is a final state, then the computation is determined by the rules given above (see 10). At the end of the computation the automaton is in a final state q_2, both tapes are blank, and there is no rule with q_2 alone on the left; P halts and hence *abcba* is accepted.

Accepted sets in specific calculations

Reflection on the example and on others easily constructed shows that a pushdown acceptor is able, in effect, to parse sentences of context-free languages.

Context-sensitive grammars and linear-bounded acceptors. A fourth type of acceptor, which is mainly of mathematical rather than applied interest, is the two-way acceptor with bounded tape—*i.e.*, tape the length of which never exceeds a linear function of the input length. These are the linear-bounded acceptors. They correspond in the present classificatory scheme to context-sensitive grammars. Unlike the context-free grammars, these latter systems use rules $g \rightarrow g'$, in which the nonterminal symbol $v \in V_N$ in g may be rewritten only in a context xvy; thus $g \rightarrow g'$ is of the form $xvy \rightarrow xwy$, $x, y, w \in (V_T \cup V_N)^*$. An example of a context-sensitive language accepted by a linear-bounded automaton is the copy language xcx.

The family of recursively enumerable languages includes the context-sensitive languages, which in turn includes the context-free, which finally includes the regular, or finite-state, languages. No other hierarchy of corresponding acceptors has been intensively investigated.

Finite transducers. The most important transducers are the finite transducers, or sequential machines, which may be characterized as one-way Turing machines with output. They are the weakest transducers with respect to computing power, while the universal machine (see above *The generalized automaton and Turing's machine*) is the most powerful. There are transducers of intermediate power, but they are not considered here.

Algebraic definition. Because the tape is one-way with output, a finite transducer T may be regarded as a "black box" with input coming in from the right and output being emitted from the left. Hence, T may be taken to be a quintuple $\langle S, Q, O, M, N \rangle$, in which S, Q, and O are finite, nonempty sets of inputs, states, and outputs, respectively, and M is a function on the product $Q \times S$ into Q and N is a function on the same domain into O. The values are written in the usual functional notation $M(q, s)$, and $N(q, s)$, $s \in$ S and $q \in$ Q. M and N may be extended to the domain $Q \times S^*$ by four relations (see 12).

Equivalence and reduction. The most natural classification is by equivalence. If two machines (finite trans-

(9)

At step (v) of the derivation in (8),
the 3rd rule of (7) could have been applied to (iv), yielding
(va) $\overline{\text{Pr}}\ \overline{\text{V}}\ \overline{\text{Art}}\ \overline{\text{Adv}}\ \overline{\text{Adj}}\ \overline{\text{N}}$.
Successive steps would again result in (vii), but now to be read with a different meaning than before because of an immediate constituent structure differing from (v). To emphasize this divergence the replacing word g' flanked by parentheses, (g'), may be inserted into a previously obtained word in a derivation. Thus at (ii),
(ii)′ $(\overline{\text{Pr}}\ \overline{\text{VP}})$
would be written; and at (iii),
(iii)′ $(\overline{\text{Pr}}(\overline{\text{V}}\ \overline{\text{NP}}))$.
Proceeding in this way, (v) and (va) would appear as
(v)′ $(\overline{\text{Pr}}\ (\overline{\text{V}}\ (\overline{\text{Art}}\ \overline{\text{Adj}}\ (\overline{\text{Adj}}\ \overline{\text{N}}))))$
and
(va)′ $(\overline{\text{Pr}}\ (\overline{\text{V}}\ (\overline{\text{Art}}\ (\overline{\text{Adv}}\ \overline{\text{Adj}})\ \overline{\text{N}})))$.
Sentences in which phrase structure is indicated by parentheses are *phrase markers*. Making the further substitutions (vi) and (vii) within (v)′ and (va)′ produces two phrase markers, which represent two readings of (vii).

(10)

1st rule: $q_0a \rightarrow aq_1$
2nd rule: $q_0b \rightarrow bq_1$
3rd rule: $q_1a \rightarrow aq_1$
4th rule: $q_1b \rightarrow bq_1$
5th rule: $q_1c \rightarrow q_2$
6th rule: $aq_2a \rightarrow q_2$
7th rule: $bq_2b \rightarrow q_2$

(11)

\end{cases}
$$

ducers) share the same inputs, then representative states from each are equivalent if every sequence x belonging to the set of words on the alphabet causes the same output from the two machines. Two finite transducers are equivalent if for any state of one there is an equivalent state of the other, and conversely. Homomorphisms between transducers can also be defined (see 13). If two automata are onto homomorphic they are equivalent, but not conversely. For automata that are in a certain sense minimal, however, the converse holds.

Homomorphisms between transducers

Each equivalence class of transducers contains a smallest or reduced transducer—that is, one having the property that equivalence between its states implies equality. There is an algorithm for finding the reduced transducer of a class, which proceeds in a natural way from equivalence classes or blocks of states of a given transducer, each such block being defined as a state of the reduced transducer. Reduced equivalent finite transducers are unique up to an isomorphism—that is to say, if two finite transducers are reduced and equivalent, they differ only in the notations for their alphabets.

Classification by semi-groups. A mathematically significant classification of transducers may be obtained in terms of the theory of semi-groups. In outline, if the transducer T is reduced, the functions ϕ_s given in terms of M, for fixed input, as maps from and to the space of states Q constitute a semi-group termed the semi-group of T (see 14). By a certain procedure these semi-groups and their associated transducers T may be decomposed into more elementary systems called serial-connected and parallel-connected transducers. In explanation, the next state (starting from state $\langle q_a, q_b, \rangle$) in the serially connected machine $T_A \rightarrow T_B$ is the pair of states made up of the next state in T_A from q_a with input s and the next state in T_B from q_b with input $N_a(q_a, s)$—which latter is the output of T_a (see 15). Schematically, the connection may be depicted, indicating that in a serial connection the output of T_A is the input to T_B.

The parallel connection of two transducers is a system that may be rigorously defined (see 16) and that may be schematically depicted with input leading in parallel to both machines and output leading in parallel out of both

$$

Serial and parallel connections between transducers

machines. It has been shown that any finite transducer whatsoever can be decomposed into a system of series-parallel-connected automata, such that each element is either a two-state automaton or one whose semi-group is a simple group (see ALGEBRAIC STRUCTURES). This affords a classification of machines that depends ultimately on the determination of the simple groups of finite order.

An earlier decomposition scheme was based on a generalization of the concept of congruence relations over sets of states, but discussion of it is omitted here.

Post machines. Types of automata have been investigated that are structurally unlike Turing machines though the same in point of computational capability. The mathematician E.L. Post (U.S.) proposed in 1936 a kind of automaton (or algorithm) that is a finite sequence of pairs $\langle 1, a_1\rangle$, $\langle 2, a_2\rangle$, $\cdots$, $\langle m, a_m\rangle$, such that a_i is either an instruction to move an associated two-way tape one square right or left, an instruction to print a symbol, including a blank from a finite alphabet, or an integer. A Post machine begins at 1 and at step n obeys the instruction a_n and then goes to step $n + 1$, unless a_n is an integer m, in which case it goes to step m if the square scanned at n is marked or to step $n + 1$ if that square is blank. Post machines are prototypes of the program schemes developed 10 years later by von Neumann and his associates. For any partial recursive function a Post machine can be found that is capable of computing it.

Generalizations to automata or information processors in which the restriction to finiteness on sets is dropped or in which additional information from arbitrary sets is available to a machine during computation continue to be considered in the literature. (R.J.Ne.)

BIBLIOGRAPHY. MICHAEL L. MINSKY, *Computation: Finite and Infinite Machines* (1967); and RAYMOND J. NELSON, *Introduction to Automata* (1967), are the most comprehensive elementary introductions. MICHAEL A. ARBIB, *Theories of Abstract Automata* (1969), is an advanced introduction. MARTIN DAVIS, *Computability and Unsolvability* (1958); and HARTLEY ROGERS, JR., *Theory of Recursive Functions and Effective Computability* (1967), are concerned with the concepts of Turing computability and the theory of recursive functions. C.E. SHANNON and JOHN MCCARTHY (eds.), *Automata Studies* (1956), contains some of the original basic material concerning neural nets and automata with unreliable components or with random elements. BAYARD RANKIN (ed.), *Differential Space, Quantum Systems, and Prediction* (1966), discusses the automaton and its environment in the sense of prediction theory and gives reference to other literature in this area as well as the area of computable probability spaces. A good account of automata theory and its relations to switching theory is MICHAEL A. HARRISON, *Introduction to Switching Automata and Theory* (1965). The best introduction to machine decomposition theory is J. HARTMANIS and R.E. STEARNS, *Algebraic Structure Theory of Sequential Machines* (1966). NOAM CHOMSKY, "Formal Properties of Grammars," in R. DUNCAN LUCE, ROBERT R. BUSH, and EUGENE GALANTER (eds.), *Handbook of Mathematical Psychology*, vol. 2 (1963), is still the best survey of the field of automata and generative grammars. Articles presenting approaches to languages and automata from very general mathematical points of view are SEYMOUR GINSBURG and SHEILAH GREIBACH, "Abstract Families of Languages," *Mem. Am. Math. Soc.*, no. 87, pp. 1–32 (1969); and GENE F. ROSE, "Abstract Families of Processors," *J. Comput. & Syst. Sci.*, 4:193–204 (1970).

(B.R./R.J.Ne.)

Automation

The term *automation* was coined in the early 1940s to describe those processes in which mechanisms are used to perform tasks that previously required the attention and control of humans. Since then the term has been applied to a wide variety of automatic machinery and automatic systems, and is commonly used to describe any operation in which there has been a substantial substitution of controlled mechanical, chemical, or electrical action for human effort or intelligence. Thus it became common to call an operation "automated" if it was substantially more automatic than its predecessor.

With the development of computers and the concepts of machine logic and control, a more sophisticated concept has evolved. Automation may be said to be the performance of automatic operations directed by programmed commands combined with automatic measurement of action, feedback, and decision-making control.

HISTORY

The history of automation begins with prehistoric man, the toolmaker. The first simple stone tools represented a conscious extension of man's physical effort under the control of human intelligence. The next advance was the development of simple machines such as the wheel, the lever, and the pulley, by which the power of human muscle could be multiplied. These still required the conscious and complete control of the human mind. The next extension was the development of powered machines. More than 2,000 years ago the Chinese developed trip-hammers powered by flowing water and water-wheels. The early Greeks experimented with simple reaction motors powered by steam. Windmills, with automatic devices for turning the sails, were developed in the Near East and Europe in the Middle Ages. The culmination of these machines, which derive their energy from moving fluids and burning fuels, was the steam engine, elaborated over the past 200 years into engines and machines deriving their energy from chemical, mechanical, and finally nuclear sources.

As man learned to harness energy sources he found that increasingly complex control devices were necessary. The earliest steam engines required a man to open and close valves first to admit steam into the piston chamber and then to exhaust it. Later, a slide valve mechanism was devised, coupled to the piston shaft, which automatically performed these functions. It was then necessary only for the operator to regulate the amount of steam to control the engine's speed and power. Next, James Watt's flying-ball governor took over that function; a weighted ball on a hinged arm, coupled to the output shaft of the engine, was moved outward by centrifugal force as the rotational speed of the shaft increased; this motion controlled a valve that decreased the steam fed to the engine, thus slowing the engine down. Watt's device remains an elegant early example of "negative feedback," by which the increasing output of a mechanism is used to decrease —*i.e.*, negate—the activity of the mechanism, reducing its output.

Negative feedback has proven one of the most effective means of automatically controlling a mechanism to achieve a constant operating level. A simple negative-feedback control is the thermostat used in most home heating systems. In this instrument a rise in room temperature causes a metallic strip to flex, opening a switch that turns off the heating source. As the room cools down the metallic strip flexes in the opposite direction, closing the switch and turning on the heat.

In 1801 J.-M. Jacquard, a French inventor, devised an automatic loom capable of producing complex patterns in textiles by automatically controlling the motions of many shuttles of differently coloured threads. The machine was "programmed" to produce the desired patterns by steel cards in which holes were punched. These cards were the ancestors of the paper cards and tapes that control modern automatic machinery. In the latter part of the 19th century, Charles Babbage (1792–1871), English mathematician, proposed a complex, mechanical "analytical engine" that embodied a primitive decision-making ability.

Building blocks of automation

These four elements—(1) an energy source and its controls, (2) sensing and feedback mechanisms, (3) programming techniques, and (4) decision-making devices—are the building blocks of automation. Elaborated and combined, they have produced machines and systems that perform without human intervention. As early as 1784 Oliver Evans of Philadelphia built an "automatic" flour-making factory in which mechanical devices conveyed the raw material through all of the flour-making steps, including the filling of the flour bags at the end. Though human operators attended the machines to aid certain critical operations, the basic objectives of a continuous automatic process were achieved, making the mill an early example of thorough "mechanization." Its lack of automatic sen-

sing and feedback devices and of decision-making mechanisms, however, remove it substantially from today's automated systems. Indeed, even today, much of the automatic machinery in industry represents a high degree of mechanization rather than complete automation in the sense defined above. To an increasing degree, however, steps are being taken to achieve truly automated operation. The invention and development of the electronic computer has been an essential step.

GENERAL PRINCIPLES OF AUTOMATION

Five components of a system. The five principal components of an automated system are (1) program elements, (2) action elements, (3) sensing elements, (4) decision elements, (5) control elements.

Program elements. Program elements determine *what* the automated system shall do and *how* the parts of the system must function in order to accomplish the desired result. The program may consist of mechanical parts such as gears, cams, and linkages that connect the various portions of a machine together and determine the timing of the various actions of the machine. In the most modern computer-controlled systems the program may be stored in the form of punched paper cards, paper tape, magnetic tape, ferrite cores, electronic circuits, or other mechanical or electronic "memory" devices.

The program can be divided into two parts: the *command program* and the *process program*. The *command program* is a series of instructions that directs the other system elements through a sequential series of steps required to complete the desired operation. The *process program* contains the instructions that tell the system elements how each step of the operation is performed. It may also contain the information that is required for the decision elements described below.

Action elements. Action elements are generally of two kinds: (1) energy application and (2) transfer and positioning. In an automated manufacturing system the transfer and positioning elements control valves and conveyors or otherwise move and align the material being processed into proper position relative to the energy-application elements that shape, heat, chemically treat, or perform other process steps.

Sensing elements. Sensing elements represent one of the principal differences between a mechanized process and an automated process. Their function is to detect and measure a specific property of the processed item and present that measurement in a form upon which the automated system can act. A typical sensing element is the thermocouple, a device capable of measuring temperature and producing an electrical voltage proportional to the temperature. Other sensors may measure a physical dimension, an electrical resistance, the magnetic permeability, the optical properties, or the weight of the processed object. Measurements obtained from the sensors are used to determine if the process is going according to plan and provide necessary corrective changes. The advantages of sensing devices lie in their ability to be absolutely accurate. Fatigue is absent and the speed of operation far exceeds that of maximum human output. Observations can also be made in places which are inaccessible to or unsafe for human beings, such as in a nuclear reactor.

Decision elements. Decision elements use information from sensors that measure how the system is operating and compare these data with information from the process program that describes how the operation should proceed. Based upon this comparison, the decision elements generate instructions, usually in the form of electrical signals, to actuate the control elements. Decision elements are typically electrical circuits, often in an electronic computer, that carry out logical operations in making comparisons and producing command signals.

Control elements. Control elements are the mechanisms by which decisions are carried out. A control element may be a valve that opens and closes on a command signal to add chemical reactant to a process stream. It may be a rheostat that controls electrical power flowing to a heating element or an electric motor. The control elements regulate the action elements described above until the sensors indicate that each step of the process is proceeding according to process program instructions, and that each of the action elements is performing as required by the instructions in the process memory.

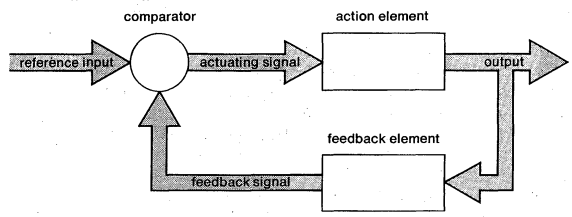
Feedback loops

These five elements provide what is called a closed-loop feedback system, the principal characteristic of modern automation. Analogous closed-loop feedback system controls may be seen in most human functions, for example, the action of reaching for a glass of water. The memory (program) contains a record of the sequence of muscular actions that must be performed and sends control signals along the nervous system that stimulate the arm muscles (action) to start the arm moving in the proper direction. As the hand approaches the glass, the eye (sensing) observes the distance and direction of the hand relative to the glass and feeds back to the brain the progress of the operation. This information is compared with the desired action from memory (program) and if there is a deviation from plan, decision elements in the brain send correction signals to the control elements that cause the muscular action pattern to change. These operations are repeated through many cycles until the glass is finally grasped.

Although there is much about the exact nature and function of the elements in the human that is not understood, the sequence of actions is well defined. The description is helpful in understanding certain diseases of the nervous systems such as palsy, in which simple muscular functions cannot be controlled, because feedback loops do not work properly.

Automation theory. A typical automated system involves a large number of action elements, sensors, and control elements combined in a series of feedback loops and, under the direction of a complex program, combined with sophisticated decision-making equipment. In addition, many of the action elements are interacting so that, for example, a change in one of the process steps may alter the course of other process steps. The principal difficulty in designing an automated system lies in obtaining a complete understanding of each of the action elements and their interactions, and incorporating this information in the program so that proper decision-making routines will be available as required.

In addition to the fundamental understanding of the process elements, a generalized theory has developed to describe behaviour of feedback loops and of systems that contain numbers of interacting elements with feedback. A simple element with feedback is shown below. An actuating signal on the input of the action element produces an output. A portion of the principal output serves as a



Simple element with feedback.

signal on the input to the feedback element. The output of the feedback element is fed to the comparator. A reference input from the process program is also fed to the comparator. If the feedback signal differs from the reference input, the difference produces a new actuating signal, and the new actuating signal acting on the action element will produce a new output. This process will continue until the feedback signal matches the reference input, which will occur only when the output has reached the desired value. Any future change in the reference input or in the output will, through the feedback loop, again cause a change in a direction to drive the output of the action element toward the desired value.

The dynamics of practical feedback systems can be complex. If the system is not properly designed, the feedback action may be too slow to control the action ele-

Results of improper design

ments properly. On the other hand, if the response is too rapid, the system may overcorrect and begin to oscillate. If several feedback elements are interconnected, the dynamics become very complex. A substantial body of theory has developed to aid the system designer in designing automated systems that are both stable and sufficiently responsive to provide adequate control without danger of failure.

Technical and economic advantages and disadvantages. Automation can produce both quantitative and qualitative improvements in human productivity. Automated systems permit a few skilled individuals to obtain results that previously required large numbers of semiskilled and unskilled personnel. In highly automated systems a few skilled people attend to general surveillance of the system, correct for unpredictable breakdowns, maintain process and control elements, and design improvements.

Automated systems also permit the performance of tasks that are effectively beyond human capabilities. The reaction speed of electronic controls and the ability of large data-processing machines to monitor and direct changes at hundreds of control points permit the optimization of complex processes to a degree finer than would be possible with human operators. The launch, tracking, control, and return of space vehicles would be impossible without highly automated systems.

Similarly, in the microminiaturized domain of modern electronic integrated circuitry, and in the inhospitable environment of nuclear reactors, automated systems can perform functions beyond the acuity of humans, in environments in which humans could not survive.

Inflexibility of automation

On the other hand, automated systems lack the flexibility and adaptability of human beings. An automated system is intolerant of error in its design. If incorrectly programmed if will function improperly until corrected by human intervention. Similarly, each element and each step must be completely defined at the beginning. All of the relationships between elements and their interactions must be completely understood and included in the design. Although there have been some experiments with machines that demonstrate a primitive "learning" ability, the practical application of such devices is probably still remote. Some functions that are very simply performed by humans, such as identifying sizes and shapes and aligning two dissimilar objects, are extremely difficult to perform by electrical or mechanical means. Thus, the design and construction of a complex automated system require substantial investment in scientific and engineering effort and in complex process, computation, and control equipment. Automated systems also tend to be relatively inflexible so that significant changes in their desired function may require massive redesigns of equipment. The use of general-purpose digital computers has moderated this problem somewhat in the areas of program and decision elements. Action, sensing, and control elements, however, must still be tailored to specific application.

For these reasons the design of an automated system is usually accomplished in stages. First, individual functions are thoroughly investigated and mechanized. Separate stages are automated and their interactions observed and controlled by flexible human intervention. In the final stages increasing portions of the system may be placed under automatic closed-loop control. Human "override" of the automatic functions is provided until the system's basic soundness has been proved and completely automatic control can be instituted.

During these stages there is a careful study of the points of meeting (interfaces) between man and machine. The most effective systems continue to rely upon human action with machine aid in those areas in which computers and machines are inadequate substitutes for human knowledge and flexibility. Thorough understanding of the man–machine interaction remains one of the keys to successful design and operation of automated systems.

Economic requirements are also a key determinant in the evolving applications of automation. The large commitments in research and development and the subsequent large capital investment required to implement an automated system can be a deterrent to application. These large investments, which must often be made years in advance of system use, increase the risks associated with automation.

As an industry becomes more automated, the capital outlays necessary to finance a given expansion increase rapidly. Thus, availability and cost of capital become prime determinants of industry growth rate. Because of

these heavy capital requirements, the growth of automation is determined both by technological advances that reduce the cost of automated facilities, and by the availability of large capital funds.

APPLICATION OF AUTOMATION

Automation finds application in almost every area of human endeavour. Although the term initially brings to mind the automatic factory, some of the earliest applications of automation were in communications, especially telephony; important modern examples are found in the utility industries, transportation, distribution, clerical and administrative activities, education, and even in the design of automated systems themselves.

Manufacturing industries. *Chemical processing.* The most highly automated manufacture is found in the chemical process industries. The processing of gases and liquids is especially amenable to automation because of the ease with which materials can be transported between process stations, the relatively simple design of sensors required for measurement and the existence of fundamental understanding of many chemical processes.

Divisions of a typical petrochemical system

In one advanced petrochemical system that manufactures more than 20 different products, the facility is divided into three areas each containing two to six different chemical units and each with a separate process control computer to provide scan, alarm, and control functions. The three process computers are connected to a central computer that calculates how to obtain maximum yield from each process, provides equipment regulation control, and generates management information reports.

Each process computer scans and monitors up to 2,000 process characteristics such as temperature, pressure, flow rate, liquid levels, densities and compositions. Time between measurements varies from 2 to 120 seconds. Each computer controls up to 400 processes. If process parameters exceed specified normal and safe ranges, a computer actuates a signal light and alarm horn and prints an alarm message for the process technician.

The central computer receives information from the process computers and performs calculations to determine the functioning of each chemical unit. The results of these calculations pass to the process computer in the form of commands to change the various processes in such a manner as to optimize unit operations.

In this kind of application, the integrated control system was not instituted as a manpower reduction matter, for a staff of more than 700 personnel is required. But, substantial economic advantages are realized from advanced and unique process control schemes that can be used and that were not possible with conventional control techniques. Increased productivity and process efficiency are obtained by better equipment regulation and optimization. Also, improved safety is achieved because the computers continuously monitor the entire operation and can initiate corrective actions and sound alarms.

Papermaking. In a large papermaking machine, automated for optimum control, a process control computer monitors more than two hundred critical points in the papermaking process. The collected operating data are analyzed; the control operator is advised of any unacceptable conditions. Journals of operating and management information are automatically prepared.

Iron and steel. The iron and steel industry has adopted the principles of automation in many of its production processes. Direct control has been applied to blast furnaces in which iron ore is reduced to pig iron. Automatic instruments measure the pressure and composition of the gases that leave the blast furnace and thereby follow the course of the reduction reaction. This information is analyzed by computer and the results used to control the blast air volume, temperature, humidity, the stoves that fire the furnace, and other variables that affect the efficiency of the process and the quality of the resulting iron.

Many of the chemical operations in the production of iron and steel are dependent on the detailed shape and construction of the blast furnaces, oxygen converters, and other large process units in which they are carried out. Because of this complexity, theoretical analysis of all the process variations and their interaction is often exceedingly difficult. In these cases the tremendous data storage and analysis capabilities of modern computers have been of special importance. Practical automatic control systems operate by collecting the history of previous operations in a specific process unit, and correlating it with the results. By approximations, an empirical model, or series of equations based on this history, is derived that indicates optimum operation of the specific unit.

In a current example the operation of a converter used to produce steel is controlled by using such an empirical model. Eight variables are continuously monitored, including temperature, quantity of molten steel, and concentration of several chemical elements such as carbon, phosphorus, and manganese. In addition, the computer controls the operating sequences including the charging of the converter, provides operating guides, monitors and reports any abnormal operating conditions, and prepares logs of all operating data.

Automated ingot rolling

One of the earliest steelmaking operations in which the principles of automation were applied was the rolling of steel ingots into their final shapes; *e.g.*, coils and strips. In this process the ingot of steel is passed through a rolling mill consisting of one or more sets of large cylindrical rollers that force the ingot into the desired shape. Usually several passes through the rolls are required. In a typical application, automatic instruments measure dimensions and temperature of the steel sheet after each pass through the rolls, and a control computer calculates and directs the optimum settings for the next pass.

Because a large modern rolling mill represents a large capital investment, it is necessary that the equipment be used as efficiently as possible. Automated controls have been developed to pace and schedule the rate at which steel ingots are fed to the rolling mill and the resulting product is withdrawn. Since, in a large operation, several different steel ingots for various customers with various specifications may be in process at any given time, the production control task of scheduling these various orders through the mill at maximum efficiency and keeping track of the different products requires rapid, massive information gathering and analysis while the process is in operation. In the most modern of mills, this production control task has been effectively integrated with the pacing and rolling control operations.

Machining. The shaping of metal by cutting tools was one of the first processes to be mechanized and then automated. The earliest numerically controlled machine tools were direct adaptations of conventional machines. Starting with conventional milling machines, motors were attached to the handles and shafts that moved the work piece. These motors replaced the skilled hands of the machinists and eventually were actuated by a digital controller. Control instructions were prepared in the form of magnetic or punched paper tape. The program information was read from the tape and converted to electrical signals that controlled the actuating motors. Thus the workpiece was programmed through a series of passes under the cutting tool until shaping was completed.

In the earliest machines there was no feedback; it was assumed that the control instructions would move the workpiece to the appropriate position. In later models, automatic correction devices in the form of servomechanisms were used to assure proper positioning. In both cases it was necessary to determine by experimentation in advance the optimum speeds of the cutting head, the feed rate, lubrication feeds, and all other variables to insure acceptable tool wear and finish of the cut surface.

In more recent variations, instrumentation has been developed to permit "adaptive" control of the metal cutting process. In this further step of automation, torque, deflection, and vibration of the cutting head are continuously measured and the cutting speed is varied to optimize the process. In this "adaptive mode" the machine can respond to changes in the properties of the metal and can compensate for tool wear, substantially improving the quality of the finished part and the productivity of the

machine. Cutting machines can now automatically reset the cutting tool.

Numerically controlled machine tools have been developed to produce extremely large pieces, such as wing sections of airliners and turbine rotors of large power generating stations. Once the control tapes for a given part are available, any desired number of identical parts are readily produced, and precision and reproducibility are usually far greater than can be achieved by a human operator. Modern tools can be controlled in five axes of motion: three linear directions and rotation about two perpendicular axes.

Preparing control tapes

Preparing control tapes is still a major problem, even though special computer languages have been developed to simplify the procedure. Even with these aids, however, special skills are required to prepare efficient program control tapes from the designer's sketches of the part to be produced. As automated design aids (see below) are developed, the procedure may be greatly simplified and the effectiveness of numerically controlled, material-shaping machinery greatly increased.

Assembly. In the assembly industries, such as automobile production, automation's initial impact was on isolated areas of production. Thus, there exists a pattern of integrated manufacturing steps carried out by automated equipment, followed by manual operations in which human dexterity and flexibility maintain a substantial advantage over automatic equipment.

Automated assembly lines are still in a relatively primitive stage of development. The design of mechanisms that can manipulate piece parts of various sizes and shapes and align them with adequate precision for assembly has been a challenging and difficult task. The most common solution has been to design specialized machines and standardized piece part shapes especially adapted for automatic handling and assembly. Another approach is to develop robot mechanisms that simulate the articulation and movement of the human arm and hand. The movements of these mechanical arms can be programmed by physically moving the arm through the desired path, and automatically recording the various positions in an electronic memory that can then direct the mechanism to repeat the motion. Such mechanisms are quite flexible and are finding increasing application (see also ROBOT DEVICES).

Robot mechanisms

When mechanized assembly machines in the automotive and electronics industry are associated with transfer mechanisms that carry subassemblies between assembly machines, these later generally require human supervision and operate on an open-loop basis; *i.e.*, without feedback. When feedback is supplied it is often of a primitive type, such as a simple mechanical feeler arm or photoelectric cell to determine whether or not a piece part is in position.

In a few, more sophisticated assembly machines, automatic gauging insures that the assembly or machining operation has been performed with proper precision. In most cases the control action resulting from feedback simply accepts or rejects the assembled part. Again, in some more sophisticated cases, feedback automatically adjusts the assembly or machining mechanisms to improve operations.

An automated assembly operation

An example of a relatively highly automated assembly operation is the manufacture of a clutch assembly for an automatic automobile transmission. The line consists of 20 stations. Subassemblies are mounted on pallets and moved between assembly stations by a chain conveyor. A small computer monitors approximately 650 points in the operation and provides signals to some 200 control elements that adjust the operations as required. The basic control cycle of monitoring performance and providing adjustment is repeated three times a second. When the computer is unable to adjust the station as required, action is stopped and an alarm message is automatically printed out at a control centre. The computer also monitors pneumatic and hydraulic power and the lubrication of the entire machine. Malfunctions are signalled by printing an alarm message, and the computer keeps a complete record of all operating difficulties and also counts the assemblies produced and the rejects.

Electronic equipment manufacture. In the production of electronic equipment, automated systems have been developed for the manufacture of components, the assembly of circuits, and the wiring and testing of complete systems.

In the manufacture of components such as transistors, integrated circuits, resistors, and capacitors, automated subsystems that perform certain process operations are often combined with manual operations, especially for positioning and transfer. Thus a modern component factory is a mixture of automated subsystems and human operators. In some instances fully automated systems have been designed. In one installation, for example, raw materials such as ceramic and metal piece parts and hydrocarbon gases are fed into the line, and fully tested and labelled precision carbon resistors are produced without human intervention.

Automated systems are widely used in the manufacture and test of printed circuits. Program-controlled machines are used for generating circuit patterns for both conventional circuits and integrated circuits. Automated systems are used to assemble components on printed wiring boards and to check that proper components have been used. Testing of completed complex circuits is also performed by automatic equipment often controlled by digital computers that not only test circuit performance but also diagnose and report the source of any malfunction.

Testing completed electronic equipment

In the manufacture of complex electronic systems, such as a telephone switching system or a general purpose computer, there are often tens of thousands of wired connections that must be made and tested to assure against mistakes. After final assembly it is necessary to test the completed equipment and systems by operating them under conditions similar to those that can be expected in the field. Thus, in a telephone switching system, final tests are designed to exercise the equipment under the conditions it will experience when thousands of telephone customers are attempting to call each other simultaneously.

Automated wiring machines have been built to operate under numerical control using a control tape to position a wiring head over the desired terminal, make the connection, lead the unconnected end of the wire through a prescribed path to the second desired terminal, make a final connection, and cut the wire. The machine then makes an electrical test to assure that the proper terminals have been connected before proceeding to the next programmed operation. If a connection is faulty, it is identified on a printout.

Automatic testing machinery has been developed to check equipment that has been manually wired. In these cases the equipment will test each connection against every other connection, assuring that only the proper terminals have been wired together. Again, errors are printed out for manual correction. A piece of equipment containing 1,000 terminals requires 500,000 measurements to assure correct wiring. Such an automatic testing machine can do the task in a few minutes.

Communications. One of the earliest practical applications of mechanization and automation was in telephone switching. The earliest switching machines, invented near the end of the 19th century, were simple mechanical switches that the telephone user controlled remotely by pushing buttons or turning a dial on his telephone.

Automatic switching equipment

The next generations of automatic switching equipment were the electromechanical common control systems that first appeared in the 1920s and 1930s. Constructed of relays and other electromechanical switches, they presaged today's electronic computers. They can monitor thousands of telephone lines, determine which are demanding service, provide dial tone, remember the digits of each number as it is dialed, translate the number to identify the central office and line of the called party, transmit appropriate billing and other data between offices, send ringing current to the called party, set up the required connections, monitor the call during its progress, and disconnect the phones when the call is completed. They thus

perform most of the functions of a human operator. They also can time and bill toll calls, make repeated attempts to find alternate routings of calls if the most direct path is busy or not functioning, run tests of their own operations, and automatically print out trouble reports.

Modern electronic telephone switching machines contain highly sophisticated electronic computing elements that provide major improvements in economy and function over their electromechanical predecessors. In addition to the functions mentioned above, the newest electronic systems automatically transfer calls to alternate numbers, call the user back when a busy line becomes free, and perform other customer services in response to simple dialled codes. These systems also automatically check their function, diagnose difficulties when they arise, and print out detailed instructions for repairmen.

Today's huge-volume telephone service would hardly be possible without automation. Even the operators who handle the services that machines cannot provide, such as directory assistance and person-to-person calls, rely on electronic machines for assistance.

"Store and forward" systems

Automation is employed in other areas of communications such as in automatic "store and forward" systems that accept, store, and deliver a message to one or more destinations. The ability to store and introduce a prescribed delay allows handling of multiple-address messages and improves circuit utilization. An example of such a system is the automatic dispatch of teletypewriter messages. Other communication systems automatically perform functions such as the monitoring, adjusting, and alarm reporting on telephone, radio, and television networks. Satellite communications would not be possible without the automated guidance systems that place and retain satellites in predetermined orbits.

Many national postal systems have mechanized functions such as the grading of letters and parcels by size, orientation of letters for automatic stamp cancellation and, most important, sorting of mail. Completely automated systems to aid in the collection and redistribution of postal communications have yet to be designed.

Power and utilities. The principles of automation have been applied to both the generation and distribution of electric power. These installations have become particularly complex and critical as power systems from several geographic areas have been interconnected to pool the generating capacity of many different utilities. Special attention has been given to automated control systems designed to insure continuous power service and to prevent wide-area "blackouts."

In the early 1970s there was a strong trend toward automated control of power stations, occasionally for direct, on-line control under regular operation and sometimes for control during starting up or shutting down generating capacity. Most such systems supervise and monitor operating functions; they compile data, compare it to normal operating limits, and provide alarm signals to supervisory personnel when normal limits are exceeded.

The start-up of a multimegawatt power generator is a period of major and rapid change both for the generator itself and for the power grid to which it is connected. It is important that the power output of the generator be phased smoothly into the network without overloading or otherwise stressing the generator or the network.

Similar conditions apply when a generator is shut down. In both cases a large number of variables must be monitored and controlled. An automated system can often control the transition, reacting to unexpected events much more effectively than a human operator. In a typical application involving a 300-megawatt coal-fired steam turbogenerator, the automated control system monitors 600 inputs such as temperatures and pressures and switch positions. Each input is scanned repeatedly during the start-up period and controls may be changed as frequently as every second. Critical control signals are displayed for an operator who can override the automatic system if malfunction occurs.

During the normal operation of a power generating station, when conditions are changing much more slowly, automation has been limited to monitoring and alarm functions. In these cases advantage is taken of the ability of a computer controlled system to scan a large number of measurement points, compare the results with predetermined limits, and call to the operator's attention only those parameters which require adjustment. In one example, a monitoring system for a 750-megawatt generating station scans over 1,000 analog and 1,500 digital inputs. Deviations from the desired operating ranges are brought to the operator's attention immediately through cathode-ray tube display devices similar to television screens. They are also printed out on electric typewriters for a permanent record. The operator can call for data on any operating part of the system through a command console. In addition, overall boiler efficiency is constantly monitored, computed, and recorded. Any unwarranted change in temperature is noted and an alarm message is then printed out.

A near-automated electric power distribution system

In the distribution of electric power, automation has been limited primarily to the collection and analysis of data and the presentation of signals to operators who in turn actuate the switching gear or other devices to control and balance network loads. On-line direct digital control of a large power distribution grid has not yet been entrusted to an automated system. However, great advantages are obtained in the monitoring and alarm functions. An excellent example is an automated distribution system designed to include eight hydroelectric generating plants with a total annual output of 6,200,000,000 kilowatt-hours, 21 pumping stations, several storage reservoirs, and a 450-mile aqueduct that connects the water supply for the entire project. Along the 450-mile length the system contains 170 separate electromechanical units such as generators and pumps, 213 separate water control gates, and 49 major water turnouts where the water flow can be diverted for other purposes. The entire system is divided into four control areas, each with its own control centre and independent monitoring computer. In addition, a single master control centre was planned, with a computer to receive data from the four separate control areas and aid the central control operators in integrating the entire system. Again decisions and actions are taken by human control operators on the basis of data and analyses supplied by the automated monitoring systems and electronic computers, but the system has been designed so that completely automated control can be instituted in the future.

These distribution network concepts have application to other utility functions such as gas and oil pipe lines. Here also computer-controlled monitoring and alarm systems have been most effective in aiding the control of many hundreds of miles of large integrated networks.

Transportation. *Lunar missions.* The applications of automation in transportation range from the control of automobile traffic to the guidance and control of lunar landing missions. The most sophisticated applications of automation have been made in aviation and astronautics. Missions such as the Apollo Project would not have been possible without automated control and guidance systems. The launching of a complex and large rocket and the subsequent guidance and staging of the various modules require a coordination of measurement and control signalling well beyond human response time. Beginning with the countdown, the checking of all systems is programmed and monitored by automatic controls, the results compared automatically with predetermined limits, and deviations reported back to the launch team. From the moment of ignition all critical factors are automatically checked and controls adjusted as required. In case of major malfunctions emergency routines are automatically called upon to abort the mission. During the powered phases of the launch the vehicle is continuously tracked by radar and optical means and any deviations from the predetermined trajectory produce automatic control signals that correct the vehicle's flight. During the flight itself there is continuous telemetry of all critical data that again are automatically compared with preselected values with resultant alarms as required. Simi-

larly, the details of lunar landings, return, and re-entry are automatically guided and controlled. Manual overrides are provided for critical malfunctions, but the general system plan represents one of the most sophisticated examples of closed-loop automation.

Aviation. Automation plays several roles in aviation. Major airlines use automated reservation systems to keep continuous track of the status of all flights, compare requests for space with the status of each flight, grant space when available, and automatically update the reservation status files. This permits ticket agents at widely dispersed locations to confirm the availability of space on any flight in a matter of seconds.

Control of air traffic and piloting of aircraft still depend on human control. Although the air traffic controller is greatly aided by radar and other instruments he himself determines traffic patterns and airplane spacings and gives verbal commands by radio to the pilots.

Automatic pilots and navigation systems

Most commercial aircraft are equipped with automatic pilots that under normal flying circumstances can guide the craft over a predetermined route by detecting changes in the aircraft's orientation and heading from gyroscopes or similar instruments, and provide control signals to the aircraft's steering mechanisms to keep it on the desired course. Automatic navigation systems and instrument landing systems use radio signals from ground beacons and provide signals to the pilot to aid him in following a proper course. In general, though, when the aircraft is within the traffic pattern for ground control, the pilot assumes total control.

Flight simulators, used for aircrew training, are now used widely. A cockpit with controls and instruments is provided and the pilot's movements are transmitted to a computer that displays the results on instruments. Necessary adjustments are made by the pilot. Different problems can be fed into the computer and then presented to the crew for a solution. The simulator is a money-saving device for the airlines, having reduced actual training time by 25 percent.

Although automatic landing systems have been developed and experimentally tested, they are not generally applied in commercial aviation. As the reliability of these systems improves, the time can be foreseen when much of the traffic and aircraft control is automated with human supervision and human intervention only in case of system malfunction.

Railroads. Automation is only now beginning to have a significant impact on ground transportation. A series of successful tests of new automatic controls applied to a moving train have been reported from the U.S.S.R. The equipment is in essence an electronic analog computer designed to give optimal control of an electric locomotive running on a given track and following a given timetable. It limits the action of the driver to simple on and off operations of the automatic equipment during stops at the stations; he takes full control of the engine only in an emergency. The control commands are continuously fed to a series of servomechanisms in response to data gathered by sensing elements placed in strategic positions on the engine and track. The system operates the train with greater precision and economy than even the most experienced driver; results show a 7 percent saving in power consumption and a 15 percent increase in traffic. Similar systems have met with success in other countries, especially Japan, where the high-speed New Tokaido Line is highly automated.

A major problem for the railroads is keeping track of freight shipments and empty rolling stock over such vast and international areas as western Europe and North America. In North America an information network and a system of automatic car identification by colour code was under development in the early 1970s. The system will maintain an inventory of the over 2,000,000 Mexican, United States, and Canadian rail cars and notify each of the 65 participating railroads of the interchange of their rolling stock.

The management of rail yards is being substantially aided by automated systems that integrate the signalling and communication functions in the classification yard. Beginning with records of the car complement of an incoming train, the computer-based system automatically controls switches in the yard to sort the cars onto tracks with other cars with a common destination. As each outgoing string of cars is assembled, a record of the cars and their weight is automatically prepared for use at the next destination.

Rail yard management

BART system. One of the most ambitious automated rail transportation systems was planned for the Bay Area Rapid Transit (BART) system in the San Francisco, California, area. The system consists of over 75 miles of track with 105 trains operating at peak hours between 33 stations. The trains can attain speeds of 80 miles per hour with spacings as short as 90 seconds. Each train carries one operator whose role is that of an observer and communicator able to override the automatic system in an emergency. The design includes one subsystem, to protect trains by assuring a safe distance between them and by controlling their speed, and a second to control routing and adjust the performance of each train to keep the entire system operating on schedule.

Limited service began in 1972. Under full operation, as a train enters the station it will automatically transmit to a receiver its identification, destination, and length, thus lighting up a display board for passenger information and transmitting signals to the control centres. Signals will be automatically returned to the train to control its time in the station and its running time to the next station. At the beginning of each day an ideal schedule will be determined, and as the day progresses the performance of each train will be compared with the schedule, and adjustments to individual train performance made as required. If unexpected situations arise, such as train breakdown, the system can automatically adjust itself to minimize the effect. The entire system is controlled by two identical computers so that if one malfunctions the other assumes control while the first is under repair. Should the automated control fail, manual controls can keep traffic flowing.

Traffic control. Although there is much experimentation with automated highways for automobiles, economically practical systems have not yet been designed. The principles of automation have, however, been applied to traffic signal control for several years. These range from signal controllers that respond to an automobile crossing a treadle to lines of traffic lights whose interrelated timing is controlled from a remote traffic-control centre. Essentially every large city has automatic systems for remotely monitoring and controlling traffic flows. In most cases, changes in signal patterns are under the direct control of human traffic directors at the control centres.

Systems are being developed, however, in which decision and control will be determined by computer. In one of these, 77 intersections with traffic signals are under automated control; there are 26 primary sensor points at which traffic flow is continuously and automatically measured, and a central computer analyzes the data and selects a control program from a repertoire of signal control patterns stored in the computer. Commands are sent automatically to the traffic light controllers at each of the intersections to produce whatever changes are required.

Experience with the system has brought a 16 percent reduction in the number of stops that a vehicle must make, a 30 percent reduction in the average delay experienced by each car, and an 8 percent decrease in accidents. The average peak hour speed on the approaches to and from the downtown area has increased from about 20 miles an hour to greater than 30 miles an hour. It is estimated that the system is saving motorists approximately 19,500 hours of travel time annually. Advanced traffic-control systems also exist in Munich and Toronto.

Ships. Automation has also found application in ships, principally in the form of monitoring systems that measure the performance of boilers, turbines, diesels, etc. and provide operating data and alarms to engine officers and pilots. These systems permit more accurate and efficient control of the vessels as well as reduction in crews.

Management, services, research, and education. *Management information.* The principal uses of electronic computers in industry today are in information systems, which range from the simple mechanization of clerical operations, such as the computation and printing of payroll checks, to highly integrated systems that collect, analyze, and report management information required to operate a major plant or industrial complex. In the latter cases the systems may provide long-range business forecasts, receive customer orders over data communication links, schedule the orders through the plant, automatically generate orders for raw materials, keep complete track of orders as they progress through various stages of manufacture, maintain inventories, prepare priority lists for rush orders, prepare bills and invoices, and issue detailed shipping instructions. Some advanced systems include on-line data collection stations dispersed throughout the manufacturing plant so that the completion of manufacturing operations, both by people and by production machines, may be recorded as they happen. The memory banks of the computers contain information that describes the complete status of the manufacturing plant. It can compare the actual status with detailed schedules and plans and inform management when there are deviations from plan. There are very few modern manufacturing plants that do not use some kind of computer-based mechanized or automated information system for inventory and production control, although only a few have highly developed management-information systems.

Types of automated management operations

Automated warehouses. Automated warehouses are becoming increasingly common. As merchandise arrives at the warehouse, a vacant location is assigned by a computer that generates a punched card or similar record associated with the merchandise. The punched card can be used with mechanized handling equipment that automatically transports the material to the assigned location. When the item is needed the computer determines its location and presents a card that is used by the automatic materials-handling equipment to retrieve the item. The computer also updates its files to maintain an accurate inventory list and prints out notices or orders if inventories fall below prescribed limits. The computer maintains records of stock activity and changes stock levels to provide desired service levels.

Driverless trucks are a popular addition to the new automated warehouses. Trucks are battery-electric-powered and controlled to follow a continuous wire embedded in the floor. The trucks are then able to make scheduled stops around the warehouse and the routes can be easily changed. Safety devices, designed to stop the trucks automatically if they contact another object, have been devised.

Banks and financial institutions. Automated systems are used in many other areas of service that require the manipulation and analysis of data. The sorting of checks and verification of bank balances have been mechanized in most financial institutions. The stock exchanges use automatic systems to report stock transactions by ticker tape or closed circuit television. Stock certificates may be issued in the form of punched paper cards to facilitate record keeping in sales and exchanges. Restaurants, retailers, and credit-card organizations are using systems that automatically check the validity of a credit card and the credit standing of its holder in a matter of seconds while the customer waits.

Retail trade. Automation in retail trade is mainly concerned with inventory control or stock balances in stores. Valuable information can be obtained, such as analyses of sales and stock positions. The system can work at night, so that all information can be obtained the next morning. Information can also be got using special tapes that are printed or punched.

Medicine. Hospitals throughout the world are increasing their use of automation; these systems replace labour and sometimes are capable of surpassing human effort. For example, in hospitals in Sweden, several measurements such as heartbeat, pulse rate, blood sugar level, etc. are taken simultaneously every hour from seriously ill patients in intensive care wards. At any time, the doctor can request a complete printed record of his patient's hourly progress. The system also provides continuous monitoring, sounding an alarm should any critical measurement pass beyond the limits of safety. Even a large team of medical personnel using conventional methods could not provide such precise monitoring.

Automated hospital laboratories can perform ten different tests on a blood sample in the time it takes to do one manually. In one pilot operation, doctors who requested a specific test received the results of ten at no additional charge. These data caused changes in half the original diagnoses and led to widespread adoption of the system in Europe and America.

Automated laboratories

Libraries. Library information-retrieval systems are available that automatically search titles and abstracts contained in computer memory and present a bibliography of sources that appears to match a requested subject or combination of subject areas. The lack of low-cost, large capacity data-storage files with random access at electronic speeds has been a primary limitation. Substantial improvements in the cost–performance characteristics of data storage and retrieval devices and systems would increase the attractiveness of automation in this area.

Research. In the research laboratory, automated instruments are used to analyze chemical composition and determine crystal structure. Other systems automatically collect data from instruments, analyze the data, instruct the instrument to take the next series of readings, and present calculated results to the researcher.

Teaching machines. Automated teaching aids are expected to improve the teachers' ability to give large numbers of students more individualized attention. In one experimental system a student is presented a series of questions and he indicates the answers through a typewriter keyboard. Each succeeding question is automatically chosen depending upon his answers to the preceding questions. In this way areas in which his knowledge is weak can be explored and appropriate instructional material presented. Thus, each student, with the help of the machine, can study at his own pace, calling on a teacher if he reaches difficulties that the machine cannot help him resolve.

Automated design. Automated systems based on the data-handling ability of electronic computers are being used as aids to the designers of products, machinery, and even other automated systems. In their simplest and currently most widely used forms, these serve as mechanized aids to drafting. Thus a designer may use a "light pen" and sketch the details of a part on the face of a cathode-ray tube display. The automatic drafting system can convert the designer's rough lines and circles into precise lines and curves of specified mathematical shape. As the designer completes his sketch, information describing the details of his drawing is recorded in digital form in the drafting system's electronic memory. This information can later be used to drive an automatic drafting machine that will make a paper-and-ink copy of the design. The information can also be processed to produce a tape to drive a numerically controlled instrument to machine a part or produce a printed circuit pattern. In some sophisticated systems still under active development, especially in the automotive industry, the designer can sketch several plan views of his conception. The automated design system combines these views into a three-dimensional image that can be displayed in any desired aspect or rotated in perspective on the cathode-ray display. Similarly, the information can be used to drive a numerically controlled machine that will produce a three-dimensional model to any desired scale.

In more sophisticated automated design systems a more substantial part of the designer's task can be performed for him; rules (*e.g.*, the means for partitioning a circuit into modules, the permitted placement of electronic components, and the wire routing paths in a complex circuit) can be fed into the system. Then the designer need only state the basic electronic function that he desires and the

system will automatically determine the required modules and select the required components and their interconnection paths. The system may also generate graphic plots of the response of the described circuit to various inputs, thus enabling the designer to determine if the circuit design is satisfactory. The system may then provide manufacturing information such as parts lists, printed circuitry patterns, and component insertion programs as well as information to control automatic test sets to measure the finished product.

Though such automated design systems are still in their earliest state of development, they suggest the potential of a technology in which machines aid in the design as well as manufacture of other machines. The image of a self-generating and perpetuating machine technology has been a source of stimulation for science-fiction writers as well as pioneering students of cybernetics. Although still remote in time, the basic elements and concepts for their development are rapidly becoming available.

AUTOMATION AND SOCIETY

Stages of industrial development. Automation is the third stage in the development of industrial society.

In the first stage, the age of craftsmanship, each individual craftsman was responsible for a total production process from raw material to finished product. Each manufactured item differed from similar products, because each reflected the skill of its maker. The volume and cost of production tended to be directly proportional to the number of craftsmen.

The second stage, the period of mechanization, produced a complete reorganization of the methods of production. The period is characterized by the analytical study of the production process and the development of scientific management in the early years of the 20th century. Analysis led to the subdivision of the production process into a number of well-defined steps and the design of specialized machines to aid in the performance of each step. Workers were carefully but narrowly trained to operate their own tools and machines with great efficiency. This led to the economies of scale associated with mass production, by which the volume of production increased far more rapidly than the number of employees, and the unit costs of production decreased.

The third stage, automation, carries many of the characteristics of mechanization a large step further and introduces qualitatively new characteristics as well. A much broader and deeper base of engineering planning and design is required. The nature and character of the product are completely determined during the course of this planning. Capital investment is substantially larger. The volume of product is only loosely related to the number of productive employees. The cost of production is strongly dependent upon the cost of raw materials, capital investment, and equipment maintenance, rather than on the cost of labour. Productive employees no longer enter directly into the production process. Instead, the individual monitors and maintains machines, and takes control only in case of severe malfunction.

Effects on the individual. Each of these stages of industrial development has had profound effects on the role of the individual, his skill level, and his productivity. During the craft period each craftsman's skill was relatively unique. The value of his product was closely related to his skill level and the volume of individual productivity was relatively constant with time. The capital investment required for production was relatively small and business was organized on an individual or family level.

With the beginning of the Industrial Revolution and mechanization, production per employee began to rise rapidly. At any given time production was generally proportional to employment, but the ratio changed rapidly as a function of time, with labour content decreasing as productivity increased. Mechanization also created a demand for a broader range of skills including the highly skilled machine-design engineer, the machine builders and toolmakers, skilled maintenance technicians, and a wide range of skilled machine operators. The capital investment required for efficient production increased rapidly. This factor and the production economies that mechanization made possible led to the growth of business enterprises. In turn, complex organizational structures were developed to coordinate the highly subdivided and specialized parts of the production process. The management skills required to run large organizations became increasingly important.

As automation becomes more important the relationships between production and employment become very complex. The man-hours of labour per unit of production diminish while the level of skills and the responsibilities of employees increase. There is a large increase in the level of engineering required and in capital investment. This increases the growth tendencies of businesses and accentuates the requirements for close coordination and planning.

Effects on society. Mechanization and the Industrial Revolution produced profound changes in society. The growth of large industries stimulated migration from country to city. The ability to use narrowly trained and relatively low skill levels and the concentration of employees in large centres led first to cases of labour abuses and then to labour laws and unionization.

Massive increases in productivity stimulated population growth and also created opportunities for expansion of education, of the arts and sciences, and of leisure time. Increased productivity must be coupled with increased consumption and this, in turn, accentuated man's effect on the environment, depleting some resources and abusing others.

Automation and unemployment. During the early periods of the Industrial Revolution there was great concern about massive unemployment as machines took over the jobs formerly performed by human muscle. The feared unemployment, as a continuing factor, however, never materialized. Population growth, human tastes, and human consumption have kept up with increased productivity, and except for brief dislocations, the increased productivity that has resulted from mechanization has created many more jobs than it has destroyed.

In the 1960s automation prompted similar questions. Most studies were controversial and generally inconclusive, but as with the earlier mechanization, widescale unemployment did not materialize. Productivity continued to increase but consumer desires equalled or surpassed the increases. Some effects of automation on employment have, however, become more evident. There have been significant dislocations. In mining regions automation has produced a net decrease in local employment. More widely, increases in consumer demand have outpaced increases in productivity resulting from automation, leading to an increase in employment and a change in its nature. Routine repetitive tasks have been replaced by more broadly skilled jobs of designing, installing, maintaining, and monitoring the automated systems. The need for a higher ratio of the newer skills has obvious implications for education of the young and re-education of the displaced.

Finally, the increased interest in the quality of living in the early 1970s has significance in respect to automation. Automation will be needed to monitor and control new productive systems that will relieve the burden on the physical environment as well as in systems designed to cleanse and restore the environment.

BIBLIOGRAPHY. Much has been written in the popular and lay press about the principles of automation and its specific applications. General discussions in this vein include: G.H. and P. AMBER, *Anatomy of Automation* (1962); A.D. BOOTH, *Automation and Computing*, 2nd ed. (1966); D.B. FOSTER, *Automation in Practice* (1968); and J. ROSE, *Automation: Its Uses and Consequences* (1964), *Automation: Its Anatomy and Physiology* (1967).

Detailed articles on automated systems are found throughout the technical literature. Review articles are appearing in increasing numbers. References relating to two specific industries are: T. ISOBE, "Automatic Control in the Iron and Steel Industry," *Automatica*, 6:111–121 (1970); and G. QUAZZA,

"Automatic Control in Electric Power Systems," *ibid.*, pp. 123–150.

Broad discussions of the impact of automation on industrial management, workers, and the social structure are found in: J.R. BRIGHT, *Automation and Management* (1958); W.S. BUCKINGHAM, *Automation: Its Impact on Business and People* (1961); J. DIEBOLD, *Automation: Its Impact on Business and Labor* (1959), *Man and the Computer* (1969); W.A. FAUNCE, *Problems of an Industrial Society* (1968); G.W. TERBORGH, *The Automation Hysteria* (1966); and the NATIONAL COMMISSION ON TECHNOLOGY, *Automation and Economic Progress* (1966).

Automobile

An automobile is a self-propelled passenger vehicle designed to be operated on ordinary roads. In general, motor vehicles may be classified into several types, according to the service they render. Most numerous are the private passenger cars described in this article, intended usually to transport up to nine individuals; a subdivision of this type is formed by the so-called sports cars, which are designed primarily for speed and good road-handling characteristics, with passenger comfort a secondary consideration. Commercial passenger vehicles for carrying larger numbers of persons—buses and motor coaches—and commercial freight vehicles for carrying goods and materials are described in the article TRUCKS AND BUSES. The development of the relevant manufacturing technology is covered in AUTOMOTIVE INDUSTRY.

This article is divided into the following sections:

I. History

EARLY DEVELOPMENTS

Unlike many other major inventions, the original idea of the automobile cannot be attributed to an individual, and many individuals worked simultaneously on self-powered road vehicles. Certainly, the idea occurred long before it was first recorded in the *Iliad*, in which Homer (in Alexander Pope's translation) states that Vulcan in a single day made 20 tricycles, which

> Wondrous to tell instinct with spirit roll'ed
> From place to place, around the blest abodes,
> Self-moved, obedient to the beck of gods.

Early experiments. Leonardo da Vinci considered the idea of a self-propelled vehicle. In 1760 a Swiss clergyman, J.H. Genevois, suggested mounting small windmills on a cartlike vehicle, their power to be used to wind springs that would move the road wheel. Genevois's idea probably derived from a windmill cart of about 1714. Two-masted wind carriages were running in the Netherlands in 1600, and a speed of 20 miles (30 kilometres) per hour with a load of 28 passengers was claimed for at least one of them. The first recorded suggestion of wind use was probably Robert Valturio's unrealized plan (1472) for a cart powered by windmills geared to the wheels.

Other inventors considered the possibilities of clockwork. Probably in 1748, a carriage propelled by a large clockwork engine was demonstrated in Paris by the versatile inventor Jacques de Vaucanson.

The air engine is thought to have originated with a 17th-century German physicist, Otto Von Guericke. Guericke invented an air pump and was probably the first to make metal pistons, cylinders, and connecting rods: the basic components of the reciprocating engine. In the 17th century, a Dutch inventor, Christiaan Huygens, produced an engine that worked by air pressure developed by explosion of a powder charge. Denis Papin of France built a model engine on the vacuum principle, using the condensation of steam to produce the vacuum. An air engine was patented in England in 1799, and a grid of compressor stations was proposed to service vehicles. An air-powered vehicle is said to have been produced in 1832.

As early as the 16th century, steam propulsion was proposed, and in 1678, Ferdinand Verbiest, a Belgian Jesuit missionary to China, made a model steam carriage based on a principle suggestive of the modern turbine. Another early proponent of steam power encountered such skepticism, however, that he was certified insane.

In the 18th century a French scientist, Philippe Lebon, patented a coal-gas engine and made the first suggestion of electrical ignition. In Paris, one Isaac de Rivas made a gas-powered vehicle which he patented in 1807; his engine used hydrogen gas as fuel, the valves and ignition were operated by hand, and the timing problem appears to have been difficult.

The first automobile. The Royal Automobile Club of Great Britain and the Automobile Club de France now agree that Nicolas-Joseph Cugnot of Lorraine was the constructor of the first true automobile. Cugnot's vehicle

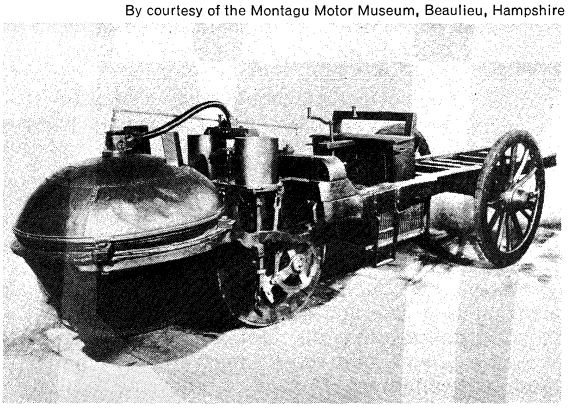

Figure 1: The 1769 Cugnot steamer, a three-wheeled artillery tractor with front-wheel drive, carried four passengers at a speed of 2¼ miles per hour.

was a huge, heavy, steam-powered tricycle, and his model of 1769 was said to have run for 20 minutes at 2.25 miles (3.6 kilometres) per hour while carrying four people and to have recuperated sufficient steam power to move again after standing for 20 minutes. Cugnot was an artillery officer, and the more or less steam-tight pistons of his engine were made possible by the invention of a drill that accurately machined cannon bores. A replica of the Cugnot vehicle, partially original, is preserved in the Conservatoire des Arts et Métiers in Paris.

Cugnot's steam tricycle

Most authorities are inclined to honour Carl Benz and Gottlieb Daimler of Germany as the most important pioneer contributors to the gasoline-engine automobile. Benz ran his first car in 1885, Daimler his in 1886. Although there is no reason to believe that Benz had ever seen a motor vehicle before he made his own, he and Daimler had been preceded by a Frenchman, J.-J.-E. Lenoir, and an Austrian, Siegfried Marcus, in 1862 and 1864–65, respectively, but neither Lenoir nor Marcus had persisted. Benz and Daimler did persist—indeed, to such purpose that the firm of Daimler–Benz could, in the

1960s, trace its origins back to 1895 and claim, with the Panhard firm of France, to be one of the oldest automobile-manufacturing firms in the world. Oddly, Benz and Daimler never met.

The four-stroke principle upon which most modern automobile engines work was discovered by a French engineer, Alphonse Beau de Rochas, in 1862, the year in which Lenoir ran his car from Paris to Joinville-le-Pont. The four-stroke cycle is often called the Otto cycle, after the German Nikolaus August Otto, who designed an engine on that principle in 1876. De Rochas held prior patents, however, and litigation in the French courts upheld him. Lenoir's engine omitted the compression stroke of the Otto cycle; fuel was drawn into the cylinder on the intake stroke and fired by a spark halfway on the next reciprocal stroke.

The idea for Siegfried Marcus' 1864–65 car apparently came to him by chance while he was considering the production of illumination by igniting a mixture of gasoline and air with a stream of sparks. The reaction was so violent that it occurred to him to use it as a power source. His first vehicle was a cart carrying a two-cycle engine geared to the rear wheels without any intervening clutch. It was started by having a strong man lift the rear end while the wheels were spun. It did run, however, a distance of about 200 yards. In 1898 the Austrian Automobile Club arranged an exhibition of motor cars, and Marcus was a guest of honour. He denied interest in the entire idea of the automobile, however, calling it "a senseless waste of time and effort." Marcus' second model, the 1874–75 car, was sturdy and sufficiently well-preserved to make a demonstration run in the streets of Vienna on April 16, 1950, at a rate of three miles per hour.

Other inventors have been put forward as originators of the internal-combustion automobile. In 1823 or 1826 an English mechanical engineer named Samuel Brown drove a self-powered road vehicle up Shooter's Hill in London. Brown's patent specifications and an eyewitness account of his drive both exist. His engine had separate combustion and working cylinders and apparently used carbureted hydrogen as fuel. Léon-Paul-Charles Malandin of France produced a four-wheel vehicle with a four-stroke, two-cylinder gasoline engine in 1883, and he, too, is sometimes cited as the first to run an automobile with a true internal-combustion engine. His claim, like the others, falters before the continuity of the Benz–Daimler efforts.

The age of steam. Before any internal-combustion engine had run, followers of Nicholas Cugnot were on the road, notably in England, although the first post-Cugnot steam carriage appears to have been that built in Amiens, France, in 1790. Steam buses were running in Paris about 1800. Oliver Evans of Philadelphia ran an amphibious steam dredge through the streets of that city in 1805. Less well known were Nathan Read of Salem, Massachusetts, and Apollo Kinsley of Hartford, Connecticut, both of whom ran steam vehicles during the period 1790–1800.

English inventors appear to have been active, and by the 1830s the manufacture and use of steam road carriages approached the status of a minor industry in the British Isles. James Watt's foreman, William Murdock, ran a model steam carriage on the roads of Cornwall in 1784, and Robert Fourness showed a working three-cylinder tractor in 1788. Watt was opposed to the use of steam engines for such purposes; his feelings were so strong that he inserted into the lease of a house he owned a clause stating that "no steam carriage should on any pretense be allowed to approach the house." Watt's low-pressure steam engine would have been too bulky for road use in any case, and all of the British efforts in steam derived from the earlier researches of Thomas Savery and Thomas Newcomen.

Richard Trevithick developed Murdock's ideas, and at least one of his carriages, with driving wheels ten feet (three metres) in diameter, ran in London. Sir Goldsworthy Gurney, the first commercially successful steam-carriage builder, based his design upon an unusually efficient boiler. He could not, however, be convinced that smooth wheels could grip a roadway, and so he arranged propulsion on his first vehicle by iron legs digging into the road surface. His second vehicle was said to weigh only 3,000 pounds (1,400 kilograms) and to be capable of carrying six persons. He made trips as long as 84 miles (135 kilometres) in a running time of nine hours 30 minutes and once recorded a speed of 17 miles (27 kilometres) per hour. A rate of 32 miles (51 kilometres) per hour was later claimed by two other builders. To allay the public's fear of boiler explosions, Gurney designed a "drag," which was in effect a tractor, or locomotive, pulling one or more unpowered coaches.

Steam coaches on British roads

Gurney equipment was used on a regularly scheduled Gloucester–Cheltenham service of four round trips daily that at times did the nine miles (14 kilometres) in 45 minutes. Between February 27 and June 22, 1831, steam coaches ran 4,000 miles (6,400 kilometres) on this route, carrying some 3,000 passengers. The equipment was noisy, smoky, destructive of roadways, and admittedly dangerous; hostility arose, and it was common for drivers to find the way blocked with heaps of stones or felled trees. A minor accident occurred and finally aroused so much public feeling that the passenger service was ended. Nevertheless, many passengers had been carried by steam carriage before the railways had accepted their first paying passenger.

The most successful era of the steam coaches lasted from 1831 to 1838. Ambitious routes were run, including one from London to Cambridge. But by 1840 it was clear that the steam carriages had little future. They had had much to contend with, including the anti-machinery attitude of the public and the enmity of the horse-coach interests, which resulted in such penalties as a charge of £5 for passing a tollgate that cost a horse coach only 3*d*. The government was of small help: a select committee of Parliament recommended a research grant of £16,000 for Goldsworthy Gurney, but the treasury refused to pay it. The crushing blow was the Locomotives on Highways Act of 1865, which reduced permissible speeds on public roads to two miles (three kilometres) per hour within cities and four miles (six kilometres) per hour in rural areas. This legislation was known as the Red Flag Act because of its requirement that every steam carriage mount a crew of three, one to precede it carrying a red flag of warning. The act was amended in 1878, but it was not repealed until 1896, by which time its provisions had effectively stifled the development of road transport in the British Isles.

Inventors in other countries also experimented with steam carriages, and a few ran on roads in Europe and the United States.

The decline of the steam carriage did not prevent continued effort in the field, and much attention was given to the steam tractor for use as a prime mover. Beginning in about 1868, Britain was the scene of a vogue for light steam-powered personal carriages; if the popularity of these vehicles had not been legally hindered, it would certainly have resulted in the appearance of widespread enthusiasm for motoring in the 1860s rather than in the 1890s. Some of the steamers were designed to carry as few as two people and were capable of speeds on the order of 20 miles (30 kilometres) per hour. The public climate remained unfriendly, however.

Light steam cars were being built in the United States, France, Germany, and Denmark during the same period, and it is possible to argue that the line from Cugnot's lumbering vehicle runs unbroken to the 20th-century steam automobiles made as late as 1926. The grip of the steam automobile on the American imagination has been strong ever since the era of the Stanley brothers (one of whose "steamers" took the world speed record at 127.66 miles [205.4 kilometres] per hour in 1906), and in the 1960s it was estimated that there were still 7,000 steam cars in the United States, about 1,000 of them in running order. Though the pollution crisis of the 1960s inspired a resurgence in steam-car research, the major Detroit companies were unwilling to finance a crash program, and of the individuals who attempted construction only

The Stanley steamer

the industrialist William Lear maintained a long-term program. In 1972 Lear demonstrated a steam-powered bus.

Benz and the gasoline car. Carl Benz was completely dedicated to the proposition that the internal-combustion engine would supersede the horse and revolutionize the world's transportation. He persisted in his efforts to build a gasoline-fuelled vehicle in the face of many obstacles, including lack of money to the point of poverty and the bitter objections of his associates, who considered him unbalanced on the subject.

Benz's day of triumph

Benz ran his first car, a three-wheeler powered by a two-cycle, one-cylinder engine, early in 1885, on a happy and triumphant day. He circled a cinder track beside his

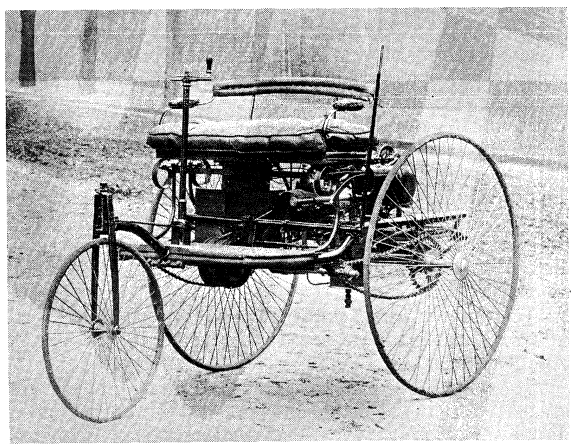

Figure 3: The first Benz, 1885, a three-wheeled vehicle with a steel frame in the shape of a horseshoe. This car was first driven in public in Mannheim on July 3, 1886, where a speed of 15 kilometres per hour was reached.

small factory, his workmen running beside the car, his wife running, too, clapping her hands; the little machine made four circuits of the track, stalling only twice, before a broken chain stopped it. Even Max Rose, Benz's skeptical partner, whose money had made the car possible, conceded that he was mildly impressed; but, like Siegfried Marcus, he remained convinced to the end of his association with Benz that there was no future in the horseless carriage.

In the autumn of 1885, when Benz attempted a public showing of a slightly improved model, he forgot to steer and smashed it against the brick wall surrounding the yard of his own house.

Benz made his first sale to a Parisian named Émile Rogers in 1887. Gradually, however, the soundness of his design and the quality and care that went into the material and the construction of his cars bore weight, and they sold well. By 1888 he was employing 50 workmen to build the tricycle car; in 1890 he began to make a four-wheeler.

In his way, Benz was almost as dogmatic and reactionary as Marcus had been; he objected to redesign of his original cars, and some authorities believe that he was never really convinced that his original concepts had been improved upon.

Development of the Daimler. Gunsmithing was Gottlieb Daimler's first vocation, and he showed marked talent, but he abandoned the trade to go to engineering school, studying in Germany, England, Belgium, and France. In Germany he worked for various engineering and machining concerns, including the Karlsruhe Maschinenbaugesellschaft, a firm that much earlier had employed Benz.

In 1872 Nikolaus A. Otto offered Daimler the position of technical director of his firm, then building stationary gasoline engines. Daimler was of notable utility to Otto during the next decade, when important work was done on the four-stroke engine. Daimler brought in several brilliant researchers, among them Wilhelm Maybach, but in 1882 both Daimler and Maybach resigned because of Daimler's conviction that Otto did not understand the potential of the internal-combustion engine. They set up a shop in Bad Cannstatt and built an air-cooled, one-cylinder engine. The first high-speed internal-combustion engine, it was designed to run at 900 revolutions per minute (rpm), while Benz's first tricycle engine had operated at only 250 rpm. Daimler and Maybach built a second engine and mounted it on a wooden bicycle, which first ran on November 10, 1885. The next year the first Daimler four-wheeled road vehicle was made: a carriage modified to be driven by a one-cylinder engine. Daimler appears to have believed that the first phase of the automobile era would be a mass conversion of carriages to engine drive; Benz apparently thought of the motorcar as a separate device. Daimler's licensees in France were René Panhard and Émile Levassor. In 1889 they entered the field independently, and the Panhard–Levassor designs of 1891–94 are of primary importance. They were true automobiles, not carriages modified for self-propulsion.

Daimler's 1889 car was a departure from previous practice. It was based on a framework of light tubing, it had the engine in the rear, its wheels were driven by belt, and it was steered by tiller. Remarkably, it had four speeds. This car had obvious commercial value, and in the following year the Daimler Motoren-Gesellschaft was founded. The British Daimler automobile was started as a manufactory licensed by the German company but later became quite independent of it. (To distinguish machines made by the two firms in the early years, the German cars are usually referred to as Cannstatt–Daimlers.) Products of the Daimler–Benz company (the two firms were merged in 1926) are sold under the name Mercedes-Benz.

In France the giants were De Dion-Bouton, Peugeot, Renault (the last two are still in existence). The Italians were later in the field: the Steffanini-Martina of 1896 is

thought of as the foundation of the industry in Italy, and Isotta-Fraschini was founded about 1898. Giovanni Agnelli founded Fiat (Fabbrica Italiana Automobili Torino) in 1899, saw it grow into one of the weightiest industrial complexes in the world, and maintained personal control until his death in 1945. Fabricators of lesser puissance but great repute were Lancia, Alfa Romeo, Maserati, and Ferrari, for years the standard against which other Grand Prix and Gran Turismo motorcars were judged.

The Grand Prix and Gran Turismo cars

The smaller European nations produced makes that were to remain less well known: the Belgian Minerva, Métallurgique, and Excelsior; the Swiss Martini; the Austrian Austro-Daimler, Steyr, Gräf, and Stift; and the Czechoslovakian Skoda and Tatra, the latter technically interesting for its big (V-8) rear-mounted engine. Spain had the Elizalde, and the classic Hispano-Suiza by the great Swiss designer Marc Birkigt was Spanish financed. Curiously, what some authorities believe to be the oldest automobile still in running order early in the 1970s was an 1886 Hammel, made in Denmark.

Early efforts in the United States. The Daimler–Benz claim to the invention of the automobile was attacked in 1895 when U.S. patent 549,160 was granted to George B. Selden as inventor of the automobile. Selden had filed on May 8, 1879, although he had not at that time built an automobile. He was successful in an effort to keep the patent pending for 16 years.

Some authorities credit Charles E. and J. Frank Duryea with creating the first American gasoline-powered automobile, in 1892–93. The idea for the car apparently originated with Charles, and the machine was built by Frank. The Duryea consisted of a one-cylinder gasoline engine,

Figure 6: Duryea, 1893, a one-cylinder gasoline engine with electrical ignition.

with electrical ignition, installed in a secondhand carriage. It ran first on September 21, 1893. Driving a later model, J. Frank Duryea won the first automobile race in America in which more than two cars competed, the *Chicago Times-Herald* Race from Chicago to Evanston, Illinois, and return, in November 1895; the distance was 54.36 miles (87.47 kilometres). Duryea cars remained on the market until 1917. Despite this, many historians are convinced that the Duryea was not the first U.S. internal-combustion automobile and that this distinction should be assigned to a car built in 1890 and run in 1891 by John William Lambert of Ohio City, Ohio.

The Duryea was certainly not the first U.S.-built road vehicle. A number of steam carriages had been built after Oliver Evans' first example. In March 1863 the magazine *Scientific American* described tests of a vehicle that weighed only 650 pounds (about 300 kilograms) and achieved a speed of 20 miles (30 kilometres) per hour. Another American, Frank Curtis of Newburyport, Massachusetts, is remembered for building a personal steam carriage to the order of a Boston man who failed to meet the payment schedule, whereupon Curtis made the first recorded repossession of a motor vehicle.

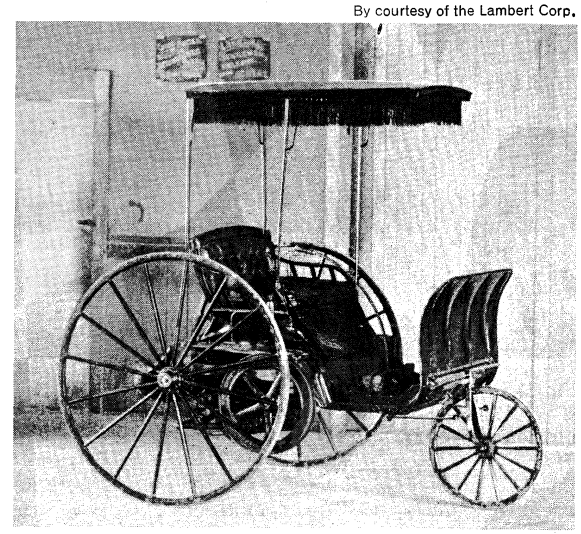

Figure 7: The Lambert, 1891, a gasoline-driven, single-cylinder automobile with a maximum speed of 15 miles per hour.

The U.S. Patent Office issued patents in September 1889 and April 1893 for three-wheeled gasoline-engine carriages, and Gottfried Schloemer of Milwaukee, Wisconsin, in 1890 built a successful car that still exists. A machinist of Allentown, Pennsylvania, in 1899 produced an automobile that ran quite well despite its dependence on the most primitive possible carburetor: a wooden wick that delivered fuel to the cylinder by capillary attraction. Charles Black in 1891, aided by Elwood Haynes, constructed a car in Indianapolis, Indiana, and Haynes followed the Duryea brothers with a gasoline car demonstrated in Kokomo, Indiana, on July 4, 1894. Charles Brady King built a car in Detroit, the first of the millions to issue from the city, that first ran on March 6, 1896.

Ransom Eli Olds, whose name survives in the Oldsmobile, was active in gasoline-engine research in the 1890s, after initially being interested in steam; so were Alexander Winton and James Ward Packard. By 1898 there were more than 50 automobile companies in existence—although the name automobile had not been settled upon (also considered were motor fly, diamote, automotive, autometon, mocole, oleo locomotive, motorig, bolvite, locomotive car, autobaine, autokenetic, and electrobat).

The first commercially successful U.S. car

The three-horsepower, curved-dash Oldsmobile was the first commercially successful American-made automobile: 425 of them were sold in 1901 and 5,000 in 1904 (the model is still prized by collectors), and the firm prospered. Its prosperity was noted by others, and, from 1904 to 1908, 241 automobile-manufacturing firms went

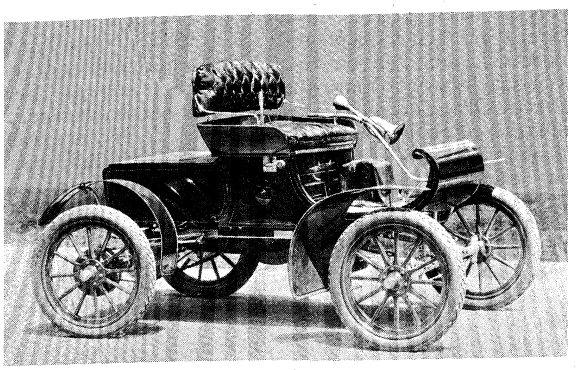

Figure 8: Oldsmobile, 1903, curved dash.

into business in the U.S. One of these was the Ford Motor Company, which was organized as a corporation in June 1903 and sold its first car on the following July 23; the company produced 1,700 cars during its first full year of business.

RECENT DEVELOPMENTS

Electric power. At the turn of the century, 40 percent of U.S. automobiles were powered by steam, 38 percent by electricity, and 22 percent by gasoline. In the face of the gasoline car's unreliability, noise, and vibration and the steamer's complications and thirst, the electric offered attractive selling points: notably, instant self-starting, silence, and minimal maintenance. The first automobile to exceed 100 kilometres (60 miles) an hour was an electric (Camille Jenatzy's La Jamais Contente, 1899). An electric, also Jenatzy's, had been the easy winner in 1898 of a French hill-climb contest to assay the three forms of power.

Invention of the storage battery, by Gaston Planté of France in 1859–60, and its improvement by Camille Faure in 1881 made the electric vehicle possible, and what was probably the first, a tricycle, ran in Paris in 1881. It was followed by other three-wheelers in London, 1882, and Boston, 1888. The first American battery-powered automobile, built in Des Moines, Iowa, in 1890, could maintain a speed of 14 miles (23 kilometres) per hour.

The peak year of the electric's acceptance was 1912, when 20 companies were in the trade and 33,842 cars were registered in the United States, the country in which the electric car had maximum acceptance. It was another application of battery power, the electric self-starter, that did as much as anything to doom the electric car by eliminating the dreaded hand crank and making the internal-combustion engine car amenable to operation by women. Further, the electric had never been really suited to any but limited urban use because of low speed (15–20 miles per hour), short range (30–40 miles), and dependence on recharging equipment.

The electric came in for its share of attention during the general re-examination of the automobile following World War II; many variations on the theme were proposed, and a number of vehicles were constructed and marketed. The problems of battery weight, low speed, and short range were not notably diminished, however, and new forms of battery—tubular lead–acid, silver peroxide–zinc, cobalt, ceramic—were expensive, exotic, or dangerous. Manufacturers of gasoline-powered cars resisted proposals on electric propulsion on the grounds that, like the steam car, it posed technical problems of such complexity that solutions would require large expenditure and many years.

Universal changeover to the electric automobile, seriously proposed in some quarters as an antipollution imperative, would have vast effects on the world's economy. The electric car is extraordinarily durable, is mechanically almost trouble-free, cannot support a host of accessories, and uses almost no oil, but would impose a serious demand on the world's electric-power system, much of which is fossil fuelled.

Ford and the automotive revolution. Henry Ford produced eight versions of cars before the Model T of 1908, with which his name is synonymous; these were the models A, B, C, F, K, N, R, and S. They were not remarkable automobiles, but public response to the less expensive ones (the firm made some fairly costly cars at first) indicated the soundness of Ford's idea—to turn the automobile from a luxury and a plaything into a necessity by making it cheap, versatile, and easy to maintain.

Within two decades, the American automobile had won the revolution Henry Ford had begun. The country was on wheels, and the manufacture and sale of the automobile were a main prop under the U.S. economy. The closed car was no longer exclusively a rich's man possession. In 1920 most cars had been open models, the occupants protected from the weather by canvas-and-isinglass side curtains; ten years later Detroit was producing closed models almost exclusively.

The 1920s saw also the emergence of the great European producers, Austin, Morris, Singer, Fiat, Citroën, companies founded between 1906 and 1919, as the Ford doctrine was carried forward on the Continent and elsewhere. Universal motor transportation was a long way off, but the concept of the small car that arose in the Austin Seven and the Fiat Topolino, to name two of the descendants of Ettore Bugatti's tiny Bébé Peugeot of 1911, was to have a profound effect.

Age of the classic cars. The decade 1925–35 was notable not only for the appearance of many new small automobiles; it also saw the building of many ultralarge ones. The years from 1925 to 1942 are cited by collectors of automobiles as the classic years, a period that saw the rise of the luxurious fast motorcar to a peak it seemed unlikely to reach again.

Rolls-Royce and Bentley

The first name in this field was Rolls-Royce, founded in 1904. Most Rolls-Royce chassis are designed for limousine and large sedan bodies, but the firm once made a comparatively light car (called the Twenty), and it has throughout its history produced fast models in addition to its regular line; *e.g.*, after World War II, the Continental, built under the Bentley Motors Ltd. label.

Other motorcars of this type included the Hispano-Suiza of Spain and France; Bugatti, Delage, Delahaye, Hotchkiss, Talbot (Darracq), and Voisin of France; the Duesenberg, Cadillac, Packard, and Pierce-Arrow of the United States; the Horch, Maybach, and Mercedes-Benz of Germany; the Belgian Minerva; and the Italian Isotta-Fraschini. These were costly machines, priced roughly from $7,500 to $40,000; fast, at 90 to 130 miles (140 to 210 kilometres) per hour and as comfortable as the state of the art would allow; and limited in luxury only by the purse of the purchaser. The great custom coach builders of England who furnished bodies for Rolls-Royce machines, unruffled by the whims of their clients, were prepared to satisfy any request, whether for upholstery in matched ostrich hide with ivory buttons or for a dashboard in rosewood.

The most expensive standard automobile of which there exists convincing record was the Type 41 Bugatti, pro-

duced in the 1920s by Ettore Bugatti, an Italian of extraordinary gifts who built cars in France, most of them racing and sports types, from 1909 to 1939. The Type 41 Bugatti, also called La Royale, was cataloged at a chassis price of 500,000 francs, about $20,000. Only six of the cars were built, and one of them, carrying a four-passenger convertible sedan body by a German coach maker, cost $43,000.

The market collapse of 1929 ended the era of the really luxurious motorcar. After World War II even Rolls-Royce abandoned its long-held policy of producing a standard chassis with custom-made bodies and offered a standard sedan that could be bought straight off the showroom floor. Custom bodies were still available to Rolls-Royce purchasers through the old-line suppliers, of course. In 1971 an overextension of Rolls-Royce's aero-engine division put the company into receivership and resulted in nationalization and a separate corporate entity for the profit-making automobile division, which continued in production without interruption.

The antique car

A few hundred persons in the 1930s were seriously interested in the collection of antique automobiles, purchasing pre-World War I specimens for $10, $25, $50—or the trouble of towing them away from a junkyard. Distaste for the mechanically dull and stylistically unpleasant 1946–50 U.S. cars attracted many Americans to the hobby, prices rose, and membership in concerned organizations such as the Antique Automobile Club of America increased. In 1951 the Museum of Modern Art in New York held an exhibition of the automobile as art object that notably influenced opinion molders. Publications devoted to the automobile proliferated; the old European idea of the *concours d'élégance* (competition in design elegance) began to be reflected in formal showings of fine pre-1939 motorcars. Shops specializing in the restoration of old automobiles were set up, and the best of them were soon booked months ahead. Collectors worked over primary sources so heavily that the discovery of a desirable car tucked away in a forgotten corner of a barn became rare indeed, and interest in the automobile as a hedge against inflation drove prices steeply upward. For example, a 1913 Mercer Raceabout, which had cost $1,250 in 1951, appreciated, in 20 years, to $45,000, and a 1936 Bugatti, $5,000 in 1954, fetched $59,000 at an auction in Los Angeles in June 1971. An offer of $50,000 for a 1933 Duesenberg was thought risible, and market observers confidently predicted six-figures for desirable items in the 1970s.

But rare motorcars were increasingly being taken off the market by museums; the first of which to do so may have been the Dangerfield Museum set up in England in 1912. The Harrah Collection in Reno, Nevada, became by far the largest, with about 1,350 vehicles, and, by many standards, incomparably the best of the world's 170-odd motorcar museums. The Montagu Motor Museum in England, the Museo dell'Automobile Carlo Biscaretti di Ruffia in Italy, and the Daimler–Benz Museum in Germany house superb collections, and there are many splendid smaller exhibits throughout Europe.

Developments after World War II. The effect of Italian ideas on the world's automobile-body designers was profound when manufacture began to be resumed in 1946. Pininfarina of Turin was the best known of the coach makers who established the characteristic Italian approach: grace, lightness in line and substance, and minimal use of decoration. Designs clearly derivative of those of Italian origin appeared everywhere, and manufacturers in France, England, and the United States contracted for the services of Italian *carrozzerie* (body factories).

The trend toward the small automobile in the United States, clear if not obtrusive after 1932, was strongly accelerated by World War II. A leading factor was the return from duty in Europe of servicemen who had previously not known of the existence of the sheer variety of automobiles the world afforded. The sports car, designed for pleasure, not transport, was particularly new to young Americans. The characteristics of automobiles such as the British sports two-seater M.G., plus their availability at a time of short domestic supply, made them attractive, and the importation of European-made models into the U.S. increased rapidly.

Auto racing as a major sport

At this time, automobile racing, which in the Vanderbilt Cup days around 1910 had drawn the biggest crowds in U.S. sports history, began to regain popularity. By 1954 motor racing had become a high-ranking American spectator sport, and by 1969 estimated attendance was 41,300,000, higher than that for baseball or football. Only horse racing showed a total higher than auto racing. In the 1950s and 1960s, U.S. manufacturers returned to racing as exploitation (a standard practice 1900–30); Ford was most successful, winning the Le Mans 24-hour Grand Prix d'Endurance race—the first U.S.-built car to do so—in 1966 and 1967 and producing, in a remarkably short time, a racing engine that dominated major U.S. tracks.

While the size of the standard U.S. motorcar increased steadily from the late 1940s to the early 1960s, and its design seemed to many to become even more bizarre, a small segment of the population was demonstrating a preference for smaller cars and for comparatively uncluttered styling. The success of the German Volkswagen and other small cars eventually led the major U.S. producers simultaneously to undertake the production of automobiles generically termed compact. At around 110-inch (280-centimetre) wheelbase, they were smaller than the less big U.S. cars, bigger than the average European models. By the mid-1960s a demand for more highly individualized luxury models of compact size had brought in the "fastback," a two-door coupé with roof line extending in a continuous curve to a rear bumper, a design reflecting the European tradition of simpler, cleaner lines. Not only in design but also in more basic engineering problems, much U.S. experimentation followed research begun by the European industry: development of gas turbine engines; experimentation with fuel-injection systems; disk brakes; return to body-and-frame assembly; introduction of rear-engine and later, conversely, of front-wheel-drive models.

In Europe and Japan, which became a major producer in the 1960s, the small car continued to dominate, though the number of larger automobiles increased. In the United States the market remained significantly influenced by European small-car design, and a new generation of "really small" cars appeared.

A possibly significant sign in popular taste discernible in the early 1970s was a new fad among young people, especially in California. Young Californians, whose fads had often presaged trends, began to show disinterest in the high acceleration and top-speed characteristics that had preoccupied them since the 1930s and were shopping the used-cars lots for vans, which they transformed into mobile recreation rooms and ran sedately at legal speeds.

(K.W.P.)

II. Modern automobiles

AUTOMOTIVE SYSTEMS

The modern automobile is a complex technical system composed of more than 14,000 parts. The subsystems that comprise the complete vehicle have evolved over many decades and include the body, or passenger compartment; the engine, or power source; the chassis, or framework supporting the engine and body; a system of shafts and gears (transmission) for transmitting power from the engine to the wheels; braking and steering mechanisms; cooling and electrical systems; fuel and lubrication; and an increasingly sophisticated group of accessories. The principal mechanical subsystems, such as gears, drives, couplings, brakes, bearings, and shafts, are treated in detail in the article MACHINES AND MACHINE COMPONENTS.

Between 25,000,000 and 30,000,000 automobiles a year were being produced throughout the world in the 1970s. While the number of manufacturers was declining, the number of designs and models was proliferating. In an effort to increase effectiveness, cars were being engineered for longer production runs to utilize tooling more fully. Specific designs for individual segments of the

market—subcompact, compact, sporty, intermediate, regular, and luxury—have been more successful. Firms with less capital have developed designs to meet particular needs. By late 1970 there were 243,000,000 cars, trucks, and buses in the world.

Motorists in the United States in the early 1970s numbered about half the world's total and drove about 1,000,000,000,000 miles each year, one-fifth of that total at speeds of 60 to 70 miles (100 to 110 kilometres) per hour on limited-access express highways linking major cities of the nation. Similar road networks and driving patterns were emerging in other industrialized nations. Vehicle stability and properly selected, manufactured, and assembled vehicle components are important in highway driving. Vehicle stability depends principally upon the distribution of weight between the front and rear wheels, the height of the centre of gravity and its position relative to the aerodynamic centre of pressure of the vehicle, suspension characteristics, and whether front or rear wheels are used for propulsion. Weight distribution depends principally upon the location and size of the engine. The common practice of front-mounted engines exploits the stability that is more readily achieved with this layout. The development of aluminum and magnesium engines and new manufacturing processes have, however, made it possible to locate the engine at the rear without necessarily compromising stability.

Stability and weight distribution

Bodies. Automotive body styles are frequently categorized according to the number of doors in the body and the manner in which the roof is supported. Automobile roofs are conventionally supported by three pillars on each side of the body. Convertible models with retractable fabric tops rely upon the pillar at the side of the windshield for upper body strength, as convertible mechanisms and glass areas are essentially nonstructural. Beginning in 1956, automotive stylists sought to increase the openness of conventional bodies by eliminating the side pillar behind the front door. This became known as hardtop styling, and the two-door hardtop was the most popular body style in 1970.

The high cost of new tools makes it impractical for manufacturers to produce totally new designs every year. New designs are usually programmed on three- to six-year cycles with generally minor refinements appearing during the cycle. As much as four years of planning and new tool purchasing is needed for a completely new design.

Automotive bodies are generally formed out of sheet steel. Elements are added to the alloy to improve its ability to be formed into deeper depressions without wrinkling or tearing in manufacturing presses. Steel is used because of its general availability, low cost, and good workability. For special applications, however, other materials, such as aluminum and fibre-glass-reinforced plastic, are used because of their special properties. Plastics have low ductility (are more brittle) in comparison with the same weight of steel or aluminum. Therefore, they are used in generally nonstructural areas.

To protect bodies from corrosive elements and to maintain their strength and appearance, special priming and painting processes are used. Bodies are first dipped in cleaning baths to remove oil and other foreign matter. They then go through a succession of dip and spray cycles. Enamel and acrylic lacquer are both in common use. Electrodeposition of the sprayed paint, a process in which the paint spray is given an electrostatic charge and then attracted to the surface by a high voltage, helps assure that an even coat is applied and that hard-to-reach areas are covered. Ovens with conveyor lines are used to speed the drying process in the factory.

Chassis. The chassis of the modern automobile is the main structure of the vehicle. In most designs a pressed-steel frame forms a skeleton on which the engine, wheels, axle assemblies, transmission, steering mechanism, brakes, and suspension members are mounted. The body is flexibly bolted to the chassis during the manufacturing process. The combination of body and frame absorbs the reactions from the movements of the engine and axle, receives the reaction forces of the wheels in acceleration and braking, absorbs aerodynamic wind forces and road shocks through the suspension, and absorbs the energy of impact in the event of an accident.

Since the 1930s there has been a trend toward combining the chassis frame and the body into a single structural element. In this arrangement the steel body shell is reinforced with braces that make it rigid enough to resist the forces which are applied to it. While this arrangement has been almost universally adopted for small cars, there has been a return to separate frames for other cars in order to achieve better noise-isolation characteristics and simplified tooling for body changes. The presence of a heavy-gauge frame member at the perimeter of the body also tends to limit intrusion in accidents.

Engines. A wide range of energy-conversion systems has been used experimentally and in automotive production. These include electric, steam, solar, turbine, rotary, and a variety of piston-type internal-combustion engines. The most successful for automobiles has been the reciprocating-piston internal-combustion engine, operating on a four-stroke cycle (see also GASOLINE ENGINE), while diesel engines are widely used for trucks and buses (see also DIESEL ENGINE). The gasoline engine was originally selected for automobiles because it could operate more flexibly over a wide range of speeds and the power developed for a given weight engine was reasonable, it could be produced by economical mass-production methods, and it used a readily available, moderately priced fuel—gasoline. Reliability, compact size, and range of operation later became important factors.

Predominance of gasoline engines

Beginning in the 1960s there has been a reassessment of these priorities with new emphasis on the pollution-producing characteristics of automotive power systems. This has created new interest in alternate power sources, but by 1972 there were no commercially successful replacements for the gasoline engine, which had developed new emission-control devices to improve its emission performance.

The pollutants requiring control include hydrocarbons that are unburned fuel compounds, carbon monoxide, and oxides of nitrogen. It was estimated in 1970 that automotive emissions produced 39 percent of the national tonnage of pollution in the United States, a proportion that was being reduced as old cars were replaced by new ones with better control systems.

In the late 1940s a trend began to increase engine horsepower, particularly in United States models. Design changes incorporated all known methods of increasing engine capacity, including increasing the pressure in the cylinders to improve efficiency, increasing the size of the engine, and increasing the speed at which power is generated.

The higher dynamic forces and pressures created by these changes created engine vibration and size problems that led to stiffer, more compact engines with V and opposed cylinder layouts replacing longer straight-line arrangements. In passenger cars, V-8 layouts were adopted for all piston displacements greater than 250 cubic inches.

The advent of smaller cars brought a return to smaller engines, four- and six-cylinder designs rated as low as 80 horsepower, compared with the standard-size V-8 of large cylinder bore and relatively short piston stroke with horsepower ratings in the range from 250 to 350.

Multiplicity of engine types

European automobile engines were of a much wider variety, ranging from one to 12 cylinders, with corresponding differences in overall size, weight, piston displacement, and cylinder bores. A majority of the models had four cylinders and horsepower ratings from 19 to 120. Several three-cylinder, two-stroke-cycle models were built. Most engines had straight or in-line cylinders. There were, however, several V-type models and horizontally opposed two- and four-cylinder makes. Overhead camshafts were frequently employed. The smaller engines were commonly air cooled and located at the rear of the vehicle; compression ratios were relatively low.

Fuel and lubrication. Gasoline is essentially the only fuel used for automobile operation, although diesel fuels are used for many trucks and buses and a few automo-

biles. The most important requirements of a fuel for automobile use are proper volatility, sufficient antiknock quality, and freedom from polluting by-products of combustion. The volatility is adjusted seasonally by refiners so that sufficient gasoline vaporizes, even in extreme cold weather, to permit the engine to be started but without being so volatile that vapour lock (a bubble of vapour that blocks gasoline flow) will prevent proper functioning of the fuel system at the highest outdoor temperatures encountered.

Antiknock qualities are controlled by refining processes that produce compact, stable molecules instead of long, straight-chain molecules. Antiknock compounds, principally tetraethyl lead, are added to some gasolines as a more economic way of attaining the same result. Small deposits of lead on such places as engine-valve seats serve to improve valve life. These same deposits, however, can contaminate certain emission-pollution-control systems such as catalytic converters. Antiknock quality is rated by the octane number of the gasoline. The octane-number requirement of an automobile engine depends primarily upon the compression ratio of the engine but is also affected by combustion-chamber design and deposits formed on the chamber walls. Various additives intended to minimize the effects of deposits are used in most automotive gasolines. No advantage is gained by using a fuel of octane number higher than that necessary to eliminate objectionable knock. In the early 1970s regular gasoline carried an octane rating of around 93 and high-test in the neighbourhood of 100. All moving parts of an automobile require lubrication. Without it, friction would increase power consumption and damage the parts. The lubricant also serves as a coolant, a noise-reducing cushion, and a sealant between engine piston rings and cylinder walls.

The engine lubrication system consists of an oil sump and a gear-type pump that delivers the oil under pressure to a system of drilled passages leading to various bearings. Drilled passages in the crankshaft conduct oil to lubricate the connecting-rod bearings, and leakage from these bearings sprays oil up into the cylinder bores to lubricate the pistons, piston pins, and piston rings. The spray also lubricates the cams and valve lifters. Usually the oil passes through a paper or cotton-waste filter before it enters the distribution passages; bypass filters sometimes are used to receive a small stream of oil from the system continuously and return it to the sump after removing any solids.

Engine oils

Engine oils may be identified by letters designating the severity of service for which the oil is suitable and by numbers indicating the viscosity range. Selection of the proper oil depends upon the conditions under which it will be used—for example, continuous high speeds, heavy loads, frequent starts and stops—and engine components such as hydraulic valve lifters that are sensitive to oil condition.

Wheel bearings and universal joints require a fairly stiff grease; other chassis joints require a soft grease that can be injected by pressure guns. Hydraulic transmissions require a special grade of light hydraulic fluid, and manually shifted transmissions use a heavier gear oil similar to that for rear axles. Hypoid gears used in most rear axles require oils that are compounded to resist heavy loads on the gear teeth. Gears and bearings in lightly loaded components, such as generators and window regulators, are fabricated from self-lubricating plastic materials (see also LUBRICATION).

Cooling system. The vast majority of automobiles employ liquid cooling systems for their engines. A typical automotive cooling system comprises (1) a series of channels cast into the engine block and cylinder head, surrounding the combustion chambers with circulating water or other coolant to carry away excessive heat; (2) a radiator, consisting of many small tubes equipped with a honeycomb of fins to radiate heat rapidly, that receives and cools hot liquid from the engine; (3) a water pump, usually of the centrifugal type, to circulate coolant through the system; (4) a thermostat, which maintains constant temperature by automatically varying the amount of coolant passing into the radiator; and (5) a fan, which draws fresh air through the radiator.

For operation at outdoor temperatures below freezing, it is necessary to prevent the coolant from freezing. This is usually done by adding some compound to depress the freezing point of the coolant. Alcohol formerly was commonly used, but it has a relatively low boiling point and evaporates quite easily, making it less desirable than organic compounds with a high boiling point, such as ethylene glycol. By varying the amount of additive, it is possible to protect against freezing of the coolant down to any minimum temperature normally encountered.

Air cooling offers the important advantage of eliminating not only freezing and boiling of the coolant at temperature extremes but also corrosion damage to the cooling system. Control of engine temperature is more difficult, however, and the engine temperature is more likely to vary with the outside temperature. Air-cooled cylinders operate at higher, more efficient temperatures, but compression ratios (with the same fuels) must be lower, because combustion control is more difficult. In addition, it is more difficult to utilize engine heat to warm the car interior during winter. In spite of these disadvantages, in the early 1970s a sizable number of cars with air-cooled motors were being manufactured.

With the aim of eliminating seasonal draining of liquid cooling systems, manufacturers in the later 1950s and early 1960s introduced liquid coolants intended to replace water–antifreeze mixtures. These contained corrosion inhibitors that were designed to make it necessary to drain and refill the cooling system only once a year.

Permanent coolants

Other compounds under development in the early 1960s, some of which were organic silicates, contained no water and were permanent in characteristics. Such liquids permit the cooling system to be sealed and require no attention. The ultimate practicability of these permanent coolants depends upon their ability to carry heat away from the engine. All previously known liquids with appropriate boiling and freezing points were poorer than water in this respect and so were not as effective as engine coolants.

Pressurized cooling systems with operating pressures up to 14 pounds per square inch have been used to increase effective operating temperatures. Partially sealed systems using coolant reservoirs for coolant expansion if the engine overheats were introduced in 1970.

Electrical system. Originally, the electrical system of the automobile was limited to the ignition equipment. With the advent of the electrical starter on a 1912 model, electric lights and horns began to replace the kerosene and acetylene lights and the bulb horns. Electrification was rapid and complete, and by 1930 six-volt systems were standard everywhere. The electrical system comprises a storage battery, generator, or dynamo, starting (cranking) motor, lighting system, ignition system, and various accessories and controls.

Increased engine speeds and higher cylinder pressures of the post-World War II cars made it increasingly difficult to meet high ignition voltage requirements. The larger engines required higher cranking torque. Additional electrically operated features, such as radios, window regulators, and multispeed windshield wipers, also added to system requirements. To meet these needs, 12-volt systems generally replaced the six-volt systems in 1956 production.

The ignition system provides the spark to ignite the air–fuel mixture in the cylinders of the engine. In order to jump the gap between the electrodes of the spark plugs, the 12-volt potential of the electrical system must be stepped up to about 20,000 volts. This is done by a circuit that starts with the battery, one side of which is grounded on the chassis and leads through the ignition switch to the primary winding of the ignition coil and back to the ground through an interrupter switch, or circuit breaker. Interrupting the primary circuit induces a high voltage across the secondary of the coil. The high-voltage secondary terminal of the coil leads to a distributor that acts as a rotary switch, alternately connecting the coil to each of the wires leading to the spark plugs. The system

consists of the spark plugs, contact breaker, coil, distributor, and battery.

The generator

The source of electrical energy for the various electrical devices of the automobile is a generator, or dynamo, that is belt driven from the engine crankshaft. The generator is usually a two-pole, direct-current type with a field controlled by a voltage regulator the function of which is to match the generator output to the electrical load and also to the charging requirements of the battery, regardless of engine speed. High-wattage electrical loads, resulting from the addition of many electrical accessories, has made it increasingly difficult to design direct-current generators with sufficiently high capacity to maintain the battery in a fully charged condition. Alternating-current generators, or alternators, with built-in rectifiers were introduced in 1958 to provide for these loads.

A lead–acid battery serves as a reservoir to store excess output of the generator by chemical changes in the sulfuric acid electrolyte and in the composition of the lead plates. Energy for the starting motor is thus made available along with power for operating other electrical devices when the engine is not running or when the generator speed is not sufficiently high to carry the load (see also BATTERIES AND FUEL CELLS).

The starting motor drives a small spur gear so arranged that it automatically moves into mesh with gear teeth on the rim of the flywheel as the starting-motor armature begins to turn. When the engine starts, the small gear is disengaged, thus preventing damage to the starting motor from overspeeding. The starting motor is designed for high current consumption and delivers considerable power for its size for a limited time.

Headlights that satisfactorily illuminate the highway ahead of the automobile for night driving without temporarily blinding approaching drivers have long been sought. Early dimming devices of the resistance type, which decreased the brightness of the headlights when meeting another car, gave way to mechanical tilting reflectors and later to double-filament bulbs with a high and a low beam, called sealed-beam units.

The double-filament headlight unit of necessity has only one of its filaments at the focal point of the reflector. Because of the greater illumination required for high-speed driving with the high beam, the lower beam filament was placed off centre, with a resulting decrease in lighting effectiveness. In the 1950s some manufacturers began equipping their models with four headlights to improve illumination. In most instances the outer lamps were double-filament types with a high-wattage low beam and a "soft" high beam for city driving. The inner lamps have a single-filament high beam of high wattage that produces a spotlight effect. The low beam of the two outer lamps is focussed slightly to the right and is used when overtaking or meeting other vehicles. The high beams of all four lamps are used on the open highway when there is no approaching traffic. Dimming is automatically achieved on some cars by means of an automatic photocell-controlled switch in the lamp circuit that is triggered by the lights of an oncoming car. Larger diameter double-filament lamps with improved photometrics permitted a return to two-headlamp systems on some cars. Total intensity of forward lighting systems in many places is limited by law to 75,000 candlepower.

Signal lamps and other special-purpose lights increased in usage in the 1960s. Amber-coloured front and red rear signal lights are flashed as a turn indication; all these lights are flashed simultaneously in the "flasher" system for use when a car is parked along a roadway or is travelling at a low speed on a high-speed highway. Marker lights that are visible from the front, side, and rear are also widely required by law. Red-coloured rear signals are used to denote braking, and, on some models, cornering lamps to provide extra illumination in the direction of an intended turn are available. These are actuated in conjunction with the turn signals. Backup lights provide illumination to the rear when backing up.

Transmission. The gasoline engine must be disconnected from the load (the rear wheels) when it is started and when idling. This characteristic necessitates some type of unloading and engaging device to permit gradual application of load to the engine after it has been started. In starting the engine, the crankshaft is rotated (cranked) by an electric motor; this in turn starts action in the cylinders. The torque, or turning effort, that the engine is capable of producing is low at low crankshaft speeds, increasing to a maximum at some fairly high speed representing the maximum, or rated, horsepower.

Engine efficiency

The efficiency of an automobile engine is highest when the load on the engine is high and the throttle is nearly wide open. At moderate speeds on level pavement the power required to propel an automobile is only a portion of the power the engine is capable of developing in its upper range of speeds. Thus, under normal driving conditions at constant moderate speed, the engine may operate at an uneconomically light load unless some means is provided to reduce its speed and power output.

The transmission is such a speed-changing device. It is installed in the drive train that connects the crankshaft of the engine to the driving wheels. This permits the engine to operate at a higher speed when its full power is needed and to slow down to a more economical speed when less power is needed. Under some conditions, as in starting a stationary vehicle or in ascending steep grades, the torque of the engine is insufficient, and amplification is desirable. Most devices employed to change the ratio of the speed of the engine to the speed of the driving wheels multiply the engine torque by the same factor by which the engine speed is increased.

The simplest automobile transmission is the sliding-spur-gear type with three or four forward speeds and reverse. The desired gear ratio is selected by manipulating a shift lever which slides a spur gear into the proper position to engage the various gears. Early devices of this type required considerable skill on the part of the operator to shift the gears smoothly and without clashing the teeth. The shift from low to second gear was the most troublesome, because this shift required that two gears, moving at different speeds, be slid sidewise into tooth engagement. This problem was eliminated by a constant-mesh second gear in which the driven gear of the train is not keyed to the driven shaft of the transmission. Second gear is engaged by means of a toothed or jaw clutch, similar to that used to engage direct drive, arranged so that it can keep the driven gear from turning on the driven shaft.

Ease of shifting into second and high was further improved by the use of synchronizing clutches that engaged ahead of the toothed clutches and caused the two portions of the positive clutch to turn in unison before their engaging teeth touched each other. Another device, a blocker ring, was added later; its function was to block the two members of the clutch from contacting each other before their speeds were synchronized. The only difficulty remaining in the operation of the sliding-gear transmission was the need for simultaneously operating the accelerator pedal, the clutch pedal, and the gearshift lever. The automatic transmission was developed to eliminate this manipulation. Most automatic transmissions employ either a fluid coupling or a hydraulic torque converter, a device for transmitting and amplifying the torque produced by the engine. One manufacturer, DAF of The Netherlands, uses a mechanical linkage. Each type provides for manual selection of reverse and a low range that either prevents automatic upshifts or employs a lower gear ratio than is used in normal driving. Grade-retard provisions are also sometimes included to provide engine braking on hills. By 1970 the hydraulic torque-converter-type automatic transmission dominated its field. In hydraulic transmissions, shifting is done by a speed-sensitive governing device that changes the position of valves that control the flow of hydraulic fluid. The vehicle speeds at which shifts occur depend upon the position of the accelerator pedal, and the driver can delay upshifts until higher speed is attained by depressing the accelerator pedal further. Control is by hydraulically engaged bands and multiple-disk clutches running in oil, either by the driver's operation of the selector lever or by a speed-sensitive governor. Compound planetary gear

Hydraulic transmissions

trains with multiple sun gears and planet pinions have been designed to provide a low forward speed, an intermediate speed, a reverse, and a means of locking into direct drive. This unit is used with various modifications in almost all hydraulic-torque-converter transmissions.

In hydraulic-torque-converter transmissions, torque is multiplied by means of gear trains and a hydraulic member with three or more elements.

As shown schematically in Figure 10, oil in the housing

Adapted from *Automotive Industry* (October 1970)

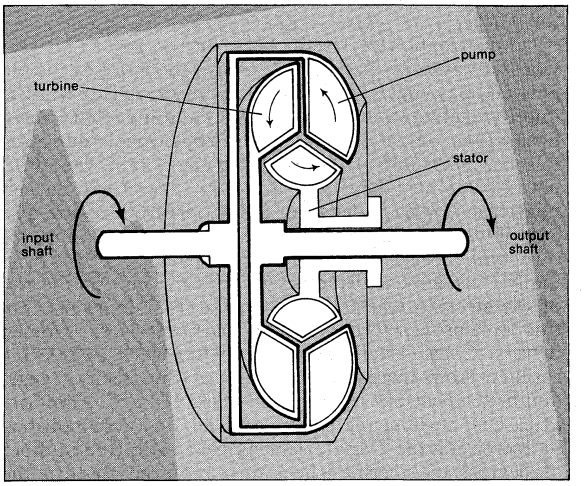

Figure 10: Torque converter.

is accelerated outward by rotating vanes in the pump impeller and, reacting against vanes in the turbine impeller, forces them to rotate. The oil then passes into the stator vanes, which redirect it to the pump. The stator serves as a reaction member providing more torque to turn the turbine than was originally applied to the pump impeller by the engine. Thus, it acts to multiply engine torque by a factor of up to 2½ to 1.

Blades in all three elements are specially contoured for their specific function and to achieve particular multiplication characteristics. Through a clutch linkage, the stator is allowed gradually to accelerate until it reaches the speed of the pump impeller. During this period torque multiplication gradually drops to approach 1 to 1.

The hydraulic elements are combined with two or three planetary gear sets, which provide further torque multiplication between the turbine and the output shaft.

Automatic transmissions not only require no skill to operate but make possible better performance than is obtainable with transmissions that necessitate the release of a clutch during gear shifts. Power is applied to the driving wheels continuously whenever the accelerator pedal is depressed, and gears are shifted without closing the engine throttle or interrupting the drive.

Small, low-powered European cars usually have manually shifted, four-speed transmissions. Power-operated clutches are sometimes used in combination with pre-selective or semi-automatic transmissions. Fully automatic transmissions are used for the most part in larger cars with ratings above 60 horsepower.

Other mechanical subsystems. *Axles.* Power is conveyed from the transmission to the rear axle by a propeller shaft and universal joints. As body lines were progressively lowered, the floor level came closer to the propeller shaft, necessitating floor humps or tunnels to provide clearance. The adoption of hypoid or offset spiral bevel gears in the rear axle provided an increase in this clearance by lowering the drive pinion below the center of the axle shafts.

The differential

The ring gear of the rear axle surrounds the housing of a differential gear train that serves as an equalizer in dividing the torque between the two driving wheels while permitting one to turn faster than the other when rounding corners. The axle shafts terminate in bevel gears that are connected by several smaller bevel gears mounted on radial axles attached to the differential housing and carried around with it by the ring gear. In its simplest form this differential has the defect that one driving wheel may spin when it loses traction, and the torque applied to the wheel, being equal to that of the slipping wheel, will not be sufficient to drive the car. Several differentials have been developed to overcome this difficulty.

European manufacturers quite generally adopted a wide variety of articulated rear axles that provide individual wheel suspension at the rear as well as the front. Individual rear suspension not only eliminates the heavy rear axle housing but also permits lowered bodies with no floor humps, because the transmission and differential gears can be combined in a housing mounted on a rear cross member moving with the body under suspension-spring action.

In some instances, European manufacturers use articulated or swing axles similar to American rear axles except that the tubular housings surrounding the axle shafts terminate in spherical head segments that fit into matching sockets formed in the sides of the central gear housing. Universal joints within the spherical elements permit the axle shafts to move with the actions of the suspension springs. The gear housing is supported by a rear cross member of the chassis and moves with the sprung portion of the vehicle, as does the drive shaft. Other types eliminate the axle shaft housings and drive the wheels through two open axle shafts, each fitted with two universal joints. The wheels are then individually supported by radius rods or other suitable linkage.

The driving trains for rear engine, rear-wheel-drive cars and front engine, front-wheel-drive cars are simplified by individually supported wheels in that a combined transmission and differential assembly can form a unit with the engine. Two short transverse drive shafts, each having universal joints at both ends, transmit power to the wheels. In this case there is no axle as such, and the wheels may be individually suspended. Front-wheel-drive vehicles built in the United States since 1966 have, however, employed solid rear axles.

Brakes. Most automobile brakes are of the internally expanding shoe type, in which two nearly semicircular brake shoes are pressed against the inner surface of a drum attached to the wheel. Until the 1930s, most brake systems were of the mechanical type; *i.e.*, foot pressure exerted on the brake pedal was carried directly to the brake shoes by a system of flexible cables. Mechanical brakes, however, are difficult to keep adjusted so that equal braking force is applied at each wheel; and, as vehicle weights and speeds increased, more and more effort on the brake pedal was demanded of the driver.

Hydraulic brakes

Mechanical brakes have been almost universally supplanted by hydraulic braking systems, in which the brake pedal is connected to a piston in a master cylinder and thence by steel tubing with flexible sections to individual cylinders at the wheels. Front and rear hydraulic circuits are separated. The wheel cylinders are located between the movable ends of the brake shoes, and each is fitted with two pistons that are forced outward toward the ends of the cylinder by the pressure of the fluid between them. As these pistons move outward, they push the brake shoes against the inner surface of the brake drum attached to the wheel. The larger diameter of the piston in the master cylinder provides a hydraulic force multiplication at the wheel cylinder that reduces the effort required of the driver.

Further increases in vehicle weights and speeds in the 1950s made even hydraulic brakes difficult for drivers to operate effectively, and many of the larger automobiles consequently were equipped with power brake systems. These are virtually the same as the hydraulic system except that the piston of the master cylinder is operated by a vacuum piston and cylinder instead of by the pressure exerted on the brake pedal (see Figure 11). The master cylinder and vacuum power cylinder are formed in one unit. When the driver starts to depress the brake pedal, the control valve closes the atmospheric ports. Further movement of the valve opens the vacuum port connecting the vacuum inlet to the cylinder chamber at the left of the piston. The vacuum inlet pipe leads to the intake

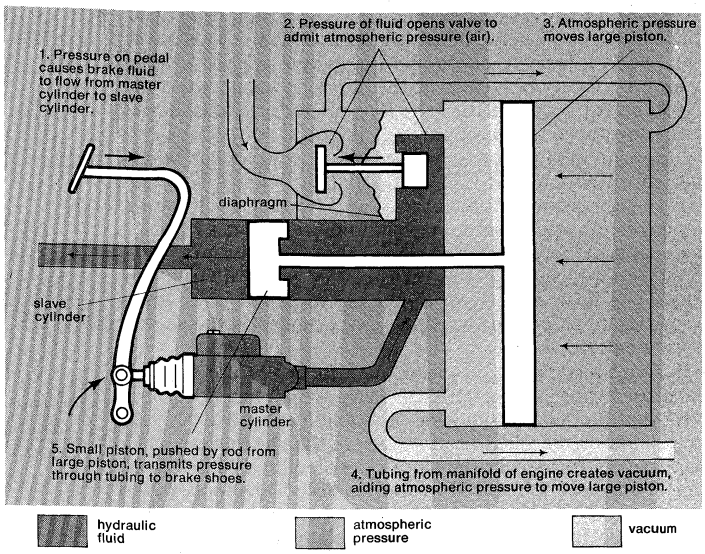

Figure 11: Schematic cross section of vacuum-actuated power brake.

manifold, and, when the vacuum valve opens the port, a vacuum is formed on the left side of the power piston. Atmospheric pressure acting on the right side of the piston causes it to move to the left. Plungers in the master cylinder cover the compensating ports and place the hydraulic brake fluid under pressure in the wheel cylinders. As the brake-fluid pressure builds up, the control valve is pushed back. If the pedal is not depressed further, the vacuum port will close, and the brakes will be held in application until the pedal is released. The amount of brake-fluid pressure depends upon how far the pedal is depressed; the driver feels a resistance to pedal movement proportional to the fluid pressure actuating the brakes. The force he must exert is much smaller, however, than is necessary with ordinary brakes, and no appreciable physical effort is necessary to apply the brakes fully.

Overheating of the brake drums and shoes causes the brakes to fade and lose their effectiveness when held in engagement for a considerable length of time. This problem has been attacked by the use of aluminum cooling fins bonded to the outside of the brake drums to increase the rate of heat transfer to the air. Vents in the wheels are provided to increase the air circulation for cooling.

Disk brakes, originally developed for aircraft, have been fitted to some automobiles. Although there are some four-wheel systems, usually disks are mounted on the front wheels, and conventional drum-type units are retained at the rear. Disk designs are somewhat more costly but have become increasingly popular. They were fitted on 56 percent of all new cars in 1970. Each wheel has a hub-mounted disk and a brake unit or caliper rigidly attached to the suspension. The caliper employs two friction-pad assemblies, one on each side of the disk. When the brake is applied, hydraulic pressure forces the friction pads against the disk. This arrangement is self-adjusting, and the ability of the disks to dissipate heat rapidly in the open airstream makes them practically immune to fading.

Parking brakes

Parking brakes usually are of the mechanical type, applying force only to the rear brake shoes by means of a flexible cable connected to a hand lever or pedal. On cars with automatic transmissions, an additional lock is usually provided in the form of a pawl that can be engaged, by placing the shift lever in the "park" position, to prevent the drive shaft and rear wheels from turning.

Steering. Automobiles are steered by a system of gears and linkages that transmit the motion of the steering wheel to the pivoted front wheel hubs. The gear mechanism, located at the lower end of the shaft carrying the steering wheel, is usually a worm-and-nut or cam-and-lever combination that rotates a shaft with an attached crank arm through a small angle as the steering wheel is turned. Tie rods attached to the arm convey its motion to the wheels. In cornering, the inner wheel must turn through a slightly greater angle than the outer wheel, because the inner wheel negotiates a sharper turn. The geometry of the linkage is designed to provide for this.

When the front wheels are independently suspended, the steering must be designed so the wheels are not turned as the tie rods lengthen and shorten as a result of spring action. The point of linkage attachment to the steering gear must be placed so that it can move vertically with respect to the wheel mountings without turning the wheels.

The distribution of weight between the front and rear wheels of automobiles shifted toward the front as the engine and passenger compartment were moved forward to improve riding comfort and road-handling characteristics. As the weight carried on the front wheels increased to more than half of the total vehicle weight, the effort necessary to turn the wheels in steering increased. Larger, heavier cars with wider tires and lower tire pressure also contribute to drag between tires and road that must be overcome in steering, particularly in parking. It was originally considered satisfactory to limit the pull on the rim of the steering wheel to 30 pounds (14 kilograms), but this limit proved to be too high, particularly for women drivers. Considerable reduction in the work of steering resulted from increased efficiency of the steering gears and better bearings in the front wheel linkage. Additional ease of turning the steering wheel was accomplished by increasing the overall steering gear ratio (the number of degrees of steering-wheel turn required to turn the front wheels one degree). Large steering gear ratios make high-speed manoeuvrability more difficult, however, because the steering wheel must be turned through greater angles. On the other hand, steering mechanisms of higher efficiency are also more reversible; that is, road shocks are transmitted more completely from the wheels and must be overcome to a greater extent by the driver. This causes a dangerous situation on rough roads or when a front tire blows out, because the wheel may be jerked from the driver's hands.

Power steering gear was developed to solve the steadily increasing steering problems. Power steering was first applied to heavy trucks and military vehicles early in the 1930s, and hundreds of patents were granted for devices to help the driver turn the steering wheel. Most of the proposed devices were hydraulic; some were electrical and some mechanical. A pump driven by the engine maintains the hydraulic fluid under pressure. A valve with a sensing device allows the fluid to enter and leave the power cylinder as necessary.

Suspension systems. The suspended portion of the automobile is attached to the wheels by elastic members designed to cushion the impact of road irregularities. The nature of the attaching linkages and spring elements varies widely among United States, European, and Japanese automobiles. Riding comfort and the handling qualities of the vehicle are greatly affected by the functioning of the suspension system. Mechanical simplification is gained by connecting the front wheels with a rigid front axle just as the rear wheels are connected by the conventional rear axle housing. Several important advantages, however, are gained by so-called independent-suspension systems that permit the wheels to move independently of each other. The unsprung weight of the vehicle is decreased, softer springs are permissible, and front-wheel vibration problems are minimized. Independent front suspensions entirely replaced the rigid-axle type after World War II, and numerous independent rear suspensions came into use, first on European cars. Spring elements used for automobile suspension members, in increasing order of their ability to store elastic energy per unit of weight, are leaf springs, coil springs, torsion bars, rubber-in-shear devices, and air springs.

Independent suspension systems

The leaf spring, although comparatively inelastic, has the important advantage of accurately positioning the wheel with respect to the other chassis components, both laterally and fore and aft, without the aid of auxiliary linkages.

Some cars equipped with rear leaf springs employ a drive in which the axle housing is rigidly attached to the spring seats so that the driving torque reaction, the brake torque, and the driving force are all imparted to the spring. Those using rear coil springs may have a torque tube enclosing the drive shaft that takes these forces to its point of attachment at the front of the axle housing. A diagonal transverse rod connecting one outer end of the axle housing to the chassis frame at the opposite side is provided to position the axle laterally. Other types with open drive shafts provide for these forces by radius rods and other linkages.

An important factor in spring selection is the relationship between load and deflection known as spring rate, defined as the load in pounds divided by the deflection of the spring in inches. A soft spring has a low rate and deflects a greater distance under a given load. A coil or a leaf spring retains a substantially constant rate within its operating range of load and will deflect ten times as much if a force ten times as great is applied to it. The torsion bar, a long spring-steel element with one end held rigidly to the frame and the other twisted by a crank connected to the axle, can be designed to provide an increasing spring rate.

A soft-spring suspension provides a comfortable ride on a relatively smooth road, but the occupants move up and down excessively on a rough road. The springs must be stiff enough to prevent a large deflection at any time because of the difficulty in providing enough clearance between the sprung portion of the vehicle and the unsprung portion below the springs. Lower roof heights make it increasingly difficult to provide the clearance needed for soft springs. Road-handling characteristics also suffer because of what is known as sway, or roll, the sidewise tilting of the car body that results from centrifugal force acting outward on turns. The softer the suspension, the more the outer springs are compressed and the inner springs expanded. Front-end "dive" under brake action is more noticeable with soft front springs. Air springs offer several advantages over metal springs, one of the most important of which is the possibility of controlling the spring rate. Inherently, the force required to deflect the air unit increases with greater deflection, because the air is compressed into a smaller space, and greater pressure is built up, thus progressively resisting further deflection.

A combination hydraulic-fluid-and-air suspension system has been developed in which the elastic medium is a sealed-in, fixed mass of air, and no air compressor is required. The hydraulic portion of each spring is a cylinder mounted on the body sill and fitted with a plunger that is pivotally attached to the wheel linkage to form a hydraulic strut. Each spring cylinder has a spherical air chamber attached to its outer end. The sphere is divided into two chambers by a flexible diaphragm, the upper occupied by air and the lower by hydraulic fluid that is in communication with the hydraulic cylinder through a two-way restrictor valve. This valve limits the rate of movement of the plunger in the cylinder, since fluid must be pushed into the sphere when the body descends and returned when it rises. This damping action thus controls the motion of the wheel with respect to the sprung portion of the vehicle supported by the spring.

The amount of hydraulic fluid in each spring unit is varied by front and rear levelling valves that transfer fluid to and from a central hydraulic system in which pressure is maintained by an engine-driven pump. These leveling valves serve to maintain constant clearance between the wheels and the sprung portion of the vehicle under varying passenger and luggage load.

Tires. The pneumatic rubber tire is the point of contact between the automobile and the road surface. It functions to provide traction for acceleration and braking and limits the transmission of road vibrations to the automobile body. Inner tubes within tires were standard until the 1950s, when seals between the tire and the wheel were developed, leading to tubeless tires, now used almost universally.

Tire-tread design

Tire-tread designs are tailored for the characteristics of the surface on which the vehicle is intended to operate. Deep designs provide gripping action in loose soil and snow, while smooth surfaces provide maximum contact area for applications such as racing. Current passenger-car treads are a compromise between these extremes.

A typical tire casing is fabricated from layers, or plies, of varying proportions of rubber compounds reinforced with synthetic fibres or steel wire. The composition of the reinforcement and the angle of its application to the axis of the tread affect the ability of the tire to respond to sidewise forces created during cornering. They also affect harshness or vibration-transmission characteristics.

By 1970, longitudinal-, bias-, and radial-ply constructions were in use, with layers of two, four, or more plies, depending on the load capacity of the design. An additional factor relating to the load capacity of a particular construction is the pressure to which the tire is inflated. New designs also have lower height-to-width ratios to increase the road-contact area while maintaining a low standing height for the tire and consequently the car.

PROBLEMS OF AUTOMOTIVE DESIGN

Safety considerations. From its beginnings, the automobile exhibited a serious defect from the point of view of safety. Its speed and weight gave it an impact capacity both for its occupants and for pedestrians or other automobile passengers that produced great numbers of fatalities and serious injuries. Over the 20th century, the rates of death and injury declined in terms of passenger miles, yet, in both Europe and the United States and more recently in Japan and other countries, the total numbers rose because of the increased number of vehicles on the road. The worldwide pattern in the early 1970s varied little. Most fatal accidents occurred on either city streets or secondary rural roads; national expressway systems were relatively safer. Driver training, vehicle maintenance, highway improvement, and law enforcement were identified as key areas with potential for improving safety, but the basic design of the vehicle itself and the addition of special safety features were receiving increasing attention. Safety features of automobiles come under two distinct headings: accident avoidance and occupant protection.

Accident avoidance. Accident-avoidance systems are designed to help the driver maintain better control of his car. The dual-master-cylinder brake system is a good example. This protects the driver against sudden loss of brake-line pressure. Front and rear brake lines are separated so that if one fails the other continues to function. This system is sometimes coupled with an indicator lamp on the instrument panel to warn the driver if one section of the brake circuit has a failure.

Occupant protection. Systems to protect occupants in the event of an accident fall into four major classes: maintenance of passenger-compartment integrity, occupant restraints, interior-impact energy-absorber systems, and exterior-impact energy absorbers. Statistics indicate a far higher chance for survival among accident victims remaining inside the passenger compartment. Passenger-compartment integrity depends significantly on the proper action of the doors, which must remain closed in the event of an accident and must be sufficiently strong to limit deflection during intrusions. Door-latch mechanisms have been designed to resist forward, rearward, and sideward forces and incorporate two-stage catches, so that the latch may hold if the primary stage fails. Reinforcement beams in doors are designed to deflect impact forces downward to the more rigid frame structure below the door. Forces are directed through reinforced door pillars and hinges.

Occupant restraints are used to help couple the passenger to the car. They permit decelerating with the car rather than free flight into the car structure or into the air. Combination lap- and shoulder-belt systems are the most common restraint system. These consist of web fabrics that are able to withstand 6,000-pound (2,700 kilogram) test loading and are bolted to the car underbody and roof rail. Button-type latch release mechanisms for buckles, together with belt-operation reminder sys-

tems that detect unlatched belts, became legal requirements for all cars in the United States in 1972. This is intended to help offset the major drawback of belt systems or any other arrangements that require active participation of the occupant to insure proper operation. A 1970 survey indicated that 60 percent of car occupants do not use lap belts, and shoulder-belt usage is less than 3 percent. Another line of research aimed at overcoming this problem has centred on passive restraints that do not require any action on the part of the occupant. Experimental air-cushion restraint systems have been developed; an inflatable fabric bag pops out of the instrument panel and is filled with high-pressure gas within 40 milliseconds after an impact. The system is triggered by a sensor that is automatically actuated at impact. The occupant flies forward into the inflated cushion, which then controls his further motion and absorbs some of his energy. Energy is absorbed by forcing gas out of the cushion through a series of ports or orifices in the fabric. This system had not been accepted in the early 1970s because of developmental problems, including the possibility of inadvertent actuation, failure to actuate, the effect on occupants who are not sitting in the proper positions, the possible harmful effect on occupant hearing created by the high noise level of actuation, and the necessary safety precautions that must be taken when working with pyrotechnic devices and high-pressure gas cylinders.

Air-cushion restraint systems

Interior-impact energy-absorbing devices are designed to augment restraint systems by absorbing energy from the occupant while minimizing his injuries. The energy-absorbing steering column, introduced in 1967, is a good example of such a device (see Figure 12). In front-end collisions, the column resists being pushed rearward. The lower end compresses while the upper end is retained by U-shaped support brackets and bolts. A few milliseconds after impact the driver hits the steering wheel, and the support brackets break away, allowing the upper end of the column to move downward, absorbing energy by deforming a metal jacket surrounding the column. Instrument panels, windshield glass, and other surfaces that may be struck by an unrestrained occupant may be designed to absorb energy in a controlled manner.

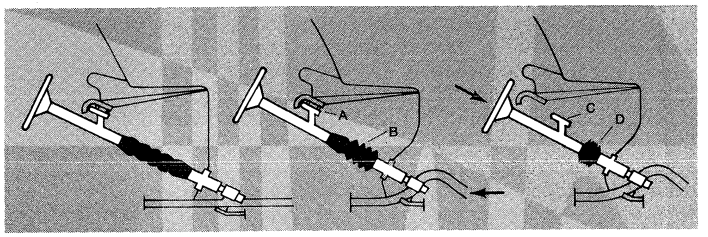

Figure 12: *Energy-absorbing steering column action* (see text). (Left) Assembly before impact. (Centre) An instant after impact. (A) Attachment bracket still holds; (B) lower steering column has started to collapse. (Right) An instant later. Impact of driver striking steering wheel breaks loose (C) attachment bracket and energy of impact is absorbed by further collapse of (D) lower steering column.

Exterior-impact-energy devices include the structural elements of the chassis and body, which may be tailored to deform in a controlled manner to decelerate the automobile more gradually and, as a result, leave less force to be experienced by the occupants. Stress risers in the form of section irregularities have been built into front frame members of some cars. These are designed to buckle under severe loads and absorb energy in the process. Retractable bumpers that have been developed absorb some of the impact energy of a collision as the bars move inward against the restraint of springs.

Pollution problems. Governments have also found a role in the automotive-air-pollution problem, to establish quality standards and to perform sample inspections to insure that standards are met. Standards have become progressively more stringent, and the equipment necessary to meet them has become more complex.

Positive crankcase ventilation (see Figure 13) was introduced in the United States in 1963, for the purpose of eliminating engine blow-by gas that formerly had been vented to the atmosphere as an emission source. This was achieved by routing the gas, along with crankcase-ventilation air, into the engine intake, where it could be recycled through the cylinders and properly burned. A small valve in the circuit was necessary to maintain the direction of flow. Beginning in 1966, cars increasingly were provided with air pumps to supply excess air to the exhaust stream near the exhaust valves. High gas temperatures in this zone promote thermal oxidation of hydrocarbons and carbon monoxide to form carbon dioxide and water.

By courtesy of General Motors Corporation

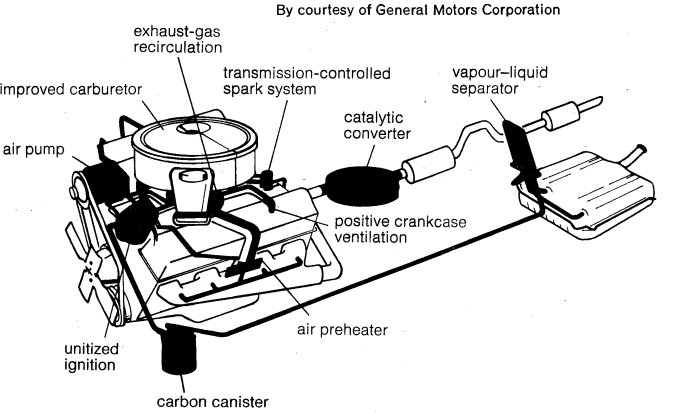

Figure 13: Emission-control systems for automobile engines (see text).

Various engine modifications that alter emission characteristics have been successfully introduced. These include adjusted carburetor air–fuel ratios, lowered compression ratios, retarded spark timing, reduced combustion chamber surface-to-volume ratios, and closer production tolerances. To improve drivability of some arrangements, preheated air from a heat exchanger on the exhaust manifold is ducted to the air cleaner.

Engine modifications to lower pollution

The undesired evaporation of gasoline hydrocarbons into the air has been controlled by sealing the gas tank and venting the tank through a liquid–vapour separator into a canister containing activated charcoal. During engine operation these vapours are desorbed and burned in the engine.

The effect of these controls was well established by the early 1970s. The average hydrocarbon emissions from equipped vehicles was reduced by about 87 percent. A 65 percent reduction in carbon monoxide was also obtained. Controls to reduce the formation of oxides of nitrogen brought a 30 percent reduction result. The chemical conditions that tend to reduce hydrocarbon and carbon monoxide sometimes tend to increase the formation of undesirable nitrous oxide. This presents a formidable challenge to research scientists and engineers.

Among emission-control devices under development in the early 1970s were catalytic converters (devices to promote combustion of unburned hydrocarbons in the exhaust), exhaust-gas-recirculation systems, manifold reactors, fuel injection, unitized ignition elements, and stratified charge combustion engines (see Figure 13).

A catalytic converter consists of an insulated chamber containing a porous bed of catalytic material through which hot exhaust gas must pass before being discharged into the air. The catalyst is in the form of pellets of a variety of metal oxides, which are heated by exhaust gas to about 900° F (500° C). At this temperature unburned hydrocarbons and carbon monoxide are further oxidized. Problems with catalysts involve their intolerance for leaded fuels and the need to prevent overheating.

Exhaust-gas recirculation is a technique to control oxides of nitrogen, which are formed by the chemical reaction of nitrogen and oxygen at high temperatures during combustion. Either reducing the concentrations of these elements or lowering peak cycle temperatures will reduce the amount of nitrous oxides produced. To achieve this, exhaust gas is piped from the exhaust manifold to the in-

take manifold. This dilutes the incoming fuel–air mixture and effectively lowers combustion temperature. The amount of recirculation is a function of throttle position but averages about 2 percent.

Manifold reactors are enlarged, insulated exhaust manifolds into which air is injected and in which exhaust gas continues to burn. The effectiveness of such units in experimental projects depends upon the amount of heat generated and the length of time the gas is within the manifold. Stainless steel and ceramic materials are used to provide durability at high operating temperatures (approaching 2,300° F [about 1,300° C]).

Fuel injection

Fuel injection, as a replacement for carburetion, has potential for reducing exhaust emissions. The precise metering of fuel for each cylinder provides a means of ensuring that the chemically correct air–fuel ratio is being burned in the engine. This eliminates cylinder-to-cylinder variations and the tendency of cylinders that are most remote from the carburetor to receive less fuel than is desired. A variety of metering and control systems are commercially available. A continuous-flow system was in use as early as 1957. Timed injection, in which a small quantity of gasoline is squirted into each cylinder or intake-valve port during the intake stroke of the piston, is employed on a number of European cars.

In one timed-injection system, individual pumps at each intake valve are regulated (timed) by an electronic controller. This unit monitors intake vacuum, engine temperature, ambient-air temperature, and throttle position and adjusts the time and duration of injection accordingly.

Another direction of emission control involved ignition performance. Unitized or solid-state ignition circuitry was introduced on some cars in the late 1960s to improve starting and ignition reliability and durability.

Another approach is the stratified charge engine, a variation from conventional cylinder combustion. Fuel is injected into a combustion-chamber pocket, and the nonhomogeneous, stratified charge is spark ignited. Operation is possible at very lean fuel–air ratios, thus permitting high thermal efficiency at light engine loads. This provides excellent reductions in exhaust hydrocarbons, carbon monoxide, and oxides of nitrogen. The primary problem with the system is to make it function over a wide range of speeds and loads with good transient response.

Future systems. Expansion of the total potential automotive market in the future and concern for the environment may be expected to change cars of the future. Special-purpose vehicles designed for specific urban or rural functions, with appropriate power systems for each type of use, may be needed. Possibilities include electric, steam, gas-turbine, nuclear, and other power sources.

In the early 1970s electric propulsion was possible for relatively short-range vehicles using power from batteries or fuel cells. Such systems powered vehicles used on the moon in 1971.

Conventional storage-battery systems do not possess high power-to-weight ratios for acceleration or energy-to-weight ratios for driving range to match gasoline-powered general purpose vehicles. Special-purpose applications, however, such as urban delivery vehicles, may be practical because of the excellent low-emission characteristics of the system. It may also be coupled with gasoline or other power sources to form a hybrid power plant with electric operation in cities and gasoline operation in less congested areas. Storage batteries having high power-to-weight ratios are under active development and may stimulate the production of electric cars in the future.

Steam power plants have been re-examined in the light of modern technology and new materials. The continuous-combustion process used to heat the steam generator offers potentially improved emission characteristics. Closed systems using vapours other than steam are also under active development, but further work is necessary to improve power-plant size, weight, and working fluid characteristics.

Gas turbines have been tested extensively and are expected to power high-speed, long-haul trucks and buses in the 1970s. Turbines have good torque characteristics, operate on a wide variety of fuels, have high power-to-weight ratios, and offer quiet operation. Studies have shown that the advantages of the system are best realized in heavy-duty vehicles operating on long, nearly constant speed runs. Successful designs require regenerative systems to recover energy from hot exhaust gas and transfer it to incoming air. This improves fuel economy, reduces exhaust temperatures to safer levels, and eliminates the need for a muffler in some designs.

Gas turbines

Nuclear energy offers the advantage of extremely low fuel weight. The obstacle for automotive use, however, is the great weight and volume of shielding required to protect the occupants from excessive nuclear radiation. This source can probably best be applied indirectly to produce stable chemical compounds or electricity, which could be converted to automotive uses.

A number of other energy-conversion systems have been studied for future automotive applications. Many of these are variations of engine combustion cycles such as turbocharged four-stroke, two-stroke, and diesel (two- and four-stroke). Free-piston and other geometric configurations, including rotary engines, offer other possibilities. Great interest has been shown in the Wankel, a type of rotary engine invented by Felix Wankel of Germany, and several auto manufacturers are conducting tests on the motor. In 1971, at least one company (Japanese) was manufacturing a Wankel-powered automobile.

Because the automobile promises to remain a part of the overall mobility system of modern man for some time to come, it requires continuing improvement in safety and emission control as well as in its older values of performance characteristics and economic contribution.

BIBLIOGRAPHY

Historical development: G.N. GEORGANO (ed.), *The Complete Encyclopedia of Motorcars, 1885–1968* (1968), the definitive work on the subject, copiously illustrated, covering some 4,000 makes of automobile; THE AUTOMOBILE QUARTERLY, *The American Car Since 1775* (1971), an exhaustive treatment of some 5,000 makes of car produced or projected in North America; LAWRENCE J. WHITE, *The Automobile Industry Since 1945* (1971), based on critical, scholarly research; NEW ENGLISH LIBRARY, *History of the Motorcar* (1971), a lavishly illustrated, brightly-written treatment of the self-propelled vehicle from Leonardo da Vinci to the present: T.R. NICHOLSON, *The World's Motor Museums* (1970), brief descriptions of some 170 museums wholly concerned with the motorcar.

Modern automobiles: WILLIAM H. CROUSE, *Automotive Mechanics*, 5th ed. (1965) and *Automotive Engine Design* (1970), provide a complete introductory course on each subject and cover the theory of operation and construction, maintenance, repair, and adjustment of automotive components, as well as their design. Important textbooks on the subject include: LESTER C. LICHTY, *Combustion Engine Processes* (1967), a technical book dealing particularly with fuels and combustion, carburetion and fuel injection, fuel properties, manifolding, and ignition, including the new transistorized systems; E.F. OBERT, *Internal Combustion Engines*, 3rd ed. (1968), which presents the fundamental and practical development of the application of science in the design of combustion engines, including material on pollution; M.W. STOCKEL, *Auto Mechanics Fundamentals* (1969), which contains basic information about various devices; C.F. and E.S. TAYLOR, *The Internal-Combustion Engine*, 2nd ed. (1961), which provides analytical methods that lead to a basic understanding of engine behaviour; and COLIN CAMPBELL, *The Sports Car: Its Design and Performance*, 2nd ed. rev. (1959), a discussion of the design and performance primarily of high-powered vehicles, sometimes called muscle cars, but with much broader fundamental information also included. Periodicals that provide much current information include: *Auto World*, a widely recognized semi-monthly Detroit publication largely dealing with developments in the automotive industry; *Automobile Engineer*, a monthly British publication that presents much international information; *Automotive Engineering*, the monthly journal of the Society of Automotive Engineers, a standard reference magazine in the industry; and *Automotive Industries*, a comprehensive semi-monthly magazine.

Automotive Industry

The term automotive industry is generally applied to all those companies and activities involved in the manufacture of motor vehicles, including most components, such as engines and bodies, but excluding tires, batteries, and fuel. The industry's principal product is passenger automobiles; commercial vehicles, though important, are secondary, and are discussed in the article TRUCKS AND BUSES.

The history of the automobile industry, while brief compared with many others, has exceptional interest because of its implications for 20th-century history. Though the automobile originated in Europe, the United States completely dominated the world industry for the first half of the century through the invention of mass-production techniques. In the second half of the century the situation altered sharply as the western European countries and Japan became major producers and exporters.

HISTORY OF THE AUTOMOTIVE INDUSTRY

Though steam-powered road vehicles were produced earlier, the origins of the automotive industry are rooted in the development of the gasoline engine (*q.v.*) in the 1860s and 1870s, principally in France and Germany. (For an account of the invention of the automobile, see AUTOMOBILE.) By the turn of the 20th century, German and French manufacturers had been joined by British, Italian, and United States makers.

Developments before World War I. The typical early automobile companies were small shops, hundreds of which produced a few hand-manufactured cars, and nearly all of which abandoned the business soon after going into it. The handful that survived into the era of large-scale production had certain characteristics in common.

Types of early shops
