Whereas applications of soft and hard ferrites exploit the properties of the hysteresis loop, the fundamental mechanism in microwave applications is interaction of electromagnetic waves with properly aligned, precessing (a motion at right angles to the direction of spin) electron spins in the crystal lattice. An applied adjustable magnetic field supplies the alignment; and the microwave energy, impinging on the ferrite at right angles to the magnetic field, causes the precession of spinning electrons, producing an effect similar to that of an array of spinning tops. The electron spins go through a gyromagnetic resonance phenomenon the frequency range of which increases as the strength of the magnetic field increases and lies somewhere in the microwave region. If

microwave  
applications

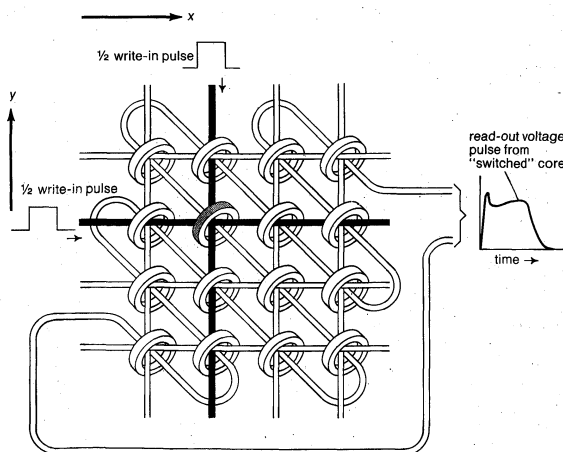

Figure 1: Array of ferrite cores wired for coincident memory use.

microwave energy of the proper sense of circular polarization interacts with a ferrite at its resonance frequency, much of the microwave energy will be absorbed. The frequency range over which this absorption takes place is very narrow, leading to the designation of low-loss ferrites as narrow line-width materials.

This highly selective absorption permits the ferrite to distinguish between forward and reverse propagation of microwave energy and to act as an isolator by absorbing energy flow in one direction while letting energy flowing in the other direction pass through essentially unattenuated, much as traffic on a one-way street.

If electric fields in a microwave signal are oriented in a specific direction (linearly polarized), this direction can be changed by transmission through a ferrite rod in a steady magnetic field, through an effect called Faraday rotation. The effect is nonreciprocal; *i.e.*, it can be used to distinguish between opposite directions of propagation. Because variation of the superimposed magnetic field changes the angle of rotation, electrically controlled microwave circuit elements such as switches and attenuators can be designed.

The ability to rotate electromagnetic field configurations and to distinguish between two directions of propagation have led to the invention of perhaps the most important and versatile microwave ferrite device, the junction circulator. Equally suitable for several different types of microwave transmission lines, this device functions somewhat like a traffic circle in which every traveller must leave by the first available exit. As shown in Figure 2, energy entering at port 1 emerges at port 2, energy en-

continue to be in isolators and circulators in which their unique nonreciprocal properties are exploited.

**Single-crystal ferrites.** Grown by conventional crystal-growing techniques, from liquid melt or by a flame fusion process, these ferrites have a spinel or garnet structure and various compositions. Of greatest practical importance are single-crystal rare-earth garnets grown in a flux of molten lead oxide. Because some of these crystals are transparent, their magnetic domains can be observed under a microscope. Other important properties are extremely narrow line width, as described above, and a highly nonlinear response to a microwave signal of increasing power. The narrow line width is used to build microwave filter circuits with tiny yttrium-iron garnet spheres. The nonlinear behaviour permits design of microwave power limiters that protect sensitive microwave circuits from prohibitively strong signals.

Other single-crystal rare-earth garnets have been grown on a substrate as thin plates with a preferred direction of magnetization perpendicular to the plate. In these plates, tiny round magnetic domains called bubbles can be formed by an applied magnetic field. These bubbles can be propagated, erased, manipulated, and detected. Thus, very compact devices can be built that perform binary (two-state) functions in computers including logic, memory, counting, and switching. Because the bubbles are extremely small in diameter, memory densities of one million bits (individual units of information) per square inch are possible. Manipulation of the bubbles proceeds at high speeds and requires little energy. A typical data rate is 3,000,000 bits per second.

The interaction of infrared and visible light with the electron spins in single-crystal ferrites is called the magneto-optic effect. This effect permits electronic modulation of a beam of light that propagates through a single-crystal garnet. Devices of this type are of great potential interest as possible modulators for laser beams.

**Production.** Ferrite materials are produced mainly in the United States, the Soviet Union, Great Britain, Japan, France, West Germany, and The Netherlands. Worldwide figures on ferrite production and consumption are not available because much of the material is produced and used in the same company, never reaching the open market.

In the United States, the estimated dollar volume for ferrite production rose from \$125,000,000 in 1966 to \$160,000,000 in 1970. An annual increase of 9 percent in production was forecast for the early 1970s. Manufacture of ferrite cores for computer memories accounted for 32 percent of the total in 1966. Hard ferrites for permanent magnets followed with 26 percent, soft ferrites for telephone applications with 13 percent, and microwave ferrites with 3 percent. The balance of 26 percent goes to soft ferrites for miscellaneous applications. Because research in materials and development of ferrite applications is continuing, production of ferrite materials is expected to increase for some time to come. Hard ferrites in small motors and generators for automobiles and single-crystal ferrites in computer applications may claim an increasing share of the market.

**BIBLIOGRAPHY.** Excellent discussions of ferrite materials are found in J. SMIT and H.P.J. WIJN, *Ferrites: Physical Properties of Ferrimagnetic Oxides in Relation to Their Technical Applications* (1959); and K.J. STANDLEY, *Oxide Magnetic Materials* (1962). Of more specialized interest is W.H. VON AULOCK (ed.), *Handbook of Microwave Ferrite Materials* (1965). Soft ferrites and their applications are covered in detail in E.C. SNELLING, *Soft Ferrites* (1969). Applications of square-loop ferrites to computer memories and logic circuits are discussed in C.J. QUARTLY, *Square-Loop Ferrite Circuitry* (1962). The physics of microwave ferrites and the theory of ferrite devices are covered in exhaustive detail in B. LAX and K.J. BUTTON, *Microwave Ferrites and Ferrimagnetics* (1962). Further information on microwave ferrite devices is found in two more recent books: W.H. VON AULOCK and C.E. FAY, *Linear Ferrite Devices for Microwave Applications* (1968); and J. HELSZAJN, *Principles of Microwave Ferrite Engineering* (1969). Advances in the state of the art of all types of ferrite materials and devices are recorded periodically in *IEEE Transactions on Magnetics*.

## Faraday rotation

Figure 2: Three-port junction circulator wave guide.

tering at port 2 leaves from port 3, and so on. Both three- and four-port circulators for radar and carrier telephony applications have been built in large numbers.

The effective permeability of the ferrite material for circularly polarized microwave signals can be varied by varying an external biasing (superimposed) magnetic field. This feature can be used to control the flow of microwave energy in switches and phase shifters. Both reciprocal and nonreciprocal control is possible. A relatively new class of ferrite devices takes advantage of the square-loop properties of certain ferrites similar to those discussed earlier. In these devices, the external biasing field is replaced by a current pulse on a wire threading a ferrite shaped like a rectangular toroid and placed in a wave guide. Pulsed into saturation, the ferrite retains its magnetization as if it had been inserted into a biasing field until a current pulse of opposite direction reverses the magnetization. Devices of this type can insert a phase shift of fixed magnitude into a microwave circuit. They have been used for electronic steering of a radar beam.

A variable biasing field can be used to change the microwave permeability in a ferrite that is part of a tuned circuit. Thus, remote electronic tuning becomes possible. In applications of this type, however, ferrites must compete with other elements such as semiconductor diodes.

garnets

## Ferromagnetism

Ferromagnetism is the phenomenon in which certain electrically uncharged materials strongly attract others. Two materials found in nature, lodestone or magnetite (an oxide of iron,  $\text{Fe}_3\text{O}_4$ ) and iron, possess or have the ability to acquire such attractive powers, and they are often called natural ferromagnets. They were discovered over 2,000 years ago, and all early scientific studies of magnetism were conducted on these materials.

Ample evidence exists that some atoms or ions, depending on their electronic structure, have a permanent magnetic moment,  $\mu$ . This moment may be pictured as a dipole consisting of a positive, or north pole, of strength  $m$  separated from a negative, or south, pole  $-m$  by a distance  $d$  and with  $\mu = md$ . In ferromagnets, which need not contain iron, the large coupling between the atomic magnetic moments leads to some degree of dipole alignment and hence to a net magnetization,  $M$ , the magnetic moment per unit volume. Presence of a spontaneous magnetization, from which the attractive property originates, has sometimes been used as the definition of a ferromagnet. Mainly since 1950, however, research on ferromagnetic metals, alloys, semiconductors, and insulators has shown that a variety of arrangements of the atomic moments occurs and, therefore, further classifications have been made to distinguish the different kinds of ferromagnets.

**Magnetic order.** The principal types of magnetic ordering found in solids are illustrated in Figure 1. In the clas-

Figure 1: Principal types of magnetic ordering in various solids identified by their chemical formulas. Subscripts  $H$  and  $L$  refer to temperatures higher and lower than that required for ferromagnetic ordering;  $I$  indicates intermediate temperature (see text).

sical concept of a ferromagnet, the dipole moments were envisaged to be aligned parallel by the strong coupling (Figure 1A). This is indeed the magnetic arrangement found for the elemental metals iron (Fe), nickel (Ni), and cobalt (Co) and for their alloys with one another and with some other elements. These materials still constitute the largest group of ferromagnets used in applications (see MAGNETS AND ELECTROMAGNETS). The other elements that possess a colinear ordering are the rare-earth metals gadolinium (Gd), terbium (Tb), and dysprosium (Dy), but the last two become ferromagnets only well below room temperature. Some alloys, although not composed of any of the elements just mentioned, nevertheless have a parallel moment arrangement. Examples are the Heusler alloy  $\text{CuAlMn}$ , and  $\text{MnAs}$ , where the manganese (Mn) atoms have magnetic moments; manganese metal itself is not ferromagnetic.

Since 1950, and particularly since 1960, several ionically bound compounds have been discovered to be ferromag-

netic, many with a parallel moment structure. Some of these compounds are electrical insulators; others have a conductivity of magnitude typical of semiconductors. The compounds investigated to date include oxides, chalcogenides (sulfur [S], selenium [Se], tellurium [Te]), halides (fluorine [F], chlorine [Cl], bromine [Br], iodine [I]), and their combinations. (Examples are  $\text{La}_{0.7}\text{Pb}_{0.3}$ ,  $\text{MnO}$ ,  $\text{CuCr}_2\text{Se}_4$ ,  $\text{CdCr}_2\text{S}_4$ ,  $\text{CrBr}_3$ ,  $\text{EuO}$ ,  $\text{EuS}$ , and  $\text{EuSe}$ , of which only  $\text{CrBr}_3$  is an insulator.) The ions with permanent dipole moments in these materials are manganese (Mn), chromium (Cr), and europium (Eu); the others are diamagnetic.

At low temperatures, the rare-earth metals holmium (Ho) and erbium (Er) have a nonparallel moment arrangement that gives rise to a substantial spontaneous magnetization. These solids have a hexagonal crystal structure in which the atoms are packed in layers called the basal plane; the direction perpendicular to this plane is known as the  $c$ -axis. The atomic moments have a conical or spiral structure about the axis, which corresponds to the vertical direction in the diagrams of Figure 1B. Clearly there is a net moment in the  $c$ -direction, whereas in the basal plane the components of the moments average to zero. Some ionic compounds with the spinel crystal structure (for example,  $\text{HgCr}_2\text{S}_4$  and possibly  $\text{CdCr}_2\text{S}_4$ ) also possess a spiral ferromagnetic ordering.

A different structure leads to a spontaneous magnetization in thulium (Tm) below  $32^\circ\text{K}$ , which can be represented by a longitudinal wave, or antiphase structure, in which three atomic moments point "up" along the  $c$ -axis for each four that point "down" (Figure 1C).

In some solids, the strong coupling between the atomic dipoles favours an antiparallel arrangement. As originally conceived by L. Néel, these materials would consist of two sublattices, one with atomic moments aligned antiparallel to those of the other. If the magnetic moments of the two sublattices are equal (Figure 1D), the net moment of the material will be zero. Such materials are called antiferromagnets. It has been established that many solids have this simple antiparallel ordering, including manganese oxide ( $\text{MnO}$ ), cobalt oxide ( $\text{CoO}$ ), nickel oxide ( $\text{NiO}$ ), manganese fluoride ( $\text{MnF}_2$ ), chromium oxide ( $\text{Cr}_2\text{O}_3$ ), iron sulfide ( $\text{FeS}$ ), iron chloride ( $\text{FeCl}_2$ ), and copper chloride hydrate ( $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ ) (see MAGNETISM).

If the two sublattices have differing magnetizations, however, a spontaneous magnetization results (Figure 1E); this phenomenon is known as ferrimagnetism. Lodestone is actually a ferrimagnet. (Other examples are  $\text{NiFe}_2\text{O}_4$ ,  $\text{MnFe}_2\text{O}_4$ ,  $\text{CoFe}_2\text{O}_4$ , and  $\text{Y}_3\text{Fe}_5\text{O}_{12}$ , which are often referred to as ferrites.) Because most ferrimagnetic materials have low electrical conductivity and sizeable magnetizations, they have numerous applications in high-frequency devices (see FERRITES). The concept of ferrimagnetism has been broadened to include materials with more than two sub-lattices (the rare-earth iron garnets) and with the triangular moment arrangement shown in Figure 1F (note that the net magnetization is nonzero).

In some simple two sublattice antiferromagnets there exists an additional interaction that tilts the atomic moments towards each other, as depicted in Figure 1G. As a result, there is a small spontaneous magnetization. Materials with this structure are often said to possess parasitic or weak ferromagnetism and are a type of antiferromagnet. Examples include rust or hematite, rhodochrosite, and the rare-earth orthoferrites. Weak ferromagnetism can also be produced in some antiferromagnets by the application of an external stress; this effect, called piezomagnetism, has been detected in the fluorides of manganese and cobalt.

More complex antiferromagnetic structures, for which the spontaneous magnetization is zero, have been observed. The helical arrangement of Figure 1H is found for terbium (Tb), dysprosium (Dy), and holmium (Ho) metals in a temperature range above that required for ferromagnetic ordering, the oblique helix of Figure 1I for erbium between  $20^\circ$  and  $54^\circ\text{K}$ , and the oscillatory longitudinal wave of Figure 1J for erbium between  $54^\circ$  and

Ferromagnetic substances

85° K and for thulium between 40° and 56° K. (This list does not exhaust all the possibilities.)

**Sources of ferromagnetism.** The permanent magnetic moment of atoms or ions has two possible sources: the motion of the electrons about their atomic nucleus (orbital angular momentum) and the rotation of the electron about its own axis (spin angular momentum). The plane of an electron's orbit can have only certain orientations, and as a consequence the magnetic moment along a specified direction, usually the direction of an applied magnetic field, is some integral multiple of a basic atomic unit, the Bohr magneton, that is equal to one-half the product of the electronic charge and  $h$ -bar (Planck's constant divided by  $2\pi$ ) divided by the product of the electron mass and the velocity of light, or  $\mu_B = e\hbar/2mc$  ( $-9.274 \times 10^{-21}$  erg/gauss), in which  $\mu_B$  is the Bohr magneton,  $e$  is the electronic charge,  $\hbar$  is Planck's constant/ $2\pi$ ,  $m$  is the electron mass, and  $c$  is the velocity of light. The component of magnetic moment along the field direction associated with an electron's spin is almost equal to one Bohr magneton. Only atoms or ions with an unfilled shell have a nonzero total angular momentum and therefore a magnetic moment. Elements in the periodic table important in ferromagnetism are some of the iron group with unfilled 3d shells and the rare-earth group with unfilled 4f shells. With iron group atoms or ions, the internal electrostatic fields in solids reduce or eliminate the orbital contribution to the moment, whereas for the rare-earth elements both the orbital and spin angular momentum contribute.

A magnetic structure that is not collinear can be inferred if the measured magnetization is less than that expected for complete alignment of the atomic dipoles. The most information on structure, however, has been obtained from neutron diffraction studies. A neutron, although electrically neutral, has a nuclear spin and hence a magnetic dipole moment. The interaction of the dipole moment of a neutron with the electronic dipole moment of an atom will produce magnetic scattering. In a magnetically ordered material, the scattering is coherent, and lines characteristic of the magnetic structure appear in the diffraction pattern. Other techniques useful for the determination of spin ordering are nuclear magnetic resonance ( $q.v.$ ) and the Mössbauer effect ( $q.v.$ ); both these methods depend on the hyperfine interaction between the electronic and nuclear magnetic moments.

**Domain structure.** Ferromagnets have another type of magnetic order of a more macroscopic nature, postulated by Pierre-Ernest Weiss, and called domain structure. For simplicity, consider a ferromagnet with collinear order and suppose that the configuration of Figure 2A occurs.

Figure 2: Domain structure in ferromagnetic material (see text).

Magnetic poles appear on the specimen's ends, and a magnetic field is established in the surrounding space, as indicated by the flux lines. The magnetostatic energy associated with the field can be reduced if two antiparallel regions, called domains, appear (Figure 2B). The transition region between the domains is called a domain wall, and its introduction requires energy. The preferred, or stable, configuration will be the one with minimum total free energy. Some domain configurations reduce the magnetostatic energy to zero; an example is given in Figure 2C. The net magnetization is also zero. Basically this is the way some ferromagnets, such as soft iron, may be in an unmagnetized state.

Domain structure can be observed directly. In one technique, a colloidal solution of small magnetic particles, usually magnetite, is placed on the surface of a ferromagnet. When surface poles are present, the particles tend to concentrate in certain regions to form a pattern, which is readily observed with an optical microscope. Patterns with some regularity are only observed on well-polished surfaces of single crystals. Iron whiskers contain relatively few imperfections, and indeed are the nearest things to perfect crystals known. Even weak ferromagnets that have a small magnetostatic energy, such as hematite ( $\text{Fe}_2\text{O}_3$ ), have a domain structure. Domain patterns have also been observed with polarized light, polarized neutrons, electron beams, and X-rays.

**Ferromagnets in an external magnetic field.** To consider the effect of applying an external magnetic field, first suppose the domain structure is such that the net magnetization of the ferromagnet averages to zero (the origin [O] of Figure 3). When a field is present, a domain

The techniques of observation

Figure 3: Magnetization curve OABC and hysteresis loop CDEFG of a typical ferromagnet. Each material has a curve that differs only in detail from the general one.

with magnetization direction parallel to the field direction has the lowest energy. As a consequence the domain walls tend to move in order to enlarge the volumes of the favourably oriented domains. The net magnetization in the field direction ( $M_H$ ) increases in the manner indicated by the curve OAB in Figure 3. For the instep region of the curve, OA, the wall motion is reversible; that is, on removal of the field the domain walls return to their initial positions. At higher fields, between A and the knee of the curve at B, the domain walls are displaced beyond internal energy barriers that arise from nonmagnetic inclusions or inhomogeneous strains. Then, on decreasing the field, the walls do not return to their previous location—that is, the motion is irreversible, and energy is required. At still higher fields (region BC), the domain walls may be almost or entirely removed; further increase in  $M_H$  may then occur by rotation of the domain's magnetization toward the field direction. At C the specimen is a single-domain with magnetization direction parallel to the field  $H$ . The magnetization then has its saturation value and is essentially equal to the spontaneous magnetization within a domain. By performing the sequence of operations of reducing the field to zero, increasing it in the reverse direction, decreasing it to zero, and then increasing it to the initial value, the curve CDEFGC, known as a hysteresis curve or loop, is obtained. The work performed on taking the ferromagnet through one cycle is equal to the area enclosed by the loop.

Ferromagnetic materials are often described by quantities associated with the curves of Figure 3. The magne-

tization at point *D* is called the remanence,  $M_r$ , and the field at point *E* the coercive force,  $H_c$ . The susceptibility,  $\chi$  (chi), defined as the ratio of the net magnetization in the field direction to the magnetic field, or  $M_H/H$ , has an initial value given by the slope of  $\bar{O}x$  and a maximum value given by the slope of  $\bar{O}y$ .

No domain structure may be possible in a ferromagnet that is a very small particle; instead it will be a single domain even in a zero applied field. The only way the magnetization can be changed is by rotations. These rotations will be difficult and require a large applied field if, for example, the particle is needlelike in shape.

A material composed of aligned particles makes an excellent permanent magnet. Alnico, an alloy, is believed to owe its good permanent magnet properties to aligned rodlike ferromagnetic precipitates. Recently developed materials with superior permanent magnet characteristics are combinations of cobalt with platinum and with samarium, PtCo and SmCo<sub>5</sub>.

It is sometimes possible to change the moment arrangement with applied fields, depending, of course, on whether or not a state of lower free energy will be achieved. For bromides and chlorides of iron, cobalt, and nickel (FeBr<sub>2</sub>, CoCl<sub>2</sub>, NiCl<sub>2</sub>) and others in which adjacent ferromagnetic layers are arranged antiferromagnetically via a weak coupling, a sufficiently large magnetic field produces a transition from the antiferromagnetic to the ferromagnetic state. This phenomenon is often called metamagnetism. When a field is applied parallel to the axis of a simple antiferromagnet (collinear with the moments of Figure 1D), at a certain critical value the moments will rotate through 90°. This change from parallel to perpendicular orientation is called spin flopping. A type of spin flop or metamagnetic behaviour may also be observed in a helical spin system; examples are manganese gold (MnAu<sub>2</sub>), dysprosium (Dy), holmium (Ho), and erbium (Er).

**The temperature dependence of ferromagnetism.** Above a critical temperature, called the Curie temperature,  $T_f$ , the spontaneous magnetization vanishes. At the Curie point the thermal energy, or Boltzmann constant times the Curie temperature—i.e.,  $kT$ —is sufficient to overcome the internal aligning forces. The Curie temperatures for some important ferromagnets are: iron (Fe), 1,043° K; cobalt (Co), 1,388° K; nickel (Ni), 631° K; gadolinium (Gd), 289° K; and dysprosium (Dy), 85° K.

Above the Curie point, the ferromagnetic material becomes a paramagnet. For temperatures a few degrees above the Curie temperature, the inverse susceptibility ( $1/\chi$ ) of many materials including iron (Fe), nickel (Ni), cobalt (Co), and gadolinium (Gd), is a linear function of the temperature described excellently by the Curie-Weiss law: the inverse susceptibility is equal to the difference of the absolute temperature and the paramagnetic Curie point, divided by the Curie constant.

$$\frac{1}{\chi} = \frac{T - \theta}{C}$$

in which  $1/\chi$  is the inverse susceptibility,  $T$  is the absolute temperature,  $\theta$  is the paramagnetic Curie point, and  $C$  is the Curie constant. The intercept with the  $T$ -axis, when the susceptibility is plotted versus the absolute temperature, is the paramagnetic Curie point, and has the values 1,093° K, 1,428° K, and 650° K for iron (Fe), cobalt (Co), and nickel (Ni), respectively. Just above the Curie point, a small curvature, concave upward, appears in the plot of  $1/\chi$  versus  $T$ . This effect is believed to be the result of order persisting within small atomic groups. Data from other measurements, including that of specific heat, support this short-range order theory.

Although below the ordering temperature ( $T_f$ ) the spontaneous magnetization is nonzero, only at absolute zero are all the atomic moments or spins aligned parallel in a collinearly ordered ferromagnet. Just above  $T = 0^\circ$  K, the thermal energy ( $kT$ ) may reverse the direction of an atomic spin. If so, this reversed spin will not remain localized at one atom, but instead will travel from one

atom to another to form a spin wave, or magnon. As the temperature is raised further, more spin waves are created and the spontaneous magnetization decreases, slowly at first but then rapidly as the Curie temperature is approached. Experimentally, the saturation magnetization is measured and the spontaneous magnetization obtained by extrapolation to zero applied field. The difference between the spontaneous and saturation magnetization is negligible except near the Curie point, where the difference is about 1 percent. The variation of the spontaneous magnetization with increasing temperature observed for iron, cobalt, and nickel is shown in Figure 4 below.

Figure 4: The change of spontaneous magnetization with temperature.

The theoretical curves correspond to different values of spin momenta ( $J = 1/2, 1$ , and  $\infty$ ,  $J = 1/2$  being the best fit to experimental data). Magnetization at temperature  $T$  [i.e.,  $M(T)$ ] is expressed as a fraction of magnetization at absolute zero [ $M(T)/M(0)$ ]; temperature is expressed as a fractional value of the Curie temperature ( $T_f$ ).

**Theories of ferromagnetism.** One of the primary objectives in a theory of ferromagnetism is to understand the strong interactions that produce the magnetic ordering. The idea that each atom or molecule has a permanent magnetic moment was first proposed by W.E. Weber in 1852. Then, in 1890, J.A. Ewing assumed that atomic magnets interacted via the same magnetic forces (now often called the dipole-dipole interaction) that enter in the attraction and repulsion of laboratory or household-sized bar magnets. Ewing showed from calculations and from models composed of many small bar magnets that magnetization curves and hysteresis loops with the shape of those shown in Figure 3 were obtained.

The magnetic forces considered by Ewing, however, are not large enough to create ferromagnetic alignment; this fact was recognized by P. Weiss who, in 1907, postulated the existence of a large internal magnetic field, which he called the molecular field ( $H_m$ ). Although Weiss did not concern himself with the origin of the molecular field, he assumed it was proportional to the (spontaneous) magnetization ( $M$ ) and was equal to a constant due to the molecular field (called the Weiss constant) times the magnetization, or  $H_m = N_w M$ , in which  $H_m$  is the molecular field,  $N_w$  is the Weiss constant, and  $M$  is the magnetization. Earlier, in 1905, P. Langevin had derived an expression for the magnetization of a paramagnet when an external magnetic field is applied (see MAGNETISM). In addition to the external field, Weiss substituted the molecular field into Langevin's expression and obtained the curve marked  $J = \infty$  in Figure 4 for the magnetization as a function of the temperature. With the advent of quantum mechanics, it became clear that the angular momenta, and hence the magnetic moment,

Ewing's contribution

Origin  
of the  
molecular  
field

of the atomic electrons could not take any possible orientation but instead were spatially quantized. As a consequence, Langevin's expression required modification to one derived by L. Brillouin in 1927 in which  $J$  is a quantum number that characterizes the angular momentum. The temperature dependence of the magnetization for  $J = \frac{1}{2}$  and  $J = 1$  is shown in Figure 4. The best fit to the experimental data is obtained for  $J = \frac{1}{2}$ , which corresponds to the spin angular momentum of one electron.

The origin of the molecular field remained obscure until a German physicist, Werner Heisenberg, in 1928, showed that it was the result of the quantum-mechanical exchange interaction. This exchange interaction has no classical analog. Consider two atoms, each with a magnetic moment of one Bohr magneton because one electron's spin is unpaired. Suppose there is an interaction between the two unpaired electrons. Because the two electrons are indistinguishable, when they are interchanged an energy term occurs known as the exchange integral, or constant,  $J_e$ . To have ferromagnetism,  $J_e$  must be positive. The magnitude and sign of  $J_e$  depend on the distance between the two atoms. In accordance with an analysis made by Hans A. Bethe in Germany, a positive  $J_e$  is most likely if the interatomic spacing is large compared to the radius of the electron's orbit. Thus, this condition is met in iron, nickel, cobalt, and gadolinium metals and almost, although not quite, in manganese and chromium metals. The increase in the interatomic spacing of some manganese and chromium alloys, however, leads to ferromagnetism. Of course, an equation relating the exchange constant,  $J_e$ , and the molecular field constant,  $N_W$ , can be derived.

In the Heisenberg model, the electrons that contribute to the magnetic moment are assumed to be localized at the atoms. Metals are good electrical conductors, however, and hence, it is necessary to consider that the electrons may be mobile and able to move throughout the crystal lattice (see METALS, THEORY OF). E.C. Stoner, in 1938, developed the collective electron theory of ferromagnetism for itinerant electrons in the 3d band; he assumed that the exchange interaction between the electrons could be represented by a molecular field. Good agreement with the experimental data for iron and nickel was achieved. Current opinion appears to favour the view that the magnetic electrons for both iron and nickel are itinerant. On the other hand, the 4f electrons of the rare-earth metals are believed to be localized. Even here, however, the interaction between the 4f electrons on adjacent atoms is believed to proceed via the conduction electrons (the outer 6s-5d electrons), which become polarized; that is, more conduction electrons have their spins parallel than antiparallel.

In many calculations of the exchange interaction, only adjacent atoms are considered. It is now clear that in some materials, for example, those with spiral ordering, atoms farther away must be considered. In compounds such as the oxides and the chalcogenides, the atoms with a magnetic moment are separated by a nonmagnetic atom or anion (for example, oxygen  $[O^{2-}]$  and sulfur  $[S^{2-}]$ ). It is believed that the coupling proceeds via the intermediate anion, and it is known as the superexchange interaction. Even with a better knowledge of the functions that describe the state of an atom and the employment of modern digital computers, calculations of the exchange energy still leave much to be desired and continue to be an active area of investigation.

Crystal  
structure  
and  
magnetism

Thus far the magnetization has been treated as though it has no preferred orientation with respect to the crystal axes. The electron orbits, however, reflect the symmetry of the lattice because of the crystalline electric field and the overlap of the orbits of adjacent atoms. Therefore, the atomic moments tend to lie only along certain directions; for example, the preferred or easy direction for a single crystal of iron is along the cube edge, whereas for nickel it is along the cube diagonal. Within a domain, the magnetization will lie along the easy direction, provided that other factors, such as strain, are absent. In some materials, the crystalline anisotropy (physical char-

acteristics differing greatly from different directions) may be very large; in some rare-earth metals it is larger than the exchange energy and must be included in an analysis of the magnetic ordering. The magnetic or dipole-dipole interaction is also anisotropic, though usually smaller than the crystalline anisotropy. In recent years, more complex magnetic systems have been discovered and studied; an interpretation of their properties has required the extension of existing theories and the inclusion of all pertinent, and some new, interactions.

**BIBLIOGRAPHY.** Classical treatments of the subject include: J.H. VAN VLECK, *Theory of Electric and Magnetic Susceptibilities* (1932); R. BECKER and W. DÖRING, *Ferromagnetismus* (1939), in German; E. KNELLER, *Ferromagnetismus* (1962), an updating and revision of the work by Becker and Döring, also in German; and E.C. STONER, *Magnetism and Matter* (1934), on a more elementary level than those previously cited. A.H. MORRISH, *The Physical Principles of Magnetism* (1965); D.H. MARTIN, *Magnetism in Solids* (1967); and S. CHIKAZUMI and S.H. CHARAP, *Physics of Magnetism* (1964), are general texts, the last more technologically oriented. Experiments and apparatus have been described by L.F. BATES, in *Modern Magnetism*, 4th ed. (1961); extensive experimental data in R.M. BOZORTH, *Ferromagnetism* (1951). For an elementary and pictorial treatment of domains, see D.J. CRAIK and R.S. TEBBLE, *Ferromagnetism and Ferromagnetic Domains* (1965). Advanced theoretical work may be found in D.C. MATTIS, *The Theory of Magnetism: An Introduction to the Study of Coop. Phenomena* (1965); and in the multi-volume reference work by G.T. RADO and H. SUHL (eds.), *Magnetism: A Treatise on Modern Theory and Materials* (1963-67).

## Fertilization

Fertilization, the completion of the cycle of sexual reproduction, may be formally defined as the union of a spermatozoal nucleus, of paternal origin, with an egg nucleus, of maternal origin, to form the primary nucleus of an embryo. In all organisms the essence of fertilization is, in fact, the fusion of the hereditary material of two different sex cells, or gametes, each of which carries half the number of chromosomes typical of the species. The most primitive form of fertilization, found in microorganisms and protozoans, consists of an exchange of genetic material between two cells.

**Summary of events.** The first significant event in fertilization is the fusion of the membranes of the two gametes resulting in the formation of a channel that allows the passage of material from one cell to the other. Fertilization in advanced plants is preceded by pollination, during which pollen is transferred to, and establishes contact with, the female gamete or macrospore. Fusion in advanced animals is usually followed by penetration of the egg by a single spermatozoon. The result of fertilization is a cell (zygote) capable of undergoing cell division to form a new individual.

The fusion of two gametes initiates several reactions in the egg. One of these causes a change in the egg membrane(s), so that the attachment of and penetration by more than one spermatozoon cannot occur. In species in which more than one spermatozoon normally enters an egg (polyspermy), only one spermatozoal nucleus actually merges with the egg nucleus. The most important result of fertilization is egg activation, which allows the egg to undergo cell division. Activation, however, does not necessarily require the intervention of a spermatozoon; during parthenogenesis, in which fertilization does not occur, activation of an egg may be accomplished through the intervention of physical and chemical agents. Invertebrates such as aphids, bees, and rotifers normally reproduce by parthenogenesis.

In plants certain chemicals produced by the egg may attract spermatozoa. In animals, with the possible exception of some coelenterates, it appears likely that contact between eggs and spermatozoa depends on random collisions. On the other hand, the gelatinous coats that surround the eggs of many animals exert a trapping action on spermatozoa, thus increasing the chances for successful sperm-egg interaction (see also REPRODUCTION).

The eggs of marine invertebrates, especially echino-

derms, are classical objects for the study of fertilization. These transparent eggs are valuable for studies observing living cells and for biochemical and molecular investigations because the time of fertilization can be accurately fixed, the development of many eggs occurs at about the same rate under suitable conditions, and large quantities of the eggs are obtainable. The eggs of some teleosts and amphibians also have been used with favourable results, and techniques for fertilization of mammalian eggs in the laboratory may allow their use even though only small numbers are available.

**Characteristics of the mature egg.** Maturation is the final step in the production of functional eggs (oogenesis) that can associate with a spermatozoon and develop a reaction that prevents the entry of more than one spermatozoon; in addition, the cytoplasm of a mature egg can support the changes that lead to fusion of spermatozoal and egg nuclei and initiate embryonic development.

**Egg surface.** Certain components of an egg's surface, especially the cortical granules, are associated with a mature condition. Cortical granules of sea urchin eggs, aligned beneath the plasma membrane (thin, soft, pliable layer) of mature eggs, have a diameter of 0.8–1.0 micron (0.0008–0.001 millimetre) and are surrounded by a membrane similar in structure to the plasma membrane surrounding the egg. Cortical granules are formed in a cell component known as a Golgi complex, from which they migrate to the surface of the maturing egg.

The surface of a sea urchin egg has the ability to affect the passage of light unequally in different directions; this property, called birefringence, is an indication that the molecules comprising the surface layers are arranged in a definite way. Since birefringence appears as an egg matures, it is likely that the properties of a mature egg mem-

brane are associated with specific molecular arrangements. A mature egg is able to support the formation of a zygote nucleus; *i.e.*, the result of fusion of spermatozoal and egg nuclei. In most eggs the process of reduction of chromosomal number (meiosis) is not completed prior to fertilization. In such cases the fertilizing spermatozoon remains beneath the egg surface until meiosis in the egg has been completed, after which changes and movements that lead to fusion and the formation of a zygote occur.

**Egg coats.** The surfaces of most animal eggs are surrounded by envelopes, which may be soft, gelatinous coats (as in echinoderms and some amphibians) or thick membranes (as in fishes, insects, and mammals). In order to reach the egg surface, therefore, spermatozoa must penetrate these envelopes; indeed, spermatozoa contain enzymes (organic catalysts) that break them down. In some cases (*e.g.*, fishes and insects) there is a channel, or micropyle, in the envelope, through which a spermatozoon can reach the egg.

The jelly coats of echinoderm and amphibian eggs consist of complex carbohydrates called sulfated mucopolysaccharides; it is not yet known if they have a species-specific composition. The envelope of a mammalian egg is more complex. The egg is surrounded by a thick coat composed of a carbohydrate protein complex called zona pellucida. The zona is surrounded by an outer envelope, the corona radiata, which is many cell layers thick and formed by follicle cells adhering to the oocyte before it leaves the ovarian follicle.

Although it once was postulated that the jelly coat of an echinoderm egg contains a substance (fertilizin) thought to have an important role not only in the establishment of sperm-egg interaction but also in egg activation, fertilizin now has been shown identical with jelly-coat material, rather than a substance continuously secreted from it. Yet there is evidence that the egg envelopes do play a role in fertilization; *i.e.*, contact with the egg coat elicits the acrosome reaction (described below) in spermatozoa.

**Events of fertilization. Sperm-egg association.** The acrosome reaction of spermatozoa is a prerequisite for the association between a spermatozoon and an egg (Figure 2), which occurs through fusion of their plasma membranes. After a spermatozoon comes in contact with an egg (2A), the acrosome, which is a prominence at the anterior tip of the spermatozoa, undergoes a series of well-defined structural changes. A structure within the acrosome, called the acrosomal vesicle (labeled a), bursts, and the plasma membrane (labeled s) surrounding the spermatozoon fuses at the acrosomal tip with the membrane surrounding the acrosomal vesicle to form an opening (2B). As the opening is formed, the acrosomal granule (labeled g), which is enclosed within the acrosomal vesicle, disappears. It is thought that dissolution of the granule releases a substance called a lysin, which breaks down the egg envelopes, allowing passage of the spermatozoon to the egg. The acrosomal membrane region opposite the opening adheres to the nuclear envelope of the spermatozoon and forms a shallow outpocketing, which rapidly elongates into a thin tube, the acrosomal tubule (labeled t) that extends to the egg surface and fuses with the egg plasma membrane (2C, 2D). The tubule thus formed establishes continuity between the egg and the spermatozoon and provides a way for the spermatozoal nucleus to reach the interior of the egg. Other spermatozoal structures that may be carried within the egg include the midpiece and part of the tail; the spermatozoal plasma membrane and the acrosomal membrane, however, do not reach the interior of the egg. In fact, whole spermatozoa injected into unfertilized eggs cannot elicit the activation reaction or merge with the egg nucleus. As the spermatozoal nucleus is drawn within the egg, the spermatozoal plasma membrane breaks down; at the end of the process, the continuity of the egg plasma membrane is re-established. This description of the process of sperm-egg association, first documented for the acorn worm *Saccoglossus* (phylum Enteropneusta), generally applies to most eggs studied thus far.

During their passage through the female genital tract of mammals, spermatozoa undergo physiological change,

Acrosome reaction

Cortical granules

From Colwin and Colwin, *Journal of Cell Biology*, vol. 19 (December 1963)

called capacitation, which is a prerequisite for their participation in fertilization; they are able to undergo the acrosome reaction, traverse the egg envelopes, and reach the interior of the egg. Dispersal of cells in the outer egg envelope (corona radiata) is caused by the action of an enzyme (hyaluronidase) that breaks down a substance (hyaluronic acid) binding corona radiata cells together. The enzyme may be contained in the acrosome and released as a result of the acrosome reaction, during passage of the spermatozoon through the corona radiata. The reaction is well advanced by the time a spermatozoon contacts the thick coat surrounding the egg itself (zona pellucida). The pathway of a spermatozoon through the zona pellucida appears to be an oblique slit.

Association of a mammalian spermatozoon with the egg surface occurs along the lateral surface of the spermatozoon, rather than at the tip as in other animals, so that the spermatozoon lies flat on the egg surface; several points of fusion occur between the plasma membranes of the two gametes (*i.e.*, the breakdown of membranes occurs by formation of numerous small vesicles).

**Specificity of sperm-egg interaction.** Although fertilization is strictly species-specific, very little is known about the molecular basis of such specificity. The egg coats may have a role. Among the echinoderms solutions of the jelly coat clump, or agglutinate, only spermatozoa of their own species. In both echinoderms and amphibians, however, slight damage to an egg surface makes fertilization possible with spermatozoa of different species (heterologous fertilization); this procedure has been used to obtain certain hybrid larvae.

The eggs of ascidians, or sea squirts, members of the chordate subphylum Tunicata, are covered with a thick membrane called a chorion; the space between the chorion and the egg is filled with cells called test cells. The gametes of ascidians, which have both male and female reproductive organs in one animal, mature at the same time; yet self-fertilization does not occur. If the chorion and the test cells are removed, however, not only is fertilization with spermatozoa of different species possible, but self-fertilization also can occur.

**Prevention of polyspermy.** Most animal eggs are monospermic; *i.e.*, only one spermatozoon is admitted into an egg. In some eggs, protection against the penetration of the egg by more than one spermatozoon (polyspermy) is due to some property of the egg surface; in others, however, the egg envelopes are responsible. The

ability of some eggs to develop a polyspermy-preventing reaction depends on a molecular rearrangement of the egg surface that occurs during egg maturation (oogenesis). Although immature sea urchin eggs have the ability to associate with spermatozoa, they also allow multiple penetration; *i.e.*, they are unable to develop a polyspermy-preventing reaction. Since the mature eggs of most animals are fertilized before completion of meiosis and are able to develop a polyspermy-preventing reaction, specific properties of the egg surface must have differentiated by the time meiosis stops, which is when the egg is ready to be fertilized.

In some mammalian eggs defense against polyspermy depends on properties of the zona pellucida; *i.e.*, when a spermatozoon has started to move through the zona, it does not allow the penetration of additional spermatozoa (zona reaction). In other mammals, however, the zona reaction either does not take place or is weak, as indicated by the presence of numerous spermatozoa in the space between the zona and egg surface. In such cases the polyspermy-preventing reaction resides in the egg surface. Although the eggs of some animals (*e.g.*, some amphibians, birds, reptiles, and sharks) are naturally polyspermic, only one spermatozoal nucleus fuses with an egg nucleus to form a zygote nucleus; the other spermatozoa degenerate.

**Formation of the fertilization membrane.** The most spectacular changes that follow fertilization occur at the egg surface. The best known example, that of the sea urchin egg, is described below. An immediate response to fertilization is the raising of a membrane, called a vitelline membrane, from the egg surface. In the beginning the membrane is very thin; soon, however, it thickens, develops a well-organized molecular structure, and is called the fertilization membrane. At the same time an extensive rearrangement of the molecular structure of the egg surface occurs. The events leading to formation of the fertilization membrane require about one minute.

At the point on the outer surface of the sea urchin egg at which a spermatozoan attaches, the thin vitelline membrane becomes detached. As a result the membranes of the cortical granules (*cg*, see Figure 2F) come into contact with the inner aspect of the egg's plasma membrane and fuse with it, the granules open, and their contents are extruded into the perivitelline space; *i.e.*, the space between the egg surface and the raised vitelline membrane. Part of the contents of the granules merge with the

Effects on  
membrane  
properties

vitelline membrane to form the fertilization membrane; if fusion of the contents of the cortical granules with the vitelline membrane is prevented, the membrane remains thin and soft. Another material that also derives from the cortical granules covers the surface of the egg to form a transparent layer, called the hyaline layer, which plays an important role in holding together the cells (blastomeres) formed during division, or cleavage, of the egg. The plasma membrane surrounding a fertilized egg, therefore, is a mosaic structure containing patches of the original plasma membrane of the unfertilized egg and areas derived from membranes of the cortical granules. The events leading to the formation of the fertilization membrane are accompanied by a change of the electric charge across the plasma membrane, referred to as the fertilization potential, and a concurrent outflow of potassium ions (charged particles); both phenomena are similar to those that occur in a stimulated nerve fibre. Another effect of fertilization on the plasma membrane of the egg is a several-fold increase in its permeability to various molecules; this may be the result of activation of some surface-located membrane transport mechanism.

**Formation of the zygote nucleus.** After its entry into the egg cytoplasm, the spermatozoal nucleus, now called the male pronucleus, begins to swell, and its chromosomal material disperses and becomes similar in appearance to that of the female pronucleus. Although the membranous envelope surrounding the male pronucleus rapidly disintegrates in the egg, a new envelope promptly forms around it. The male pronucleus, which rotates 180° and moves towards the egg nucleus, initially is accompanied by two structures (centrioles) that function in cell division. After the male and female pronuclei have come into contact, the spermatozoal centrioles give rise to the first cleavage spindle, which precedes division of the fertilized egg. In some cases fusion of the two pronuclei may occur by a process of membrane fusion; two adjoining membranes fuse at the point of contact to give rise to the continuous nuclear envelope that surrounds the zygote nucleus.

**Biochemical analysis of the events of fertilization.** Many of the early studies on biochemical changes occurring during fertilization were concerned with the respiratory metabolism of the egg. The results, however, were deceiving; the sea urchin egg, for example, showed an increased rate of oxygen consumption as an immediate response to either fertilization or parthenogenetic activation, in apparent support of the idea that the essence of fertilization is the removal of a respiratory or metabolic block in the unfertilized egg. Extensive comparative studies have shown that the increased rate of oxygen consumption in fertilized sea urchin eggs is not a general rule; indeed, the rate of oxygen consumption of most animal eggs does not change at the time of fertilization and may even temporarily decrease.

At the time of fertilization the egg contains the components required to carry out protein synthesis, and hence development, through an early embryonic stage called the blastula. Most immediate post-fertilization protein synthesis is directed by molecules of ribonucleic acid, known as messenger RNA, that were formed during oogenesis and stored in the egg. In addition, protein synthesis up to the blastula stage (up to a much earlier stage in the mammalian embryo) is directed by the cell components called ribosomes, which are present in the unfertilized egg; new ribosomes, as well as molecules of another type of RNA involved in protein synthesis, and called transfer RNA, are synthesized at a later stage in embryonic development (gastrulation). Eggs fertilized and allowed to develop in the presence of the antibiotic actinomycin, which suppresses RNA synthesis, not only reach the blastula stage but their rate of protein synthesis is the same as that in untreated embryos.

Unfertilized sea urchin eggs, as well as those of other marine animals studied thus far, have a very low rate of protein synthesis, suggesting that something in the unfertilized egg inhibits its protein synthesizing machinery. Since the rate of protein synthesis increases immediately following fertilization, it may depend on some change in,

or removal of, an inhibitor. In the sea urchin egg, for example, the low efficiency of the protein synthesizing apparatus apparently depends on certain properties of the ribosomes. Most of the ribosomes found in an unfertilized sea urchin egg are single ribosomes (so-called monosomes); soon after fertilization, however, the single ribosomes interact with messenger RNA molecules thus giving rise to the polyribosomes, which are the active units in protein synthesis. This process also occurs in eggs of a few other marine animals that have been studied. The protein-synthesizing inefficiency of unfertilized sea-urchin-egg ribosomes is caused by an inhibitor that is associated with them and interferes with the binding of messenger RNA molecules to the ribosomes; the inhibitor is removed almost immediately following fertilization, perhaps by enzymatic breakdown.

It thus appears that at least in the sea urchin egg the overall rate of protein synthesis is controlled at the ribosome level and that the first step in the activation of protein synthesis following fertilization is the "turning on" of the ribosomes.

In vertebrates such as amphibians, activation of protein synthesis takes place at the onset of egg maturation, apparently initiated by the action of a hormone, progesterone. The effect of progesterone is not mediated by the nucleus but is a direct effect on the cytoplasm.

## Fibres, Man-Made

Man-made fibres consist of two broad groups, based upon the origin of the fibre-forming substance. The first group, of which rayon and acetate are examples, are produced by modifying natural fibre-forming materials such as cellulose. The second group, frequently called synthetics and including such fibres as nylon and polyester, are produced from synthetic chemicals. Like other textile fibres, man-made types are long and narrow; they are composed of long, threadlike molecules, which are made up of hundreds or thousands of atoms strung together in a chain.

### HISTORY AND DEVELOPMENT

The English physicist Robert Hooke suggested in the 17th century the possibility of extruding artificial silk by a mechanical imitation of the silkworm. In the 19th century, an English weaver named Louis Schwabe successfully produced filaments from molten glass by forcing the liquid through nozzles ending in fine holes; on contact with air the glass hardened into a fibre.

This first man-made fibre was not suitable for textiles. The natural cellulose of wood was subsequently considered as a potential raw material for the production of textile fibres. Wood cellulose is associated with various gummy substances, however, making it unsuitable for textile use. Experiments were undertaken with the object of dissolving the cellulose, separating the resulting liquid from its impurities, and then extruding and hardening the liquid to form a fibre. In 1846 a German chemist discovered that cellulose could be converted into another substance, nitrocellulose, by treatment with nitric acid. Unlike its parent material, nitrocellulose dissolves readily in solvent substances such as a mixture of ether and alcohol. The molecules retain their long, threadlike shape, and small groups of atoms become attached to their sides, making the new substance more soluble. A patent was issued in 1855 for the manufacture of nitrocellulose fibres, but despite their strength and flexibility, their extreme flammability made these fibres unacceptable for textile manufacture.

In 1883 Sir Joseph Wilson Swan, a British scientist working on the problem of producing a filament for an

Cellulose  
as a  
raw  
materialProtein  
synthesis

Develop-  
ment of  
rayon

electric light, patented a process for squeezing a nitrocellulose solution through holes to form filaments, then treating the filaments with chemicals to change the flammable nitrocellulose back into harmless cellulose. Swan exhibited articles made from his filament, but he did not attempt to develop its potential for textile manufacture. In France, Count Hilaire de Chardonnet produced a fibre that he called artificial silk. Like Swan, he employed a nitrocellulose solution squeezed through tiny holes, hardened in warm air, and then converted back into cellulose by chemical treatment. Chardonnet exhibited materials woven from this artificial fibre at the Paris Exposition in 1889 and secured financial backing to build a factory at Besançon, in the east of France. Manufacture of Chardonnet silk, later known as rayon, the first commercially produced man-made fibre, began in 1891.

Although Chardonnet's process was simple and involved a minimum of waste, it was slow, expensive, and potentially dangerous. In 1890 another French chemist had patented a process that made use of the earlier discovery that cellulose could be dissolved in cuprammonium liquor, a solution of copper salts and ammonia, and after extrusion be regenerated in a coagulating bath, forming continuous filaments. The cuprammonium process replaced the Chardonnet process, but was expensive and fell into disuse for some time until development of an improved spinning method, permitting manufacture of very fine filaments, revived the popularity of cuprammonium rayon. In 1892 another method of producing a regenerated cellulose fibre was devised, involving the chemical treatment of cellulose to form a crumbly material called cellulose xanthate, which could be dissolved to form a viscous liquid known as viscose. Extrusion of the fine jets of viscose into an acid coagulating bath resulted in the regeneration of the cellulose in the form of filaments. Commercial production began in 1905, and the industry developed rapidly, with viscose becoming a major man-made fibre.

A second artificial fibre made from cellulose was developed after World War I. Two Swiss brothers, Henry and Camille Dreyfus, established factories in Great Britain and the United States to produce a cellulose acetate solution used as varnish for the fabric wings of aircraft. At the end of the war, with no further demand for aircraft varnish, the Dreyfus brothers turned to fibre production, and in 1921 they began commercial manufacture of the product called Celanese. This process involves conversion of the cellulose to a derivative, cellulose acetate, which is then dissolved in a solvent such as acetone, forming a solution that is extruded to form a filament.

Although cellulose remains the most important source of man-made fibres derived from natural substances, other natural materials capable of forming fibres are also used commercially. Proteins, for example, existing in such natural fibres as wool, hair, and silk, also exist in nonfibrous forms that can be manipulated to make fibres. Fibres produced from protein materials include casein, from milk; zein, from maize (corn); and arachin, from peanuts.

The protein is dissolved and the solution is extruded in the form of fine jets that can be hardened into filaments. None of these has achieved the success for textile applications of fibres derived from cellulose.

Alginate acid, extracted from seaweed, is a chemical relative of cellulose that is also used as a raw material to produce fibres. Because they are easily dissolved, alginate fibres have specialized applications in the manufacture of very sheer wools and laces, but are of minor importance as textiles fibres.

In the period following World War I, chemists carried out extensive research on methods of forming the chainlike molecular structures called polymers by linking up atoms or groups of atoms to create long molecules. Various synthetic polymers were made, including plastic and rubber types. Finding that many of these polymers could be dissolved in solvents, researchers extruded the polymer solutions through spinneret holes to determine whether filaments could be formed in the same way as rayon.

Develop-  
ment of  
synthetic  
polymers

An experimental fibre had been produced by German chemists from the organic chemical compound polyvinyl chloride as early as 1913, but it had little potential for textile use. In 1928 fibres were spun in Germany from a copolymer, a chainlike molecular structure formed of two or more simple chemical compounds, in this case vinyl chloride and vinyl acetate. Possibly the first synthetic textile fibre was commercially produced in 1936 from chlorinated polyvinyl chloride but was of limited value for textile applications.

The real beginning of the synthetic fibre industry began with research on polyesters and polyamides, both chemically produced substances having their atoms assembled in long molecular chains, under the direction of Wallace H. Carothers at E.I. du Pont de Nemours & Company, in the United States. This work led to the development of nylon fibre in 1935.

Increasing research in polymer chemistry after World War II resulted in the development of many new classes of commercially important synthetic polymers for use as textile fibres, including polyamides, polyesters, polyacrylonitriles, polyvinyl chloride, polyvinyl alcohol, polyolefins, and polyurethanes.

Outside the textile field, new fibres have been produced to fill the technological needs of modern industry. The space industry employs carbon, boron, and metallic fibres in the construction of composite materials having high strength and heat resistance. Glass, aluminum silicate, and other inorganic fibres have varied applications in industry, ranging from the filtration of corrosive materials to insulation of equipment against heat and sound.

Industrial  
uses of  
new fibres

### Fundamentals of production

The manufacture of a synthetic or semisynthetic fibre requires a raw material having the requisite long threadlike molecules. Although the raw material for semisynthetic fibres already exists in nature, in synthetic fibres the substance is built up from simpler chemicals.

#### SPINNING

A substance that is to be converted into fibre must first be converted to a liquid or semiliquid state either by being dissolved in a solvent, or by being heated until it melts. This process frees the long molecules from close entanglement with each other, allowing them to move independently.

The resulting liquid is extruded through small holes, or spinnerets, emerging as fine jets of liquid that are hardened, forming solid rods having all the superficial characteristics of a very long fibre, or filament, such as silk.

The extrusion of liquid fibre-forming material, followed by hardening to form filaments, is called spinning, and is similar to the spinning process of silkworms and spiders, producing continuous filaments.

Several spinning techniques are used in practice, including wet spinning, dry spinning, or melt spinning.

*Wet spinning.* In wet spinning the solution of fibre-forming material is extruded into a coagulating bath that causes the jets to harden as a result of chemical or physical change.

Viscose, for example, is wet spun. The solution of cellulose xanthate is extruded into an aqueous solution of acids and salts, in which the cellulose, being insoluble in water, is regenerated to form solid filaments.

*Dry spinning.* In dry spinning the fibre-forming substance is dissolved in a solvent before the solution is extruded. As the jets of solution emerge from the spinneret, a stream of hot air causes the solvent to evaporate from the spinning solution, leaving solid filaments. Acetate is dry spun by extruding acetone solutions of cellulose acetate into hot air.

*Melt spinning.* In melt spinning the fibre-forming material is melted and extruded through spinnerets, and the jets harden into solid filaments as they cool on emerging from the spinneret. Nylon is a melt-spun fibre.

#### STRETCHING AND ORIENTATION

The extrusion process produces some orientation of the long molecules forming the filament. Orientation is espe-

Skin  
effect

cially pronounced on the outer surface of the filament, where the molecules have been influenced by the edges of the spinneret hole, and the surface of an extruded filament is usually more highly oriented than the inner portion. This surface alignment, known as the skin effect, influences the dyeing properties of the fibre.

Orientation of the long molecules is completed by stretching the filament, pulling the long molecules into alignment along the longitudinal axis of the fibre, and causing them to lie alongside one another and develop cohesion. The degree of orientation depends upon the amount of stretch to which the filament is subjected, and by controlling the stretching, or drawing, it is possible to control the tensile strength to a high degree.

The production of a synthetic fibre allows control over the chemical nature of the fibre-forming substance, producing a fibre with well-defined chemical properties and characteristic behaviour. Control of the chemical structure also allows control of the shape and physical behaviour of the long threadlike molecules produced.

Slender, uniform molecules may be packed alongside one another more efficiently than irregular molecules having awkward knobs and angles that destroy their uniformity, just as a bundle of bamboo canes will pack together more tightly than a bundle of twigs.

In producing a synthetic fibre, it is usual to design the long-chain molecules in a form allowing them to pack together with reasonable efficiency. Large groups of atoms attached to the sides of long molecules prevent the close packing that contributes to fibre strength.

*Crystalline and amorphous regions.* Wherever the threadlike molecules are able to pack closely together in a fibre, there is a tendency toward an ordered arrangement of the atoms with respect to one another. These tight-packed bundles of thread molecules are regions of crystallinity, possessing the regular and precise arrangement of atoms characteristic of all crystals.

Between these regions of crystallinity are regions in which the molecules have not been able to align themselves so precisely. These are the amorphous, or noncrystalline, regions of the fibre. In considering fibre structure the long threadlike molecules may be regarded as passing through regions of ordered crystalline arrangement that are embedded in amorphous material.

During the stretching operation the long molecules slide over one another as they are pulled into alignment in the direction of the fibre's longitudinal axis. As drawing continues, more and more of the molecules are brought to a state where they can pack alongside one another into crystalline regions; in these regions, the molecules are able to hold tightly together as a result of their cohesive forces and will resist further movement with respect to one another.

When nylon is drawn after spinning, the filament may stretch to as much as five times its original length, and will then resist further stretching. At this point the molecules are aligned as effectively as possible into crystalline regions and are holding tightly together. The filament is then able to withstand great force without further stretching; if the load becomes too great the filament will rupture.

*Effects of stretching and orientation.* The degree of alignment of fibre molecules affects the properties of a fibre in several ways. The more closely the molecules pack together, the greater is the tenacity, or breaking strength, of the fibre. This increase in tenacity is accompanied by a decrease in the amount of elongation the fibre can sustain before reaching its breaking point; the molecules are not able to slide over one another as they could before alignment took place. Because the closely packed molecules no longer have great freedom of movement, a high degree of orientation also tends to increase fibre stiffness or rigidity.

Water is unable to penetrate between the molecules in a crystalline region of the fibre as readily as it penetrates the amorphous regions; therefore, increased alignment tends to lower the moisture absorption of the fibre. Increased resistance to water penetration affects the dyeing properties in highly oriented fibres; the molecules of dye-

stuff cannot migrate from the dyebath into the spaces between the fibre molecules. Increased resistance to penetration by foreign molecules improves the general chemical stability of a fibre; highly oriented fibres are more resistant to chemical attack.

Fibres change in appearance as they are drawn. In the undrawn state, nylon is usually dull and opaque; as the filaments are drawn and orientation increases, the filaments acquire the transparency and lustre characteristic of drawn nylon.

#### FILAMENT MODIFICATION

Manipulation and modification of the spinning process can produce various changes in the physical structure and form of a filament, which in turn affect the behaviour in use and the "hand" of fabrics made from them. Hand, or handle, is a general term for the characteristics perceived by the sense of touch when a fabric is held in the hand, such as drapability, softness, elasticity, coolness or warmth, stiffness, roughness, and resilience.

*Cross section.* The cross-sectional view of a filament may be varied by the shape of the spinneret holes through which the material is extruded. Such modification is increasingly important because of the many changes it can produce in the characteristics of both yarns and fabrics. Because circular cross-section filaments have poorer covering power, or ability to occupy space, than the lobed cross sections typical of the normal viscose filament, many synthetic fibres are now produced with dog-bone and trilobal cross sections, providing greater density when made up into fabric.

Straw-shaped filaments are sometimes produced; flat filaments are formed by extrusion through slit orifices instead of circular openings. Although these filaments have improved covering power, they tend to have a harsh feel.

Special effects may be produced in fabrics by the use of filaments in which the diameter is varied continuously between thick and thin.

*Bubble-filled filaments.* Yarn that has relatively high bulk for its weight produces fabrics having good covering power. The covering power of the filaments used to make up a yarn may be increased by spinning methods that cause bubbles of air or other gas to be trapped inside the filament. This effect may be achieved by spinning a solution that has been previously agitated to entrap air bubbles. A disadvantage of this technique is the tendency for the air bubbles to cause breaks in the filament during the spinning process. Breakage may be overcome by generating the gas bubbles after spinning. This effect may be achieved by adding a small proportion of sodium carbonate to viscose, so that bubbles of carbon dioxide are formed inside the filament by reaction with the acid of the coagulating bath.

Bubble-filled viscose filament was produced in the United States during World War II for use as a kapok substitute in life jackets, pontoons, insulated clothing, and similar items. In the production process, air injected in the filament during extrusion produced a continuous filament containing discrete bubbles about  $\frac{1}{8}$  to  $\frac{1}{4}$  inch (three to six millimetres) long.

*Spun-dyed filament and staple.* Control of the spinning process enables the manufacturer to mix finely dispersed pigments with the solution or melted substance before extrusion. When spinning is completed, the pigments are locked inside the filaments, thus providing spun-dyed fibres that have good colour retention when exposed to light and laundering conditions. White titanium dioxide is sometimes added by this method to dull the natural sheen of man-made fibres.

*Crimp.* Man-made fibres cut to predetermined lengths in preparation for spinning into yarn are called staple, or staple fibre. The spinning qualities of staple are usually enhanced if the fibre has a waviness, or crimp, similar to that of wool. This crimp may be introduced mechanically by passing the filament between gear-like rollers, or chemically by controlling the coagulation of the filament to create a fibre having an asymmetrical cross section.

Chemical crimp has mainly developed from experimental work carried out in Japan, where much of the viscose

Resistance  
of nylon  
to stretch-  
ing

Chemical  
crimp

staple produced is now crimped. The crimp is introduced by spinning viscose into a coagulating bath containing less acid and more salt than usual, followed by carefully controlled stretching. The resulting crimped filament is cut into staple and dried.

Filaments produced in this way have an asymmetrical cross section, with one side thick-skinned and almost smooth, and the other side thin-skinned and highly serrated. When wet, such fibres swell to a greater extent on the thin-skinned side than on the thick-skinned side, causing a tendency to curl.

A similar effect may be introduced into rayon by using the bicomponent technique originally developed for use in the production of certain synthetic fibres. This process involves the extrusion of twin filaments through orifices set side by side in such a way that the two filaments join as they coagulate. The composite filament is composed of two viscose solutions, each having different swelling properties. Moisture encourages the filament to curl as one side swells more than the other.

The amount of crimp given to a fibre depends greatly upon the denier, or fibre size (the denier is the weight in grams of 9,000 metres of fibre). Fibres of 1½ denier may have 12 crimps per inch (1 inch is 2.5 centimetres); 3-denier fibres may have 8 crimps per inch. Too much crimp may cause neps, or tangles, during processing; too little crimp may cause low cohesion during processing.

**Surface-modified fibre.** The nature of the fibre surface influences the processing properties of the fibre and affects its behaviour in use. The striated surface of a regular viscose fibre, with its typical lobed cross section, influences the spinnability of viscose staple and affects the appearance and feel of viscose yarns. Because particles of dirt tend to cling to such indentations, fibres of this type are often more difficult to clean than similar fibres having nonserrated surfaces.

The scaly surface of wool contributes to the ability of this fibre to resist soil and wear, and attempts have been made to create similar surfaces on man-made fibres. One use for such fibres would be to provide improved blends with wool. Surface modified fibres have been produced by means of finishing treatments, and also by extruding the fibre through vibrating spinnerets.

#### PHYSICAL FORMS OF MAN-MADE FIBRES

Man-made fibres may be produced in almost any desired length. When a number of filaments produced from a spinneret are twisted together, they form continuous filament yarns. Continuous filaments may be combined to form a thick rope, called a tow, containing thousands of individual filaments. A tow may be cut or broken into short lengths of staple fibre, similar in length to such natural fibres as wool or cotton. Staple fibre may be combed and spun into yarns by techniques similar to those used in spinning natural fibres. The yarns produced in this way are called staple, or spun, yarns.

**Continuous filament yarns.** Continuous filament yarns, consisting of unbroken filaments, tend to be smooth and compact and are used for satins, taffetas, failles, and similar fabrics.

For many applications, continuous filament yarns are less satisfactory than the looser, fuller staple yarns. Techniques have been developed to modify the texture of continuous filament yarns, however, to give them some of the characteristics of spun yarns. Yarns modified in this way are known as textured yarns. Various texturizing processes may be employed to introduce crimps, loops, or curls, giving these yarns a fuller, more open form; to introduce a high degree of elasticity, forming stretch yarns; or to increase the bulk of a yarn without necessarily introducing stretch characteristics.

**Spun, or staple, yarns.** Spun, or staple, yarns consist of short fibres held together by the twist given to an attenuated (reduced in size) strand of fibres. The short fibres lie at various angles with respect to the long axis of the yarn, with the degree of uniformity depending on the combing and other treatments given to the fibre strands before they are twisted together. The surface of a spun yarn is rougher to the touch because of the protruding

fibre ends, and spun yarns generally have a fuller hand and are warmer than continuous filament yarns. Spun, or staple, yarns are popular for sports shirts, suitings, sheets, blankets, upholstery materials, and other fabrics.

**Monofilaments.** Monofilaments, used for fishing lines and nets, consist of fibre-forming polymers spun into filaments sufficiently thick to be used singly.

#### Natural polymer fibres

Polymers are large molecules made by linking together many smaller, unattached molecules, or monomers. Natural polymer fibres are produced by altering substances of natural origin to raw materials that can be made into fibres suitable for textiles. Such products include rayon and acetate, made from cellulose; casein and zein fibres, from protein materials; and alginate fibre, from a seaweed substance.

#### RAYONS

The production of rayon requires the conversion of cellulose to a soluble compound. The original Chardonnet process converted the cellulose to the highly flammable nitrocellulose. The development of safer methods led to the growth of the rayon industry.

**Viscose rayon.** One of the new methods, developed in 1892 by three British chemists, dissolved the cellulose to form a viscous liquid called viscose. A method of producing textile filaments from viscose was developed, as well as an aging process to improve spinning qualities, a multiple hole spinning jet, and a spinning box that coils the newly formed filaments by centrifugal force.

The raw materials for viscose rayon may be cotton linters, the short fibres adhering to the cotton seed, or wood pulp derived from such timber as northern spruce, western hemlock, eucalyptus, or southern slash pine. The pulps of these soft woods, containing about 94 percent cellulose, are especially suited to fibre manufacture.

The cellulose is purified and formed into thin sheets that are steeped in caustic soda and then shredded, forming powdery crumbs. During the aging period that follows, the caustic soda reacts with the cellulose, forming alkali cellulose. The aged crumbs of alkali cellulose are mixed with carbon disulfide in a revolving drum, forming cellulose xanthate, and are then treated with a dilute solution of caustic soda, forming sodium cellulose xanthate, a thick orange-brown solution.

The result is the viscose spinning solution, which is allowed to ripen for several days at carefully controlled temperatures, during which time it undergoes repeated filterings and increases in viscosity. After a final filtering stage, the solution is forced through the tiny holes bored in the metal cap forming the spinneret. Emerging from the spinneret hole, the jet of viscose enters a coagulating bath of acids and salts, in which it is reconverted to cellulose, which coagulates to form a solid filament (see lower left of illustration). The filament may be manipulated and modified during the spinning process to produce variations of the cross-sectional shape, to increase covering power, to allow solution dyeing, or to introduce crimp or is cut into short fibres (see lower right of illustration).

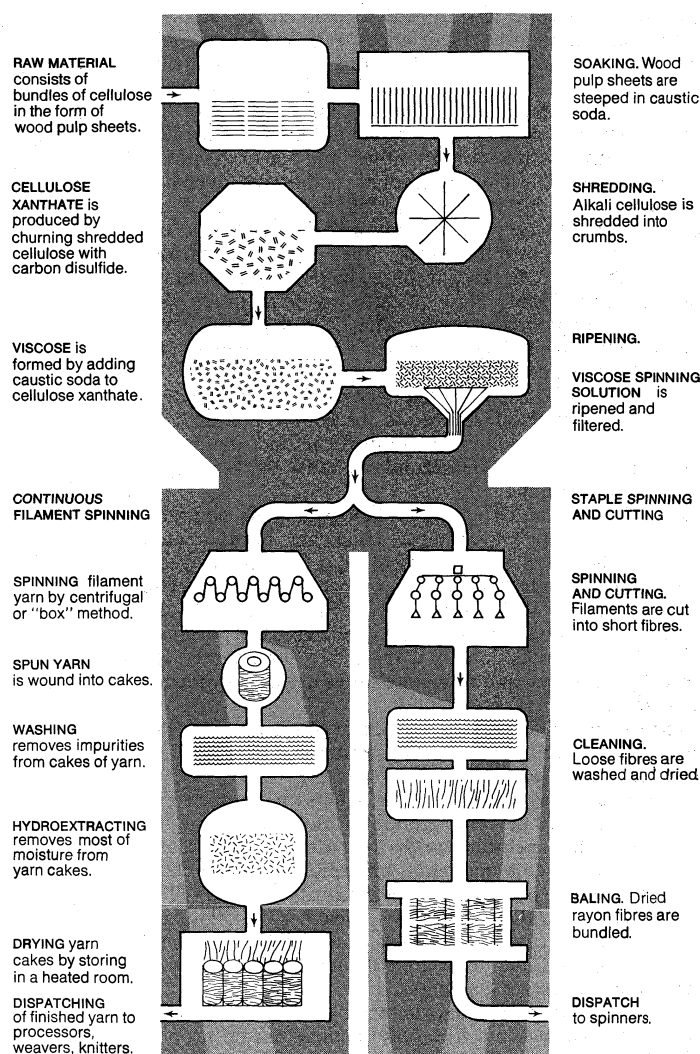

The use of high-strength rayon in tires, conveyor belting, transmission belting, hosepipes, and similar products developed rapidly during World War II. The high-tenacity yarns employed for such uses are produced by application of a high degree of stretch during manufacture, when the individual filaments are in a pseudoplastic state. The stretching is influenced by selection and control of the chemicals used in both the spinning solution and spinning bath.

Increased understanding and control of spinning and processing techniques have led to the development of new types of viscose. The high-wet-strength, or polynosic, fibres are high-tenacity viscose rayons in which modification of the molecular structure has resulted in a fibre having high strength, especially when wet, and good dimensional stability and firmness.

In man-made fibres, the importance of rayon is similar to that of cotton among the natural fibres. Viscose rayon,

produced in greater quantity than any other man-made fibre, is cheap and has a wide range of applications. It is a cellulose fibre, similar to cotton in its cellulosic structure, but it provides a range of yarns and fabrics with their own characteristic properties.

Viscose rayon conducts heat more readily than silk, has a cooler feel against the skin, and is highly absorbent, enhancing its value as a clothing material. The loss of strength occurring in most rayons when wet is a serious shortcoming, but modern resin finishes are overcoming this problem, and properly finished rayon garments have high-dimensional stability when wet.

The introduction of rayon staple has allowed the blending of rayon with other natural and synthetic staple fibres, contributing moisture absorption and other cellulosic characteristics to blends of stronger and less absorbent fibres, among them most of the synthetics. Staple lengths suit particular blends and systems; a two-inch staple can be handled on cotton machinery and a four- to six-inch staple may be used with wool.

Rayon in its many forms is highly versatile, and is used in every branch of the textile industry, including men's, women's, and children's outerwear and underwear; furnishings and carpets; household textiles; and medical fabrics. Crimped rayons are widely used in the manufacture of tufted carpets and rugs, tufted chenilles, curtains, upholstery, and nonwoven fabrics for surgical use. Spun-dyed rayon provides exceptional stability in textiles subjected to light, as in curtains and car upholstery.

Rayon and acrylic fibre blends are popular for knitted

goods. Jersey knit fabrics, plain knits without a distinct rib, have long been made of cotton, characterized by low shrinkage; good hand, or feel; and good cover, or density. The introduction of foam-backed fabrics and laminates, in which two layers of fabric are joined together, has allowed other textiles to offer the advantages of cotton, and the use of spun-dyed rayon has increased in this field.

Flat filament viscose is used in materials for which increased lustre and a firmer hand are required. A potentially important use of flat filament staple is in blending with wood pulp in paper production.

**Cuprammonium rayon.** Cuprammonium rayon, also known by the trademark name Bemberg, was developed in 1890, six years after the introduction of Chardonnet's process, but was not commercially successful until 1919. In the cuprammonium process, cellulose is dissolved in a solution of copper salts and ammonia, called cuprammonium liquor, and regenerated cellulose fibres are produced by extrusion of this solution into a coagulating bath.

Cotton linters or wood pulp are the raw material for cuprammonium rayon. Cotton linters, yielding very pure cellulose, are preferred for high-quality products, although the use of the less costly wood pulp has increased.

After purifying, the cellulose material is mixed into the cuprammonium liquor at low temperature, and stabilizing agents and caustic soda are added. The resulting solution is filtered by passing through a succession of nickel filter screens, and then is deaerated.

The filtered spinning solution is pumped to a nickel spinneret and extruded through the very fine holes. The jets of solution emerging from the spinneret holes flow into a glass funnel, meeting a stream of pure water that flows down through the funnel, and are coagulated to form plastic filaments. As the filaments are carried along by the stream of water, they are stretched continuously.

Manufacturers of cuprammonium yarns, or cupro, have been particularly successful in producing novelty yarns, such as slub yarn, having alternating thick and thin sections, and nub yarns in which lumps are intentionally introduced. These yarns may be made by extruding the spinning solution through spinnerets having two sets of orifices. The filaments from one set of orifices collect on a flat surface, forming bundles that adhere together, and are carried away at intervals to join the filaments extruded from the other sets of orifices, forming a composite yarn with the bundles creating slubs at intervals.

Cuprammonium rayon is generally more expensive than other man-made cellulosic yarns, but its extra fineness and strength, attractive hand, subdued lustre, and good draping properties justify the extra cost for the manufacture of high-quality goods. This rayon, similar to other cellulosics in behaviour during laundering and dry cleaning, should be treated in the same way as viscose.

Cuprammonium rayon is made into satins and such sheer fabrics as chiffons, nets, and ninons, and is popular for underwear, dress fabrics, and linings. Fine denier slub yarns are used in dresswear, sportswear, curtains, and fine drapery fabrics; heavier denier slub yarns are used in suitings, upholstery fabrics, bedspreads, draperies, and other fabrics.

Yarn-dyed fabrics are popular for high-quality silklike linings, and for dress and upholstery fabrics. Reel-spun yarns produced in skeins ready for yarn-dyeing in the untwisted state are especially suited for such applications. The dyed yarn remains untwisted to form the crosswise weft of the fabric, and is twisted for the lengthwise warp.

**Saponified cellulose ester.** In the early manufacture of cellulose acetate, the fibre was often treated with alkali as a prelude to dyeing, partially converting the material back to cellulose. This treatment, called saponification, was eliminated from the dyeing process with the development of new methods for dyeing cellulose acetate. The process was revived, however, for application in the stretching operation. Saponification with a caustic soda solution during stretching deacetylates the substance, producing a strong fibre, extremely fine in diameter, that

Desirable characteristics of cuprammonium rayon

Rayon staple

is no longer cellulose acetate but has been converted to a highly oriented filament of regenerated cellulose.

Saponified rayon yarns are used for applications in which a high ratio of strength to volume and excellent dimensional stability are advantageous; e.g., in parachute ropes and fabrics, tire cords, belting, hoses, and balloon fabrics. The high degree of fineness possible in filaments made by this technique has enabled the yarns made from them to replace natural silk in such applications as electrical insulation materials; e.g., in hearing-aid equipment. Coated fabrics provide light, strong tarpaulins and other protective fabrics.

#### CELLULOSE ESTER FIBRES

Viscose and cuprammonium are regenerated cellulose, resembling cotton or flax in their chemical structure. There is another important form of cellulosic man-made fibre in which treatment with acetic acid changes the wood or cotton cellulose to an entirely different substance, rendering it soluble and spinnable, and the filament remains in its changed chemical form after spinning. This fibre is made from a chemical derivative of cellulose, cellulose acetate.

Secondary  
cellulose  
acetate

Fibres spun from secondary cellulose acetate, in which the cellulose is not completely acetylated, or converted by acetic acid to cellulose acetate, were formerly described as acetate rayon. In modern terminology, rayon is used only in describing fibres consisting of regenerated cellulose, such as viscose and cuprammonium rayons. The secondary cellulose acetate fibres are now known simply as acetate, and fibres spun from primary cellulose acetate, or completely acetylated cellulose, are called triacetate.

*Acetate fibres.* In the production of acetate fibres, the spinning solution consists of secondary acetate blended from a large number of batches to assure a high degree of uniformity. The blended acetate is dissolved in a solution of the solvent acetone and a small proportion of water, up to 5 percent of the weight of the acetone, and pigments may be added at this stage. Finely divided carbon black may be added in making black fibre; titanium dioxide is added to produce a dull fibre when a high degree of lustre is not desired.

The treated spinning solution, containing 20–30 percent cellulose acetate, known as dope, is filtered and deaerated. After a final filtering the dope is pumped through very fine holes in the spinneret, then emerges into a spinning tube, an enclosed vessel through which hot air flows at a temperature of about 100° C (212° F). As the jets of spinning solution meet the hot air stream, the acetone is evaporated, leaving solid filaments of cellulose acetate. More than 90 percent of the acetone in the jets is evaporated during the fraction of a second that the jet is moving downward through the spinning tube.

The newly formed filament of cellulose acetate is stretched slightly while still plastic, aligning the long molecules and developing the strength of the filament. Acetate filament yarns produced in this way are ready for immediate textile use without any of the washing or purification treatment necessary for wet-spun fibres.

The natural attractiveness of cellulose acetate, combined with its useful practical properties, has created a demand for acetate fibre that has continuously increased since the 1920s. Modern acetate fabrics can be treated in much the same way as natural fibres and rayons. They can be dyed and finished, washed and dry-cleaned, and will withstand all the conditions met in ordinary commercial and domestic use.

Because acetate is fundamentally different in its chemical structure from the rayons and natural fibres, certain differences in behaviour must be considered in the handling of acetate materials. Acetate is thermoplastic, softening at high temperatures, and will deform under pressure at about 205° C (400° F).

The tendency for acetate fibres to soften with heating is useful in the processing of acetate goods, so that fabrics can be embossed with patterns that are impressed on the warmed material.

The relatively low-moisture absorption of acetate fi-

bres makes acetate less subject to damage by staining from many substances. Fruit juices, ink, food, and other water-soluble stains are easily sponged or washed out. Acetate fabrics dry rapidly, and are thus particularly suitable for bathing suits, rainwear, and umbrellas. Because cellulose acetate does not conduct heat readily, acetate garments are cool in summer and warm in winter.

Acetate has little natural colour, so that the dyer can produce acetate fabrics in a range of shades varying from delicate tints to deep, heavy colours. The richness and variety of the possible shades, allied with the softness and pliability of the acetate fibre, have helped to make acetate into a beauty fibre. Acetate garments drape well and have an attractive hand. They are soft and never harsh, retain their shape if treated with reasonable care, and do not easily wrinkle.

*Triacetate fibres.* Complete acetylation of cellulose yields primary cellulose acetate, or cellulose triacetate. This product is soluble in chloroform and methylene chloride, but unlike the secondary cellulose acetate, is insoluble in acetone.

In 1950 Courtaulds Ltd., London, began the commercial development of cellulose triacetate fibres. Later, Courtaulds and British Celanese Ltd., Coventry, Warwickshire, linked their efforts to produce a triacetate fibre, under the trademark Tricel, with British Celanese Ltd. as the producer. In 1954 Celanese Corporation, U.S., began production of a triacetate fibre under the trade name Arnel, and triacetate fibres are now produced in several countries.

Experience gained in the production of secondary cellulose acetate was applied in the commercial development of cellulose triacetate.

Cellulose triacetate from many batches is blended and dissolved in a 20 percent solution of alcohol and methylene chloride. The solution is then filtered, deaerated, and pumped to the spinneret, emerging into a vertical spinning tube where it meets a stream of hot air. The methylene chloride evaporates to leave solid filaments of cellulose triacetate. An antistatic and lubricating substance is applied; the fibres are collected in the same way as secondary acetate filaments.

The chemical relationship between triacetate and acetate is a close one, but it is only in their tensile properties that the two fibres bear any real resemblance to each other. Triacetate has greater heat resistance than acetate. In many respects, triacetate behaves more like a true synthetic fibre than a semisynthetic fibre, possessing the thermoplastic properties and low moisture absorption associated with synthetic fibres.

Triacetate fibres retain some 70 percent of their strength when wet, and thus fabrics made from triacetate are easily washed and quickly dried. The heat-setting characteristics of triacetate are of great practical value, because heat setting renders fabrics free from shrinkage, imparts excellent dimensional stability, and permanently sets the fabric in the desired shape. Heat treatment applied after dyeing increases the fastness of the dyestuffs to washing and light.

Permanent effects may be produced in triacetate fabrics by heat treatment. Permanent pleats may be set in woven fabrics, and permanent embossing may be set in both knitted and woven materials. The permanency of pleats in blended fabrics depends upon the amount of triacetate in the blend, and two-component blends with cellulosic fibres require a minimum of 67 percent triacetate for permanent pleating to take effect.

The high melting point of triacetate provides a wide margin of safety in high-temperature treatment used in clothing manufacture and laundering.

Because triacetate fabrics have little tendency to shrink even before heat treatment, tighter constructions are required in triacetate and triacetate-blended fabrics than in equivalent fabrics of acetate; therefore, these fabrics do not tighten up during dyeing and finishing.

#### PROTEIN FIBRES

Fibres manufactured from the regenerated protein substances obtained from plant and animal sources are

Desirable  
char-  
acteristics  
of acetate

Desirable  
char-  
acteristics  
of tri-  
acetate

sometimes known by the generic name of azlon. Sources for these materials include milk, peanuts, corn (maize), soybeans, egg albumen, chicken feathers, and gelatin.

**Casein fibres.** About 1935 Antonio Ferretti, an Italian chemist, produced pliable casein fibres having many of the properties associated with wool. Casein fibres have since been made under various names in a number of countries—e.g., Lanital in Belgium and France; Fibrolane in Great Britain; and Merinova, an improved form of the original Lanital, in Italy.

Casein is obtained by treating skimmed milk with acid, causing it to coagulate and form a curd that is washed, dried, and ground to a fine powder. It is then dissolved in caustic soda. After the solution has ripened to suitable viscosity, it is filtered and deaerated.

The spinning solution is wet-spun by extrusion through spinnerets into a coagulating bath containing such chemical ingredients as sulfuric acid, formaldehyde, and glucose with water. The jets of solution coagulate into filaments in a manner similar to the coagulation of viscose filaments, and are stretched to some degree during coagulation.

Bunches of filaments are collected together into a tow as they leave the coagulating bath and are then steeped in a formaldehyde solution to harden. Further stretching may be applied at this stage. After treatment, the tow is washed and dried, crimped mechanically, and cut into staple.

The low strength of casein fibre, and its sensitivity to water, have restricted its use, but it has found a number of applications in certain textile fields, especially as blend fibres for mixture with wool, cotton, rayon, acetate, nylon, and other synthetic staple fibres. In blends with cotton and rayon staple, casein brings warmth, resilience, and a full, soft hand. It allows production of good whites, and prolonged wear trials have shown that the whiteness of fabrics made from these yarns is preserved throughout the life of the garment, irrespective of the number of launderings.

Blends containing one part casein to two parts of either rayon staple or cotton are particularly satisfactory. Twill and float weaves bring out maximum suppleness in the fabric. Crease resistance is good and may be strengthened where required (e.g., in suitings) by application of a crease-resistant finish. Shrink-resistant finishes are also used where necessary to improve the shape, stability, and resistance to shrinkage on washing.

Because casein filaments can be spun to very fine diameter, they may be blended with the finest qualities of wool. The proportion of casein used in blends with wool depends upon the effect required; one-third casein is generally satisfactory. Because casein may increase the shrinkage in finishing in some constructions, allowance for shrinkage in the setting of the cloth is necessary.

**Alginate fibres.** In 1883 an English chemist discovered alginic acid, a substance in common brown seaweed that serves a purpose similar to that of cellulose in land plants. During World War II, coarse monofilaments of chromium alginate were first produced at the University of Leeds. They were green in colour and were originally manufactured for use in camouflage netting.

In the production of alginate fibres seaweed is dried and milled to a fine powder. The alginic acid in the seaweed is converted to sodium alginate, and a sodium alginate solution is wet spun into a coagulating bath containing dilute sulfuric acid and sodium sulfate, to produce alginic acid fibre, or a bath containing calcium chloride and dilute hydrochloric acid to produce calcium alginate fibre. The jets emerging from the spinneret are coagulated into filaments of calcium alginate that are brought together, washed, oiled, dried, and wound.

The nonflammability of the alginate fibres has made them valuable for several applications in which fire hazards might exist, as in theatre curtains. Although nonflammability is desirable for certain types of clothing, the low wet strength of the fibres is a disadvantage, and a satisfactory fibre that can survive washing and also provide wearing comfort has been difficult to devise.

The solubility of calcium alginate fibres in alkali (e.g.,

sodium carbonate solution), while a drawback to most applications, has been an advantage in some. In the production of loosely spun wool yarns the alginate fibres are dissolved away after knitting, leaving a fluffy lightweight fabric that could not have been made by normal methods.

Calcium alginate yarn is useful in hosiery manufacture. Socks are linked together by a few courses of alginate yarn, allowing continuous production, and are separated by cutting the yarn and dissolving away the remains. This technique enables perfect welts to be obtained in socks of all types.

Calcium-sodium alginate yarn has medical application, providing stytic elastic dressings and dressings that are hemostatic, nontoxic, and absorbable in the bloodstream. It is also used in dental surgery to plug cavities.

**Other protein fibres.** Other fibres have been made from protein regenerated from such natural sources as peanuts (groundnuts), corn (maize), soybeans, and collagen (insoluble fibrous animal protein). These fibres have been excessively soft and tended to lose strength when wet, and few have been successful.

Research into new uses for products of developing countries resulted in a fibre made from the protein of peanuts, a staple crop in many hot, humid regions. Experimental production of the fibre, called Ardil for the town of Ardeer in Scotland where it was first produced, began in 1946 and was suspended in 1957.

A fibre called Vicara, made from zein, the protein material of maize, was manufactured in the United States between 1948 and 1957. The woollike fibres were low in strength and were mainly used in blends.

The Ford Motor company of the U.S. pioneered in attempts to make a useful fibre from the protein of soybeans, manufacturing a fibre for use in automobile upholstery between 1939 and 1942. Production cost was high and fibre strength was poor, and the process was taken over by another company, which discontinued production after a short time.

Marena, a protein fibre manufactured in Germany from the collagen obtained from leather and hide waste, was used mainly for the bristles of brushes, and was not produced after 1959.

Continued research is aimed toward finding a cheap, waste-protein source having textile-fibre potential.

#### NATURAL RUBBER FIBRES

A technique for production of rubber filaments was perfected in the 1930s. Rubber latex, a suspension of rubber globules in water, is mixed with vulcanizing agents and other materials and extruded in the usual way. The jets of latex emerge from the spinneret into a coagulating bath, forming filaments of rubber that are subsequently vulcanized. This new technique made possible the production of very slender round filaments, in virtually unlimited lengths.

In the 1950s, rubber filaments achieved prominence because of improvements in thread quality that allowed production of white filaments that will not discolour unduly in use and are resistant to degradation by oxygen, light, and other agents. At the same time the introduction of high-speed warp knitting allowed a rapid expansion in the production of elastic fabrics with two-way stretch, thus increasing the demand for lightweight body-support garments.

Rubber threads are used in knitted and woven fabrics, either in the bare form or covered with spirally wound textile yarns. A wide variety of fabrics has been designed employing rubber threads to improve garment fit or provide support. Use of the appropriate type of rubber yarn and associated textiles allows a wide range of fabric hand, from relatively stiff batistes and nets to soft and supple swimwear and underwear fabrics, all providing exceptional comfort.

#### Synthetic fibres

The synthetic fibres are made entirely from complex organic chemicals such as polyamides, polyesters, polyvinyls, polyolefins, and polyurethanes.

Special applications of alginate fibres

Uses of casein fibre

Applications of natural rubber fibres

## POLYAMIDE FIBRES

Polyamides are polymers, or chainlike structures of linked molecular units, containing recurring amide groups as integral parts of the main polymer chains. Synthetic polyamide fibres form nylon, a major textile fibre. Synthetic polyamides are produced by a condensation reaction between small molecules, in which the linkage of the molecules occurs through the formation of amide groups. They may be produced by the interaction of a diamine, a compound containing two amino groups, and a dibasic acid—e.g., hexamethylenediamine and adipic acid—or by the self-condensation of an amino acid, or a derivative.

Fibres have been spun experimentally from thousands of polyamides produced by one of these condensation reactions, but only a very few have attained commercial importance in textile manufacture. Nylon was the first commercially successful synthetic textile fibre.

The term nylon, coined by du Pont, was defined as a generic term for any long-chain synthetic polyamide, which has recurring amide groups as an integral part of the main polymer chain, and which is capable of being formed into a filament in which the structural elements are oriented in the direction of the axis.

A method of nomenclature has been devised that retains the term nylon, but distinguishes between the different forms of polyamide. The number of carbon atoms in the constituents of the nylon are indicated by appropriate figures, with the diamine being considered first in polyamides made by condensing diamine and dibasic acid. The original nylon, made from hexamethylenediamine and adipic acid, is nylon-6,6, with the diamine and dibasic acid both containing six carbon atoms. The nylon made from hexamethylenediamine and sebacic acid is nylon-6,10.

When the polyamide is made by self-condensation of a single constituent (e.g., an amino acid), the nature of the polyamide is indicated by a single figure representing the number of carbon atoms in the molecule of the original constituent. Nylon-6 is the fibre made by self-condensation of the amide caprolactam.

**Nylon-6,6.** Nylon-6,6 fibre is spun from polyhexamethylene adipamide, a polyamide made by condensation of hexamethylenediamine and adipic acid.

Unlike rayon and acetate, nylons are melt spun. The polymer is heated until it melts, and the molten material is forced through holes in spinnerets. As the jets of molten nylon emerge, they are cooled and solidified by contact with a stream of cold air, forming solid filaments. The filaments are drawn to produce a lustrous and strong fibre. Nylon-6,6 fibres offer a range of properties that make it one of the most successful of all synthetic textile fibres.

The outstanding mechanical properties of nylon include high strength-to-weight ratio, high breaking elongation, excellent recovery from deformation, high abrasion resistance, and high flex resistance. These properties are affected only slightly by moisture, and fabrics remain strong and stable when wet.

The nylon fibre, yarn, or fabric may be heat-set readily in dry heat or steam. Nylon fabric that has been heat-set holds its shape during processing in boiling water and has wrinkle recovery characteristics commensurate with the severity of the setting operation. The thermoplastic nature of nylon-6,6 has allowed successful development of a wide variety of permanent bulking and textured effects on continuous filament yarn.

These nylons are widely used in home furnishing manufacture for carpets and upholstery. Useful characteristics of nylon for carpet manufacture include appearance retention, because of abrasion resistance; texture retention; recovery from crushing; durability; and dye fastness. In upholstery, the combination of strength, dyeability, abrasion resistance, high light-fastness, and lustre provided by nylon fabrics is valued for beauty, performance, and practicality. In wearing apparel fabrics nylon-6,6 offers protection, aesthetic appeal, ease of care, durability, appearance retention, and comfort.

Nylon lends itself to most types of fabric construction,

including such apparel fabrics as surah, plain and brushed tricot, simplex (reversible knit), various linings, circular and fully fashioned hosiery, taffeta, crepe, satin, reinforced twill, ski-wear fabric, velvet fleece, brocade, matelassé, circular and full-fashioned knits, tape and ribbon, lace, sheer, organza, and seersucker. These nylon fabrics are used for lingerie, swimwear, women's outerwear, men's outerwear, stretch sportswear, hunting apparel, uniforms, hosiery, sweaters, dresses, socks, and gloves.

The high strength, elasticity, abrasion resistance, and other characteristics of nylon-6,6 contribute to its suitability for a wide variety of industrial fabrics, including air springs, belting, filter fabrics, fish net, twine, hose, wash nets, press covers, ironer covers, paddings, parachutes, webbing, sewing thread, cordage coated fabrics, body armour or ballistic cloth, screening, felts, reinforced plastics, ropes, blend paper, papermakers' felts, tires, and the gray fabric used to back cloth to be roller printed.

The high strength and abrasion resistance of nylon-6,6, coupled with such properties as resistance to moisture and heat, and good resistance to fatigue and rupture, have made this nylon popular for tire cords.

**Nylon-6.** Nylon-6 fibre is spun from polycaproamide, a polyamide made by the polymerization, or linking together, of 6-aminocaproic acid molecules.

It is melt-spun by a process similar to that used for nylon-6,6. Nylon-6 polymer melts at 215°–217° C (419°–423° F); i.e., about 35° C (95° F) lower than polyhexamethylene adipamide, or nylon-6,6 polymer. Molten polycaproamide is comparatively stable and may be held under an inert atmosphere at 250° C (482° F) for 16–24 hours without deterioration. Polycaproamide is much less sensitive to spinning conditions than nylon-6,6, and the spinning of polycaproamide directly from the polymerization vessel may be carried out more readily.

Nylon-6 filaments are drawn by passing over two sets of rollers, the second set moving with about four times the surface speed of the first set.

Nylon-6 offers a range of properties generally similar to those of nylon-6,6, except for certain differences, such as those resulting from the lower melting point of nylon-6.

**Nylon-11.** Nylon-11 fibre is spun from polyundecanamide, made by the self-condensation of 11-amino-undecanoic acid. This fibre was developed in France, with the cooperation of an Italian firm, and is now produced in France, Brazil, India, and the U.S.S.R.

The compound used to produce nylon-11 may be made from castor oil, from ethylene and carbon tetrachloride, or from dodecane. Polymerization is carried out in three stages, with the monomer, the material in the form of small, unattached molecules, fed as an aqueous suspension into the reaction vessel.

Molten nylon-11 polymer is highly stable at the temperature used during melt spinning (about 215° C, or 419° F), and may be stored for long periods without deterioration. Oxidation is prevented by maintaining the molten polymer under an inert atmosphere.

The spinning process is similar to that used for nylon-6, and the filaments are drawn to a degree depending on the type of fibre required.

Nylon-11 resembles nylon-6 and 6,6 in many important properties, but has certain features affecting its potential applications. The melting point of nylon-11 (189° C, or 372° F) is on the low side for general textile use, and care must be taken in such elevated-temperature treatments as ironing.

The initial modulus, or stiffness, of nylon-11 is higher than those of the other nylons, making it useful in applications such as brush bristles; it also makes for easier processing. Nylon-11 yarns do not stretch as easily as nylon-6 or 6,6 yarns when subjected to such physical processing as winding.

The high initial modulus of nylon-11 makes it useful for the automobile tire cord market, because tires reinforced with nylon-11 are not subject to formation of flat

Industrial applications of nylon-6,6

Nylon nomenclature

Desirable mechanical properties of nylon

spots when the car is parked in cold weather to the extent that nylon-6 and nylon-6,6 reinforced tires are.

The low moisture absorption of nylon-11, enabling it to retain its excellent insulation properties at high humidities, is a useful characteristic in electrical applications.

Having a specific gravity of only 1.04, nylon-11 is a light fibre, with greater covering power than other polyamides. It is used in a variety of textile applications, such as tricot knitted lingerie and underwear, hosiery, and woven fabrics, and serves in the same areas as nylon-6,6 and nylon-6, combining their ease-of-care characteristics with durability and comfort.

Heat-setting processes are used in the same way as with other thermoplastic fibres, and permanent pleats and creases may be obtained effectively.

**Nylon-6,10.** Nylon-6,10 fibre is spun from polyhexamethylene sebacate, made by the condensation of hexamethylenediamine and sebacic acid.

Nylon-6,10 fibres are similar to those of nylon-6 and 6,6 in many respects, but moisture absorption is lower than that of either, and the fibres are unusually resilient.

**Other polyamide fibres.** During the 1960s a number of new types of polyamide fibre came on the market. Some were designed to serve in comparatively narrow specialized fields, and others extended the range of textile applications and brought improvements in the characteristics of nylon fabric generally.

Adjustment of the segment of the polymer chain separating the amide groups in a polyamide allows significant modification of the properties of the polyamide. This technique has been used in the production of polyamides now serving in specialized fields for which the normal nylon fibres are unsuitable. High-temperature resisting polyamides (*e.g.*, Nomex [HT-1 nylon]) and polyamides suitable for use as electric insulation (*e.g.*, nylon-11) are examples.

#### POLYESTER FIBRES

Polyesters are polymers made by a condensation reaction taking place between small molecules, in which the linkage of the molecules occurs through the formation of ester groups. They are usually made from esters of ethylene glycol and terephthalic acid.

In 1941 British researchers developed a synthetic fibre from polyethylene terephthalate by condensing ethylene glycol with terephthalic acid. These fibres are manufactured in many countries, in both their original and in modified forms. Other polyesters have been produced and spun into fibres, some achieving commercial importance.

**Polyethylene terephthalate fibres.** Polyethylene terephthalate (PET) fibres are made by the condensation of terephthalic acid, or a derivative such as dimethyl terephthalate, with ethylene glycol. The spinning procedure is like that used for polyamide fibres.

The molten polymer, pumped through holes in a spinneret, emerges in the form of filaments that solidify and are wound into packages of undrawn yarn. This yarn is stretched to about five times its original length on draw-twist machines, at elevated temperature. In the production of high tenacity yarns, the filaments are drawn to a higher degree than in the manufacture of regular tenacity yarn.

The desirable properties of PET polyester fibres, both filament and staple, include low moisture retention, high dry and wet strengths, high initial modulus, high resistance to and recovery from bending, low creep, ability to be heat-set, high abrasion resistance, good electrical insulation properties, good resistance to exposure to elevated temperatures, good resistance to most common chemicals, and good resistance to common solvents. The end uses for PET polyester fibres have developed largely around these useful characteristics, making PET one of the most versatile of all modern synthetic fibres.

**Poly-1,4-cyclohexylenedimethylene terephthalate (PCDT) fibres.** In 1958 the United States firm Eastman Chemical Products Inc., introduced a new type of polyester fibre under the trademark Kodel. This fibre is spun from the polymer made by condensing terephthalic acid with 1,4-cyclohexanedimethanol and is therefore of funda-

mentally different constitution from the polyethylene terephthalate polyesters that form the bulk of commercial polyester fibres. The polymer (PCDT) from which Kodel-211 is spun is made by condensing terephthalic acid with 1,4-cyclohexanedimethanol.

As the polymer is melt-spun, the filaments solidify as they meet cold air. They are then drawn to 4½ to 5 times their original length at a temperature of about 120° C (250° F).

Fibres of PCDT generally resemble PET fibres, but certain differences exert a significant effect on their uses. Fibres of PCDT have lower tenacity and elongation than the PET fibres but have superior recovery from stretch. They serve in applications where resilience and bounce are of greater importance than high tenacity, as in carpets, rugs, and knitwear.

The lower tenacity of these fibres contributes to their improved resistance to pilling, and the fabrics will shed pills (the small tangles of fibres resulting from friction) more readily than fabrics made from the stronger polyester fibres.

The moisture absorption of PCDT fibres is similar to that of PET fibre, producing similar behaviour. Mechanical properties are not affected by moisture and electrical properties are excellent, but the accumulation of electrostatic charges may cause difficulties.

Fibres of PCDT have a lower specific gravity than PET fibres, thus giving increased covering power and providing lightweight fabrics of great warmth and comfort. The high melting point of PCDT fibre allows a high safe-ironing temperature (about 218° C, or 424° F).

Fabrics containing PCDT fibre may be heat-set at a relatively low temperature—*e.g.*, about 160° C (320° F)—an especially useful quality in the finishing of blended fabrics containing wool.

#### POLYVINYL DERIVATIVES

**Polyacrylonitrile fibres.** During the period 1955–60, polyacrylonitrile fibre factories were established in Germany, Japan, Italy, Belgium, Canada, France, and The Netherlands, and later in many other countries.

These polyacrylonitrile fibres, known by the generic name of acrylic, are spun from polymers consisting of at least 85 percent by weight of acrylonitrile units, produced from ethylene oxide and hydrocyanic acid. The polymerization of acrylonitrile and its comonomer is commonly carried out by stirring the monomers with water in the presence of a catalyst and surfactants (detergents or other surface-active agents that reduce surface tension).

In dry spinning, the polymer is dissolved in an organic solvent such as dimethylformamide to form a solution containing 25–40 percent of polymer. This is degassed, filtered, and heated almost to the boiling point, then extruded through spinnerets.

The fine jets of solution emerge into a vertical tube or spinning cell, through which flows air or other gas at high temperature. As the jets fall through the tube, the solvent evaporates, leaving solid filaments of polymer. These filaments are brought together at the base of the spinning cell and stretched while hot to several times their original length.

In wet spinning, the polymer is dissolved in a suitable solvent and the solution degassed and filtered. It is then pumped through spinnerets into a coagulating bath containing a liquid in which the solvent is soluble, but the polymer is insoluble, and the jets of polymer solution coagulate into fine filaments. These fibres may be produced in a variety of cross-sectional shapes, each affecting the nature of the fabrics produced from them.

The stress-strain relationships of different acrylic fibres vary over a wide range, depending upon the chemical and physical structures of the specific fibre. The tenacities of acrylic fibres are generally between those of standard rayon and nylon. Acrylics are sufficiently strong for all the normal apparel applications but are rarely considered for those high-strength applications in which nylon and polyester fibres serve. Acrylic fibres are usually made into staple, although some producers

Desirable characteristics of PCDT polyester fibres

Dry spinning process for acrylic fibres

Desirable properties of PET polyester fibres

Desirable characteristics of acrylics

market continuous filament yarns, and high tenacity acrylics are also in production.

Good tenacity and extension are combined with excellent elastic recovery and high initial modulus, mechanical properties contributing to the production of fabrics of good dimensional stability, which are unaffected in conditions that would tend to bring about deterioration in many other fibres. Acrylics are not significantly affected by exposure to sunlight, moisture, micro-organisms, chemicals, or solvents. Fabrics constructed from these fibres have an attractive hand characteristic. Acrylic fibres have low specific gravity, slightly higher than that of nylon, and provide lightweight fabrics that bulk well. The water absorbency of acrylic fibres is generally low, but is higher than that of polyester fibres. Acrylics rarely accumulate static electricity to the extent that polyester fibres do, and successful static elimination can be achieved with suitable antistatic finishes. The small water absorption contributes significantly to their dyeability.

Acrylic fibres tend to be heat-sensitive, and heat-setting is necessary for good stability. At very high temperatures, the fibres decompose rather than melt, but such temperatures are unlikely to be encountered in normal textile applications. Fabrics made from 100 percent acrylic fibre or from blends with 50 percent or more acrylic fibre may be durably pleated.

Acrylic goods are only moderately flammable; they have outstanding resistance to the effects of sunlight, micro-organisms, insects, and aging; and show excellent outdoor weathering resistance. They also display good resistance to all the chemicals likely to be encountered in normal textile use, including bleaches, dilute acids and alkalies, and dry-cleaning solvents.

Mod-acrylics

The modacrylic polyacrylonitrile fibres include modacrylic fibres spun from polymers consisting of less than 85 percent by weight of acrylonitrile units, but do not include those copolymers in which acrylonitrile is not the major component. Fibres in this category are spun from an extensive range of copolymers of acrylonitrile, in which the nature and proportion of the second, and possibly additional components, may vary within wide limits. The modacrylic fibres that can be produced within this broad category provide wide variations in properties, depending on their composition and method of manufacture.

Details of the chemical structure of individual modacrylic fibres are not always available. The second component of the polymer, however, is commonly chosen from vinyl chloride, vinylidene chloride, or vinylidene dicyanide.

**Polyvinyl chloride (PVC) fibres.** Fibres of PVC, spun from polymers or copolymers of vinyl chloride, are manufactured in a variety of forms and modifications. They have achieved a limited success in textile manufacture, but their low softening point, often as low as 70° C (160° F), restricts their possible applications. Fibres of PVC, however, have characteristics that are highly suited to certain applications: they do not burn, and they have resistance to many chemicals. Their tendency to shrink at relatively low temperatures is useful in the production of high bulk yarns.

Vinyl chloride is produced in large quantity for the production of polyvinyl chloride plastics, and fibre manufacture uses only a small part of the output. It is polymerized typically as an aqueous emulsion in autoclaves (pressure vessels), under pressure of 45–50 atmospheres and a temperature of about 65° C (150° F). The polymer forms a suspension in the water and is recovered by spray drying. The fibres may be spun by dry-, wet-, or melt-spinning processes.

**Polyvinylidene chloride (saran) fibres.** In 1940 the Dow Chemical Company, of the U.S., introduced a new synthetic fibre consisting of a copolymer of vinylidene chloride and vinyl chloride that was given the generic name saran. Production of saran fibres spread to other countries, and it is now established as a specialty textile fibre.

In its production vinylidene chloride and the vinyl

chloride or other comonomer are polymerized in an aqueous emulsion in the presence of a catalyst. The copolymer is melt spun through spinnerets at about 180° C (360° F), and the filaments are immediately cooled with water before being drawn to develop satisfactory tenacity. Pigments may be incorporated in the molten polymer before spinning, and titanium dioxide is used to dull the filament.

Saran is a flexible fibre, with a soft warm hand, its smooth rounded surface contributing to soiling resistance and easy dirt removal. It is unusually tough and durable, with excellent flex resistance, and fabrics woven from this fibre have excellent resistance to abrasion and hard wear.

The moisture absorption of saran is very low, and its mechanical properties are unaffected by moisture. Saran fabrics are dimensionally stable, washing and drying easily and quickly, and their low moisture absorption contributes to stain resistance; ink, food, drink, and many other stains may be removed with soap and water.

Because of saran's low resistance to heat, coupled with its negligible moisture absorption, its use in garment fabrics has been restricted. The fibre's nonflammability is an asset, and saran fabrics are popular for draperies and other application, where fire hazards are present. Saran has excellent resistance to sunlight, aging, and general weathering conditions, and is completely resistant to attack by insects and micro-organisms.

**Polyvinyl alcohol fibres.** Polyvinyl alcohol fibres have been commercially produced in Japan since 1950, and later in South Korea, North Korea, China, France, Germany, Poland, and the U.S.S.R.

Polyvinyl alcohol is made by the hydrolysis of polyvinyl acetate, and fibres are commonly produced by wet spinning, or by a process combining features of dry and melt spinning. The fibres produced by the regular wet-spinning process are heat treated at about 240° C (450° F), followed by acetalization, usually with an aldehyde such as formaldehyde. Benzaldehyde may be used instead of formaldehyde to provide a fibre of high resilience. Aldehydes containing active groupings, such as amino groups, may be used to confer special dye affinity on the fibre.

Polyvinyl alcohol fibres have the flexibility associated with a flattened-tube type of cross section, and fabrics made from these fibres are soft and warm, with excellent hand, so that they feel comfortable when worn next to the skin. The fabrics are durable and hard wearing, with high tensile and bursting strength, and excellent impact and abrasion resistance.

The elastic recovery of polyvinyl alcohol fibres is on the low side, suggesting that dimensional stability and wrinkle resistance may not be high. Mechanical properties are not unduly affected by water, and the ability to absorb moisture contributes to the comfort of garments worn next to the skin. Fabrics made from these fibres will burn only with difficulty. The fibres are resistant to insects, micro-organisms, and other influences encountered in outdoor applications. Their high resistance to acids, alkalies, and many other chemicals is an important factor in the industrial applications of polyvinyl alcohol fibres. Polyvinyl alcohol fibres are potentially very cheap, and their future is apparently in the field of hard-wearing, low-cost fabrics and garments.

**Polytetrafluoroethylene (PTFE) fibres.** In 1954 PTFE fibre was introduced by du Pont under the trademark Teflon, and such fibres are now produced by other manufacturers and in countries other than the United States, including the U.S.S.R., where it is called Ftorlon and Polifen.

Tetrafluoroethylene is purified and polymerized under heat and pressure in stainless steel autoclaves in the presence of a peroxide catalyst. After polymerization is completed, the dispersion is extruded through a spinneret, the jets emerging into an aqueous coagulating bath of a dilute solution of hydrochloric acid. The dispersion is coagulated, and the particles of PTFE hold together as weak filaments in which the particles remain entirely separate. The filaments are then heated rapidly

Desirable characteristics of saran

to about 385° C (725° F) and maintained at that temperature for several seconds, fusing the polymer particles into a coherent filament. This product is cooled quickly and drawn at room temperature to three or four times its original length.

PTFE fibres are unique in that they combine the resistance to chemicals, solvents, and elevated temperatures associated with inorganic fibres derived from mineral sources, with the flexibility and toughness typical of many organic fibres derived from animal and vegetable sources.

Because PTFE fibres are extremely costly, they are not suitable for general textile use. In addition, they have an unpleasant, greasy hand, no moisture absorption, high density, and low modulus. The outlet for these fibres is in end-uses where performance is of greater significance than initial high cost, such as filter fabrics and felts, gaskets, electrical tapes, and low friction backings.

*Fluorinated ethylene-propylene copolymer (FEP) fibres.* Fibres spun from FEP are similar to PTFE fibres, except that they are thermoplastic, melting at about 290° C (550° F).

*Polyvinylidene dinitrile fibres.* Vinylidene dinitrile was synthesized in the United States in 1947 by the B.F. Goodrich Company. Polymers and copolymers were made that led to the development of a new type of synthetic fibre produced under the trade name Darlan, later changed to Darvan. The manufacture of Darvan was discontinued in the United States in mid-1961.

#### POLYOLEFIN FIBRES

Polyolefin fibres are spun from polymers or copolymers of such olefin hydrocarbons as ethylene and propylene. Two types of fibre, polyethylene and polypropylene, dominate the field. Polyethylene fibres are limited to certain specialized applications; polypropylene fibres are of increasing importance, showing prospects of becoming major textile fibres in the late 20th century.

*Polyethylene fibres.* In the high-pressure-high-temperature process, ethylene is polymerized by heating at temperatures in the region of 150°–200° C (300°–400° F), with pressures of 1,000–2,000 atmospheres. The reaction is promoted by traces of oxygen or other catalysts. In the low-pressure-low-temperature process polymerization takes place at much lower pressures and at temperatures below 100° C (212° F). A variety of catalyst systems is used.

Polyethylene is extruded into monofilaments of round, flat, or other cross sections by extrusion techniques similar to those used with such other thermoplastic polymers as nylon and saran.

The commercial development of polyethylene fibres in the general textile field has been hampered by low softening point, high shrinkage, low stiffness, poor creep characteristics, and inability to take dyes. Such shortcomings restrict its use to specialized nonapparel applications.

Low-density polyethylene fibres are used for various industrial applications, including ropes and cordage, filtration fabrics, and protective clothing. They are used in the form of resilient shrinkable yarns for the production of three-dimensional fabrics. High-density polyethylene fibres are used in aerial tow targets, high-altitude balloons, and in equipment designed for Arctic conditions, in which the retention of strength and flexibility at low temperatures are invaluable. The strength, lightness, and water- and rot-resistance of polyethylene fibres have established them in the marine cordage field for the production of ropes and nets that float, do not rot, and do not absorb water. Furniture fabrics, car upholstery fabrics, curtains, protective clothing, tarpaulins, and filter fabrics are other applications making use of the special properties of polyethylene fibres.

*Polypropylene fibres.* The specific conditions under which polymerization of propylene is carried out are proprietary. Catalysts are used, such as an organometallic compound of aluminum in the presence of titanium tetrachloride, and the reaction is carried out under pressure at about 100° C (212° F).

Polypropylene fibres are made by extrusion of molten

polymer, followed by drawing to orient the molecules and crystals in the filaments. Polymer of high viscosity is spun to obtain optimum fibre properties. The filaments are cooled in air as they emerge from the spinneret and are then collected on bobbins.

Polypropylene monofilaments have applications similar to those of polyethylene, but offer higher strength, increased toughness, resilience, abrasion resistance, and creep resistance, and a higher melting point. These properties are allied to their water-resistance and chemical inertness. Polypropylene monofilaments have become established in a number of fields where they compete successfully with other fibres for such uses as ropes and cordage, fishing nets and twines, filter fabrics, and protective clothing.

The introduction of fine-denier multifilament yarns and staple fibre extended the range of potential applications for polypropylene fibre to the textile and apparel fields, bringing them into competition with established natural and synthetic fibres in applications where the shortcomings of polypropylene fibres often place them at a disadvantage. Despite the attractive characteristics of polypropylene fibres, less desirable properties, such as dyeing difficulties and relatively low melting points, have tended to limit progress.

#### POLYURETHANE FIBRES

Polyurethane fibres are spun from polymers made by a reaction taking place between small molecules, in which the linkage of the molecules occurs through the formation of urethane groups. Linear polyurethanes may be made by reaction of a glycol with a diisocyanate. The reaction of butanediol with toluene diisocyanate results in the formation of a polyurethane.

In recent years, polyurethanes have achieved increasing importance in textiles, becoming the basis of a novel type of elastomeric fibre known generically as spandex. Spandex fibres are spun from segmented polyurethanes made by a series of chemical stages, beginning with production of a low-molecular-weight polymer, or prepolymer, followed by a reaction of the prepolymer with diisocyanate and the coupling of isocyanate-terminated prepolymer to form segmented polyurethane.

The technique used in spinning spandex fibres depends upon the type of polymer spun. Some segmented polyurethanes are essentially linear molecules, soluble in solvents. Other segmented polyurethanes may be insoluble branched or cross-linked structures.

Soluble polyurethanes are dissolved in an appropriate solvent, and the solutions may be extruded through spinnerets into a coagulating bath (wet spinning), or into an atmosphere that removes the solvent (dry spinning). The techniques are essentially the same as those used for spinning hard synthetic fibres, with allowance being made for the elasticity of spandex fibres.

When the molecule of polyurethane is allowed to grow into a three-dimensional structure, it is insoluble and cannot be spun by either wet or dry processes. Instead, a chemical spinning process may be used. The isocyanate-terminated prepolymer is spun at a stage when it forms a viscous melt, the jets emerging into an environment containing a chain extender that diffuses into the fibre and reacts to link the prepolymer molecules into their final form, thus producing the branched or cross-linked polyurethane in fibrous form.

Because of their segmented structure, spandex fibres may be made stronger than rubber fibres. To achieve a given stretch, spandex fibres require a force twice as high, over the entire range of elongation, as the force required by rubber. In contrast to hard fibres, such as nylon, spandex fibres have a very low modulus of elasticity. Spandex fibre has about twice the effective power of rubber at the important elongations at which additional stretch of 50 to 100 percent is available.

The durability of spandex fibre in garments, in which resistance to flexure, abrasion, and needle-cutting are necessary, is high. Spandex-fibre fabrics show high resistance to flex and low growth compared to their rubber-fibre counterparts. The durability of spandex fibres

Industrial  
uses of  
poly-  
ethylene  
fibres

Spandex

allows production of very fine, or high denier, yarns that have opened up new applications for elastic fibres. In addition, spandex fibres were the first elastomeric fibres that could be readily dyed.

### Inorganic synthetic fibres

Fibres produced from inorganic substances include glass, aluminum silicates, metallics, and various other types having special industrial applications.

#### GLASS FIBRES

Glass fibres are spun from glasses of many different compositions depending on end use. Silica sand (silica) and limestone (calcium carbonate) are the basic ingredients to which are added varying amounts of other materials such as soda ash (sodium carbonate), potash (potassium carbonate), aluminum hydroxide or alumina (aluminum oxide), magnesia (magnesium oxide), or boric oxide.

The ingredients are charged into a furnace, where they are fused at high temperature to form molten glass. Filaments may be spun directly from this melt, or the glass may be formed into marbles of about 5/8-inch (16-millimetre) diameter that are passed to the spinning machines, also called fiberizing units.

Continuous filament strands are produced by allowing molten glass to flow through perforated tips on the baseplate of a platinum melter, or bushing, drawing away a stream of glass from each tip to form a fibre, and attaching the fibres to a high-speed winding device. The bushings may be mounted on glass-melting tanks, or may form the basis of independent fiberizing units, being fed with glass by the remelting of glass marbles.

As the 50 or more filaments are drawn from the orifices, they are brought together into a strand, and a lubricating size, or finish, is applied to facilitate subsequent processing. Strands intended for use in textile weaving may be converted through conventional textile processes into suitable yarns. There are various methods of producing glass staple fibre; the most important include the centrifugal, jet, and rod-drawing processes.

In the centrifugal process, molten glass is thrown out of holes in the base of a metal spinner rotating at high speed. The resulting fibres are bonded into a web for use in heat and sound insulation. This technique is not generally used for production of textile-grade glass fibres.

In the jet process, staple fibre is produced from molten glass that flows under gravity through holes in the base of platinum bushings, as in the production of continuous filament. The streams of glass are drawn into fibres by the action of high-speed streams of turbulent gas or steam, and the turbulence breaks the solidified fibres into staples of 8 to 15 inches (200 to 380 millimetres) that are collected into a web on a revolving vacuum drum. The web may then be guided from the drum and formed into a glass staple sliver, a continuous strand of loosely assembled fibres that is processed on conventional textile machines for weaving into glass-fibre staple fabrics.

The rod-drawing process is a modern development of the traditional process for making glass filaments. In a typical modern machine, 125 glass rods, usually about four millimetres (0.2 inch) in diameter, are mounted vertically and adjacent to one another in a kind of spinning frame. The rods are kept moving slowly downward, and are simultaneously melted at a temperature of about 1,200° C (2,200° F), either by individual movable and adjustable gas burners or by electric heating coils in a fireclay chamber. Drops of glass fall away from the ends of the rods, drawing glass filaments after them.

Glass is a heavy fibre, with a specific gravity of the order of aluminum, and has good transparency. Its moisture absorbency is negligible, and the fibre shows no swelling or shrinkage. This latter characteristic is useful in applications in which dimensional stability in the presence of water is desirable, and in electrical applications, but it is detrimental in apparel, where absorption of moisture is useful.

Water affects the tensile properties of glass fibre, bringing about a reduction in tenacity after a very short time,

caused by the leaching out of some of the soluble materials from the glass, including alkali silicates; glass with a low alkali content is most satisfactory in this respect.

The high coefficient of friction of glass against glass, taken in conjunction with the high flexibility of fine glass filaments, results in poor abrasion resistance. The movement of filament against filament during use brings about fracture of the filaments, creating a hairy fabric. Suitable lubricants and finishes can minimize such effects, and metal coatings may be applied to glass fibres to reduce surface friction.

Glass fibre has the highest strength-to-weight ratio of any fibre, and one of the lowest elongations. These characteristics are useful in applications requiring high dimensional stability, as in the reinforcement of plastics. The low elongation is not useful in apparel fabrics, in which resiliency is an important factor. Glass fibres exhibit almost perfect elasticity, returning instantly and completely to their original dimensions upon release from strain. This characteristic, however, is exhibited over only a very small range.

Glass fibre has excellent resistance to the effects of heat over a wide temperature range, with fabrics showing an increase in strength up to about 205° C (401° F), after which strength and flexibility begin to fall. At 370° C (700° F), glass filaments retain 50 percent of their original strength; at 538° C (1,000° F) they retain about 25 percent. The effect of temperature depends greatly upon the composition of the glass.

Glass is completely nonflammable and is used where resistance to the spread of flame is of overriding importance. The high heat conductivity of glass is a useful attribute in electrical-insulation applications, where close-woven glass fabrics dissipate heat rapidly. Despite this quality, glass fibre is useful as a heat insulation material and is employed in the form of mats and waddings in which entrapped air provides the insulation.

Glass has high resistance to most chemicals but is disintegrated by alkalies. Glass fibres may be attacked by certain strong mineral acids and by phosphoric acid, but show complete resistance to biological degradation.

fibre to  
heat

#### ALUMINUM SILICATE FIBRES

Fibres are spun from aluminum silicate, with or without the addition of minor amounts of other materials. Aluminum-silicate fibres were developed originally for use in jet engines to provide high-temperature-resistant, lightweight, strong, fibrous material of low thermal conductivity. These fibres are also used for such products as high-temperature filters, packings, gaskets, and for thermal, electrical, and acoustical insulation.

In the production of aluminum silicate a mixture of equal parts of alumina and silica with a small proportion of sodium borate added to produce short staple, or zirconia to produce long staple, is fused in an electric furnace. The molten aluminum silicate is poured from the furnace in a small stream. As it falls, the stream disintegrates into tiny droplets or particles that are attenuated into fine fibres as they are blown through the air and collect on a mesh screen, forming a mat of fibre.

Aluminum-silicate fibres are used largely for insulation purposes, filling a gap that exists from about 400° C (about 750° F), where glass, mineral wool, and asbestos are often inadequate, to about 1,260° C (2,300° F). Aluminum silicate fibres can be used for short exposures at higher temperatures, with a slight loss of resilience and some shrinkage. The devitrification taking place at these temperatures does not affect the insulating properties of the fibres. Extremely low thermal conductivity is an outstanding feature of aluminum-silicate fibres.

Aluminum silicate provides a lightweight, high-temperature heat barrier with excellent thermal shock resistance, flame resistance, resilience, chemical stability, and electrical properties. Because the fibres of aluminum silicate interlock, there is no brittle structure to develop stresses during sudden heating or chilling.

Aluminum-silicate fibres are used for a variety of high-temperature applications, including thermal, acoustical,

Centrifugal process  
for glass  
fibres

and electrical insulation; and filters, packings, and gaskets; and containment and conveyance of molten non-ferrous metals.

#### METALLIC FIBRES

Fibres produced from metals may be used alone or in conjunction with other substances. Those used in modern textile manufacture are of two main types: (1) metallic single-component, or SC, fibres and (2) metallic multi-component, or MC, fibres.

*Metallic single-component fibres.* Late in the 1950s, the development of high-speed flight and space travel created demands for flexible materials capable of withstanding unique environmental conditions for use in the manufacture of protective garments, antenna membranes, parachutes, and other space-program structures. It was determined that the requirements for such applications could be met by the production of fibres of adequate flexibility, made from high-temperature metals or alloys; e.g., of the stainless steel type.

Methods of producing metal filaments of the required fineness were developed in the 1960s, and metal fibres have since become available in quantities and at a cost entitling them to consideration as genuine textile fibres.

Metallic SC filaments are produced by drawing either single filaments or multifilament strands. Single filament drawing produces excellent quality metallic fibres, but multifilament drawing offers the best possibility of reducing cost and increasing availability. One method of drawing multifilament yarns involves enclosing a bundle of two-mil (0.002-inch, or 0.05-millimetre) wires in a sheath of a dissimilar alloy. The sheathed bundle is drawn to the required extent, and the sheath is removed with nitric acid, leaving the multifilament yarn ready for sizing, warping, and weaving.

Metals possess a number of general characteristics that can be of practical use in textile applications. The potential high yield and fracture strengths of most metals allow production of fabrics exceeding in strength those that can be produced from existing organic or glass fibres. The absence of a significant viscous behaviour characteristic in metal fibres ensures dimensional stability in certain structures that would be difficult to achieve with conventional textile materials.

The most significant difference between organic fibres and metal fibres is in the rigidity or stiffness of the material. Most organic textiles have a stiffness less than one-twentieth that of most metals.

This high stiffness previously excluded metals from use as textile materials because it placed severe limitations on the processability and end uses of the fibres. Adequate flexibility has been achieved, however, with the advent of modern ultrafine metal fibres.

The higher weight of most metals, in comparison with organic materials, can be a serious disadvantage in the use of metal fibres for many applications. On the other hand, the resistance of metals to chemicals at room and elevated temperatures covers ranges generally exceeding those of organic fibres, thus allowing metal fibres to be employed in many military and industrial end uses in which specific chemical resistance is a requirement. In some applications, however, metals may suffer corrosion by chemical action.

Many metals can tolerate and endure temperatures higher than those that organic fibres will generally withstand. Most metals are good conductors of heat, and metal fibres may function as heat-sinks when used in adequate proportion in blends. The high electrical conductivity of most metal fibres provides an effective method of eliminating static electric charges.

*Metallic multicomponent fibres.* Multicomponent fibres are made from metal in association with other materials, commonly plastics. Modern metallic fibres of the multicomponent type are based largely on aluminum, which provides sparkle and glitter at a fraction of the cost of the early types of decorative fibre based on such substances as gold.

The aluminum in these fibres is in the form of a narrow ribbon-filament of either metal foil, or a plastic film that

has been vacuum-plated with vaporized aluminum and coated with a plastic film. In these composite structures, the metal is protected from corrosive influences of its environment and from mechanical damage. Multicomponent metallic fibres have achieved popularity as decorative fibres and are an important part of the modern textile industry.

Modern metallic filaments are made by sandwiching a thin layer of metal, usually aluminum, between thin sheets of the appropriate types of plastic film. The lamination may be carried out in several ways. In the production of the acetate butyrate aluminum-foil metallic fibre, for example, a thermoplastic adhesive, either coloured or clear, is applied to both sides of a sheet of aluminum 0.00045-inch (0.01-millimetre) in thickness. The coated foil is then heated to about 90° C (200° F) and passed through a set of rollers, together with two sheets of cellulose acetate butyrate, in such a way that the aluminum foil becomes the centre of the "sandwich." The laminated material is then slit into narrow ribbonlike filaments of the desired width; e.g., 1/8 to 1/128 inch (3.2 to 0.20 millimetres).

In some types of metallic filament, the centre of the sandwich consists of a plastic (e.g., polyester) film that has been vacuum-coated with aluminum, and this may then be protected by the application of layers of lacquer or plastic film as above.

Many types of coloured metallic filament are produced, including those with the metallic glitter of the aluminum shining through the coloured adhesive and those having coloured outer plastic films. Gold-coloured filaments are made by using an orange-yellow dyestuff or pigment in the adhesive; a silver colour requires only the natural glitter of the aluminum.

Metallic MC yarns are used almost entirely as decorative materials for the textile industry. The aluminum foil that provides the glitter in a modern metallic yarn is protected from any ambient corrosive materials by the plastic film in which it is enclosed. Polyester types will withstand repeated launderings without losing sparkle. Because metallic yarns are not affected by seawater or the chlorinated water of swimming pools, they are widely used in swimwear. The dyestuffs used in colouring metallic fibres are usually fast to light, thus retaining bright colour.

Because metallic MC yarns are used primarily for decorative purposes, they do not usually contribute significantly to the strength of fabrics or garments. They may, however, be used as weft or warp yarns, and are sufficiently strong to withstand weaving and knitting operations. When necessary, metallic yarns are combined with such supporting yarns as nylon. The plastic film of the metallic yarn is flexible, and the yarns are extensible to a degree depending upon the type.

Aluminum corrodes and tarnishes in air and in contact with seawater, but in metallic fibres it is protected so effectively that it retains its glitter for long periods. The chemical resistance of a metallic filament is generally equal to the chemical resistance of its coating of plastic film. In the case of polyester films, this is outstanding.

If metallic fibres remain in contact with strong alkaline solutions for prolonged periods, the aluminum may be attacked at the unprotected edges of the ribbon. Such fibres should not, therefore, be subjected to alkaline reagents of significant strength. Organic solvents also may attack the laminate adhesive or lacquer coating, and care is required in dry cleaning to ensure the use of an appropriate type of solvent. The plastic films in metallic fibres are thermoplastic, softening at elevated temperatures, and delamination may occur if the fibres are heated. Acetate types in particular should be processed only at low temperatures.

The plastic films may be permanently embossed by heat and pressure, thus allowing the introduction of special effects.

#### MISCELLANEOUS INORGANIC SYNTHETIC FIBRES

Fibres play an increasingly important role in engineering, where they are used as constituents of composite

Metallic filament "sandwiches"

Applications of SC fibres in space technology

materials. Embedded in a matrix, which may be plastic, metal, or ceramic, fibres contribute their unique properties to the composite to function in a manner similar to the steel rods embedded in reinforced concrete.

Composite materials containing fibres are used in applications in which high strength and low weight are needed, as in aeronautics and astronautics. Fibres retaining high strength at elevated temperatures are valuable in high temperature applications. Since World War II, many types of fibre have been used in composite materials, and the demand for new materials to meet the demands of modern engineering applications has stimulated development of new types.

Composites are heterogeneous structures consisting of a continuous matrix in which the fibrous material is dispersed and embedded. Efficient performance of the composite requires a strong bond between the fibre and the matrix. Techniques used in producing composites from fibres and matrices depend upon the nature of the materials and the purposes for which the composite is required.

Fibres may be in the form of continuous filaments, masses of staple fibre, yarns formed from continuous filaments or spun from staple fibre, or fabrics produced from yarns.

Continuous filaments may be used to build structures by a winding technique. The structure is built up by winding the filament around some kind of form, the structure being held together by a matrix as it is created. This technique is used in constructing pressure vessels and rocket bodies.

Staple fibre is commonly mixed with the matrix; *e.g.*, in the production of reinforced plastic materials. Yarns and fabrics may be used in layering processes, and glass-fibre-reinforced plastics are used in building boat hulls and car bodies.

**Carbon and graphite fibres.** Because the element carbon has the ability to form strong bonds between its atoms, carbon atoms hold together in strong three-dimensional structures, such as that of diamonds, and in two-dimensional structures, as in graphite, and they also hold together in strings, forming long, single-dimension polymer structures in the same way that molecules form the basic structural units of fibres.

The fibres used in textiles are based almost entirely on organic polymers; the molecules consist of long chains of carbon atoms, with other atoms or groups of atoms attached as appendages to the carbon backbone. By removing the appendages from an organic fibre molecule it is possible to produce long molecules consisting entirely of carbon atoms. When a chemical operation of this sort is carried out on a highly oriented organic fibre, carbon fibres can be obtained in which the molecules retain a high degree of orientation.

Such carbon fibres may be produced by treatment of organic fibres under carefully controlled conditions. Cellulosic fibres, such as viscose rayon, or acrylic fibres are the favoured starting materials, and acrylic fibres are widely used in the commercial production of carbon fibres.

The nature of the carbon fibre produced depends upon the conditions under which pyrolysis, the subjection to the action of heat, is carried out. At lower temperatures, carbon fibres are formed; at higher temperatures, the carbon atoms in the fibre are arranged in the crystalline form of graphite.

Carbon fibres have a high strength-to-weight ratio, as well as high modulus and stiffness. They are thermally stable, retaining high strength at temperatures where other engineering materials suffer significant loss of strength. Graphite fibres are softer and have high electrical conductivity.

Composite materials containing carbon fibres are used in making the compressor turbine blades in jet engines, and in the construction of aircraft and spacecraft. They are used in deep-sea submersibles, in heavy-duty bearings, and in pressure vessels. In spacecraft re-entry shields, carbon fibre composites are able to retain their structural form at the high temperatures developed.

**Boron and boron-derivative fibres.** The development of boron fibres has provided the engineering industry with high-modulus continuous filaments used in high-performance composites. Boron filaments may be made by depositing the element boron on a fine core filament of a conducting material such as tungsten or carbon. Boron trichloride is passed over such a filament, which is then heated electrically, thus causing the boron trichloride to decompose and deposit boron on the core filament.

Boron-nitride fibres are commercially useful because they have properties similar to those of graphite fibres, including high strength, low weight, and high elastic modulus. They conduct heat readily, and are thermally stable, but differ from graphite fibres in being good electrical insulators.

**Refractory oxide fibres.** In modern engineering, the demands made upon materials are of increasing stringency; materials are required to retain such properties as high strength when used at high temperatures and under corrosive conditions. These requirements have stimulated great interest in production of fibres from refractory oxides and similar materials. Alumina or silica, for example, may be used at high temperature and in an oxidizing environment. Many such materials are difficult to spin, however, because of their comparatively sharp melting temperatures and narrow viscosity ranges.

Special techniques have been devised to meet particular problems. Alumina may be spun by packing it into a tube of fused silica. The end of the tube is melted, and the fibres drawn from the molten material consist of crystalline alumina filaments enclosed in silica sheaths.

Silica-carbon fibres may be made by drawing continuous filaments from a solution of viscose rayon and sodium silicate. The filaments are pyrolyzed (heated to a high temperature) in nitrogen, to form a silica-carbon fibre that may be converted to a silicon carbide fibre by heating at temperatures above 1,500° C (2,700° F).

**Whiskers.** Single crystals of extremely high strength, called whiskers, have been the subject of scientific investigation for many years. They are a form of fibre, and have potential importance in the fibre composite field.

Whiskers produced from alumina and silicon have very high elastic moduli and do not exhibit plastic deformation. Used in composites (*e.g.*, with resins, metals, or ceramics), whiskers provide engineering materials having unique and valuable characteristics. Titanium compressor blades reinforced with silicon-carbide whiskers, for example, retain high strength at elevated operating temperatures. The future of such materials depends mainly upon the development of commercially viable techniques of producing whiskers.

### Economic aspects

From the original production of Chardonnet silk in the 19th century, synthetic fibres have had a large and growing economic impact throughout the world. Before World War II, the production of man-made fibres consisted almost entirely of cellulose-derived fibres, mainly viscose and acetate. During the 1930s, as a result of intensive fibre research, several new synthetic fibres were produced experimentally. In the late 1930s these tentative steps led to the production of nylon, the first commercially successful synthetic-textile fibre.

Since that time, the development of synthetic-fibre production has continued. The years following World War II were marked by the introduction of new types of synthetic fibre; nylon was joined by the polyesters, acrylics, polyolefins, and others as fibre producers worked to establish themselves in the new technically based industry. Some of the new types of fibre have achieved high acceptance; others have not lived up to their early promise and have disappeared.

Because the commercial development of a synthetic fibre requires substantial expenditure on research, technology, and plant construction, a commitment to produce a particular type cannot be easily changed to produce another of marginally better properties. Manufacturers, who must recoup their original investments, work

to improve the chosen fibre. A stage is commonly reached in the development of a new technologically-based industry where consolidation becomes necessary, and the synthetic industry reached this stage, to a large degree, in the 1960s. Producers who had committed themselves to the production of polyamides, polyesters, acrylics, and other commercially accepted fibres concentrated much of their attention on the improvement of basic products. There was rapid commercial development of techniques increasing the versatility of established fibre types. The development of texturizing, chemical crimping, multicomponent fibres, and film fibres extended applications of synthetic fibres, and the production of polynosic, or high wet modulus, and other modified rayons stimulated interest in the natural polymer fibres field.

Several new fibres were introduced, however, during this consolidation period. Polyurethanes and polypropylenes made a powerful impact on the textile market and other new fibres were in the experimental stage.

In the early 1950s, man-made-fibre production accounted for about 13 percent of the world fibre total. The proportion increased steadily, reaching over 29 percent in 1968-69. During this same period, the total fibre production increased from 35,212,000,000 pounds in the early 1950s to 55,281,000,000 pounds in 1968-69. The man-made-fibre industry thus increased its output from 4,630,000,000 pounds in the early 1950s to 16,164,000,000 pounds in 1968-69, achieving expansion of almost 400 percent in less than two decades. This rapid development has exerted a powerful influence on many aspects of the industrial world. New fibres have required new production techniques, new processing machinery, and new developments in textile, clothing, and other industries, and in retail merchandising.

Man-made fibres are produced almost entirely from organic polymers, constructed from various carbon derivatives. In the natural polymer fibres, cellulose is the basic material from which the most commercially important fibres are made, and, although ample supplies of cellulose are available, conversion to a form suitable for fibre production presents certain problems. The raw materials of synthetic fibres, however, are simple organic chemicals that come from stores of available carbon compounds. Initially, the industry relied heavily upon coal for such materials, but petroleum has largely superseded it. The rapid development of synthetic-fibre production has made heavy demands on the resourcefulness of the petrochemicals industry.

As world population expands, the demand for textiles may be expected to increase. In addition, a need for greater versatility in textile materials is likely. The man-made-fibre industry is expected to supply an increasingly large share of the total world fibre output, and because man-made fibres can be tailor-made to meet particular needs, a portion of the increased production will consist of specialized types. The greatest production, however, will be in "bread-and-butter" fibres, such as polypropylene, that can be produced cheaply to provide the kind of textiles that have long been produced from cotton.

**BIBLIOGRAPHY.** H.F. MARK, N.G. GAYLORD, and N.M. BIKALES (eds.), *Encyclopedia of Polymer Science and Technology: Plastics, Resins, Rubbers, Fibers*, 9 vol. (1964-68), provides a comprehensive survey of fibre science and technology. J.G. COOK, *Handbook of Textile Fibres*, 4th ed., 2 vol. (1968), treats the production, properties, processing, and applications of natural and man-made textile fibres. *Industrial Fibres* (Commonwealth Secretariat 1968), is a survey of production, trade, and consumption relating to both natural and man-made fibres. ## Fibres, Natural

A natural fibre may be defined as an agglomeration of cells in which the diameter is negligible in comparison

with the length. Although nature abounds in fibrous materials, especially cellulosic types such as cotton, wood, grains, and straw, only a small number can be used for textile products or other industrial purposes. Apart from economic considerations, the usefulness of a fibre for commercial purposes is determined by such properties as length, strength, pliability, elasticity, abrasion resistance, absorbency, and various surface properties. Although no fibre combines the optimum of all desirable properties, most have some unique property particularly adapted to the special requirements of certain textile products.

This article is divided into the following sections:

- I. General considerations
  - History of fibre production
  - Classification and properties of natural fibres
- II. Vegetable fibres
  - Seed- and fruit-hair fibres
  - Bast fibres
  - Leaf fibres
- III. Animal fibres
  - Wool
  - Specialty hair fibres
  - Silk
- IV. Mineral fibres

### I. General considerations

#### HISTORY OF FIBRE PRODUCTION

The use of natural fibres for textile materials began before recorded history. The oldest indication of fibre use is probably the discovery of flax and wool fabrics at excavation sites of the Swiss lake dwellers (7th and 6th centuries BC). Several vegetable fibres were also used by prehistoric man. Hemp, presumably the oldest cultivated fibre plant, originated in Southeast Asia, then spread to China where reports of cultivation date to 4500 BC. The art of weaving and spinning linen was already well developed in Egypt by 3400 BC, indicating that flax was cultivated sometime before that date. Reports of the spinning of cotton in India date back to 3000 BC. The use of natural fibres for spinning and weaving textiles considerably predates the establishment of these ancient civilizations. The manufacture of silk and silk products originated in the highly developed Chinese culture; the invention and development of sericulture (cultivation of silkworms for raw-silk production), and methods to spin silk date from 2640 BC. With improved transportation and communication, highly localized skills and arts connected with textile manufacture spread to other countries and were adapted to local needs and capabilities. New fibre plants were also discovered and their use explored. In the 18th and 19th centuries, the Industrial Revolution encouraged the further invention of machines for use in processing various natural fibres, resulting in a tremendous upsurge in fibre production. The introduction of regenerated cellulosic fibres (fibres formed of cellulose material that has been dissolved, purified, and extruded), such as rayon, followed by the invention of completely synthetic fibres, such as nylon, challenged the monopoly of natural fibres for textile and industrial use. A variety of man-made fibres having specific desirable properties began to penetrate and dominate markets previously monopolized by natural fibres. Between 1950 and 1970 total world fibre production increased from 35,000,000,000 pounds to 55,000,000,000 pounds (16,000,000,000 to 25,000,000,000 kilograms). About one-third of this increase was in natural fibres and two-thirds, or about 12,000,000,000 pounds, resulted from increases in the production of man-made fibres. Man-made-fibre production increased fourfold in this period, and its percentage of the total fibre production increased from 13 percent in 1951 to 29 percent in 1969. Recognition of the threat from man-made fibres resulted in intensive research directed toward the breeding of new and better strains of natural-fibre sources with higher yields, improved production and processing methods, and modification of fibre yarn or fabric properties. The considerable improvements achieved have permitted increased total production, although the actual share of the market has decreased with the influx of the cheaper, man-made fibres requiring fewer man-hours for production.

Expansion  
of man-  
made fibre  
production

In 1968–69, natural fibres accounted for over 70 percent of the world's total fibre production, with cotton remaining the most important. Estimated total annual world production of natural fibres in this period amounted to about 40,000,000,000 pounds. Table 1 provides figures on world production for the major natural and man-made fibres.

Table 1: Estimated Total World Fibre Production, 1968–69 (000,000 lb)		
	total production	percentage
Natural fibres		
Wool	3,537	6.4
Cotton	25,566	46.2
Silk	83	0.15
Flax	1,487	2.7
Hard fibres and hemp*	2,421	4.4
Jute and allied fibres*	6,023	10.9
Man-made fibres		
Rayon filaments	3,125	5.6
Rayon staple	4,747	8.5
Noncellulosic man-made	8,292	15.0
Total	55,281

CLASSIFICATION AND PROPERTIES OF NATURAL FIBRES

Natural fibres can be broadly classified according to their origin. The vegetable, or cellulose-base, class includes such important fibres as cotton, flax, and jute; the animal, or protein-base, fibres include wool, mohair, and silk; the most important fibre in the mineral class is asbestos.

The vegetable fibres can be divided into smaller groups, based on their origin within the plant. Cotton, kapok, and coir are examples of fibres originating as hairs borne on the seeds or inner walls of the fruit, where each fibre consists of a single, long, narrow cell; flax, hemp, jute, and ramie are bast fibres, occurring in the inner bast tissue of certain plant stems and made up of overlapping cells; abaca, henequen, and sisal are fibres occurring as part of the fibrovascular system of the leaves. Chemically, all vegetable fibres consist mainly of cellulose, although the various fibre types are associated with varying amounts of such substances as hemicellulose, lignin, pectins, and waxes that must be removed or reduced by processing.

The animal fibres consist exclusively of proteins, and, with the exception of silk, constitute the fur or hair that serves as the protective epidermal covering of animals. Silk filaments are extruded by the larvae of moths and are used to spin their cocoons.

Asbestos, the only naturally occurring mineral fibre currently used commercially for textile purposes, is found as asbestos rock, formed of tightly packed crystallized fibres that can be readily separated.

With the exception of mineral fibres, all natural fibres have an affinity for water in both liquid and vapour form. Under standard conditions, the moisture content of vegetable fibres is from 6 to 10 percent; while animal fibres, including silk, have a moisture content of 10 to 15 percent. This ability to absorb moisture makes natural fibres particularly suitable for clothing. The transfer of moisture from the body through the fibres to the surrounding atmosphere provides considerable comfort to the wearer. The presence of moisture also serves to inhibit the build-up of static electricity that, especially in dry weather, can cause considerable discomfort in garments made of synthetic fibres. The strong affinity of natural fibres for water, producing the swelling of the fibres connected with the uptake of water, facilitates dyeing in watery solutions. The considerable increase of diameter in water, and the very limited swelling in the longitudinal direction, are characteristic of natural fibres.

Most natural fibres consist of extended chains of polymers (large molecules formed from smaller molecules)

that can be packed together in a regular arrangement, resulting in high density. Wool and other keratin (insoluble protein, forming such horny epidermal tissue as hair, horn, and feathers) fibres are exceptions, consisting of irregular, overlapping, scalelike cells, elongated spindle-shaped cells, and either air-filled cells or a hollow tube, resulting in close packing or interlocking. The mechanical properties of the natural fibres are a direct reflection of their structure and the orientation of their molecules. The cellulosic fibres have a fairly high modulus, or resistance to stress, and are low in extensibility, or ability to stretch; but the animal fibres have a low modulus and high extensibility resulting from the unfolding of the helical structure during extension. Breaking strength, or tenacity, is measured in grams per denier (1 denier equals the weight in grams of 9,000 metres of the fibre), permitting comparison of the amount of stress that can be resisted without breakage by fibres having a specific number of units of weight for a specific unit length. The breaking strength per denier of the common fibres is: cotton, three to six grams; jute, three to six; hemp, six to seven; flax, three to eight; ramie, five to eight; abaca, six to seven and a half; wool, one to two; and silk, three to six grams.

Unlike most synthetic fibres, all natural fibres are non-thermoplastic, that is, they do not soften when heat is applied. At temperatures below the point at which they will decompose, they show little sensitivity to dry heat, and there is no shrinkage or high extensibility upon heating, nor do they become brittle if cooled to below freezing. Decomposition resulting in discoloration starts at about 225° C (437° F) for cotton at a heating rate of 5° C (40° F) per minute; wool begins to decompose at approximately the same temperature. Cellulosic fibres ignite and burn readily and present a fire hazard unless properly treated. Protein fibres are somewhat less flammable. Natural fibres tend to yellow upon exposure to sunlight and moisture and extended exposure results in loss of strength. Jute, because of its high woody tissue (lignin) content, is particularly sensitive to sunlight.

All natural fibres are particularly susceptible to microbial decomposition, including mildew and rot. Cellulosic fibres are decomposed by attack from aerobic bacteria (those that live only in oxygen) and fungi. Cellulose mildews and decomposes rapidly at high humidity and high temperatures, especially in the absence of light. Wool and silk are also subject to microbial decomposition by bacteria and molds, and wool that has been damaged chemically appears to be even more susceptible to subsequent microbial action. Animal fibres are also subject to damage by moths and carpet beetles; termites and silverfish attack cellulose fibres. Protection against both microbial damage and insect attacks can be obtained by chemical modification of the fibre substrate; modern developments allow treatment of natural fibres to make them essentially immune to such damage.

Reactive chemical groups present in the polymer molecules making up the various natural fibres make them particularly susceptible to chemical modification and therefore to alteration of characteristics that may be undesirable for a specific application. Cellulosic fibres have good resistance to alkalies but are severely degraded or even dissolved by mineral acids. Wool and other hair fibres have excellent resistance to dilute acids but are degraded or dissolved by hot alkali. Silk, attacked and dissolved by both alkalies and strong acids, has fair resistance to weak acids. The extent of fibre damage is dependent upon the type and concentration of the chemical used as well as the length and temperature of exposure.

II. Vegetable fibres

Fibres of vegetable origin are composed chiefly of cellulose, a carbohydrate substance manufactured by the plant from water and carbon dioxide gas. Although cellulose fibres are available from numerous plant sources, only a limited number of them are suitable for textile use because of the difficulties involved in separating them from other substances. The three main groups of useful vegetable fibres, based upon the portion of the plant in which

The vegetable fibres

Value of moisture-absorbing quality

Microbial decomposition

they originate, are the seed and fruit group, the bast group, and the leaf group.

#### SEED- AND FRUIT-HAIR FIBRES

The group of vegetable fibres originating as single-celled seed or fruit hairs includes the commercially most important textile fibre, cotton, together with such less important fibres as coir and kapok.

**Cotton.** *History.* Cotton, the world's most important nonfood agricultural commodity, was one of the first vegetable fibres used for textile purposes. Cotton materials have been found in tombs in India dating as far back as 3000 BC, and a Hindu hymn of 1400 BC describes the manufacture of cotton yarns and the weaving of cotton cloth. Cotton was probably cultivated in Egypt by about AD 600–700; it was also produced by early Chinese civilizations. It was produced in the Mediterranean basin during the time of the Roman Empire (first half of 1st millennium AD) and was grown on the Greek mainland from the 8th century AD. Arab traders introduced cotton to the rest of the African continent.

In the 12th century Venice became a major cotton-manufacturing city, processing cotton from the Mediterranean area into cloth for sale in central Europe, and in the Middle Ages Germany became a cotton-manufacturing centre. The cotton trade was of great importance in the development of the British East India Company and other great trading companies of the 17th and 18th centuries. In the New World, cotton grave cloth has been found in pre-Incan Peru (before 2000 BC) and cotton yarns in the prehistoric Pueblo settlements of Arizona. Columbus, landing in the West Indies, was met by Indians offering cotton yarn for barter. Cotton cultivation in the United States began early in the 17th century and was closely connected with the introduction of slavery. After the invention of the cotton gin, which separates the fibre from the seeds, in 1793, the United States became a major cotton producer, with production concentrated in the southern and southeastern states. In the post-Civil-War period the large plantations were subdivided into small plots worked by tenant farmers, but with mechanization of cotton production and other farming operations, allowing cultivation by relatively few labourers, small farms were consolidated into larger operations. By the mid-20th century, cotton cultivation was well-established on irrigated land in the Western states of California, Arizona, and New Mexico, which led the traditional cotton states in production, and the trend throughout the United States was toward even greater mechanization.

*Production.* Cotton, belonging to the botanical family Malvaceae, genus *Gossypium*, is normally cultivated as a shrubby annual in temperate climates but can be found as a perennial in treelike plants in tropical climates. The cultivated shrub grows from four to six feet tall (about one to two metres) over a growing period of six to seven months.

Warm and humid climates with sandy soil are the most suitable. Although cotton can be grown between latitudes 30° N and 30° S, yield and fibre quality are considerably influenced by climatic conditions, and best qualities are obtained with high moisture levels resulting from rainfall or irrigation during the growing season and a dry, warm season during the picking period. Rain or strong wind may cause damage to the opened bolls.

Within 80–100 days after planting, the plant develops white blossoms, which change to a reddish colour. The blossoms fall off after a few days and are replaced by small green triangular pods, called bolls, that mature after a period of 55–80 days. During this period the seeds and their attached hairs develop within the boll, which increases considerably in size. The seed hair, or cotton fibre, reaching a maximum length of about two and a half inches (approximately six centimetres) in long fibre varieties, is known as lint. Linters, fibres considerably shorter than the seed hair and more closely connected to the seed, come from a second growth beginning about ten days after the first seed hairs begin to develop. When ripe, the boll bursts into a white, fluffy ball containing

three to five cells, each having seven to ten seeds embedded in a mass of seed fibres. Two-thirds of the weight of the seed cotton (*i.e.*, the seed with the adhering seed hair) consists of the seeds. To avoid damage by wind or rain the cotton is picked as soon as the bolls open, but since the bolls do not all reach maturity simultaneously, an optimum time is chosen for harvesting by mechanical means. Handpicking, carried out over a period of several days, allows selection of the mature and opened bolls, so that a higher yield is possible. Handpicking also produces considerably cleaner cotton; mechanical harvesters pick the bolls by suction, accumulating loose material, dust, and dirt, and cannot distinguish between good and discoloured cotton. A chemical defoliant is usually applied before mechanical picking to cause the plants to shed their leaves, thus encouraging more uniform ripening of the bolls.

Cotton is attacked by several hundred species of insects, including such harmful species as the boll weevil, pink bollworm, cotton leafworm, cotton fleahopper, cotton aphid, rapid plant bug, conchuela, southern green stinkbug, spider mites (red spiders), grasshoppers, thrips, and tarnished plant bugs. Limited insect control can be achieved by proper timing of planting and other cultural practices, or by selective breeding of varieties having some resistance to insect damage. Chemical insecticides, which were first introduced in the early 1900s, require careful and selective use because of ecological considerations but appear to be the most effective and efficient means of control.

The boll weevil (*Anthonomus grandis*), the most serious cotton pest in the United States in the early 1900s, was finally controlled by appropriate cultivation methods and by the application of such organic insecticides as chlorinated hydrocarbons and organic phosphates. A species of boll weevil resistant to chlorinated hydrocarbons was recorded in the late 1950s; this species is combated effectively with a mixture of toxaphene and DDT (dichlorodiphenyltrichloroethane). The pink bollworm (*Pectinophora gossypiella*), originally reported in India in 1842, has spread throughout the cotton-producing countries, causing average annual crop losses of up to 25 percent in India, Egypt, China, the Soviet Union, and Brazil. Controls and quarantines of affected areas have helped limit the spread of the insect, and eradication has been possible in a few relatively small areas with sufficiently strict controls. The bollworm (*Heliothis zea*, also known as the corn earworm) feeds on cotton and many other wild and cultivated plants. Properly timed insecticide application provides fairly effective control.

Cotton plants are subject to diseases caused by various pathogenic fungi, bacteria, and viruses, and to damage by nematodes (parasitic worms) and physiological disturbances also classified as diseases. Losses have been estimated as high as 50 percent in some African countries and in Brazil. Because young seedlings are especially sensitive to attack by a complex of disease organisms, treatment of seeds before planting is common. Some varieties have been bred that are resistant to a bacterial disease called angular leaf spot. Soil fumigation moderately succeeded in combatting such fungus diseases as fusarium wilt, verticillium wilt, and Texas root rot, which are restricted to certain conditions of soil, rainfall, and general climate. The breeding of resistant varieties, however, has been more effective.

*Processing.* Before it is spun into yarn and woven into cloth, cotton must pass through a number of processes including ginning, baling, grading, marketing, opening, picking, carding, combing, drawing, and roving.

Ginning is the process of separating the cotton lint from the seeds. Separation was originally accomplished entirely by hand. The earliest mechanical device employed was probably the churcka gin, developed many centuries ago in India, which has the longest history of use. In this device, seed cotton is fed manually between a pair of rollers, and the lint caught between the rollers is drawn out and pulled from the seed, which is too large to pass through the compression point of the rollers. This method, best suited for Indian varieties with clean, naked, and

Damage by insects and micro-organisms

Factors influencing cotton crops

The ginning process

hardy seeds having slight fuzz, results in a very small production rate. Cotton ginning was revolutionized when hand methods were replaced by the saw gin, invented by Eli Whitney of the United States in 1793, and by an improved model, invented by Hogden Holmes, also of the United States, in 1796, which became the ancestor of the modern gin.

In modern ginning plants the gin stand is one unit in a series of machines. The modern roller gin, incorporating the basic principles of earlier versions, consists of a series of toothed circular saws projecting between the slits in a series of metal ribs. The revolving saws catch the fibres in their teeth, and the limited clearance between the saw blade and the rib plate allows only the plucked fibres to pass through the slits, leaving the seeds behind. The lint is then removed from the gin by air blast or by a large cylinder brush. Some gins are equipped with lint cleaners that further clean the cotton after it has been removed from the seed.

Because mechanical harvesting may pick up considerable leaf, twigs, boll, burrs, and plant trash, improved machines have been developed to perform extensive drying and cleaning before ginning, and to clean the lint after the seed is separated from the fibres. The separated lint is conveyed to pressing boxes, where it is pressed into bales of approximately 500 pounds (225 kilograms) each. The seeds are shipped to crushing mills where they are processed to obtain various by-products.

Cotton is sold in local markets generally held around the gin. The buyer may be the ginner, an agent for the spinning mill, or a merchant or banker to whom the grower is indebted. In the United States much cotton has gone into the cotton-loan program promulgated in 1933 and is not purchased by an independent buyer but is transferred from the gin to approved warehouses, on the basis of which the seller obtains a loan on the negotiable receipt.

Quality variations in cotton result from differences in such factors as the varieties planted, soils, irrigation methods, rainfall, fertilizers used, climatic conditions, insect damage, length of growing season, exposure of open cotton before harvesting, and ginning methods.

Classing, the classification of cotton, is a method of describing quality by grade and staple, or fibre length. Although classing systems vary throughout the cotton-producing and consuming countries of the world, they are essentially based on fibre length and grade. Grade is determined by colour, leaf (foreign matter), and preparation (ginning).

There is a strong correlation between cotton-fibre length and strength. Generally, longer staple (fibre) varieties are much finer and stronger than the shorter staple cottons and, consequently, they can be spun into finer and stronger yarns.

The three major groupings are based on length, fineness, and lustre.

1. Long-staple fibres, 1-2½ inches (2½-6 centimetres) long, fine, and of good lustre, include Sea Island varieties, grown mainly in the West Indies and in the south-western United States; Egyptian (cultivated mainly in the Nile River valley); and Egyptian-American, or Pima, a variety developed in the United States from Egyptian cotton (*Gossypium barbadense*).

2. Intermediate fibres, or medium staple, the most important type, have a length of about two inches (five centimetres) and are somewhat coarser. An example is Upland cotton (*Gossypium hirsutum*) probably originating in Central America, grown in the southern United States, and also bred into other varieties grown throughout the world. Deltapine and Acala are currently the main medium-staple cotton varieties. Medium-staple cotton has considerably higher yields than the long-staple cotton but brings lower prices.

3. Short-staple fibres, ¾ to ½ inch (about 1.2 centimetres) long, coarse, and without lustre, include Indian and Asiatic cotton (*Gossypium herbaceum* and *G. arboreum*), grown in India, Pakistan, and China.

Only the species of the genus *Gossypium* mentioned above are commercially cultivated.

To produce cotton yarn of good quality and to achieve high performance during processing, several bales of similar fibre length and fineness are intimately blended. Blending is achieved either by feeding small amounts of cotton from several bales stacked behind blending hoppers or by sandwiching quantitatively proportioned opened cotton in bins. In Egypt and the United States blending may be carried out before baling the cotton for shipment.

The blended and opened cotton is processed through the picking operation, which opens, blends, cleans, reduces the lump size, removes waste and dust, and prepares the cotton for carding. Handling, cleaning, and metering (assuring uniformity of feed) is facilitated by reducing the cotton particles or lumps to the smallest possible size. This reduction is accomplished on the picking machines, where the cotton mass is plucked by steel spikes or blades, rotating at high speed and striking the fibres against the undercasing of the beater. Three to four such machines, or beaters, are arranged in series, depending upon the cleanliness of the raw material. The cotton is moved through these machines by air currents. At the last picking machine, the cotton is condensed in a sheet form called lap.

The opened cotton, still containing small unopened tufts of fibres, is further fractionated into individual fibres on the carding machine. This process also removes trash, vegetable matter, and short fibres detrimental to processing performance and yarn quality. Carding is accomplished by the action of suitably arranged inclined wires mounted on cylinders rotating at different speeds. The fibres are teased apart, then transferred to the wire points of another large cylinder, or doffer, and eventually stripped by a high-frequency vibrating comb into a thin sheet of web. This is collected into a rope form, called sliver, about ¾ to one inch (about 2-2.5 centimetres) in diameter, and deposited in cans. Cottons may be combed to remove short fibres (about 5 to 20 percent in weight), thus achieving improved uniformity of staple length and greater lustre and strength in yarns.

Drawing, or drafting, is the process of straightening and parallelizing the fibres in the direction of the strand. It also performs the function of blending by combining several slivers, called doubling, and reducing the mass of fibres in the strand without breaking the continuity. This reduction is achieved by processing slivers through several pairs of rollers running at different surface speeds. It is customary to employ two drawing operations after carding and two after combing.

The sliver is reduced in size by roller drafting and slightly twisted to form what is called roving, which is wound on a special bobbin for feeding to the spinning frame. Carded- or combed-drawn sliver is reduced by stretching on the roving frame to a size suitable for spinning.

Spinning, the final process in the conversion of fibres into yarns, involves reduction of the size of the strand by drafting rollers; twisting the drawn material; and winding the yarn into a suitable package.

A single cotton yarn is a continuous twisted strand of fibres that has received its final attenuation. The first operation is carried out by drafting rollers; twisting and winding is accomplished by the spindle and traveller (a small metallic wire piece bent into C or D shape) on a ring spinning frame. In other modern systems twisting may be performed by a high-speed rotor disk, as in open-end spinning.

In the metric system, the size of a cotton yarn is designated as tex; i.e., the weight in grams of 1,000 metres (3,300 feet) of yarn. If 1,000 metres of a yarn weigh 20 grams, its tex is 20. Count is a numerical designation indicating yarn size and based on the number of unit lengths per pound of a particular yarn.

Cotton yarns are produced in a variety of types. The three main classifications are warp yarns, used as the longitudinal thread in the fabric; filling or weft yarns, used for crosswise interlacing and generally containing less twist; and knitted yarns, used to make knit fabrics. Knitted yarns have less twist than weft yarns and are made with considerable care to achieve good uniformity.

roving

Classifica-  
tion of  
cotton

Cotton  
scouring

Other classifications are carded and combed yarns, named for the process used.

Even after the harsh mechanical action of the gin, cotton fibres retain a certain amount of seed-coat fragments, assorted seeds, and sometimes fragments of the cotton plant. These impurities are known as motes. In addition to motes, such impurities as pectins, proteinic substances, ash, wax, and natural pigments must be removed before dyeing and finishing. The process that removes all undesirable materials is known as scouring. Most cotton is scoured (treated at the boil with caustic-soda solution), bleached, and mercerized (see below) in the form of cloth, but a small quantity is also boiled out in the loose or in yarn form. The first stage in the removal of these impurities is scouring in hot alkaline solutions. Loose cotton or yarn in skein form is boiled in pressure vats at a temperature of 240° F (116° C) for eight hours in a 4 to 6 percent sodium hydroxide solution. During this treatment, the natural impurities either become soluble in hot alkali or are rendered removable by decomposition, saponification (for fats and oils: separation into salts of fatty acids and glycerol), or emulsification (suspension of minute particles in liquid). A weight loss of 6 to 9 percent is normally experienced after scouring. Scouring tends to make cotton considerably whiter and smoother in feel.

Cotton is generally bleached by three distinct systems, which employ, in the order of their development, hypochlorite, hydrogen peroxide, and chlorite. These oxidative treatments are highly selective, attacking the impurities rather than the cellulose. Nearly 80 percent of cotton bleached in fabric form is bleached with hydrogen peroxide because of its adaptability to continuous processing. Sodium chlorite is a popular bleaching agent in Europe, where 25 percent of the cotton bleaching is done with it. When raw stock or yarn is bleached in packages with sodium hypochlorite it is piled into a kier (vat) and the bleach liquor is circulated continuously through the goods at a temperature ranging from 55° to 70° F (13° to 21° C). After bleaching, cotton is washed and treated to remove residual hypochlorite by absorbing it in sulfur dioxide or sodium bisulfite. Hydrogen peroxide bleaching is generally performed at temperatures around the boiling point of water, and the higher the temperature, the shorter the bleaching time. Sodium chlorite bleaching offers advantages in bleaching cotton because it reduces requirements for desizing and scouring, produces little or no cellulose degradation, involves low weight loss, and gives better hand (feel) to the fabric.

Cotton is mercerized to impart permanent, increased lustre. In addition, the process contributes to improvement of dye affinity, chemical reactivity, dimensional stability, strength, and smoothness and makes immature fibres readily dyeable. In mercerization, cotton is treated while under tension with caustic soda of mercerizing strength (between 16 and 24 percent), and the excess caustic soda is rinsed away before tension is released. Mercerizing may be carried out on gray cotton or after scouring and bleaching. Long-staple cottons generally respond best to mercerization.

Cotton's  
by-  
products

By-products of cotton processing include linters used for stuffing material in mattresses and upholstery, and to form the base for cellulose acetate and rayon fibres and for other cellulose derivatives used as explosives, films, lacquers, and plastics. Hulls, constituting almost half the weight of the cottonseed, are crushed and used mainly to feed cattle. Cotton cake, left after the oil has been removed from the seed, is ground into cottonseed meal, rich in nitrogen, which is used for fertilizer and cattle feed.

**Fibre properties.** Cotton fibres are single plant cells consisting of an outer, or primary, cell wall and an inner core of growth layers comprising the secondary wall. The fibre grows daily and growth layers are deposited around a central canal, or lumen, carrying liquid to the living cell. These growth layers can be observed microscopically when the fibre is fully swollen. When a ripened boll opens under the pressure of the fibres, the liquid dries rapidly and the lumen collapses. After drying, the

fibre has the appearance of a twisted ribbon. The twists or convolutions result from changes occurring in the fibre as it matures. The number of twists per inch ranges from 150 to 300, depending on the different varieties. The cross sections of dry cotton fibres are normally oval or kidney-bean shaped.

The cell walls are composed of many layers of very small fibrils arranged in a spiral pattern, with a distinct angle to the fibre axis, and with numerous reversals.

Chemical analysis of the major constituents of the cotton reveals that it is close to 95 percent cellulose. The secondary wall, or secondary layers, are nearly pure cellulose. Other substances such as waxes, are confined almost entirely to the primary wall; the protoplasmic residue, pigment, ash, and sugars, are found in the residue of the lumen.

Cotton is never truly white. All cotton samples have a soft, creamy tint with some of the long-staple strains more creamy by several shades than the Upland cotton and Sea Island types. Some of the shorter staple cottons are highly coloured, ranging from deep caramel, to khaki, to beige. In the 1970s it was reported that Soviet scientists were breeding coloured strains to produce marketable cotton with built-in colour. Most of the pigments, however, are unstable to sunlight.

The breaking strength of cotton fibres is related to the molecular-chain length and the orientation of the cellulose. Strengths ranging from 70,000 to 116,000 pounds per square inch have been determined on fibre-bundle tests. Breaking strength decreases considerably if longer test specimens are used, because the probability of finding a weak spot in the fibre increases. The elongation of cotton fibres before breaking averages 7 percent, considerably higher than that of the other natural cellulosic fibres.

The effect of moisture on cotton-fibre properties is significant. Bone-dry cotton fibres cannot be spun because of their lack of electric conductivity; the correct moisture content for spinning is essential. The considerable affinity of cotton for moisture contributes to comfort, making cotton superior to most synthetic fabrics used in apparel. Moisture content has a considerable effect on the strength of the cotton fibre, which increases with relative humidity. An oven-dried yarn may be as much as 30 percent weaker than a conditioned yarn, which increases in strength upon immersion in water. This surprising effect of moisture on strength is caused by the water in the fibre structure permitting a more uniform distribution of stresses. The cross-sectional area of cotton fibres increases by about 44 percent at saturation with water, and the average increase in length is about 1.1 percent.

Cotton cellulose is a carbohydrate composed of the elements carbon, hydrogen, and oxygen. Complete hydrolysis (decomposition in water) of the cellulose with strong mineral acids yields the sugar glucose. The basic unit of the cellulose chain is the organic molecule cellobiose, and cellulose consists of long chains of this unit. Estimates of the molecular weight, or degree of polymerization (large molecule formation), of native cotton cellulose is controversial; some workers believe that the chain molecules of native cellulose are so long that they are insoluble in all solvents in the native state. Presumably, solubilization can result only if some of the interconnecting glucosidic (consisting of compound substances derived from glucose) links are broken. It is generally agreed that cotton cellulose has a higher molecular weight than wood cellulose; ramie, nettle fibre, and flax cellulose are higher in molecular weight than the native cotton cellulose. Cotton cellulose apparently consists of a large number of cellulose chains of different degrees of polymerization, and the distribution of chain length has a maximum at a degree of polymerization of about 2,000. Cotton cellulose crystallizes in several forms. The native form, having a monoclinic unit cell (with one oblique intersection of the axes of the crystal), cellulose I, can be transformed into cellulose II by a mercerization treatment with alkali; cellulose II occurs in general in regenerated cellulose fibres. Reports on the degree of crystallinity of cotton cellulose vary over a wide range, depend-

Mechanical  
properties  
of cotton  
fibres

Chemical  
properties  
of cotton  
cellulose

ing on the testing method used. X-ray diffraction methods give an approximate value of 72–80 percent crystallinity. The degree of orientation of the crystals is considerably poorer than in a number of other textile fibres because of the spiral arrangement of the fibrils in cotton. A comparison of the average angle of the spirals for several cellulosic fibres is interesting; hemp, 0 degrees; ramie, 3.5 degrees; flax, 5.5 degrees; cotton, up to 50 degrees.

The basic building blocks of cotton fibres are chemically reactive, making cotton susceptible to chemical modifications. Research has led to an understanding of the effects of chemical modification on various cotton-fibre properties, thus helping cotton to maintain its position as a competitive textile raw material against the increasing number of synthetic fibres. One example of an industrially used chemical modification is the introduction of durable-press treatments for cotton garments. Such finishes compete in performances with garments made from synthetic fibres, although losses in strength and abrasion resistance frequently result. Durable-press cotton is obtained, at least in part, by the introduction of cross links between the cellulose chains in the fibre structure.

Cotton is resistant to the chemicals encountered in normal use, such as dyestuffs, mild bleaching agents, and many organic solvents. It is attacked, however, by strong oxidizing agents, leading to losses of tensile strength, a hazard of the bleaching process. Control of the oxidation process during bleaching is necessary. Colouring matter must be destroyed, while leaving the cellulose with a minimum of damage. Hot, dilute acids hydrolyze cellulose, leading to the disintegration of the polymer chains. Cellulose is resistant to alkali, which swells the fibres without degrading them chemically, leading to the mercerization process that changes the crystalline structure of cotton cellulose from cellulose I to cellulose II, when applied in sufficient strength. The cellulose chains are held together by hydrogen bonds, and breaking of these bonds by sufficiently strong hydrogen-bond-breaking agents leads to solubilization of the cotton cellulose without major degradation.

Esterification (chemical modification to produce desired properties) of cotton cellulose can be achieved by reaction with various acids or acid derivatives under suitable conditions. Cellulose nitrate and cellulose acetate are cellulose esters that have achieved commercial importance. Cotton linters are still used as a raw material for the production of cellulose acetate.

Cotton fibre loses strength upon exposure to moisture at elevated temperature, and this degradation is increased under the influence of sunlight. With proper storage, cotton can remain in a warehouse for extended periods without deterioration. Cotton cloth samples taken from tombs centuries old show very little deterioration in strength. Cotton is, however, affected by fungi and bacteria. Mildews cause considerable damage under warm moisture conditions, leading to rotting or weakening. Chemical modification, however, prevents such attacks, and cotton fabrics so treated become essentially rot-resistant.

**World production and consumption.** Annual world production of cotton in the late 1960s was 53,712,000 bales, each bale weighing 500 pounds (225 kilograms) gross. In the early 1970s, annual production figures in bales for the major cotton-producing countries included the United States, about 10,000,000; U.S.S.R., 9,000,000; China, 7,000,000; India, 4,850,000; Brazil, 3,100,000; Pakistan, 2,500,000; Egypt, 2,500,000; Turkey, 1,850,000; Mexico, 1,750,000; and The Sudan, 1,000,000. The first four countries accounted for nearly 60 percent of total production.

Production has nearly doubled since the early 1930s. The United States is still the world's largest producer, but its share has decreased drastically from 60 percent of the total for the season 1929–30, to 29 percent for the season 1964–65, and only 19.2 percent in the 1969–70 season.

In the late 1960s, 25,216,000 pounds of cotton were consumed annually. The world's major consuming countries were the United States, China, the U.S.S.R., India,

and Japan. The chief exporting countries were the United States, Brazil, Egypt, Mexico, The Sudan, Syria, Pakistan, and Turkey, and the major importers were Japan, the countries of the European Common Market, and India (mainly of longer staple cottons).

**Coir.** *Production.* The fruit of the coconut plant (*Cocos nucifera*) is surrounded by a husk consisting of a fibrous material yielding coir fibre. The coconut palm takes about seven to ten years to reach maturity and yields as many as 150 nuts per year. The fruits must be collected before ripening, because the fibres become increasingly coarse and darker in colour as the fruit ripens. In Sri Lanka (Ceylon), where most of the coir fibre originates, the fruits are plucked every alternate month throughout the year.

*Processing.* After removal of the fruit, the husk is quartered and subjected to retting (a soaking process accomplished by submerging in retting ponds, tanks, or saltwater lagoons, so that fermentation takes place, freeing the fibre from other materials). Depending on retting conditions, this process can require up to several months. The husks are next crushed, thus removing the woody portion, and the fibres are hackled (combed) and dried. In some factories, retting time is drastically reduced by presoaking with hot water and then crushing the husks between fluted rollers. Approximately 70 to 80 pounds (30 to 36 kilograms) of bristle fibre can be derived from 1,000 coconut husks. In the late 1960s the combined annual production of Sri Lanka and the western coast of India, the world's major coir producers, was estimated at 260,000 tons of bristle, of which 150,000 were exported, and total world output was about 280,000 tons. Other producers, on a smaller scale and limited to local production, included the Philippines, Kenya, Nigeria, and the West Indies.

*Fibre properties.* The coir-fibre cell walls are thick and rather irregular, resulting in an irregular outline of the lumen, the cavity running longitudinally through the fibre. The fibres are light, naturally resilient, durable, and resistant to dampness, and although they are less durable and rougher-surfaced than those made of other fibre, their low production cost makes them competitive despite their limitations.

*Uses.* The finest and longest variety fibre is the mat or yarn type, used for matting, ropes, and twines. The coarser and thicker bristle fibre is used for brushes and brooms, and the shorter fibres as mattress and upholstery stuffing.

*Coir (coconut) by-products.* By-products of coir production, derived from the husk or inner shell of the coconut surrounding the fruit, include coconut-oil cake, used to feed cattle; and coconut oil, a colourless, odourless oil, with the consistency of butter, that is used in foods, soap, and various industrial products.

**Kapok.** Kapok is obtained from the seeds of the silk-cotton or kapok tree (*Ceiba pentandra*) of the family Bombacaceae. It is produced mainly in Java, but also in other parts of Southeast Asia and Indonesia. Capsules containing the seeds are picked and broken open with mallets. After drying in the sun, the seeds and fibres are separated by hand, yielding a short fibre with a silky lustre and of exceedingly light weight.

*Fibre properties.* The fibre, thin-walled and of circular cross section with a wide lumen, or longitudinal central cavity, consists of a single cell, containing about 64 percent cellulose, 13 percent lignin, and 23 percent pectans. Kapok is moisture resistant, resilient, and buoyant, but because it is soft, brittle, and inelastic it does not lend itself to spinning.

*Uses.* Kapok is used as upholstery and sleeping-bag stuffing, for insulation, and in the manufacture of life jackets.

**Other seed fibres.** Other seed fibres used commercially, usually as a wadding or upholstery material, are also obtained by breaking open seed capsules and separating the seeds and fibres. Fibres obtained from several varieties of plants of the Bombacaceae family, mainly found in Brazil and other parts of tropical America, are known as bombax cotton. Indian kapok, the floss secured from the

Retting  
for coir  
process

seeds of *Bombax malabaricum*, has been used as stuffing material for pillows. It is similar to Java kapok in its extremely low weight and is used for the same purposes. The floss of the milkweeds, especially that obtained from two of the more than 80 species of the genus *Asclepias*, is also used as a substitute for kapok. The plants are distributed throughout the United States and are perennials when cultivated. Attempts to use the extremely brittle fibres for spinning have failed.

A considerable number of other seed fibres, such as caltropis floss (akund or mudar), cattail fibres (*Typhaeae*), and fibres growing on certain cacti belonging to the genus *Cereus*, have been used for the manufacture of buoyant materials, for heat insulation, and in acoustic materials.

#### BAST FIBRES

Bast fibres, obtained from the inner bast tissue of the bark of the stem of dicotyledonous plants (those having two seed leaves), include some of the most commercially important fibres, such as jute, flax, hemp, ramie, sunn, kenaf, urena, and nettle. These fibres, often several feet long, are composed of individual long cells. The designation "soft fibres" distinguishes them from leaf fibres, frequently referred to as "hard fibres."

The bast fibres lie beneath the bark and are held together by gummy materials. These tissues must be softened, dissolved, and washed away to allow extraction of the fibres from the stem, a process accomplished by steeping the stems in water, or retting. The bundles of bark, weighted down with stones or earth, are steeped in running waters or ponds for varying periods of time, depending on such factors as temperature and type of water. The process generally requires five to 30 days, and the optimum temperature for retting is 80° F (27° C). Decomposition of the gums and softening of the tissues is caused by micro-organisms. After retting is complete, the fibres are freed from the stalk and then are washed and dried.

**Jute.** *History.* Jute has been cultivated in India as a fibre-producing plant since ancient times, and records of its spinning and weaving for apparel and cordage date back several centuries. Successful modification of flax-spinning machinery for use with jute resulted in the development in the 19th century of a growing export market and considerable expansion of the area cultivated for jute in India. Jute mills were set up in the United States and France, as well as in India.

*Production.* Jute fibres are obtained from the bark of two herbaceous annuals, *Corchorus capsularis* and *Corchorus olitorius*, belonging to the family of Tiliaceae. The former is grown on about 60 percent of the jute-growing land in India; from it, white jute is obtained, while tossa or daissee jutes are obtained from the latter. Jute is the most important of all bast fibres and is cultivated in China and Bangladesh as well as India. It makes considerable demands on the soil and must compete with rice and other food plants; similar fibres, such as kenaf, roselle, and urena, are less demanding and can be grown in rotation with other crops.

Jute is usually grown as a cash crop in fairly small holdings; the grower's family cultivates, harvests, and extracts the crop. Grown during the rainy season, jute thrives best in damp heat, in humidity of about 70 to 90 percent. The sowing time must be adjusted so that the crop reaches a height of three to four feet (about a metre) before the heavy monsoon rain starts. *C. capsularis* is generally sown early in February–March, and *C. olitorius* in April–May. Depending on the time of sowing, soil, and climatic conditions, the vegetative period for both is three to five months. Plants are harvested at the flowering or pod-formation stage, when about 50 percent of the plants are in pod and both the yield and the quality of the fibre are good. Plants are cut with a sickle, close to the ground; in flooded areas the cutters often have to dive underwater to cut the stems. A trained cutter cuts as many as six to eight plants at one dive. On highlands the plants are left for two to three days after cutting to allow shedding of the leaves. The average yield, depend-

ing on soil, rainfall, and farming practices, is approximately 1,240 pounds (560 kilograms) per acre in India. Fibre content is 4.5 to 7.5 percent of the weight of the green stem.

*Processing.* Jute fibres are loosened from the bark by retting, induced by chemical or bacterial methods, so that the fibres in the stem are separated from the adjacent tissues and woody core by removal of pectins, gums, and other mucilaginous materials. In India and Bangladesh, retting is usually done in water, the steep-retting process, in which the action is bacterial. Bundles of stalks are soaked in running streams or stagnant pools, fully submerged and weighted down. This process usually takes from ten days to a month, depending upon temperature, type of water, depth of immersion, and plant maturity. During retting, the bacterial organisms decompose gums, pectins, and other substances that bind the fibres together.

The colour, lustre, and strength of jute fibres are greatly influenced by the retting process. Early stem removal can cause difficulty in fibre separation, while overretting renders the fibres weak and inferior in quality. Retting in slow-moving streams is favourable to fibre quality because of the prolonged aerobic (oxygen present) phase of retting and gradual removal of decomposition products. Rapidly moving water sweeps away the retting bacteria, adversely affecting the retting process. After retting is completed, the stalks are placed in water two to three feet deep, and the fibres are stripped from the bark by one of several methods. In the most common a few stems are treated at a time. The root end of the bundle of stems is beaten with a paddle, loosening the fibres; the stems are broken near the root end, the short broken ends are jerked away, and the loose fibres are then stripped from the remaining stems. The fibre bundle is washed to get rid of the decomposed foreign matter, wrung out, and hung to dry.

The cleaned and dried jute fibre moves from the growers to the village market and through a series of middlemen to the baling centres where a baler grades it. The graded jute is packed into bales weighing about 250 pounds (110 kilograms) for use in the home market. Next, the remaining jute moves to larger terminal markets where it is regraded for export or shipment to spinning mills in India or Pakistan. Export jute is graded for further classification according to the system used in the importing country.

Commercial grading of jute is not presently based on laboratory tests, although methods have been developed in India and the United Kingdom to relate such measurable fibre characteristics as length, fineness, and strength to the properties of the yarns spun from each grade. Fibres that can be spun into fine yarns are the most valuable. Such characteristics as colour, length, fineness, strength, lustre, cleanliness, softness, uniformity, and low percentage of root are considered in the grading process. White jute, the most common, varies from whitish yellow to gray or yellowish tan; the best grades have high lustre. Daissee jute ranges from gray to black; tossa jute has a russet tinge, varying from golden brown to reddish brown.

In the conversion of jute fibres into yarns, the jute is selected by type, mark, and grade based on quality, colour, cleanliness, strength, texture, and price. The objective is to blend fibres to achieve uniform colour, strength, and fibre-length distribution; to parallelize and orient the fibres in the long direction of the yarn; and to twist them into continuous strands.

Bales of fibre having compatible physical properties are opened and blended together. The bale opener, a massively built machine with intermeshing heavy flute rollers, makes the dried jute soft and pliable. The heads are split into smaller bundles, called stricks, that are fed to the spreader board, the root end of one strick overlapping the crop end of the previous one. The stricks move through a pair of fluted rollers and onto the pins mounted on a lattice. Oil, water, and emulsifiers are added to soften the jute to improve process performance. The spreader converts jute into sliver, which can be pre-

Retting of  
jute

Competi-  
tion with  
food plants

Conver-  
sion to  
yarn

sented to carding machines. The remaining processes of carding, drawing, roving, and spinning are similar to flax and hemp spinning.

The unit for describing the size or count of jute yarn and roving (a strand in an intermediate state between sliver and yarn) is the weight in pounds of a spynle, the equivalent of 14,400 yards. It is also described in the same way as cotton by the tex system.

**Fibre properties.** Jute fibre is a multicellular structure made up of a number of ultimate cells of regular polygonal cross section cemented together with noncellulosic substances such as lignin and hemicellulose. Chemical treatments that remove these cementing substances affect the structure and lead to the deterioration of the physical properties of the fibre. Dry tensile strength is hardly affected by removal of either lignin or hemicellulose, but wet tensile strength drops drastically because only ultimate cells remain.

Jute fibre is fairly weak, with low longation (stretchability) and elasticity, and is characterized by coarseness, stiffness, and brittleness. Jute consists of 58 to 63 percent  $\alpha$ -cellulose, 21 to 24 percent hemicellulose, 12 to 14 percent lignin and such minor components as wax, pectin, and organic salts, nitrogenous substances, and colouring matter. The  $\alpha$ -cellulose isolated from jute plant material is intimately associated with other carbohydrate constituents. Lignin is mainly responsible for the yellowing of jute when it is exposed to light.

Jute is susceptible to the action of acids and alkalis. Dilute acids have a brightening effect, but extended acid treatment at high temperatures, or use of stronger acids, leads to extensive hydrolysis (decomposition) and strength losses. Concentrated alkali causes swelling, and the fibres are also sensitive to oxidizing agents.

**Uses.** About 75 percent of the jute produced annually is manufactured into sacks and bags. It is also widely used for twine, carpet yarns, and cloth backings for linoleum and carpet. The Calcutta jute industry uses about 60 percent of the total world supply of raw jute and the European industry about another 30 percent. In the early 1970s the Indian jute industry sought to extend the use of jute to decorative fabrics.

The use of jute as a packaging material is increasingly threatened by other bast fibres, by synthetic fibres, and by new methods and techniques of packaging and transportation. The mechanization of jute production has made little progress, and manufacture is still dependent on the availability of cheap labour. Because jute is grown on soil that can also be used for growing rice and because high-yield rice varieties result in larger profits, it is likely that jute will be at least partially replaced by rice, especially in such countries as India and Bangladesh. The survival of jute as a major fibre seems to depend on the development of new jute varieties with high response to fertilizers and on further mechanization and improvement of manufacturing processes.

**World production and consumption.** Annual world production of raw jute for 1969–70 was about 2,870,000 tons, of which about 90 percent came from India and Bangladesh, then East Pakistan (India, 1,300,000 tons; Bangladesh, 1,350,000 tons), most of the rest from China, Burma, and Thailand. Production in China was estimated at about 150,000 tons. India and China retain their production for use in their own jute mills, so that Bangladesh dominates the world market. The chief importing country is the United Kingdom.

**Flax. History.** The fibre obtained from the flax plant, from which linen cloth is manufactured, is one of the most ancient textile fibres. The manufacture of linen was already an established art in Egypt by 3400 BC, where both fine and coarse canvas-like linen cloth has been found in burial chambers. Some mummies have been wrapped in as much as 1,000 yards (900 metres) of very fine linen. The use of linen spread from Egypt throughout the Mediterranean and was carried to north-west Europe by the Romans. France and the Low Countries became famous for their linen. Ireland, which has an ideal climate for linen spinning and weaving because of its dampness, became an important producer. Linsey-

woolsey, a fabric made from linen warp and wool filling, was popular for outer wear up to the mid-19th century, when the availability of cheap cotton fabrics largely eliminated it.

**Production.** The flax plant (*Linum usitatissimum*) is grown both for the linen fibre and for its seed, which is important for linseed oil; flax is the second most important bast fibre.

Flax requires a temperate climate free from heavy rains and frosts. Frequent moist winds during the growing season are advantageous. Hot, dry summers produce a short and harsh but strong fibre; moderately moist summers produce plants yielding fine, strong, silky linen. Flax is difficult to grow because of the soil preparation required before sowing and the heavy applications of artificial fertilizers needed.

After slow initial growth, the plants grow as rapidly as one inch per day for 30 to 40 days. Blossoms then begin to develop and stem growth ceases. Flax is normally a three-month crop, although this growing time varies with climatic and other growing conditions.

Flax is attacked by several fungus and virus diseases, usually kept under fair control by chemical treatments of the seed or by cultivation of resistant varieties. Harvesting is carried out when the lower two-thirds of the stem has become yellow and the leaves have fallen off, about a month after the appearance of the first flowers. The choice of harvest time is important because lignification (conversion to woody tissue) takes place if the plants are left too long before harvesting, and yield will be lower if harvesting is too early. Harvesting is normally carried out by pulling the plant from the ground by hand or machine. Pulling is considered superior to cutting; flax tends to deteriorate at the cut, and the cut straw is shorter than pulled straw, with a consequent loss of fibre. Yields of fibre per acre vary from 450 pounds to about 800 pounds (200 to 360 kilograms).

**Processing.** Like the other bast fibres, jute, hemp, and ramie, linen must be separated from the stalks by retting. Water retting, which is essentially bacterial, is practiced in areas such as the Philippines, Taiwan, and China; most of the crop grown in the Soviet Union and the United States is dew retted, which is predominantly fungal. In this method the harvested flax straw is left in the field and allowed to remain until the combined action of the moisture from dew and micro-organisms makes separation of the fibres possible. The process depends very much on the temperature and chemical nature of the water but takes only six to eight days under controlled temperature conditions. After removal of the stalks from the retting medium, thorough drying is necessary to prevent further fermentation.

The retted and dried fibres are removed from the woody remainder of the stem by the process of scutching, in which the stems are first broken by a passage through a series of fluted metal rollers, and the fine pieces of the woody portion of the straw, called shives, are beaten out. About a tenth of the original flax stem is fibre.

**Fibre properties.** Under the microscope, linen fibres show the transverse lines characteristic for most bast fibres. In cross section, they are round to polygonal with a small central lumen (horizontal cavity). The boiled-off and bleached linen fibre is almost 100 percent cellulose and shows the same reactions with alkalis and acids as does cotton. Linen is the strongest of the vegetable fibres, showing greater strength in the wet state. Colour varies, depending on the retting conditions, from cream to brown; the fibre is usually bleached to white or near white. Linen fibres range from 12 to 30 inches (30 to 75 centimetres) in length and from five to 28 microns in diameter.

**Uses.** Linen has a variety of uses. The first grades are used for such fabrics as damask, and in sheeting, lace, and apparel; the coarser grades are used for twines, canvases, bags, fishnets, sewing threads, and fire hoses.

**World production and consumption.** Flax is grown chiefly in the Soviet Union, which produced about 450,000 tons annually in the late 1960s, and eastern Europe. Together they accounted for more than 80 percent of

Clothing of linsey-woolsey

Water retting of flax

Problems of jute manufacture

total world production, which was estimated at 664,000 tons. The bulk of Soviet production is for domestic use, and only in the late 1960s did export trade achieve any importance. The Common Market countries of western Europe are substantial exporters. Belgium is the most important exporter of high-quality flax, followed by France and The Netherlands. In the late 1960s Belgium, with its exceptional retting facilities, was also the largest buyer, followed by the United Kingdom, France, and Italy.

**Ramie.** *Production.* Ramie fibre is obtained from the stem of the many-stemmed shrub *Boehmeria nivea* of the nettle family (Urticaceae). The plant, a native of China, is also called China grass, and has been cultivated for its fibre for hundreds of years, reaching Europe early in the 18th century. Several other plants of the nettle family yield fibres from their stems but have only local commercial importance. The plant producing ramie fibre is a perennial with stems three to eight feet (one to two and a half metres) high, originating from a rootstock, and having few branches. When the stems are cut during the growing season, the rootstocks send up new shoots, producing two to four crops from the plant each year, depending on climate and soil conditions.

Ramie  
cultiva-  
tion

Successful cultivation requires rich, well-drained, sandy, loam soil, which retains sufficient moisture throughout the growing season; high temperature and humidity, with an annual rainfall of not less than 45 inches (104 centimetres). Rainfall should be spread throughout the year; prolonged flooding kills the rootstocks. The necessity for heavy fertilization increases with each growing year. One crop of ramie is considered 16 times more exhausting to the soil than cotton, unless the waste material is returned to the soil.

Because raising plants from seeds takes one to two years, vegetative propagation is frequently practiced. Cuttings from reproductive underground shoots, or rhizomes, are planted in prepared holes. Weeding is important only in the early stages of growth because the plants are planted densely enough to shade the ground and smother weeds.

The time for harvesting is judged by the discoloration of the stems, which turn brown upon maturing. The plants are usually cut by hand with a sickle, close to the ground to prevent new stalks from arising from the old stump. Mechanization of harvesting is difficult because of possible damage to the new stalks. The cut stems, about five to six feet long, are dried, frequently after the leaves have been stripped from the plant. Defoliation by chemical means may be practiced. Yields, varying widely according to soil, climate, and the use of fertilizer, are usually reported as pounds of crude un-degummed ramie per acre per year and range from 800 to 2,000 pounds (360 to 900 kilograms) per acre.

A pest of ramie in Japan is the black caterpillar, which attacks plants in June or July; spraying with lead arsenate or DDT has been effective. White fungus disease occurs occasionally, attacking the root system and sometimes infecting whole areas, which then become unsuitable for ramie planting for several years.

*Processing.* Decortication, removing the bark and woody parts of the stalk and part of the gummy material, frees the fibres as strands. Decorticated fibre strands are usually known as crude ramie fibres. Decortication machines such as the raspador, invented in France in 1896, are used almost exclusively. Their efficiency varies, but yields of crude fibre in the range of 2.5 to 3.5 percent, based on the weight of the green stalks, can usually be achieved.

The crude fibres are next dried and baled in bundles ranging from 100 to 500 pounds (45 to 225 kilograms). No general grading standards are used; quality is usually based on length and cleanliness of the fibre, pliability, and colour.

The fibres are degummed before spinning to remove the gums, waxes, and pectins that remain on the crude fibre. This process, usually performed by the mills that spin the fibre, is carried out by bacteriological or chemical means. The most commonly used chemical process

consists of treating the fibres in caustic soda solutions containing wetting and reducing agents. After a 24-hour soaking period, the fibres are boiled for one to four hours, then rinsed, neutralized, washed, centrifuged, oiled, and dried.

The fibres have to be cut or sorted to the appropriate length before spinning. The spinning process employs machinery adapted from wool or cotton spinning, depending on fibre length.

*Fibre properties.* Ramie fibre is white, with high lustre, and is highly resistant to bacteria and fungi, including mildew. High moisture absorption and rapid drying are characteristic of ramie yarns and fabrics. The fibre cells are about 15 centimetres (six inches) in length, considerably longer than flax or hemp fibres. Diameters of individual bast cells range from 25 to 75 microns (.00098 to .00295 inch). The mature cell has an almost cylindrical cross section, thick cell walls, and a well-defined lumen. A longitudinal view reveals small nodulike ridges and striations without twist. The degummed fibre consists of 96 to 98 percent  $\alpha$ -cellulose with little lignin.

*Uses.* Ramie has the same uses as flax and hemp. It has considerable strength, lack of stretch, and high wet strength. It dries quickly, making it useful for fishing nets, although the use of synthetic fibres for such purposes has increased. The short tow is used for the manufacture of specialty papers, such as for cigarettes and banknotes. In the Far East, ramie is used for clothing, tablecloths, handkerchiefs, canvas, and mosquito nets. It is also used for the packing of ship propeller shafts, for hats, upholstery, and in various fabrics. It is, however, too expensive for mass-produced articles and cannot be spun into fine yarns.

*World production and consumption.* China is the world's largest producer of ramie; Japan is also a major producer. The chief importers are Germany, France, and the United Kingdom.

**Hemp.** Hemp (*Cannabis sativa*) is the common name for the only species in the genus *Cannabis*, an annual of the Cannabaceae family. Although it has many varieties, strains, types, or lines, it should not be confused with the very different Mauritius hemp, Manila hemp, sisal hemp, or New Zealand hemp, all of which are fibre-producing plants, but none of which has any botanical relationship to true hemp.

Probably the oldest cultivated fibre plant, it originated in Central Asia and spread to China, where it has apparently been cultivated for more than 6,000 years.

*Production.* Hemp grows in nearly all countries of the temperate zone and is cultivated in most of central Europe and the Balkan countries, the Soviet Union, China, Turkey, Japan, Chile, and the United States.

The form of the plant and its yield of fibre vary with climatic conditions and the variety. Those varieties cultivated for fibre production have long stalks with little branching, and only small quantities of seed, which are used mainly for propagation. Where large quantities of seed are desired, varieties are short in height and mature early. The variety *Cannabis sativa*, cultivated for the production of the drug hashish, or marihuana, is short and many-branched, with small, dark-green leaves, and is grown mainly in tropical regions.

Hemp thrives in a mild, temperate climate with humid atmosphere but can endure considerable changes in temperature. Hemp seed is sown early in the spring and requires little cultivation. The fast-growing hemp seedlings soon cover the ground, choking out the weeds. The plants are ready for harvesting when the male plants change from a deep green to a light brown. An optimum yield of high-quality fibres is obtained if harvesting is carried out when the flowers begin to open and shed pollen. Harvesting before maturity results in lower yields and weaker, but finer and softer, fibres. Harvesting considerably after maturity yields more seeds and results in harsh and brittle fibres. The normal time from planting to harvesting is about four to five months in temperate climates. The plants are normally cut off by hand with a hemp knife about one inch (2.5 centimetres) from the ground, and the stems are spread on the ground to dry.

Hemp  
growing

**Processing.** After retting, drying, and scutching to isolate the bast fibres from the bark or stem, the hemp is dressed and softened (beetled) and is ready for the market. No generally recognized grading standards exist. For shipment to the spinning mills, the hemp is pressed into bales weighing up to 790 pounds (360 kilograms).

Fibres are sorted in the spinning mill and grouped into batches of different grades. The bundles are then passed through a machine fitted with sets of fluted rollers, which make them soft and flexible. The remaining woody matter is crushed to powder. The fibres, measuring about two to three metres (seven to ten feet) in length, are reduced to about 80 centimetres (30 inches) to facilitate handling in the rest of the processing. Bundles are generally divided into base, middle, and top portions by stretching, allowing them to snap at the right places. The middle portion contains the highest quality fibres. The fibres are combed and parallelized on the hackling machine, and the hackled tow is converted into sliver on the spreadboard machine. The sliver is doubled and attenuated on draw frames and further reduced in size on the roving frame. The roving is processed into yarns by either dry or wet spinning. Wet spinning produces the finest yarns; the fibres are separated with the aid of boiling water to ensure proper drafting.

**Fibre properties.** Hemp fibres are longer and generally coarser than flax fibres but have less flexibility. Bleaching is difficult, and the fibre is not used for fine textiles. The finest quality, originating in Italy, is a white and pale-gray colour with silky lustre and softness similar to that of flax. Strands are over six feet (two metres) long. The less valuable hemp produced in the Soviet Union and the United States is coarser, with greater strength and durability. Hemp has a cellulose content of 67 percent and contains about 16 percent hemicellulose, with a Z twist in contrast to the S twist of flax.

**Uses.** Hemp is used for ropes, twines, cables, nets, sailcloth, canvas, and tarpaulins, but its main use is as a substitute for flax in the manufacture of yarn and twine. It has been replaced as a material for rope by such stronger fibres as sisal, abaca, and synthetics.

Hemp yields several by-products, and varieties are grown either for their fibre content; for the seeds, which are used as a food additive; or for the resinous juice obtained from the stalks, leaves, or flowers of a variety called Indian hemp, grown in tropical regions and yielding narcotics. Depending on the preparation or the part of the plant used, the narcotic, a composition of various compounds, is known in India as *charas* (the resinous juice), *ganja* (obtained from the dried flowering top of the female plant), *bharg* (dried leaves and flowering shoots from either the male or female), or *hashish* (Turkish preparation of the leaves). As a narcotic hemp is usually known as marihuana in the Western Hemisphere and as *kef* in North Africa. Its use is unlawful in many countries, and in the early 1970s, many studies were under way on its controversial effects.

**World production and consumption.** The world's hemp output is about 206,000 tons (excluding China for which figures are unavailable). The Soviet Union is the largest producer of hemp in the world, with annual production of about 100,000 tons in the late 1960s, with most of this production used domestically; the major exporting countries are Italy and Yugoslavia. Romania, Hungary, Poland, and Bulgaria are other major producers of hemp. West Germany and France are among the major importers.

**Sunn, or sann, hemp (*Crotalaria juncea*).** **Production.** Sunn hemp, a member of the pea family (Leguminosae), is grown for fibres or as a green manure. The plants thrive in poor soils and relatively arid areas because of their strong tap-root system that penetrates deeply into the soil to reach low-ground water levels. Sunn hemp is cultivated on a commercial scale mainly in India, where it has been used since prehistoric times, and to a lesser extent in Sri Lanka. Three distinct types of sunn-hemp fibre are grown in India, including white, having a grayish colour, shiny lustre, and fine texture; green, coloured greenish to grayish, stronger than white fibre, and

therefore more valuable; and one called *dewghuddy*, creamy in colour, with good length and fine texture. Considerable differences in fibre quality depend on cultivation and growing conditions. Most of India's production consists of the white fibre, closely followed by the green. About 1 percent consists of the *dewghuddy* type, considered to be best in quality.

**Processing.** Retting and extraction is accomplished by the same hand methods as are applied to the cleaning of jute. In modern practice the breaking operation, in which the woody portion of the stalk is crushed to set the fibres free, is done mechanically.

After scutching, the fully extended, straightened, and smooth fibres are twisted into hemp stricks, and 140 to 200 are assembled into bales weighing about 120 pounds (50 kilograms). The quality of hemp is assessed from the fibre material obtained after the process of packing. Grades include heavy, strong, clear, long, and hemp of good colour. These characteristics are essentially dependent upon proper fertilization, maturity, and retting conditions. Hemp of poor grades may result from premature or delayed harvesting, from excessive application of nitrogen fertilizers, and from insufficient drying and retting of the fibres.

**Use.** Sunn hemp is used locally to make fishing twines, thick canvas, ropes, and cordage.

**World production and consumption.** In the late 1960s, about 65,000 tons were produced annually by India, which used most of its production domestically.

**Kenaf, roselle, and urena.** Kenaf, roselle, and urena are bast fibres used as jute substitutes. These fibres closely resemble jute, although they are somewhat shorter and coarser and are usually combined with jute. All three belong to the mallow family (Malvaceae), one of the most important of all fibre-plant families.

**Production.** Kenaf is obtained from the stems of *Hibiscus cannabinus*, an herbaceous annual with a straight, slender, prickly stem that may reach heights up to 12 feet (four metres). Roselle is the fibre obtained from the stem of *Hibiscus sabdariffa*, a native of tropical Africa. *Urena lobata*, another member of the Malvaceae family, produces fibres in its stem. Both the fibre and the plant of urena are known under different names in various countries.

While jute makes considerable demands on the soil and must compete with rice and other staple food plants where it is commonly grown, kenaf is more adaptable to various kinds of soil and climatic conditions, although sensitive to frost and limited to tropical and subtropical regions. It can be grown in rotation with other crops on well-drained sandy loams. During the four-to-five-month growth period of the plant, rainfall of about 22 inches (56 centimetres) is necessary. The tap root penetrates deep into the soil, and proper development and aeration of the root systems require seedbeds prepared to an appropriate depth. Sowing usually occurs at the beginning of the rainy season, and weeding is essential in the first few weeks of growth. The stems reach 12 to 15 feet (four to five metres) under favourable conditions, and harvesting begins when the plant has a few flowers. Where seed production is required, the plants are allowed to mature fully, but at that stage the fibres are considerably coarser and of less value. Yields of fibre per acre range from 1,000 to 3,000 pounds (450 to 1,350 kilograms), depending on harvesting time and climatic and soil conditions. Most of the fibre in the kenaf stem is in the lower portion; the top part of the stem is removed before retting or ribboning, with a loss of only about 3 percent of the total fibre. The plants are cut by hand with a machete similar to the implement used in jute harvesting.

**Processing.** Removal of the fibres from the stalk is usually performed mechanically, although in some areas retting and hand stripping are still practiced. Ribboning machines remove the fibre-containing bark, which is then retted. After retting, the fibres are obtained by beating the ribbons on the surface of the water. Further processing of the fibres to the yarn stage is similar to that of jute.

Fine  
Italian  
hemp

Kenaf  
cultivation

**Fibre properties.** Fibre strands are three feet or more in length, and light and creamy in colour, with the same lustre as jute. Strength is also comparable to that of jute. Individual cells are more or less cylindrical, with thick cell walls surrounded by a layer of lignin, and an irregular and broad lumen. Fibre composition is similar to that of jute.

**World production and consumption.** Large quantities of kenaf are grown in India, where the fibre is called *mesta*. In the late 1960s India annually produced 161,000 tons, of which 18,000 tons were exported. Thailand was a large producer with 140,000 tons, and the major portion was exported. The plant was introduced into China in 1936, where it is known as *taschkenii*. Together with abutilon (see below), the kenaf production of China amounts to approximately 325,000 tons. The future importance of kenaf, still fairly new on the world market, is difficult to estimate.

The roselle fibre plant is a native of tropical Africa, where it is almost exclusively grown. *Urena lobata* has been cultivated in several countries in warmer regions, including West Africa, the Congo, Madagascar, some areas in India and Indochina, and the coastal areas of Queensland and Brazil. The fibre production is almost exclusively used in the countries of origin.

**Abutilon.** Abutilon, belonging to the Malvaceae family, has been a fibre crop in China for many years and is used there for ropes and twines and in admixtures with jute. Some of the abutilon fibre exported from China reaches the world's market as China jute. The plant, also cultivated in the Soviet Union, is known there as *kanatnik* and is better suited than jute for cultivation because it is more hardy and resistant to disease. It can be grown as far north as the 56th parallel of latitude in western Siberia.

Several other members of the Malvaceae family have fibres in their stems and are being used for fibre production. They usually grow wild and are used locally for purposes similar to jute or the other bast fibres. These plants include the *Sida* species, the *Pavonia* species, the *Thespesia* species, and several others.

#### LEAF FIBRES

Types of  
leaf fibres

Leaf fibres are structural elements in the fibrovascular system of the leaves of certain plants. Too stiff for most fabric uses, this group contains two of the most important cordage fibres: abaca, or Manila hemp, and sisal. Other leaf-fibre plants of commercial value are henequen, Mauritius hemp, and New Zealand flax or hemp (*Phormium tenax*).

Plants yielding leaf fibres are usually perennials propagated by root cuttings or rhizomes (horizontal subterranean plant stems). The most important group of plants, the agaves, store water and grow in both arid and humid climates. Their rate of plant growth and the formation of fibre-containing leaves depend on the amount of moisture available. Although the rate of growth is faster in East Africa, Indonesia, and the Philippines, the total leaf and fibre production during the life of a plant is approximately the same as that of much slower growing plants in Mexico. In harvesting, the leaves are cut at their base with sickle-like knives, then tied into bundles.

Other important leaf fibres include abaca, obtained from the banana family; and Mauritius hemp and phormium both from the agave family. These perennials, propagated by root cuttings, require considerable rain. Approximately 10 to 25 leaf stalks form one pseudostem, which is cut at the base upon maturity; then new pseudostems are formed from spreading rhizomes.

In the late 1960s annual world production of the principal hard fibres, sisal, abaca, and henequen, decreased by 5 percent to some 850,000 tons. Sisal is by far the most important of these fibres, contributing nearly 70 percent of the total output. Sisal fibre is grown mostly in Kenya, Tanzania, Brazil, Angola, and Mozambique. Other hard fibres are grown mainly in the Philippines (abaca) and Mexico (henequen). Abaca represents only 7-9 percent of the principal hard fibres.

**Abaca, or Manila hemp.** **Production.** Abaca fibre is obtained from the plant *Musa textilis*, belonging to the banana family (Musaceae), and is also known as Manila hemp, named for the port from which it was first shipped. It is not related to true hemp, a soft fibre that is the product of *Cannabis sativa*. Fibres from a number of other species of the Musaceae family are used locally in various countries but have little or no commercial value.

*Musa textilis* is of the same family as the banana plant, but its stalks are usually more slender, with smaller and narrower leaves and smaller, inedible fruit. Like other *Musa* species, *Musa textilis* has a rhizome, or branching underground stem, bearing numerous small roots, which develops 10 to 25 pseudostems growing in a cluster. Each is composed of up to 25 broad leafstalks with their broad bases overlapping one another and growing into a kind of trunk 12 to 16 inches (30 to 40 centimetres) in diameter. The leaf blade, tightly rolled until it leaves the pseudostem, unfolds into a leaf from three to eight feet (one to 2.5 metres) long and about a foot wide, which forms a crown at the top of the pseudostem. The true stem rises through the middle of this structure, forming an aerial shoot that eventually becomes a spike with many flower clusters.

Abaca requires loose soil, rich in humus and with good drainage, and humidity both in the atmosphere and in the soil. It is grown under tropical conditions with heavy rainfalls more or less evenly distributed throughout the year.

Abaca, a perennial, is usually propagated by root cuttings or from the suckers (rapidly developing shoots) rising at the base of the parent plant. Plants grown from seed take about one or two years longer to mature than those from shoots or root cuttings. The stalks mature in two to three years, but the plant will not yield a full crop of mature stalks until it is four to five years old. The fibre reaches maximum tensile strength just before the shoot flowers, at which point harvesting is carried out.

In the Philippines the minimum stem height for harvesting is eight feet. The entire stalk is cut close to the ground, and the parent root stalk then sends out rhizomes from which further stalks shoot up. Two to four stalks may be harvested every four to six months from each mat or parent root stalk. The various leaf sheaths are stripped from the stem of the parent stalk. The fibre in the sheath varies in colour and quality (depending on the position of the sheath in the stalk), becoming softer, whiter, and weaker from the outside sheath to the innermost sheath.

The most serious disease of abaca, called bunchy top disease, is caused by a virus transmitted by the brown banana aphid. Once attacked, the whole plant becomes infected and cannot recover. Destruction of infected plants or even whole plantations is the only known remedy. Another serious affliction of abaca in the Philippines is the mosaic disease, also caused by a virus and transmitted by a number of aphids. Again, the only known remedy is destruction of all infected plants. Mosaic disease has threatened the entire abaca industry in southern Mindanao.

The introduction of the abaca plant into other tropical regions such as Indonesia, India, and Central America was successful when World War II cut off abaca supplies from the Philippines. At that time, production of the abaca fibres increased considerably in Costa Rica, Guatemala, Panama, and several of the other Central American countries.

**Processing.** Operations to remove the fibres from the leaf sheaf include the tuxying process, separating the fibrous outer layer from each leaf sheaf, and the stripping process, in which the pulpy material is removed, freeing the fibre strands. Both operations must be carried out soon after the stalk has been cut. Tuxying is usually done in the field with a knife; stripping is done either by hand or with a machine, the *hagotan*. After stripping, the fibre is hung in the sun to dry.

Abaca fibres are also cleaned with decorticator ma-

Abaca  
cultivation

Grading of  
abaca  
fibres

chines, which remove the outer layers, usually operating in conjunction with a mechanical drier.

Fibres are graded and baled for export at a warehouse and sold at regularly scheduled public auctions. Official Philippine grading standards include: (1) Hand or spindle stripped fibres specially prepared for tagal braid (a straw braid mostly used for hats), and other fine textile uses; (2) hand or spindle stripped fibres prepared for cordage; and (3) decorticated fibre. Grades are based on fineness, lustre, cleanliness, colour, and strength. After grading, the fibres are pressed into export bales, weighing 278.3 pounds (126.2 kilograms) each.

**Fibre properties.** The commercial fibre consists of fibre strands made up of bundles of individual fibres held together by natural gums. Length varies from three to nine feet (one to three metres). The fibre has a natural high lustre with colour ranging from pure white to ivory and dark brown. Abaca fibres have excellent strength, reasonable elongations of 2 to 4 percent, and high resistance toward micro-organisms found in saltwater. Individual fibres can be isolated from the fibre strands by boiling in alkaline solution. Abaca has been found to consist of 63–64 percent cellulose, 19.6 percent hemicellulose, and 5.1 percent lignin, and to have a 10 to 12 percent moisture content.

**Uses.** In the Philippines, abaca is used for making slippers, ropes, twines, and hammocks. In other countries, it is also used for the manufacture of marine ropes, in which use it is sometimes preferred to sisal. Abaca's exceptional strength and resistance to water make it particularly suitable for these purposes. It is the strongest of all hard fibres, followed by sisal, phormium, and henequen. Abaca ropes can also be used for mining and well drilling, and the fibre is also used to a large extent in the paper industries for teabags, mimeograph mats, and for other specialty materials.

**World production and consumption.** The Philippines is the only important producer of abaca. Most of the 67,000-ton annual harvest in the late 1960s was exported to the United States, Japan, and the United Kingdom.

**Sisal.** *Agave sisalana* is one of about 300 species of plants belonging to the agave family (Agavaceae), all originating in the tropical and subtropical parts of the Western Hemisphere; they have been introduced to other places, including East Africa, the West Indies, Indonesia, and the Philippines. The name sisal comes from the name of the port in the state of Yucatán in Mexico, from which the fibre was first exported.

**Production.** The plant produces leaves two to six feet (0.6 to 2 metres) in length, tapering off to a sharp thorn-like point. The growth rate depends on the availability of water, for sisal is a water-storing plant, growing when water supplies are available but stopping to conserve water in times of drought. It may produce six to eight leaves per month during the wet season, and none in the dry season. Sisal grows in areas where the rainfall and soil conditions are unsuitable for other species of agave, and under a much wider range of growth conditions than henequen. The life processes and activity of the plant depend on soil conditions and climate. There are two growing seasons per year in East Africa, as against one in Mexico, but the plants live through approximately the same number of growing seasons in both areas, producing fibres at a considerably higher rate in East Africa, but with the total yield per lifetime approximately the same. Sisal prefers dry, permeable soils, with some lime, but also grows on well-drained, black, cotton land. Suckers (rapidly developing shoots) were formerly used for propagation because they can be planted immediately after their removal from the parent plant, but the modern practice is to use buds, or bulbils, for propagation, placing them in nurseries for about 12 to 18 months before they are planted in the field. Planting of the bulbils is usually done during the rainy season. Toward the end of its life, the plant starts to pole, and the pole can reach a height of 20 or more feet (six metres or more), being branched at the last five feet. After the pole stops growing, the branches throw out stems on which the yellow sisal flowers develop, eventually dying and falling off. The bulbils formed

when the flowers die grow to a length of about four inches, at which size they are easily removed. The plant dies after the pole has developed bulbils, each pole yielding about 2,000.

The time needed before a new sisal plant is ready for cutting depends on the conditions under which it is grown. From two and a half to four years may be needed. Leaves that are ready for cutting are severed at their base with a sickle-like knife. Yields of 17 tons per hectare (seven tons per acre) can be obtained from properly cut plants. The leaves weigh between one and one and a half pounds each, and are tied into bundles of 30 leaves, with 70 bundles making up a task. Each leaf contains about 1,000 individual fibres, which constitute about 2 to 5 percent of the weight of the leaves. Yields of 1,800 to 2,500 pounds of fibre per acre (2,000 to 2,800 kilograms per hectare) per year are obtained on the best plantations in East Africa and Indonesia.

**Processing.** Decortication of the leaves is carried out in large stationary machines that crush the leaf, scrape the fibre clean, and wash it to remove the remaining pulp pieces. Fibre intended for export is graded and baled. Grade designation and bale weight differ widely, depending on the country of origin.

**Fibre properties.** In world trade sisal appears as a white to yellowish fibre, three to five feet in length. One of the coarser hard fibres, it is strong but not as flexible as abaca. Like abaca, commercial sisal fibres consist of strands containing a large number of small individual fibres held together by natural gums. The average length of sisal fibres varies from three to four feet (about a metre) or longer. The strands are usually white and of high lustre. Sisal fibres have good breaking elongation, and high resistance to seawater.

**Use.** Most sisal is used for the manufacture of binder twine and bailer twine, although efforts are being made to find new uses, such as for matting. A weakness of sisal rope is a tendency to break suddenly without warning, in contrast to abaca ropes, which show threatening signs before breaking.

**World production and consumption.** Total annual world production of sisal was over 600,000 tons in the late 1960s. Tanzania was the largest producer with nearly 33 percent, followed by Brazil with nearly 30 percent, and then by Angola, Kenya, and Uganda. The largest importers of sisal were the Common Market countries, which imported 195,000 tons.

**Henequen (*Agave fourcroydes*).** Another fibre of commercial value derived from the agave family is also sometimes called sisal; to avoid confusion, the local Mexican name henequen is extensively used. The plant has been used and cultivated for hundreds of years in Yucatán by the Mayan Indians. As in other agaves, the young plant consists of a rosette of leaves rising from the ground, but a trunk is developed up to five feet high as the plant grows, because the lower leaves die off or are cut. The leaves grow up to six feet (two metres) long and four to six inches (10 to 15 centimetres) wide and are grayish in colour in contrast to those of the sisal-producing *Agave sisalana*, which are green. At the end of their life, the plants form a pole similar to that of the sisal plant. In Mexico, the life of the henequen plant is about 20 to 30 years while in East Africa it lives only about seven or eight years. Both varieties produce roughly the same number of leaves during their lifetime. A smaller number of leaves are taken each year from the henequen plant. The first harvest is made after about five or six years, and cutting with a machete is usually done twice a year. Fibre content is about 3 to 4 percent by weight. The fibre is yellow in colour, with cylindrical form, length 30–60 inches (75–150 centimetres), firm texture, and high moisture absorbency. Henequen is used for twines and small ropes and is also woven into sacking and coarse rugs. Mexico is the only country producing henequen on a large scale, with annual production of nearly 150,000 tons in the late 1960s.

**Cantala.** *Agave cantala* is another fibre from the agave family that probably originated in Mexico and was transported to the Philippines and Indonesia during

Sisal plant  
yieldStrength  
of abaca

Production and  
uses of  
cantala

the early years of the Spanish settlements in Central America. The plant is one of the few species growing well in moist and humus-rich soil. The cantala leaves can easily be distinguished from the other two commercial agave species by the black marginal spines curving upward like a cat's claw on the leaves, and also by the long, black, terminal spines, which must be removed by the cutters. The chief producers of cantala are the Philippines and Indonesia. In Indonesia the fibre is generally extracted from the leaves with machines (raspadors). Fibre production in the Philippines is carried out by retting in saltwater or freshwater. Cantala is pure white, in contrast to the other agave fibres, and can be used for binder twine, sacks, and hammocks. It is not as strong as sisal or abaca. Production has decreased considerably in the second half of the 20th century. Fibres are produced on a commercial scale from various other members of the agave family, such as *Agave letona*, *Agave lecheguilla*, and *Agave funkiana*, the last two of which are used in the manufacture of brushes.

**Mauritius hemp.** Fibre-producing plants of some commercial importance occur in the *Furcraea* species of the agave family. They resemble other agaves in form and habit, have short stems, and produce rosettes of large and fleshy leaves. The leaves are much longer than sisal; they continue to elongate for about five months after leaving the central spindle of the plant. Like other agaves, the *Furcraea* plant flowers once and dies.

Mauritius hemp is obtained from the leaves of *Furcraea gigantea*. The leaves are four to seven feet (one to two metres) in length, less rigid, wider, and longer than sisal leaves. The leaves, ending in a sharp spine, have a smaller fibre content than sisal leaves. At flowering time, the plant puts out a flowering pole up to 40 feet (12 metres) long, bearing white flowers. The plant normally has a life of seven to 10 years and is mature and ready for cutting after three to four years. Most of the fibres produced in Mauritius are obtained from plants found growing wild, although 2,000 acres (800 hectares) were under cultivation in the late 1960s. Cultivated plants give considerably higher yields than wild plants. Cutting is done every two years and yields are as high as two tons of fibre per acre. The local sugar-sack factory in Mauritius absorbs almost all the fibre production. Mauritius hemp is whiter, finer, and longer than sisal, but less strong. It is sometimes used mixed with abaca or sisal for cordage manufacture to give the ropes a better colour.

Several others of the *Furcraea* species of the agave family produce fibres from their leaves that are used commercially. The most important is *F. gigantea*, growing wild in several countries in South America, and in South Africa, India, and the West Indies. Local production, especially in Brazil, reaches considerable levels, although little is exported. Other fibres used locally are produced from such species as *F. macrophylla*, *F. andina*, *F. humboldtiana*, and *F. cubensis*.

**Phormium.** *Phormium tenax*, also of the agave family, is known in New Zealand as New Zealand flax or New Zealand hemp, and in South America as formio. The plant does not have a central trunk but a short, branched rootstock about two inches in diameter. It puts up a collection of tough, sword-shaped leaves growing in a fanlike manner. The leaves vary in length from three to 14 feet (one to four metres) and are one to five inches (2.5 to 12.5 centimetres) wide, depending on the growing conditions of the plant. One phormium plant yields about 20 to 30 rhizomes, which are used for propagation. Although almost any soil seems able to support the growth of *Phormium tenax*, the plant requires good soil for best results. The fibre produced from wild stands of phormium in New Zealand still plays a considerable part in the phormium industry, but cultivation of the plant has also been carried out. Harvesting time is judged by the texture and firmness of the leaves and varies with the geographical location. The leaves are cut about six to eight inches (15 to 20 centimetres) above the ground and tied into bundles of about 70 pounds (30 kilograms) each. They have a considerably higher percentage of fibre (10 to 14 percent) than sisal leaves, and are also longer, pro-

ducing a longer fibre. The white to pale-red fibre is soft, with considerable lustre and flexibility. The fibre has a cellulose content of 45.1 percent and contains 30.1 percent hemicellulose and 11.2 percent lignin.

Other plants that are members of the agave family containing fibres in their leaves and that are used locally for such purposes as making twines, ropes, and mats and packs for matting, are *Sansevieria*, mainly grown in Mexico, and the *Yucca* species, of which the common yucca is most suitable for fibre production. The latter was called silk grass by the early Virginia settlers and is abundant in the sandy soils of Virginia, Georgia, and Alabama.

### III. Animal fibres

Fibres of animal origin are based on proteins and include wool and other hairlike fibres and cocoon materials.

#### WOOL

**History.** Wool was probably the first fibre that man successfully made into a fabric, as far back as the earliest Stone Age, 1,750,000 years ago. Serviceable fabrics of wool have been found in the ruins of the Swiss lake dwellers. In Tall al-Asmar, Iraq, archaeologists have found seals indicating trade in wool as early as 4200 BC. It was evidently from Central Asia that sheep and wool were introduced into other areas of the world. Because sheep adapt easily to their environment, many variations of shape, fleece, or other characteristics have developed. The ancestor of the finest wool-bearing sheep is the Spanish Merino, bred from a number of different types, including that introduced into Spain by the Phoenicians long before the Christian era. Merinos contributed to the foundation of a wool-raising industry that became worldwide.

**Production.** The term wool is generally understood to refer to the fleece obtained from sheep; the fleece of other mammals used in the production of textiles is referred to as hair, such as mohair (from the Angora goat) or camel's hair. Because of the many environmental adaptations, it is impossible to determine the many original breeds of sheep contributing to modern types. Most fleece wools can be classified on the basis of fineness and length into one of five types: fine wool, medium wool, long wool, crossbred wool, and carpet, or mixed, wool. Such properties as length, fineness, strength, colour, lustre, waviness, shrinkage potential, and felting properties (ability of fibres to interlock with each other, forming a compact material) vary according to breed. Numerous breeds of sheep are covered by these five general types, but all vary slightly in certain properties.

Only the Merino families can be classified as fine-wool breeds. Many medium-wool breeds originating in Great Britain, such as Hampshire, Suffolk, Shropshire, and Oxford Down, were bred primarily for meat production. The long-wool breeds, Lincoln, Romney, Cotswold, and Leicester, famous for their fleece in the Middle Ages, are among the largest purebred sheep. Wool breeds were crossbred to obtain an optimum in both meat and wool production. Crossbreds, among the most famous being the Corriedale and Columbia breeds, produce medium-fine wool and are sometimes classified with the medium-wool breeds. Such breeds are usually developed by crossing a Merino with a long-wool type. Carpet or mixed wools are usually obtained from broadtail sheep living under primitive conditions in Asian countries.

Most of the world supply of wool is shorn. The finer qualities of wool, from the Merino sheep, are generally found in such warm and dry regions as Australia, South Africa, and northern Argentina. Richer pastures are required for crossbreds, found in the United States, the Soviet Union, and in areas of the Southern Hemisphere with more plentiful rainfall.

Shearing is seasonal and may be done whenever the fleece has grown sufficiently to warrant shearing, although it is generally unwise to shear in the cold winter months because of the need of the fleece to protect the sheep from respiratory diseases. Sheep are usually shorn with machine shears, following a definite method developed in Australia. The sheep is shorn in such a way that

Early  
wool  
tradingSheep  
shearing

the fleece is unbroken and all the parts remain in their natural position. The fleece is then rolled with the inside out, tied with paper twine, and packed in sacks or pressed into bales at the shearing shed.

Sheared wool is classed, baled, and branded on the sheep stations. The classed wool is packed in hessian (burlap) bales before export or sale. Size and average bale weight differ in various countries of origin. Wool originating in South American countries is heavily compressed; bales generally weigh 1,000 pounds (450 kilograms), except those from the United States and Commonwealth countries, which are usually smaller.

#### The wool auction

In the British Commonwealth of Nations, wool is marketed by public auction, but in South America and the United States it is sold by private treaty or direct negotiations between the individual grower and a buyer. In the auction system, representative sample bales, or sometimes whole lots, are displayed in buildings where they are exposed to the best natural light for inspection by buyers.

**Processing.** The basic steps in wool processing have remained unchanged for centuries. Wool obtained from different parts of the sheep varies in fibre fineness, length, and crimp (succession of waves). There are variations between locks, or cohering bunches of wool, and between fleece from different areas of the sheep. The quality of wool obtained from the belly is short and burry; the shoulders yield the finest wool. Sorting is the separation of the different qualities of wool from the fleece. The most important property is usually fibre fineness, closely related to softness of handle, the tactile properties that can be observed when textiles are held in the hand. In sorting, variations between locks and between fleece from different areas are taken into consideration, as well as brightness, crimp, fibre purity, fineness, softness, and length. The sorter unrolls the fleece on the sorter's board, usually waist-high, and cuts away any wool carrying tar or paint marks. He next removes the coarsest wool, placing it in a separate basket, and finally reaches the fine wool on the shoulders. A sorter can generally sort up to 10,000 pounds (4,500 kilograms) of Australian fleece in a normal working week.

Wool is scoured (washed) to remove such impurities as wax, suint (dried perspiration), dung, earth and sand, ointments, and brands. Suint is water soluble; wool wax, a mixture of compounds, is insoluble in water but soluble in organic solvents. The wool is scoured either by emulsion or by solvent extraction. In the emulsion method, wool is passed gently through a series of bowls containing scouring liquors generally composed of soap and sodium carbonate. The wool is first steeped in lukewarm water to dissolve some of the suint. The liquor is then clarified and used in the second bowl, where the hot suint liquor (130° F, or 54° C) emulsifies the wool grease. Higher temperatures may cause higher fibre breakage in carding and combing. The wool is rinsed in the third bowl; soap is added to the fourth rinse and the final rinse is completed in the fifth bowl. Wax is often recovered from the suint liquor by centrifuging while clarifying the liquor. These waxes in purified form are the source of the lanolin used in cosmetics. Wax and grease can also be recovered by the solvent extraction of greasy wool.

Vegetable matter collected in the wool must be removed, because any remaining small fragments of burr may cause end breakage in spinning and thus affect yarn regularity. Vegetable matter is removed either mechanically or by chemical (carbonizing) methods. Most of the burr remaining in the scoured wool is removed mechanically in the early stages of carding. In the chemical method, burrs are carbonized by sulfuric acid treatments. The scoured wool is steeped in a 6 percent sulfuric acid bath for 15 to 20 minutes, and the liquor is removed either by centrifuging or by squeezing the wool through a set of rollers. The squeezed wool is placed in a drier and subjected to temperatures increasing from 180° to 220° F (82° to 104° C), remaining at high temperature for only a short time. The acid and heat treatment reduces most of the burrs to carbon. The fibre mass is then passed through heavy rollers, disintegrating the carbonized

burrs, and is later shaken to remove the dust. It is then neutralized to remove acid by passing through warm water, then into a neutralizing bath containing sodium carbonate, rinsed in a weak soap solution, and dried as after scouring.

The most important factors taken into consideration in wool grading are fibre fineness, length, crimp, yield or clean-wool content, vegetable matter (burr content), and fibre strength. Wool quality is determined at the raw stage. Classers in various producing countries have their own standards. For example, the assessment of quality by Australian wool classers and wool experts is closely related to the number of crimps per inch; in the United States it is based on fibre fineness (diameter). The English quality scale was originally based on spinnability, the finest worsted count that could be spun from the tops. In the blood system, the blood designation is based on the divergence from the pure blood standard of the Merino sheep, considered the best strain for breeding and cross-breeding.

Finer wools generally contain higher numbers of crimps per inch. There is a strong correlation between fibre fineness and the finest yarn that can be spun. Staple length is of great significance in processing because it governs the spinning performance when spinning at the limiting count or size. Fibre crimp, in the range in which it is encountered in Merino and fine crossbred wools, does not play an important role in spinning, but classers do not emphasize staple length when assessing quality. Other criteria include colour, soft handling, and suitability for weaving.

Blended wool fibres are carded to disentangle the locks, mix the fibres, remove remaining foreign matter, and convert the fibre into a sliver for further processing. The carding action is accomplished by teasing the fibres between sets of wire points moving at different surface speeds. In woollen carding the top set of wires is held in a series of rotating rolls. The card web is fed to a condenser and divided into continuous strips along its length, then rubbed to impart some cohesion, and wound onto a bobbin. The resulting material, called slubbing, is taken to the spinning frame for conversion into yarn.

Wools may be classified as woollen or worsted types, according to the spinning method employed. Woollen yarns are made up of fairly short fibres, loosely spun and with little twist. Fabrics woven from woollen yarns have a soft, fuzzy surface and are somewhat loosely woven. Worsted yarns are smooth and even, with high twist, and fabrics made from them are usually closely woven with a smooth surface.

In worsted spinning, the wool card sliver of Merino and fine crossbred wool is first cleaned, or backwashed, by scouring, and the fibres made parallel by gilling, or pin-controlled drafting. In this process movement of the fibres in the space between two pairs of rollers is controlled by rows of pins moving forward with the sliver. The gilled, parallelized slivers are combed to remove short fibres and burr from the bulk. In combing, fibres are drawn through a bed of pins while one end of the fibre beard is held and the combed short fibres are collected. Two types of combing machines are used in worsted processing—the Noble, or circular comb, and the French, or rectilinear comb. The combed sliver, or the top, is finished by gilling and wound into a ball. It is then blended and attenuated by a series of drawing processes and finally spun into yarn.

Wool that is to be dyed to bright or light shades, or made into white yarns and fabrics, is bleached to achieve whitening, usually in yarn or fabric form, by either the storing method or by hydrogen peroxide bleaching. In storing, the wool is placed in a closed chamber and exposed to sulfur dioxide. Coloured impurities are converted to colourless substances by gas produced by burning sulfur. This process may not produce permanent whitening, as oxygen in the air may cause the changed substances to take on colour again. The hydrogen peroxide bleaching process is more permanent, as the wool is immersed in a dilute solution of hydrogen peroxide, which destroys the coloured impurities.

Main factors in wool grading

Carding and spinning

Bleaching processes

**Fibre properties.** Wool is the fibre constituting the protective covering of the sheep and is similar to the fibres of similar function occurring in many of the mammals. Its origin is related to that of various other mammalian skin tissues such as nails, horns, and hoofs, and it consists mainly of keratin, an insoluble protein. The wool fibre is an organized structure consisting of cells growing from a root, or follicle, situated in the dermis, or the middle layer of the skin. The fibre is extruded from the shaft of the follicle by the pressure of newly formed cells. During this process, just before emergence of the fibre from the skin, a partial alignment of the protein chains occurs and is stabilized by the process of keratinization. Mature keratinized fibre seen above the skin surface is dead tissue, consisting of three structural components. The cuticle forms a skin consisting of various cuticular layers and scale cells. The scales are laid down in an overlapping fashion with their scale edges pointing toward the fibre tip, much like the arrangement of seeds in a pinecone. The cortex constituting the bulk of the fibre consists of elongated spindle-shaped cells arranged parallel to the fibre axis. The core of the fibre is formed by the medulla, consisting of a number of air-filled cells or a completely hollow tube. The medulla is absent in fine wool, and some coarse wools are also only partially medullated. The cortex can be separated into the *ortho*-cortex and the *para*-cortex, slightly differing in amino-acid composition and physical properties. The distribution of these two cortical segments, either bilateral or radial, determines the crimp or lack of crimp of the wool fibre. In the radial distribution the *ortho*-cortex is in the centre of the fibre; in the bilateral distribution the *ortho*-cortex is on the inside of the crimp.

The  
medulla

Fleece density varies among breeds, ranging from about 100,000,000 fibres per sheep for the fine Merinos to 15,000,000 to 20,000,000 in the coarse-wool breeds. The distribution of density within the fleece of a sheep varies considerably, with density greatest along the spine region and decreasing toward the belly. Before selective breeding, the body covering of sheep consisted of two distinctly different fibres, an outer coat of long, coarse, medullated, and brittle hairs, and an inner one of fine, short, and wavy wool.

As a result of selective breeding, most sheep used mainly as a source of wool have a high proportion of the inner coat, or wool, and a very small amount of the outer coat, or coarse hair. Although annual shedding of any remnant of the outer coat occurs, the wool can attain a length of several times its annual growth if not shorn. Kemp fibres, particularly coarse hairs, relatively flattened, with long tapering tip and heavy medulla, are shed periodically, with considerable differences existing between breeds in this respect.

Technologically, the diameter, or fineness, of the wool fibre is one of its most important properties, determining to a large extent the grade assigned to a lot of wool. Diameters range from 16 microns (millionths of a metre) in the finest Merinos to over 40 microns in the coarsest long-wool types. Changes in nutrition result in considerable variation in both diameter and cross-sectional shape between fibres within a lot of wool, as well as along the length of the individual fibre. The staple length of the wool fibre is determined both by breed and by the environmental conditions during the growth of the wool. Staple length generally increases with increasing fibre diameter, ranging from 1½ to three inches (four to eight centimetres) for fine Merino up to 10 to 14 inches (25 to 35 centimetres) for coarse Cotswold wool. Staple length is lower than mean fibre length because of the crimp that results in a helical configuration in an individual fibre and a uniplanar wave in the staple. Crimp frequency per inch is related to fibre fineness.

Moisture  
content

Wool fibres are hygroscopic, absorbing water vapour from a moist atmosphere in a reversible way. Because most fibre properties are dependent on moisture content, this characteristic is extremely important, especially in numerous processing steps, including carding, combing, spinning, and weaving. Relative humidity in the processing plants must be controlled for optimum processing

conditions. Upon uptake of water, the fibre swells anisotropically (nonuniformly), increasing up to 16 percent in diameter while the change in length is only about 1.2 to 1.5 percent. The ability of wool fibres to absorb and release moisture contributes to wearing comfort in garments made of wool.

The mechanical properties of wool are a reflection of the complex structure of the fibre, and mechanical properties depend strongly on the moisture content of the wool as well as the rate of extension. The outstanding properties of wool are its high extensibility and its unusual elastic properties, permitting recovery from very high deformations.

The molecules of wool fibres have a curled structure, and the fibre has a natural crimp, or waviness, both factors contributing to the high resiliency of wool fibres. At an extension of 2 percent wool has 99 percent recovery, so that upon release the fibre returns almost completely to its original length. The fibre breaks at extensions of about 40 to 50 percent.

Wool has unique frictional properties because of the arrangement of the cuticular scales. Friction is greater when the fibre is rubbed against the scales, from the tip to the root end, than when it is rubbed with the scales. Mobility of the fibre is therefore preferential in the direction of the root end. This phenomenon, called the directional frictional effect, forms the basis of felting. When a mass of fibres is subjected to mechanical action, especially in the wet state, the fibres preferentially move in one direction relative to other fibres, forming irreversible entanglements. The property of felting, unique for wool, is used industrially to produce fabrics or large continuous felted structures such as the papermaking felts. The felting tendency in loosely structured wool goods, such as sweaters, is a disadvantage because laundering causes matted structures that shrink. Considerable research has resulted in improved control of the felting process. Various chemical processes have been devised to reduce shrinkage and avoid felting, leading to the manufacture of machine-washable woollen garments. Tensions in fabrics may be used by preshrinking, in which the cloth is wetted and allowed to relax. Antifelting treatments involve chemical modification of the fibre surface, greatly reducing the friction produced when the fibre is rubbed against the scales.

Directional  
frictional  
effect

Wool has the most complex molecular structure of all textile fibres, reflecting the fact that wool is composed of about 20 different  $\alpha$ -amino acids (organic acids forming the chief constituent of proteins) with side chains containing various functional groups and that these amino acids are grouped in unique spatial arrangements.

Amino-acid composition varies considerably with the breed of the sheep and can be substantially influenced by changes in the diet. Typical figures for the average amino-acid composition of Merino wool are given in Table 2. The table figures are averages, not reflecting the differ-

Chemical  
composition  
of wool

**Table 2: The Amino-Acid Composition of Wool**

type of side chain	amino acid	mole (percent)
Hydrocarbon (or hydrogen)	glycine	8.8
	alanine	5.5
	valine	5.6
	leucine	7.6
	isoleucine	3.1
	phenylalanine	2.8

	cystine	6.3
	methionine	0.5
Heterocyclic	proline	7.5
	tryptophan	0.9

ences among the various components of the wool structure. For example, considerable differences exist between the cortex and the cuticle, and differences in amino-acid composition have also been reported between the *ortho*-cortex and the *para*-cortex. The amino-acid composition of the whole wool fibre, as well as that of the various components, is known with a considerable degree of accuracy, but very little is known about the sequence in which the amino acids are arranged to form the protein molecules. As the Table shows, wool consists of amino acids containing functional groups. Because of the presence of acidic and basic groups, wool is amphoteric, combining reversibly with acids as well as with bases. The existence of positively (amino) and negatively (carboxyl) charged groups is of considerable importance in the dyeing process.

The disulfide bond of the amino acid cystine, which is colourless crystalline, is one of the most important reactive centres in wool. The reactivity of combined cystine in wool has been extensively studied and its importance in many industrial processes is acknowledged. The breaking of the disulfide bond by chemical reduction is essential for various setting treatments of wool used to introduce irreversible deformations. Reductive treatments lead to the formation of free thiols that can act as catalysts for a disulfide interchange mechanism. This mechanism, in which disulfide bonds can exchange position, forms the basis of all irreversible deformations of the wool fibre. Under basic conditions disulfide bonds can be converted into the amino acids lanthionine and lysinoalanine, which are incapable of participating in interchange reactions and therefore help stabilize the keratin structure. Oxidative treatments are of considerable importance in bleaching and shrink-proofing treatments. In these processes the treatment is intentionally restricted to the surface layers having considerably higher cystine content than the cortex. Oxidation usually leads to a breaking of the disulfide bonds and the formation of cysteic acid. This oxidative degradation of the proteins in the cuticular region is essential for improved felt resistance.

Complete breaking (scission) of the disulfide bonds and subsequent solubilization of the keratin chains has led to isolation of two major fractions of modified proteins. One fraction has a high sulfur content and has been associated with the highly disulfide-crosslinked matrix; the other fraction is low in sulfur and probably originates from the protein chains forming the microfibrils. The molecular weights of these two major fractions and various subfractions that have been isolated vary over a considerable range, indicating that wool must be considered as made up of a complex mixture of polypeptides. There is still little evidence that polypeptides with identical sequences of amino acids exist, or that certain amino-acid sequences are repeated over an extended chain length of the protein chain.

**World production and consumption.** Annual world wool production in 1970 reached an all-time record of 1,590,000 tons of raw wool. The major finer quality wool-producing countries are Australia, the Soviet Union, New Zealand, Argentina, and South Africa. India, Pakistan, China, the Middle East, and North Africa are the major producers of carpet-type wool. Leading consuming countries are the United Kingdom, United States, Japan, France, and the Soviet Union.

#### SPECIALTY HAIR FIBRES

Many animal fibres not taken from the fleece of sheep are used industrially, mostly in the manufacture of clothing. Frequently used in blends with sheep's-wool fibres, they add softness, lustre, or colour. The largest group, called specialty hair fibres, is taken from the fleece of goats and camels and is often classified as wool. Other such fibres are obtained from cows, horses, and fur-bearing animals.

**Mohair.** Mohair, the most important specialty fibre, is taken from the fleece of the Angora goat, named for the province of Angora (historic name for Ankara), in Turkey, where it has been raised for many centuries. The United States, Turkey, and South Africa are the only

countries in which this goat is currently bred and raised commercially.

Three principal fleece types exist. The finest, called tight lock, is produced by a variety bred in late fall; the kids are born five months later. The first shearing takes place when the kid is six to seven months old, producing fall kid, the finest type of mohair. The next shearing, carried out the following spring, results in spring kid. A shearing at the age of a year and a half produces yearling mohair; from then on the mohair is classified as adult. Shearing is performed with hand shears or machine clippers, and the fleeces are packed separately.

The hair of the Angora goat grows in long, uniform locks with little crimp and no felting properties. The microscopic structure is much like wool, although the scale structure is less developed and there is little overlapping of the scales. A problem in processing mohair is the existence of kemp fibres, much coarser and stiffer than the normal mohair fibre, that adversely affect spinability and dyeability. Moisture content and physical properties of mohair fibres are similar to those of wool. Because mohair consists almost exclusively of orthocortical cells, it is more sensitive to various chemicals than wool, a consideration in such manufacturing processes as scouring, dyeing, carbonizing, and bleaching. Mohair fibres are used mainly in apparel.

**Cashmere.** Cashmere, a very fine and soft animal fibre, is obtained from the undercoat of several types of goats designated as Kashmir or down goats, found in the mountainous regions of Asia. The Kashmir goat has two coats, the fine down, or undercoat, and the coarse outer coat. The undercoat is particularly well developed. The annual production of the three major cashmere producing countries, China, Mongolia, and Iran, is about 8,000,000 to 12,000,000 pounds (4,000,000 to 5,000,000 kilograms). The average goat yields about one-half pound; thus the total number of Kashmir goats can be estimated as from 16,000,000 to 24,000,000. Grading and pricing of cashmere fibre depends upon the country of origin, and is usually based on the amount of down fibres, or true cashmere, present; in commercial samples it varies between 15 percent and 90 percent. The finest down fibres originate in China and Mongolia.

The strength of cashmere fibres is about 10 percent below that of the finest wool, and moisture content and chemical properties are very similar to fine wool. Sensitivity to chemical treatment is even more pronounced than that of mohair, essentially because of the extreme fineness of cashmere fibres. This characteristic particularly applies in the bleaching process, a common practice because of the higher price brought by white cashmere fibres. The heavy pigmentation of dark cashmere fibres requires special bleaching processes, sometimes leading to considerable fibre damage and reductions in tensile strength. Dehairing processes, separation of the hair and the down fibres, are necessary for the production of high quality cashmere. Considerable losses occur in these processes and the resulting dehaired product commands high, though fluctuating, prices. It is used mainly in apparel, either alone or combined with sheep's wool, which increases durability.

**Common goat hair.** Common goat hair, produced in countries producing cashmere and in Greece and Argentina, is used mainly for the production of cheap felts and automobile carpets. The down and beard hairs, occurring in a ratio of 1 to 9, are not separated, and the fineness varies over a wide range.

**Camel's hair.** Camels used as camel's-hair sources include both the Arabian or Syrian camel having one hump, also known as the dromedary, and the Eastern Asiatic, or Bactrian, camel with two humps. The camel's hair, gathered in the molting season in late spring or early summer, is usually collected after it has fallen off. Frequently a man at the end of a camel caravan collects the hair tufts and strands that fall off during the journey, and the total yield is sold at the first town the caravan reaches. Each animal yields about five pounds of hair per year.

Camel fleece is similar to that of the Kashmir goat,

with a soft down of great fineness underneath a coarse outer coat reaching up to 15 inches (38 centimetres) in length. A dehairing process, usually accomplished by combing, is necessary for a high-grade camel's-hair wool. Considerable differences exist between the hair of the Bactrian and that of the Arabian camel, so that the origin of the hair may be established easily, even in the finished fabric.

Camel's hair is used in the apparel industry for high-grade overcoating and knit wear; in addition it is used for rugs and in industrial fabrics in which high strength is desired.

**Llamas.** The higher grasslands of the Andes, in South America, form the exclusive habitat of animals of the genus *Lama*, close relatives to the camels. Species belonging to the camel family include the llama, alpaca, vicuña, and guanaco.

The llama, the largest of the Andean Camelidae, is chiefly a burden carrier, although it is also used for its meat, milk, and fleece. There are about 3,000,000 llamas in the Andean Highlands. The heavy, thick coat is a mixture of fine and coarse hairs and kemp and is frequently of a brown colour, although pure whites and blacks have also been found. The other domesticated species is the alpaca, occurring in two varieties, the *huacayo* (or *huacaya*) and the *suri*. The alpaca, smaller than the llama, has been used for its fleece since pre-Inca days. Hybrids of llama and alpaca frequently occur, and are called *huarizo* with a llama sire, and *misti* when sired by an alpaca. Fleeces of these hybrids are not as fine in quality as that of the alpaca.

Llama fleece, similar to that of the camel, consists of an outer coat of coarse, straight hairs and an undercoat of woollike, crimped fibres. Coarse-fibre content in commercial lots usually amounts to about 20 percent.

Fleece production is dominated by the alpaca, providing up to 90 percent of the export. The alpaca is usually kept in flocks ranging from 200 to 300 up to several thousands. The flocks are shorn during the rainy season, from November to March. The fleece, generally allowed to grow for two years, averages about seven to eight pounds per animal. Shearing with conventional machines is difficult. The fleeces, separately rolled and tied, are sold to the exporters in the city of Arequipa, Peru. Fleeces are classed and sorted according to colour and quality, then pressed into bales of 220 pounds (100 kilograms).

The main difference between the fleece of the two alpaca varieties, *huacayo* and *suri*, is that the *huacayo* fibres are crimped and *suri* fibres are straight or occasionally widely waved. Considerable variation of fineness occurs along the length of the two years' growth of the fibres. This difference is caused by the seasonal conditions connected with the lack of rainfall and availability of food.

The mechanical properties of the two fibre varieties show considerable differences; the *huacayo* fibres are more extensible and show greater tensile strength. The *suri* fibres have a high elastic modulus, resulting in stiffer fibre. This rigidity and the lower scale profile probably contribute to the lower felting rates and less dense entanglements formed during felting, compared with wool fibres of the same diameter. *Huacayo* fibres have a silver lustre; *suri* has a silky lustre close to that of kid mohair. The similarities between *huacayo* fibres and coarse wool and the *suri* fibre and mohair also extend to the amino-acid composition, considerable differences between the two alpaca varieties being found.

Bleaching of dark alpaca fibres is frequent because of the price difference between white and coloured alpacas. Bleaching frequently produces considerable fibre damage and reduction of wet tensile strength.

**Vicuña.** The vicuña, the smallest of the *Lama* species, is less than three feet (one metre) in height and weighs 100 pounds (45 kilograms) or less. Its fibre is the rarest and finest, much sought after since pre-Inca times. Before the Spanish Conquest, hunting was strictly regulated and only persons of high rank were permitted to use its skin and wool. During the colonial period hunting

with firearms threatened the species with extinction. In 1825 the killing of vicuñas was prohibited. Domestication was encouraged but has met with limited success.

Shearing occurs in early summer. Most of the annual vicuña exports, however, estimated at up to 50,000 pounds (23,000 kilograms), are obtained from killed animals, mainly from Bolivia.

Vicuña fleece contains about 10 percent beard hair mixed with fine wool-type hair. Vicuña fibres closely resemble the *huacayo* alpaca variety but are finer. Because of their extreme fineness, vicuña fibres are very sensitive to chemical treatment. Vicuña is used in rugs, blankets, and apparel of the highest quality.

**Guanaco.** Another luxury fibre, the down of the guanaco, was introduced into the woollen industry about the middle of the 20th century. The swiftest of the four llama species, guanacos are shy and travel in small herds ranging as far south as the Straits of Magellan. Argentina is the principal source of guanaco furs and peltries (undressed skins). The fibres are very fine, much softer and of higher lustre than wool fibres of comparably small diameter.

**Cow hair.** Cow hair, usually pulled from the skin after slaughter, is extensively used for coarse carpet yarns, blankets, felts, and mattress stuffings. The body hair is graded into long, medium, and short and also according to colour. Cow-tail fibres are much coarser.

**Horsehair.** Horsehair is used in textile manufacture to make haircloth interlinings for tailored garments. The best quality tail hair from Argentina is packed in bales in the form of bundles and graded according to length. Horsehair is also usually dressed in the United Kingdom and then sold to brush makers. Mane and tail horsehair undergoes a series of treatments including sorting and washing, hackling (combing out of short fibres), bundling (sorting according to length), dressing (trimming of the ends), and flagging (splitting of tip ends for paint-brushes). Horsehair is also used for violin bows, upholstery, and mattress filling.

**Fur fibres.** *Angora-rabbit fibres.* The fibre of the Angora rabbit has been used in the textile industry since the mid-19th century. The animal is usually raised on a very small scale. The rabbits generally molt four times a year, when the hair is approximately three to 3½ inches (eight to nine centimetres) long, and it is collected, shorn, clipped or plucked. The fibres are silky, light in weight, and warm. Because of their high cost, Angora-rabbit fibres are used only in luxury fabrics, sometimes in blends with other fibres.

*Common rabbit fibres.* The felt-hat industry uses a considerable number of other rabbit-fur fibres, and a certain amount is also used in the textile industry. The pelts are graded according to size, length of fibre, and yield, and the production of fur fibres involves softening, stretching, plucking, clipping (removal of undesirable guard hair), carroting (improvement of felting properties by chemical treatment), cutting (removal of fibres from the skin), and blending and blowing (elimination of guard hairs and dirt particles). A bleaching process usually follows.

## SILK

**History.** Silk is said to have originated in 2640 BC, when the Chinese empress Hsi-ling Shih discovered the method of raising silkworms and unwinding the silk filaments of the cocoons. This knowledge was jealously guarded in China for 3,000 years, but eventually sericulture, the art of raising silkworms, spread to Japan, India, and Iran. It may have been brought back from India by Alexander III (the Great), but if so the knowledge was subsequently lost to Europe. A silk industry was finally established in Byzantium under the emperor Justinian (AD 527–565), after two Persian monks returned from China with silkworm eggs and seeds of the mulberry tree concealed in hollow staves. The Arabs acquired the knowledge of sericulture by the 8th century, and in the 12th century the Italians introduced it to Europe, where for centuries silk remained the premier luxury fabric.

Composition of vicuña fleece

Introduction of sericulture to the West

**Production.** Silk fibre is a continuous protein filament secreted by various insects, especially the larvae of a certain caterpillar, in forming cocoons. This caterpillar, the silkworm, belongs to the order of Lepidoptera, or scale-winged insects, genus *Bombyx*. The principal species, the *Bombyx mori*, or mulberry silkworm, produces most of the raw silk used commercially. Various strains of Japanese, Chinese, and European worms have been crossbred in Japan, where silk from their cocoons is used in the raw-silk reeling industry. These cocoons yield filaments with a reelable length of 600 to 900 metres (2,000 to 3,000 feet).

Eggs laid by the moth are kept in cold storage for six to ten months, and germination is started in an incubator at the appropriate season of the mulberry tree, the leaves of which serve as food for the larvae. After ten days in an incubator, one ounce of eggs produces 40,000 to 60,000 worms. During their growth and development the caterpillars shed their skins four times, drastically increasing in size and weight until they are about five to nine centimetres (two to 3½ inches) long. After about 30 days the worm begins to develop two large silk-producing glands in which the silk secretion is formed. The liquid fibroin flows through channels to one common exit tube in the head of the insect. The two fibroin filaments are connected together by the silk glue, or sericin. The worm builds an oval cocoon by adding layer after layer, moving its head in arcs of circles crossing in figure eights, and the cocoon is completed in 24 to 72 hours. The silkworm then undergoes the transformation from a caterpillar to the inert pupa, and then rapidly develops into a moth that cuts an opening through the cocoon with the aid of a secretion. The whitish-gray moth, with rudimentary wings, has no mouth and is unable to eat. After mating the female lays about 500 eggs and dies after a life of one to four days.

Only enough moths to supply eggs for the next crop are allowed to emerge from the cocoon. For the rest, growth of the pupa is usually interrupted by refrigeration. The cocoons are sorted and transferred to the filature, or silk-reeling, establishment. Before they are reeled, they are boiled in water to soften the gum, causing the original figure eights of the cocoon filament to straighten out. After the boiling, the loose ends are picked up through brushing and the number of necessary filaments to form the size of the raw-silk thread desired is passed through porcelain guides. Two general systems are used, the Chambon, or French system, and the Tavelle, or Italian system. In the Chambon system, two groups of cocoon filaments are twisted around each other to yield a thread; in the Tavelle system, the thread is twisted around itself. From four to nine cocoon filaments are required to produce a 14-denier silk thread (14 grams per 9,000 metres).

The tussah silkworm, *Antheraea pernyi*, a native of China, feeds exclusively on one type of oak tree, *Quercus serrata*, and only out of doors on trees of shrub height. Although it can produce both a spring and an autumn crop, only the autumn crop is usually used for silk production. Tussah cocoons contain more gum and calcium compounds than mulberry worm cocoons, and must be boiled in sodium carbonate solution for one and a half hours, followed by the normal boiling procedure before reeling.

**Processing.** Silk throwing requires a special skill. The raw silk thread, after soaking in an oil or soap emulsion, is wound onto bobbins, and the threads are doubled together and twisted. This process converts the raw silk thread into a yarn of the proper size by regulating the twist, producing the various silk yarns for the manufacturing process.

Waste silk originating from processing or from the original production is degummed in soap solutions, dried, processed for the removal of short fibres and foreign matter, and spun into a silk yarn used for the production of fabrics with soft, pliable finish, known for its spreading qualities in pile.

**Fibre properties.** The silk filament consists of two fibroins, or brins, of triangular cross section. Slight surface striations parallel to the fibre axis indicate that the

fibre is structurally composed of minute filaments, or fibrils. The moisture content of silk varies between 9 percent and 12 percent at 65 percent relative humidity, depending upon whether it is raw silk or degummed. Silk has a tensile strength of about four grams per denier and a breaking elongation of about 20 percent. The truly elastic region is only about 1 to 2 percent, followed by a yield region in which slippage of the extended chains past one another occurs. The silk protein consists of extended chains, in contrast to the helical configuration found in wool proteins. The packing of these extended chains into what is called a  $\beta$  (beta)-pattern results in the formation of sheets that are packed into crystallites. The density of degummed silk is somewhat lower than that of cotton, wool, and hair fibres. Silk has been used as an electrical insulator because of its poor electric conductivity. Static electricity is easily accumulated on silk, and processing must be carried out at high humidity.

Silk fibroin and sericin are the two major components of raw silk. Silk fibroin is the predominant component, comprising 70–76 percent; sericin constitutes about 15–25 percent. Minor components are about 2 percent wax, which presumably acts as a water repellent for the cocoons, and about 1 percent salt.

Sericin, an albuminoid protein mixture consisting of about 15 amino acids, is a gummy coating on raw-silk filaments. It is an excellent buffer for dye solutions, making the silk fibres stiff and harsh and forming a protective layer for the various manufacturing processes. Soap or oil is applied in soaking solutions, softening the sericin and permitting the introduction of twist during the throwing operation.

Sericin is removed by a treatment called degumming, or stripping, to make silk fabric soft and glossy. Degumming, essentially an alkaline scouring operation, is carried out at a temperature of 205° F (96° C). The degumming process probably involves a chemical reaction leading to a progressive degradation and solubilization of the sericin molecules. The boil-off solution, heavily charged with sericin, is used as a buffer agent in the dye bath.

Silk fibroin consists of extended protein chains of various molecular weights formed by amino acids, with glycine (44 percent) and alanine (30 percent) predominant. Strong alkaline solutions and various mineral acids may cause it to dissolve. Silk fibres treated with concentrated sulfuric acid for several minutes, then rinsed and neutralized, contract up to 50 percent in length without significant damage. This action of concentrated acid has been used to introduce crepon effects (crepe effects produced by variations in the twist of the yarns) by printing the silk fabric with wax and then immersing it in concentrated acids.

Silk, valued for its lustrous appearance, resiliency, elasticity, and strength, has a wide variety of textile uses and can be woven or knitted into fabrics ranging from light chiffons to heavy velvet piles.

**World production and consumption.** The Far East, India, and the Mediterranean countries are the main silk-producing areas. Annual production of raw silk during the late 1960s amounted to nearly 83,000,000 pounds, of which slightly more than half was produced in Japan. The other major producing countries were China, the Soviet Union, India, South Korea, and Italy. Japan, China, and South Korea were the three major silk exporters. The five largest importers of raw silk were Italy, Japan, the United States, France, and Switzerland.

#### IV. Mineral fibres

The only mineral fibres of commercial importance are a group of magnesium silicates comprising the asbestiform group.

**History.** The use of asbestos was recorded in the 1st century AD by Pliny the Elder, a Roman naturalist. It was apparently used by the Greeks considerably before that date; the Romans used it for lampwicks and cremation cloths, but it was apparently forgotten in medieval Europe. In the 13th century Marco Polo brought back from China news of cloths that did not burn when thrown into

Major components of raw silk

a fire. The commercial importance of asbestos began with its use in steam engines in the 19th century.

**Production.** The name asbestos is given to a group of 30 or more minerals of fibrous crystalline structure of which only six have economic significance. These are, in order of their importance: chrysotile (which accounts for about 95 percent of the world production of natural mineral fibres), crocidolite, amosite, anthophyllite, tremolite, and actinolite. Chrysotile is a fibrous form of serpentine; the other five are amphiboles (rock-forming minerals composed mainly of silica).

The yield of fibres from the ore is relatively small, ranging in Canadian mines from 3–12 percent. Of the total asbestos fibres extracted from the rock, only about 3–4 percent consist of grades suitable for spinning or processing into textiles. The fibres are separated from the mother rock by several stages of crushing, each followed by screening and air separation. The fibres are then further opened, cleaned, graded according to length, and bagged for shipment. The longer fibres, separated by hand, are the most expensive grade and are used in textiles. Crude, or unmilled, fibres and the longest milled grades are suitable for spinning into yarn.

**Processing.** The processing steps necessary to make the milled or crude fibres into an asbestos yarn involve blending and mixing to arrive at the desired characteristics of tensile strength in the finished product. Carriers, or supporting materials, are usually such organic fibres as cotton or rayon. In the carding operation, opening and cleaning of the fibres is completed, leading to a relatively parallel arrangement and a continuous web. This web, or sliver, is turned into roving and the finer yarn is produced from these untwisted strands. The roving is twisted to provide tensile strength and the resulting single yarn is twisted with other single yarns.

**Chrysotile fibre properties.** Chrysotile is a hydrated magnesium silicate. Other elements such as iron, calcium, and aluminum appear as impurities in the crystal structure. Chrysotile fibres are particularly useful for the manufacture of asbestos textiles because of their length, strength, toughness, and flexibility or pliability. Their tensile strength is high, values of up to 800,000 pounds per square inch having been recorded. The heat resistance of chrysotile is high among asbestos fibres. Loss of water occurs upon long exposures at 1,110° F (600° C) and fusion eventually at 2,770° F (1,520° C). Under short-time exposure, however, the fibres have been shown to withstand temperatures as high as 6,000° F (3,300° C). Chrysotile fibres are extremely fine. Canadian chrysotile has a dark-green lustre, but the fibres appear white when fully opened and are known as white asbestos.

**Uses.** Asbestos textiles are used for numerous purposes usually connected with their incombustibility or ability to endure extremely high temperatures. Safety clothing, fire blankets, fireproof curtains and draperies, and insulation material for wires and cables in home and industrial appliances and for rocket nose cones and combustion chambers are some of the applications.

**World production and consumption.** World production in the late 1960s reached over 3,000,000 short tons, with Canadian output amounting to over 1,500,000 tons a year. Rhodesia (formerly Southern Rhodesia), Swaziland, and the U.S.S.R. are also important suppliers.

**BIBLIOGRAPHY.** D.S. HAMBY (ed.), *The American Cotton Handbook*, 3rd ed., 2 vol. (1965–66), a collection of authoritative contributions on subjects ranging from cotton growing to the final finished fabric; KYLE WARD, JR. (ed.), *Chemistry and Chemical Technology of Cotton* (1955), a reliable, detailed reference source dealing with such topics as the chemical properties of cotton cellulose and the chemistry and chemical technology of various preparatory and finishing processes; EVELYN E. STOUT, *Introduction to Textiles*, 3rd ed. (1970), a general introduction to textile fibres and yarn and fabric technology, with natural fibres receiving comparatively brief, but well-written coverage; MARJORY L. JOSEPH, *Introductory Textile Science* (1966), a college-level introduction to textile science intended for students with some background in chemistry; W. VON BERGEN (ed.), *Wool Handbook*, 3rd enl. ed., 2 vol. (1963–70), a standard reference and textbook for the wool industry covering all phases from wool growing to cloth

manufacture, with contributing authors who are experts in their specific fields; M.L. RYDER and S.K. STEPHENSON, *Wool Growth* (1968), a series of college lectures in which the authors attempt to link physiology with the genetics of wool growth and fleece structure; R.H. PETERS, *Textile Chemistry*, vol. 1, *The Chemistry of Fibres* (1963), an introduction to the field of the chemistry of fibre-forming polymers, with a number of chapters treating the structure in chemistry of natural fibres, for students with a knowledge of chemistry and physics; R.H. KIRBY, *Vegetable Fibres* (1963), a study of the botany, cultivation, and utilization of vegetable fibres with the exception of cotton, with emphasis on the production of fibres; R.R. ATKINSON, *Jute: Fibre to Yarn* (1965), a detailed treatise on jute covering the botanical background, cultivation, and marketing up to the spinning and winding of jute yarns; M.S. SARMA, "Jute," *Fld. Crop Abstr.*, 22:323–336 (1969), a brief review article on the botany and cultivation of jute, as well as retting, disease, and pest control; W.J. ONIONS, *Wool* (1962), a comprehensive survey of the entire field of wool technology covering the rearing of sheep as well as all the processes to the finished wool fabric; LUIGI CASTELLINI, "Hemp," *Ciba Rev.*, no. 5, pp. 2–31 (1962), a short review article on the botany, cultivation, and processing of the hemp fibre, with excellent illustrations; ASBESTOS TEXTILE INSTITUTE, *Handbook of Asbestos Textiles*, 2nd ed. (1961), a comprehensive treatise on the manufacture of asbestos fibres with emphasis on the various textile products made from asbestos; LONDON, COMMONWEALTH ECONOMIC COMMITTEE, *Industrial Fibres* (annual), a review of the production, trade, and consumption statistics relating to industrial fibres, with considerable emphasis on natural fibres; E.V. TRUTER, *Wool Wax: Chemistry and Technology* (1956), a discussion of the chemical characteristics of wool wax and the technology used for its isolation and purification; P. ALEXANDER and R.F. HUDSON, *Wool: Its Chemistry and Physics*, 2nd ed. by C. EARLAND (1963), the classic textbook on wool fibre science.

(H.-D.H.W.)

## Fichte, Johann Gottlieb

Johann Gottlieb Fichte was the first major representative of the movement called transcendental Idealism that developed out of the work of the German philosopher Immanuel Kant and dominated German philosophy during the first third of the 19th century. His thought, which is termed ethical Idealism, and his personal life were characterized by a moral rigorism. Fichte constructed a systematic deduction of the entire body of knowledge, based on the unconditioned absolute principle of the ego, or self-affirmation.

Fichte was born at Rammenau in Upper Lusatia on May 19, 1762, the son of a ribbon weaver. Educated at the Pforta school (1774–80) and at the universities of Jena (1780) and of Leipzig (1781–84), he started work as a tutor. In this capacity he went to Zürich in 1788 and to Warsaw in 1791 but left after two weeks' probation.

The major influence on his thought at this time was that of Kant, whose doctrine of the inherent moral worth of man harmonized with Fichte's character; and he resolved to devote himself to perfecting a true philosophy, the principles of which should be practical maxims. He went from Warsaw to see Kant himself at Königsberg, but this first interview was disappointing. Later, when Fichte submitted his *Versuch einer Kritik aller Offenbarung* ("An Attempt at a Critique of All Revelation") to Kant, the latter was favourably impressed by it and helped to find a publisher (1792). Fichte's name and preface were accidentally omitted from the first edition, and the work was ascribed by its earliest readers to Kant himself; when Kant corrected the mistake while commending the essay, Fichte's reputation was made.

In the *Versuch*, Fichte sought to explain the conditions under which revealed religion is possible; his exposition turns upon the absolute requirements of the moral law. Religion itself is the belief in this moral law as divine, and such belief is a practical postulate, necessary in order to add force to the law. The revelation of this divine character of morality is possible only to someone in whom the lower impulses have been, or are, successful in overcoming reverence for the law. In such a case it is conceivable that a revelation might be given in order to add strength to the moral law. Religion ultimately then rests upon the practical reason and satisfies the needs of man, insofar as he stands under the moral law. In this

Deutsche Fotothek, Dresden, Ger.

conclusion are evident the prominence assigned by Fichte to the practical element and the tendency to make the moral requirements of the ego the ground for all judgment on reality.

In 1793 Fichte married Johanna Maria Rahn, whom he had met during his stay in Zürich. In the same year he published anonymously two remarkable political works, of which *Beitrag zur Berichtigung der Urtheile des Publikums über die französische Revolution* ("Contribution to the Correction of the Public's Judgments Regarding the French Revolution") was the more important. It was intended to explain the true nature of the French Revolution, to demonstrate how inextricably the right of liberty is interwoven with the very existence of man as an intelligent agent, and to point out the inherent progressiveness of the state and the consequent necessity of reform or amendment. As in the *Versuch*, the rational nature of man and the conditions necessary for its realization are made the standard for political philosophy.

The philosophy of Fichte falls chronologically into a period of residence in Jena (1793–1798) and a period in Berlin (1799–1806), which are also different in their fundamental philosophic conceptions. The former period is marked by its ethical emphasis, the latter by the emergence of a mystical and theological theory of Being. Fichte was prompted to change his original position because he came to appreciate that religious faith surpasses moral reason. He was also influenced by the general trend that the development of thought took toward Romanticism.

In 1793 there was a vacant chair of philosophy at the University of Jena, and Fichte was called to fill it. To the ensuing period belongs his most important philosophical work. In this period he published, among other works: *Einige Vorlesungen über die Bestimmung des Gelehrten* (1794; Eng. trans., *The Vocation of the Scholar*, 1847), lectures on the importance of the highest intellectual culture and on the duties that it imposed; several works on the science of knowledge (*Wissenschaftslehre*), which were revised and developed continually throughout his life; the practical *Grundlage des Naturrechts nach Principien der Wissenschaftslehre* (1796; Eng. trans., *The Science of Rights*, 1869 and 1889); and *Das System der Sittenlehre nach den Principien der Wissenschaftslehre* (1798; Eng. trans., *The Science of Ethics as Based on the Science of Knowledge*, 1897), in which his moral philosophy, grounded in the notion of duty, is most notably expressed.

The system of 1794 was historically the most original and also the most characteristic work that Fichte produced. It was incited by Kant's critical philosophy and especially by his *Kritik der praktischen Vernunft* (1788; Eng. trans., *Critique of Practical Reason* . . . , 1949). From the outset it was less critical, precisely be-

cause it was more systematic, aiming at a self-sufficient, well-rounded doctrine in which the science of knowledge and ethics were intimately united. Fichte's ambition was to demonstrate that practical (moral) reason is really (as Kant had only intimated) the root of reason in its entirety, the absolute ground of all knowledge as well as of humanity altogether. To prove this, he started from a supreme principle, the ego, which was supposed to be independent and sovereign, so that all other knowledge was deduced from it. Fichte did not assert that this supreme principle was self-evident but rather that it had to be postulated by pure thought. He followed, thereby, Kant's doctrine that pure, practical reason postulates the existence of God, but he tried to transform Kant's rational faith into a speculative knowledge on which he based both his theory of science and his ethics.

In 1795 Fichte became one of the editors of the *Philosophisches Journal*; and in 1798 his friend F.K. Forberg, a young, unknown philosopher, sent him an essay on the development of the idea of religion. Before printing this, Fichte, to prevent misunderstanding, composed a short preface, "On the Grounds of Our Belief in a Divine Government of the Universe," in which God is defined as the moral order of the universe, the eternal law of right that is the foundation of all man's being. The cry of atheism was raised, and the electoral government of Saxony, followed by all of the German states except Prussia, suppressed the *Journal* and demanded Fichte's expulsion from Jena. After publishing two defenses, Fichte threatened to resign in case of reprimand. Much to his discomfort, his threat was taken as an offer to resign and was duly accepted.

Except for the summer of 1805 (which he spent at Erlangen, delivering a longer version of his Jena lectures of 1794), Fichte resided in Berlin from 1799 to 1806. Among his friends were the leaders of German Romanticism, A.W. and F. Schlegel and Friedrich Schleiermacher. His works of this period include *Die Bestimmung des Menschen* (1800; Eng. trans., *The Vocation of Man*, 1848), in which he defines God as the infinite moral will of the universe who becomes conscious of himself in individuals; *Der geschlossene Handelsstaat* (also 1800), an intensely socialistic treatise in favour of tariff protection; two new versions of the *Wissenschaftslehre* (composed in 1801 and in 1804; published posthumously), marking a great change in the character of the doctrine; *Die Grundzüge des gegenwärtigen Zeitalters* (1806; lectures delivered 1804–05; Eng. trans., *The Characteristics of the Present Age*, 1844), analyzing the Enlightenment and defining its place in the historical evolution of the general human consciousness but also indicating its defects and looking forward to belief in the divine order of the universe as the highest aspect of the life of reason; and *Die Anweisung zum seligen Leben, oder auch die Religionslehre* (1806; Eng. trans., *The Way Towards the Blessed Life*, 1844). In this last-named work the union between the finite self-consciousness and the infinite ego, or God, is handled in a deeply religious fashion reminiscent of the Gospel According to John. The knowledge and love of God is declared to be the end of life. God is the All; the world of independent objects is the result of reflection or self-consciousness, by which the infinite unity is broken up. God is thus over and above the distinction of subject and object; man's knowledge is but a reflex or picture of the infinite essence.

The French victories over the Prussians in 1806 drove Fichte from Berlin to Königsberg (where he lectured for a time), then to Copenhagen. He returned to Berlin in August 1807. From this time his published writings were practical in character; not until after the appearance of the *Nachgelassene Werke* ("Posthumous Works") and of the *Sämtliche Werke* ("Complete Works") was the shape of his final speculations known. In 1807 he drew up a plan for the proposed new university of Berlin. In 1807–08 he delivered at Berlin his *Reden an die deutsche Nation* (Eng. trans., *Addresses to the German Nation*, 1922), full of practical views on the only true foundation for national recovery and glory. From 1810 to 1812 he was rector of the new Berlin University. During the great

Years in  
Berlin

Years

University  
of Jena

Last years

effort of Germany for national independence in 1813, he lectured "Über den Begriff des wahrhaften Krieges" ("On the Idea of a True War").

At the beginning of 1814, Fichte caught a virulent hospital fever from his wife, who had volunteered for work as a hospital nurse. He died on January 27, 1814.

#### BIBLIOGRAPHY.

**Collected works:** Neither I.H. FICHTE's edition of his father's collected works, 8 vol. (1845-46, reprinted 1965), nor the reliable selected works edition of FRITZ MEDICUS, 6 vol. (1908-11, reprinted 1962), can compare with the scholarly definitive edition issued by der Bayerischen Akademie der Wissenschaften (Bavarian Academy of the Sciences), J.G. Fichte—*Gesamtausgabe*, ed. by REINHARD LAUTH and HANS JACOB (1962). As to translations, WILLIAM SMITH published *The Popular Works of Johann Gottlieb Fichte*, 2 vol. (1848-49; 4th ed., 1889).

**Life:** For analytical evidence about Fichte's life, see FRITZ MEDICUS, *Fichtes Leben* (1914; 2nd rev. ed., 1922); XAVIER LEON, *Fichte et son temps*, 3 vol. (1922-27, reprinted 1959); and HANS SCHULZ, *Fichte in vertraulichen Briefen seiner Zeitgenossen* (1923), which builds up a picture of Fichte as his contemporaries saw him. How subjective this image has become today emerges from a comparison of the Festschrift of the Free University of Berlin, in West Berlin, *Idee und Wirklichkeit einer Universität*, published in 1960 on the sesquicentennial anniversary of its foundation with the Festschrift that resulted from a colloquium held at the Humboldt-Universität zu Berlin, in East Berlin, *Johann Gottlieb Fichte: Ein deutscher Patriot* (1962).

**Thought:** For a balanced evaluation of Fichte the thinker, see ROBERT ADAMSON, *Fichte* (1881; 1903 ed. reprinted 1969) and his article in the *Encyclopædia Britannica*, 11th ed. (1910); XAVIER LEON, *La Philosophie de Fichte: ses rapports avec la conscience contemporaine* (1902); and ELLEN B. TALBOT, *The Fundamental Principle of Fichte's Philosophy* (1906). For an overall view of Fichte's philosophy within the framework of European thought and with specific reference to German Idealism and Romanticism, see RICHARD KRONER, *Von Kant bis Hegel*, 2 vol. (1921-24; 2nd ed., 1 vol., 1961); RENE WELLEK, *Confrontations: Studies in the Intellectual and Literary Relations Between Germany, England and the United States During the Nineteenth Century* (1965); and the Festschrift *Wissen und Gewissen*, ed. by MANFRED BUHR (1962).

**Bibliography:** For citations of books and articles on specific aspects of Fichte's work, see J.G. Fichte: *Bibliographie*, ed. by H.M. BAUMGARTNER and W.G. JACOBS (1968).

## Fielding, Henry

The 19th-century novelist Sir Walter Scott called Henry Fielding the "father of the English novel," and the phrase still indicates Fielding's place in the history of literature. Though not actually the first English novelist, he was the first to approach the genre with a fully worked-out theory of the novel; and in *Joseph Andrews* (1742), *Tom Jones* (1749), and *Amelia* (1751), which a modern critic has called comic epic, epic comedy, and domestic epic, respectively, he had established the tradition of a realism presented in panoramic surveys of contemporary society that dominated English fiction until the end of the 19th century. In his lifetime a controversial figure, Fielding was often seen by the Victorians as a writer who was "offensive to delicacy": what is impressive today, apart from his uninhibited comedy, is the breadth of his sympathies, his concern for morality, and his compassion for human weaknesses. His other activities, too, are important for his work as a novelist. As a playwright he learned how to handle dialogue and how to compose the scenes he incorporated in his fiction, while both his novels and his zeal as a police magistrate reflect his aim of reforming the manners of his age. He was at once its historian and its critic, and in his works, particularly *Tom Jones* and *Amelia*, a relatively new literary form achieves a degree of perfection that, despite changes in literary fashion, is still unsurpassed.

**Early life.** Fielding was born at Sharpham Park, near Glastonbury in Somerset, on April 22, 1707, of a family that by tradition traced its descent to a branch of the Habsburgs; hence the 18th-century English historian Edward Gibbon's remark in his memoirs (1796):

Fielding, engraving by James Basire, after a drawing by William Hogarth; frontispiece to *Fielding's Works* (1st ed., 1762). In the British Museum.

By courtesy of the trustees of the British Museum; photograph, J.R. Freeman & Co., Ltd.

The successors of Charles the Fifth may disdain their brethren of England; but the romance of *Tom Jones*, that exquisite picture of human manners, will outlive the palace of the Escorial, and the imperial eagle of the house of Austria.

The 1st earl of Denbigh, William Fielding, was a direct ancestor, while Henry's father, Colonel Edmund Fielding, had served under John Churchill, duke of Marlborough, an early-18th-century general, "with much bravery and reputation," and his mother was a daughter of Sir Henry Gould, a judge of the Queen's Bench, from whom she inherited property at East Stour, in Dorset, where the family moved when Fielding was three years old. His mother died just before his 11th birthday. His father having married again, Fielding was sent to Eton College, where he laid the foundations of his love of literature and his considerable knowledge of the classics.

Leaving school at 17, a strikingly handsome youth, he settled down to the life of a young gentleman of leisure; but four years later, after an abortive elopement with an heiress and the production of a play at the Drury Lane Theatre in London, he resumed his classical studies at the University of Leiden in Holland. After 18 months he had to return home because his father was no longer able to pay him an allowance. "Having," as he said, "no choice but to be a hackney-writer or a hackney-coachman," he chose the former and set up as playwright. In all, he wrote some 25 plays. Although his dramatic works have not held the stage, their wit cannot be denied. He was essentially a satirist, and his target was the political corruption of the times. In 1737 he produced at the Little Theatre in the Hay (later the Haymarket Theatre), London, his *Historical Register, For the Year 1736*, in which the prime minister, Sir Robert Walpole, was represented practically undisguised and mercilessly ridiculed. It was not the first time Walpole had suffered from Fielding's pen, and his answer was to push through Parliament the Licensing Act, by which all new plays had to be approved and licensed by the lord chamberlain before production.

The passing of this act marked the end of Fielding as a playwright. The 30-year-old writer had a wife and two children to support but no source of income. He had married Charlotte Cradock in 1734, this time after a successful elopement, the culmination of a four-year courtship. How much he adored her can be seen from the two characters based on her, Sophia Western in *Tom Jones* and Amelia in the novel of that name: one

Distinguished antecedents and relatives

Portraits of his wife in novels

the likeness of her as a beautiful, high-spirited, generous-minded girl, the other of her as a faithful, much-troubled, hard-working wife and mother. To restore his fortunes, Fielding began to read for the bar, completing in less than three years a course normally taking six or seven. Even while studying, however, he was editing, and very largely writing, a thrice-weekly newspaper, the *Champion; or, British Mercury*, which ran from November, 1739 to June, 1741.

**Maturity.** As a barrister, Fielding, who rode the Western Circuit (a judicial subdivision of England) twice a year, had little success. In 1740, however, Samuel Richardson published his novel *Pamela: or, Virtue Rewarded*, which tells how a servant girl so impressed her master by resistance to his every effort at seduction that in the end "he thought fit to make her his wife." Something new in literature, its success was unparalleled. A crop of imitations followed. In April 1741, there appeared a parody entitled *An Apology for the Life of Mrs. Shamela Andrews*, satirizing Richardson's sentimentality and prudential morality. It was published anonymously, and, though Fielding never claimed it, *Shamela* was generally accepted as his work in his lifetime, and stylistic evidence supports the attribution. Moreover, there is a similarity to his *Joseph Andrews*.

Described on the title page as "Written in Imitation of the Manner of Cervantes, author of *Don Quixote*," *Joseph Andrews* begins as a burlesque of *Pamela*, with Joseph, Pamela's virtuous footman brother, resisting the attempts of a highborn lady to seduce him. The parodic intention soon becomes secondary, and the novel develops into a masterpiece of sustained irony and social criticism, with, at its centre, Parson Adams, one of the great comic figures of literature and a striking confirmation of the contention of the 19th-century Russian novelist Fyodor Dostoyevsky that the positively good man can be made convincing in fiction only if rendered to some extent ridiculous. Fielding explains in his preface that he is writing "a comic Epic-Poem in Prose." He was certainly inaugurating a new genre in fiction.

*Joseph Andrews* was written in the most unpropitious circumstances; Fielding was crippled with gout, his six-year-old daughter was dying, and his wife was "in a condition very little better." He was also in financial trouble, from which he was at least temporarily rescued by the generosity of his friend the philanthropist Ralph Allen, who appears in *Tom Jones* as Mr. Allworthy.

In 1743 Fielding published three volumes of *Miscellanies*, works old and new, of which by far the most important is *The Life of Mr. Jonathan Wild the Great*. Here, narrating the life of a notorious criminal of the day, Fielding satirizes human greatness, or rather human greatness confused with power over others. Permanently topical, *Jonathan Wild*, with the exception of some passages by his older contemporary the Anglo-Irish satirist Jonathan Swift, is perhaps the grimmest satire in English and an exercise in unrelenting irony.

After the *Miscellanies* Fielding gave up writing for more than two years, partly, perhaps, out of disappointment with the rewards of authorship, partly in order to devote himself to law. His health was bad; his practice at the bar did not flourish; worst of all, his wife was still ill. In the autumn of 1744 he took her to Bath for the medicinal waters; she "caught a fever, and died in his arms." According to Lady Mary Wortley Montagu, the 18th-century letter writer and Fielding's cousin, his grief "approached to frenzy," and it was almost a year before he recovered his fortitude. By then he had taken a house in London in the Strand (on the site of the present law courts), and there he lived with his daughter, his sister Sarah, also a novelist, and Mary Daniel, who had been his wife's maid. In 1747, to the derision of London, he married Mary, who was pregnant by him. According to Fielding himself, writing shortly before his death, she discharged "excellently well her own, and all the tender offices becoming the female character . . . besides being a faithful friend, an amiable companion, and a tender nurse."

In 1745 came the Jacobite Rebellion (an attempt to re-

store the descendants of the deposed Stuart king James II), which led Fielding to write the pamphlet "A Serious Address to the People of Great Britain. In Which the Certain Consequences of the Present Rebellion, Are Fully Demonstrated. Necessary To Be Perused by Every Lover of his Country at This Juncture." As a strong Church of England man, he warned his readers of the implications of this rising led by the Roman Catholic pretender to the throne, Prince Charles Edward. A month later, he became editor of a new weekly paper, *The True Patriot: And the History of Our Own Times*, which he wrote almost single-handedly until it ceased publication on the defeat of the Pretender at the Battle of Culloden (April 16, 1746). A year later, Fielding edited another one-man weekly called *The Jacobite's Journal*, the title of which indicates its ironical approach to current affairs. Its propaganda value was deemed so great that the government purchased 2,000 copies of each issue for free distribution among the inns and ale-houses of the kingdom.

Fielding was now a government man. His reward came in 1748, when he was appointed justice of the peace (or magistrate) for Westminster and Middlesex, with his own courthouse, which was also his residence, in Bow Street in central London. The office carried no salary; former Bow Street magistrates had made what they could out of the fees paid by persons brought before them and, often, out of bribes. Fielding was a magistrate of a different order; as he wrote in *The Journal of a Voyage to Lisbon*:

... by composing, instead of inflaming, the quarrels of porters and beggars (which I blush when I say hath not been universally practised), and by refusing to take a shilling from a man who undoubtedly would not have had another left, I had reduced an income of about £500 a year of the dirtiest money upon earth, to little more than £300; a considerable portion of which remained with my clerk.

According to a 20th-century British historian, G.M. Trevelyan, Fielding was one of the two best magistrates in 18th-century London, the other being his blind half brother Sir John Fielding, who succeeded him at Bow Street. Together, they turned an office without honour into one of great dignity and importance and established a new tradition of justice and the suppression of crime in London. Among other things, Fielding strengthened the police force at his disposal by recruiting a small body of able and energetic "thieftakers"—the Bow Street Runners. To improve relations between the law and the public, he started a newspaper, *The Covent Garden Journal*, in which the following appeared regularly:

All persons who shall for the future suffer by robbers, burglars, etc., are desired immediately to bring or send the best description they can of such robbers, etc., with the time, and place, and circumstances of the fact, to Henry Fielding, Esq., at his house in Bow Street.

**Last years.** *The History of Tom Jones, a Foundling* was published on February 28, 1749. With its great comic gusto, vast gallery of characters, and contrasted scenes of high and low life in London and the provinces, it has always been the most popular of his works. The reading of this work is essential both for an understanding of 18th-century England and for its revelation of the generosity and charity of Fielding's view of humanity.

Two years later *Amelia* was published. Being a much more sombre work, it has always been less popular than *Tom Jones* and *Joseph Andrews*. Fielding's mind must have been darkened by his experiences as a magistrate, as it certainly had been by his wife's death, and *Amelia* is no attempt at the comic epic poem in prose. Rather, it anticipates the Victorian domestic novel, being a study of the relationship between a man and his wife and, in the character of Amelia, a celebration of womanly virtues. It is also Fielding's most intransigent representation of the evils of the society in which he lived, and he clearly finds the spectacle no longer comic.

His health was deteriorating. By 1752 his gout was so bad that his legs were swathed in bandages and he often had to use crutches or a wheelchair. In August of 1753 he decided to go to Bath for rest and the waters. That

Career in government

year was a particularly bad one for crime in London, however, and, on the eve of his leaving, he was invited by Thomas Pelham-Holles, duke of Newcastle (then secretary of war) to prepare a plan for the Privy Council for the suppression of "those murders and robberies which were every day committed in the streets." His plan, undertaking "to demolish the then reigning gangs" and to establish means of preventing their recurrence, was accepted, and despite the state of his health—to gout had been added asthma and dropsy—he stayed in London for the rest of the year, waging war against criminal gangs with such success that "there was, in the remaining month of November, and in all December, not only no such thing as a murder, but not even a street-robbery committed."

In the following June, Fielding set out for Portugal to seek the sun, writing an account of his journey, *The Journal of a Voyage to Lisbon*. This work presents an extraordinarily vivid picture of the tortuous slowness of 18th-century sea travel, the horrors of contemporary medicine, the caprices of arbitrary power as seen in the conduct of customs officers and other petty officials, and, above all, his indomitable courage and cheerfulness when almost completely helpless, for he could scarcely walk and had to be carried on and off ship. Fielding landed at Lisbon on August 7, 1754. At first it seemed that the Portuguese climate was therapeutic, but he died on October 8 and was buried in the British cemetery at Lisbon.

#### MAJOR WORKS

NOVELS: *The History of the Adventures of Joseph Andrews and His friend Mr. Adams*, Written in Imitation of the Manner of Cervantes (1742); *The History of Tom Jones, a Foundling* (1749); *Amelia* (1751, dated 1752).

PLAYS: *Love in Several Masques* (1728); *Tom Thumb* (1730); *The Temple Beau* (1730); *The Modern Husband* (1732); *The Mock Doctor; or, the Dumb Lady Cur'd* (1732); *The Miser* (1733); *An Old Man Taught Wisdom; or, the Virgin Unmasked* (1735); *Pasquin: A Dramatick Satire on the Times* (1736); *Historical Register, For the Year 1736* (1737).

NEWSPAPERS: *The Champion; or, British Mercury* (1739–41); *The True Patriot: And the History of Our Own Times* (1745–46); *The Jacobite's Journal* (1747–48); *The Covent Garden Journal* (1752).

OTHER WORKS: *Miscellanies*, 3 vol. (1743, including *The Life of Mr. Jonathan Wild the Great*); *A Serious Address to the People of Great Britain* (1745); *The Journal of a Voyage to Lisbon* (1755).

BIBLIOGRAPHY. *The Complete Works of Henry Fielding, Esq.*, ed. by W.E. HENLEY, 16 vol. (1903), is at present the standard edition, but it is expected to be displaced by the more scholarly and comprehensive *Complete Works*, ed. by FREDERSON BOWERS and MARTIN C. BATTESTIN, now in process of publication. Standard biographies are WILBER L. CROSS, *The History of Henry Fielding*, 3 vol. (1918, reprinted 1963); and F. HOMES DUDDEN, *Henry Fielding: His Life, Works and Times*, 2 vol. (1952); many scholars prefer the earlier book. MARTIN C. BATTESTIN, *The Moral Basis of Fielding's Art: A Study of Joseph Andrews* (1959); and ANDREW H. WRIGHT, *Henry Fielding, Mask and Feast* (1965), are valuable critical studies; RONALD PAULSON (ed.), *Fielding: A Collection of Critical Essays* (1962), gathers together important critical statements. ERNEST A. BAKER, *The History of the English Novel*, 10 vol. (1924–39); and IAN P. WATT, *The Rise of the Novel* (1957), place Fielding in the context of the history of fiction.

(W.E.A.)

## Fields, Theory of, in Physics

A field in physics may be defined as a continuous distribution of some observable quantity in space and time. The observable quantity, which must be measurable, may be any of a variety of phenomena, including (but not limited to) such things as the colour in a liquid, the density of dust in the atmosphere, temperature distribution in a body, the flow pattern of a stream, or the magnetic field surrounding the earth. But under all circumstances, whatever is described as a field must be measurable by some technique.

If the observed quantity varies in space but does not change with time, the field is said to be static. Otherwise

it is called a time-varying field. In the examples above, the field was considered in three-dimensional space; i.e., in terms of length, breadth, and depth. The field concept is capable of generalization, however, to spaces of more than three dimensions, as will be indicated later in this article, just as the idea of space can be expanded to any number of dimensions. Though a time-varying field is, strictly speaking, a field in four dimensions, it is customary to describe such a field as a variable three-dimensional field.

**Mathematical treatment of fields.** The mathematical description of the field is in terms of the measurable dimensions of the space under consideration. This means that the field is considered to be a function of the space; i.e., in order to discuss the properties of the field mathematically, it is necessary that points in the field must be discussed. Any point in the field is identified in terms of its position in space relative to other points. To locate any point in the field, several types of three-coordinate systems may be used; for example,  $x$ ,  $y$ , and  $z$  represent three spatial directions and distances of the points from a common point. When the measured property has magnitude but no direction it is called a scalar. When a measured property has direction it is called a vector and the spatial coordinates are, therefore, vectors. In mathematical language, then, a field is a function, signified by  $f$ , of the three space coordinates, signified by  $r$ , and the time coordinate, signified by  $t$ . This is written  $f(r, t)$ . Ordinarily  $r$  is a vector designating a point in three-dimensional space with coordinates  $x$ ,  $y$ ,  $z$ , but it may also symbolize a space of any number of dimensions. A field is said to be known when: (1) the function  $f(r, t)$  is known, and (2) the observable property to which  $f$  refers is given.

While the preceding statements formally define a field, they do not fully characterize the kinds of fields that are useful in physical science. Such fields must satisfy one additional requirement: they must be defined by a known law that permits their calculation and prediction. The law is usually expressed as a differential equation (an equation that contains rate of change of variable quantities).

This article is devoted to a description of various fields useful in science and the laws that apply to them. The physical disciplines in which the fields occur are treated elsewhere; e.g., under ELECTRICITY; MAGNETISM; ELECTROMAGNETIC RADIATION; NUCLEUS, ATOMIC; GRAVITATION; THERMODYNAMICS, PRINCIPLES OF; ENERGY; and MECHANICS, QUANTUM.

**Classification of fields.** *Material and nonmaterial.* There are various ways of classifying fields. One important distinction, that between material and nonmaterial fields, must be made at the outset but need not be pursued further in its manifold philosophical implications. In a material field, the observable property signified by  $f$  describes some property of matter, such as the density, pressure, or the temperature of a gas, or the velocity of a portion of liquid. A nonmaterial field is not descriptive of any material property (although it is usually caused by matter) but describes some latent effect that would take place at a point of space under certain circumstances. The electric field is of this kind. Its "observable" is the electrostatic field indicated by  $E$  and its value at a point defined by the coordinates  $x$ ,  $y$ ,  $z$  is given by the field function. Nothing, however, may actually exist or be evident at that point. What matters is that if a charge were placed at the point defined by  $x$ ,  $y$ ,  $z$  it would experience a force proportional to the function of the field; i.e., as explained above,  $E(x, y, z)$ . Other nonmaterial fields are the magnetic field, the field of general relativity, and a variety of what are called probability fields, which are discernible as a statistical probability of occurrences, such as the state of an electron in an atom, treated as a function of quantum mechanics.

Material fields are introduced into physics because the variables to which they refer are of direct physical interest. Nonmaterial fields are usually introduced to simplify the theoretical description of phenomena by replacing the notion of action at a distance with that of local interactions. By saying that a charge located at  $r$

Vectors  
and  
scalars

Non-  
material  
fields

( $\mathbf{r}$  is the resultant vector at a point identified by  $x, y, z$  coordinates) sets up an electric field designated as  $E(\mathbf{r})$ , throughout space, one can more simply describe how a second charge at  $\mathbf{r}_2$  is affected by the first: the second charge interacts locally with the electric field at  $\mathbf{r}_2$ .

**Scalars.** Fields can be classified according to whether the observable function  $f$  (*i.e.*, the field quantity) is a scalar, a vector, or a tensor. A scalar is ordinarily defined as a quantity having magnitude but no direction. Examples include mass, density, and temperature.

**Vectors.** A vector is said to be a quantity endowed with direction in space, like a force, or the strength of an electric or magnetic field. A vector field is symbolized by  $\mathbf{V}(\mathbf{r})$  and has three space components, as has been explained, and these are symbolized by  $V_x(\mathbf{r})$ ,  $V_y(\mathbf{r})$  and  $V_z(\mathbf{r})$ .

**Tensors.** When the measurable function of a field cannot be expressed as a simple scalar or vector quantity, but many such quantities must be considered together, and their dependency must also be taken into account, a tensor may be set up. The nature of a tensor can be illustrated by the example of the stress tensor, denoted by  $\mathbf{S}$ . It has nine components, signified as  $S_{ij}$ , both  $i$  and  $j$  ranging from 1 to 3. This means that  $i$  and  $j$  together have three times three, or nine different quantities. Each subscript corresponds to a direction in space;  $S_{ij}$  is the component of force along the  $j$ -direction of a cube of matter due to a deformation along  $i$ . Thus  $\mathbf{S}$ , when fully written, amounts to an assemblage of nine quantities, as follows:

$$\mathbf{S} = \begin{pmatrix} S_{11} & S_{12} & S_{13} \\ S_{21} & S_{22} & S_{23} \\ S_{31} & S_{32} & S_{33} \end{pmatrix}$$

The idea of a tensor can be generalized in two ways. First, the number of dimensions in space can be increased from three to  $n$ , as was suggested in the introduction, and the tensor then takes on  $n$  times  $n$ , or  $n^2$  components. Second, the rank of the tensor can be raised; *i.e.*, the number of suffixes may be changed from two to  $m$ . For example, in  $n$  dimensions,  $S_{ijk}$ , a tensor of rank 3, has  $n^3$  components.

Given a field of a certain type (*e.g.*, a vector field), it is possible to generate for purposes of study and calculation other vector fields, scalar fields, tensor fields, and so on. Certain transformations between scalar and vector fields are also useful and have their own symbols.

**Examples of fields in ordinary space.** Some examples of different kinds of fields are here given in very general terms. It should be noted that the same differential equation may control the behaviour of quite different fields, and it should be stressed that differential equations have many solutions and, therefore, the field is not specified simply by the equation. Boundary conditions must also be imposed; that is, the field must be specified in certain regions. The differential equation then allows computation of the field at certain points in space and time if the value at some other point has already been specified.

**Scalar fields.** A simple example is provided by the pressure at different heights in the atmosphere. It is known that pressure exists everywhere in the atmosphere and that it is actually the result of gravitational attraction between the earth and gas molecules. In other words, pressure is the result of air molecules accelerating toward the earth in the gravitational field. This movement, however, is then offset by the motion of the molecules due to their heat energy, which makes them bombard one another continuously, with the result that there is a constant tendency in the atmosphere to expand, and the expansion can only be upward. A steady state is achieved between the two tendencies: the gas does not all collect on the surface of the earth, as a liquid does, nor does it expand and vanish into space against the gravitational attraction (as it does on the moon, where the gravitational field is not strong enough to counteract the expansion). The atmosphere is most dense closest to the earth, where the gravitational field is strongest and the tendency of the gas to expand is most effectively balanced by its tendency to move toward the earth. Thus, the pressure is a function of the height, decreasing with height.

The differential equation, then, states that the change in pressure over a specific, small difference in height equals the acceleration of gravity times the change in density at that height. With this equation, therefore, the whole field—which is pressure of the atmosphere—can be mapped to its outer limits.

The density of matter in a moving fluid forms a scalar field, which can be said to obey a general law, the factors to be considered being: change in density at a point in the flow over a small period of time, the rate of diffusion, and the variation in density between two points.

An equation of the same form holds for the temperature field (also a scalar field) in a medium that, because its temperature is not uniform, is involved in a temperature readjustment; *i.e.*, heat is being transmitted from one area to another. The differential equation then relates the change in temperature over a small period of time, the coefficient of heat conductivity, the specific heat, the density, and the temperature at the point of observation.

The gravitational potential (*i.e.*, the work done on a unit mass in bringing it from infinity to the point defined by the space coordinates) obeys an equation (known by the name of its originator, Siméon-Denis Poisson) that is also applicable to other fields. It relates the gravitational potential (a scalar quantity), the gravitational constant, and the density of matter there.

Electrostatic potential, the repulsion between like charges or the attraction between unlike charges, is given as a differential equation of the scalar field; it relates the potential to the charge density (the number of charges per unit volume of space). A similar equation is used for the magnetostatic field potential, the magnetostatic field being taken to be the attraction or repulsion between unlike or like magnetic poles.

Any medium pervaded by a wave becomes the site of a wave field that satisfies the wave equation. As an example, with sound, the pressure in an acoustic field is controlled by the wave equation.

**Vector fields.** In a moving fluid the velocity vector forms a field each of whose components is a function of the  $x, y, z$  coordinates. They must satisfy the equations of continuity, which include the fluid density, which may vary from place to place. If it is constant (*i.e.*, if the fluid is incompressible) then the full equation asserts that the amount of fluid flowing from a point is equal to the amount flowing into it.

Perhaps the most important vector field of mathematical physics is the electromagnetic field, characterized by vectors for the electric field and for the magnetic field. When these two fields are nonstatic, they interact in characteristic ways, and the law governing them cannot be written for either one alone. It takes the form of equations that, in free space, include the velocity of light in vacuum.

The field quantity in many types of waves (*e.g.*, light waves, elastic disturbances in solids, seismic waves in the earth's crust) is a vector. It obeys the same form of wave equation but with the proper vector quantity.

**Tensor fields.** One important example will be considered, namely the pressure field in a hydrodynamic system; *i.e.*, a fluid in complicated motion with different temperatures at different points inside the fluid. In this case the vectors are: the average velocity of particles at a point in the fluid, the heat flow vector (calories changing per second), and the force per unit area in the direction resulting from the motion in the  $i$ -direction. The tensor appears in numerous important hydrodynamic equations, notably that of energy flow. Its knowledge, together with velocity and heat flow vectors, provides a complete understanding of the behaviour of the hydrodynamic system. The law controlling it consists of five differential equations, known as the Navier-Stokes equations. They contain the coefficient of viscosity and the thermal conductivity.

This example illustrates the interaction of several fields: the pressure, temperature, and flow fields.

**Fields with distributions in more than three dimensions.** *Thermodynamic phenomena.* In connection with the laws of thermodynamics, a space can be constructed of  $6n$  di-

Phase space

mensions to account for the behaviour of a system of  $n$  particles. It is called phase space, and certain rules of correspondence relate  $\rho$ , the field quantity representing density in this space, to such thermodynamic observables as temperature, entropy (a measure of disorder in a system), free energy, and others. To aid visual intuition,  $\rho$  is thought of as a cloud of dust of varying density in phase space, and the movement of the cloud (*i.e.*, the field under consideration) determines the values of the quantities measured in thermodynamics.

**Relativity.** Perhaps the most interesting example of a field in more than three dimensions occurs in the theory of general relativity, where the behaviour of all matter is described in what is called the metric field. It operates in a space of four dimensions,  $x, y, z, t$  (see above *Mathematical treatment of fields*). A metric field tensor defines empty space as Euclidean (or flat). The presence of matter causes curvature of the space. Once the tensor is known, the motion of any particle can be calculated. The components of the tensor obey Einstein's law of gravitation, which relates them to the distribution of matter in the universe.

**Quantum mechanics.** The fundamental constructs (or quantities) of quantum mechanics, the state functions, are also fields. In classical mechanics, the motion of a particle is described by specifying its position as a function of time. In quantum theory, one deals no longer with the particle's position but with the probability of finding it at that position, and that probability forms a field.

**BIBLIOGRAPHY.** Popular accounts concerning the nature of fields and their uses in physical theories may be found in A. EINSTEIN and L. INFELD, *The Evolution of Physics*, ch. 3 (1938); and in R.E. PEIERLS, *The Laws of Nature*, ch. 2 (1956). For a general account of the types of fields used in physics, the equations they satisfy, and techniques for solution of the equations, see H. MARGENAU and G.M. MURPHY, *The Mathematics of Physics and Chemistry*, 2nd ed., ch. 4, 7, and 12 (1956); and P.M. MORSE and H. FESHBACH, *Methods of Theoretical Physics*, ch. 1-2, 10-11 (1953).

(H.Ma.)

## Fiji

Fiji (Viti in the Fijian language), an independent dominion in the Commonwealth of Nations, is an archipelago surrounding the Koro Sea in the South Pacific Ocean, about 1,300 miles (2,100 kilometres) north of Auckland, New Zealand. It forms part of the Melanesian island group.

The archipelago consists of about 840 islands and islets scattered over about 1,000,000 square miles. The Fiji group includes more than 300 islands, of which about 100 are inhabited. The total land area is 7,055 square miles (18,274 square kilometres), and the population numbers almost 531,000. The capital, Suva, which has a population of about 63,000, is on the southeast coast of the largest island, Viti Levu ("Great Fiji"). About 400 miles north of Suva, the island of Rotuma has an area of about 18 square miles (47 square kilometres) and a population of about 6,000.

Fiji, for 96 years a British colony, gained independence on October 10, 1970. The population of Fijian descent (which is of mixed Melanesian and Polynesian origin) is outnumbered by the Indian population, which is descended from 19th-century immigrants. There are also European, Chinese, and Rotuman minorities. The economy of Fiji, which has a humid tropical climate, is primarily agricultural; sugar is the principal export. It is expected that the various racial groups on the islands will cooperate in upholding a tradition of inter-racial harmony. (For coverage of the region as a whole, see PACIFIC ISLANDS; PACIFIC OCEAN; for coverage of historical aspects, see OCEANIA, HISTORY OF.)

**The natural environment.** *Relief.* The islands forming the Fijian archipelago present varied relief types. The larger islands are of volcanic origin; the smaller ones are mostly formed of low coral reefs. To the east are the low-lying coral islands of the Lau group; the two main islands, Viti Levu to the west and Vanua Levu to the north, are volcanic masses of complex shape; the islands of Ovalau and Taveuni consist of volcanic craters. Encircling the islands is a series of intricate coral reefs that are a constant menace to shipping. The islands are all situated on a submerged platform, created by the uplift that raised the volcanic areas above sea level. The coral deposits were formed after the main uplift.

Viti Levu, with an area of 4,011 square miles (10,388 square kilometres), and Vanua Levu, with an area of 2,137 square miles (5,535 square kilometres), both have a complex geological structure, having been formed of volcanic and sedimentary rocks jumbled together. Neither has much level country. In Viti Levu, the main level areas occur in the Sigatoka River Valley and in the deltas of the other principal rivers—the Rewa, the Ba, and the Navua. The Dreketi is the chief river of Vanua Levu; it breaks through the island's mountainous backbone to form a particularly fine valley.

Mountains  
and coastal  
features

Mt. Tomaniivi (4,341 feet [1,323 metres]) is the highest point on Viti Levu, and Mt. Nasorolevu (3,386 feet [1,032 metres]) the highest on Vanua Levu. More spectacular scenery, however, often occurs near the coasts, which are marked by ravined hills that often reach down to the sea to form headlands. The coastal landscape is also occasionally dominated by an old volcanic plug (a dead volcano with its vent filled with solidified material), the best known of which is Joskes Thumb (1,570 feet), a landmark among the hills that flank Suva's harbour to the west.

**Climate.** Fiji is generally hot and wet, but many annual and seasonal variations occur, as well as differences due to local topography. The islands lie in the path of the southeast trade winds, which blow fairly steadily throughout the year, creating moist air conditions. The weather is warmest from about December to April and coolest from June to September, although "warm" and "cool" are relative terms. The temperature, which rarely falls below 65° to 70° F (18° to 21° C), for much of the year ranges during a day from about 75° to 85° F (24° to 29° C) with the daily maximum usually rising to over 90° F (32° C) in the hot season. The main characteristics are high and uniform temperatures, high humidity, and winds from the east and southeast. Rainfall is heavy but uncertain on slopes to windward and is light and uncertain on the leeward slopes. The mean annual rainfall on the western or dry sides of Vanua Levu and Viti Levu is less than 70 inches (1,780 millimetres), but at Suva, on the eastern or wet side of Viti Levu, it is over 120 inches (300 centimetres). Considerable variations in rainfall may occur from year to year. Bright skies and long hours of sunshine occur in the west and southwest, but Suva and the eastern areas frequently experience rainy or cloudy weather. Hurricanes develop occasionally between December and April, often causing severe damage.

**Vegetation.** In the centre of the two main islands the annual rainfall is often over 300 inches; the mountains are consequently covered with thick forest. To the west, a somewhat dry savanna (grassland) type of vegetation occurs; it is often parched brown and is locally known as *talasiga*, meaning sunburned country. It contrasts vividly with the forest and luxuriant bush country that occurs to the east.

Mangrove swamps are found around the coasts, particularly in the east. Behind many of the beaches in the west and in land under cultivation in general, coconut palms provide a graceful backdrop; the pandanus, or screw-pine tree, with its curiously rooted trunk, adds a bizarre touch, as also does the multi-trunked banyan tree. The forests contain such valuable timber tree species as the dakua and dilo, which are related to mahogany.

**Animal life.** Animals, which are few and are small in size, include bats, dogs, pigs, and mongooses; birdlife is limited, the most numerous species probably being the minah and the bulbul, both introduced from India. Pigeons and parrots are also found.

**Human settlement.** The different types of landscape under human settlement and the patterns of life that have developed them are as diversified as the relief and climate. The original Fijian pattern of life was based on the village, a settlement of large, single-roomed houses (bures), with thatched roofs arranged around a central open space. The land around the village was cultivated mainly for such subsistence crops as yams, taro (a stemless plant with a tuberous, starchy, edible root; its Fijian name is *dalo*), bananas, coconuts, breadfruit, papaw, and mangoes. Because of the mountainous and frequently inaccessible interior, many of the villages were situated close to the sea, thus facilitating fishing in the lagoons. This pattern of settlement is still widespread, but its original simplicity has been considerably modified by the arrival of Europeans, who initiated the development of towns, and by an influx of Indian labourers, who established a different pattern of rural settlement. The Indians usually live in scattered houses built of wood and corrugated iron. They form the bulk of the sugarcane farmers, often working farms of ten acres or more. They use the plow extensively, and have developed a cash economy.

Suva, the capital, has a deep-water harbour much used by tourist ships; many goods are obtainable free of tax. Large shops are European-owned while many smaller shops are Indian-owned. There are several modern hotels. The University of the South Pacific is located nearby, at Laucala Bay. Suva's total population is about 63,000, and includes over 28,000 Indians, 16,000 Fijians, 3,000 Europeans, and 2,000 Chinese. Lautoka, the second town of Viti Levu, has a population of about 12,000 and a similar racial pattern.

The average density of population for the whole country is about 75 persons per square mile; this figure, however, conceals wide variations, from the uninhabited mountain areas and waterless islands at one extreme, to the high population density of Suva at the other.

**People and population.** Indigenous Fijians, mostly of Melanesian stock, show strong resemblances to the Solomon Islanders and to the inhabitants of Papua New Guinea, although they are generally of larger physique. There has been some intermarriage with Polynesians, especially Tongans, particularly in the eastern islands. The majority of the Fijians are Christian, with Methodists forming almost 40 percent of the total. Roman Catholics form the next largest group, followed by Anglicans. The Fijian language belongs to the Malayo-Polynesian group, but there are several dialects; the most widely used is that from Bau, the old Fijian centre, built on a tiny island off the east coast of Viti Levu.

The Indians, who now outnumber the Fijians, are mainly descendants of indentured labourers who first went to Fiji in 1879 to work on the sugar estates. The indenture system continued until after World War I. More recently, Indians with professional, technical, and commercial skills have also emigrated to Fiji. Most of the Indians are Hindus, who form over 40 percent of the total population. There is also a significant Muslim group. Those who are part European form another group, but with a less easily defined identity. Most of them use English as their first language and are Christian.

The Europeans are mainly of British origin, often from Australia and New Zealand, as well as from Great Britain itself.

The three other main ethnic groups are formed by the Chinese, by other Pacific islanders, and by the Rotumans. (Rotuma was annexed by Great Britain in 1881; its population is mainly Polynesian.)

The total estimated population at the end of 1970 was about 524,000; of these, Fijians were estimated to number 225,000; Indians 266,000; part-Europeans 10,000; Europeans 5,000; Chinese 5,000; other Pacific islanders 7,000; and Rotumans 7,000.

In Suva, the streets are thronged by the various races, with the Hindu sari (woman's outer garment of silk or other cloth) contrasting with Fijian sulus (wrap-around skirts worn by men and women), as well as with the European style of dress. In some of the more remote rural areas, the population is almost exclusively Fijian, while in some of the sugarcane-growing areas it is almost exclusively Indian. There is virtually no intermarriage between Fijians and Indians.

The age distribution pattern among the population is typical of many developing countries: about 45 percent of the total population is under 15, and about 55 percent is under 19. The major demographic factor of recent years, however, has been the fall in the birth rate that followed an intensive family planning campaign. The decrease in births, it is expected, will allow Fiji to plan its education and welfare services more effectively.

**The national economy.** In the past, Fiji has relied for its livelihood on agricultural produce, particularly sugar and copra. Some gold is mined at Vatukoula. In 1969 the per capita gross national product was estimated at about U.S. \$390—a higher figure than that of many developing countries. There is, however, a need to diversify crops, to develop industry (especially with a view to manufacturing goods that now have to be imported), to increase mineral exploitation, and to promote the tourist industry, if a good growth rate is to be maintained.

One of the handicaps to agricultural development has

been the system of land tenure. Over 80 percent of the land belongs, by communal right, to the Fijians; although Indians are able to rent land, few of them have been able to buy it in order to develop it intensively.

In 1970 exports increased to about \$54,000,000 and imports to about \$79,000,000. The visible trade deficit was more than covered by the "invisible" earnings of the tourist industry and by a considerable investment of foreign capital.

Apart from sugar and copra, other exports are coconut oil, gold, bananas, molasses, biscuits, and manganese.

The United Kingdom is the biggest importer of Fiji's produce, followed by the United States, Canada, Australia, and New Zealand. Imports are mainly from Australia, Great Britain, Japan, New Zealand, and the United States.

Fiji's sixth development plan, covering the period from 1971 to 1975, envisages an annual increase in the gross domestic product of more than 6 percent, providing that world conditions continue to be favourable. Great Britain's entry into the European Common Market, however, could affect the marketing of sugar. It is anticipated that gross receipts from tourism, which amounted to an estimated \$21,000,000 in 1970, will triple by 1975.

Apart from the general intensification of agriculture, it is hoped that other new developments in forestry and fishing will strengthen the economy. The government intends to pursue a monetary policy designed to encourage new projects considered desirable by granting tax concessions. Industrial expansion is now limited by lack of a cheap source of power. About 80 percent of governmental revenue is obtained from customs and excise duties, income taxes, and other forms of direct taxation.

**Transport.** Fiji's two main ports of entry are Nandi (or Nadi) International Airport and the port of Suva. Nandi accommodates the largest aircraft used on world routes and is used regularly by seven major airlines as well as the locally based Air Pacific (formerly Fiji Airways). Almost 3,200 miles (5,100 kilometres) from Honolulu, almost 2,000 miles (3,200 kilometres) from Sydney, and about 1,300 miles (2,000 kilometres) from Auckland, Nandi provides a convenient refuelling and servicing stop as well as a tourist disembarkation point. Suva's own airport, at Nausori, 135 miles (217 kilometres) by road from Nandi, is served by Air Pacific, with air routes linking it to Tonga, Western Samoa, Cook

Islands, Gilbert and Ellice Islands, Nauru, New Hebrides, the Solomons, and Papua New Guinea.

Suva is the major port of Fiji; the second port is Lautoka on the west coast of Viti Levu. Both are served by interisland ships, cargo and passenger, some of which run to a scheduled timetable.

The roads are usually unpaved, except in the towns, although there are plans to tar the road from Suva to Nandi. Although there are more than 1,500 miles (2,500 kilometres) of all-weather motor roads, there is a need for feeder roads to move agricultural produce to the towns. Some of the rivers are used to float bananas and other crops down to the coast by raft. A narrow-gauge railway is operated by the sugar-refining industry; free passenger service is available on part of the railway twice a week.

**Administration and social conditions.** Fiji is a dominion, with the British sovereign as head of state, represented by a governor general. The legislature is bicameral, consisting of a House of Representatives and a Senate. Under a constitution introduced at the time of independence, a general election was held in May 1972, when 52 members of a new House of Representatives were elected; 12 Fijians, 12 Indians, and 3 general members (*i.e.*, members elected by voters, mainly European and Chinese, who are ineligible for inclusion on the Fijian and Indian voting rolls) were elected on communal rolls; and ten Fijians, ten Indians, and five general members were elected on national rolls in which electors of all races voted together. The upper house, the Senate, was inaugurated in November 1970; it consists of 22 members, eight nominated by the Great Council of Chiefs, seven by the prime minister, six by the leader of the opposition, and one by the Rotuman Council.

Apart from Suva and Lautoka, seven other urban areas constitute townships. These are Ba, Nandi, Sigatoka, and Nausori (all on the island of Viti Levu); Levuka (on the island of Ovalau); and Labasa and Savusavu (on the island of Vanua Levu). Members of the city council of Suva and Lautoka and the boards of the seven townships are elected; the elections are frequently keenly contested.

The most interesting feature of the rural local administration is the Fijian Administration, which was first established in 1876 and deals exclusively with Fijians. The Great Council of Chiefs, the supreme body of the Fijian Administration, advises the government on the general welfare of Fijians. The Fijian Affairs Board is responsible for the administration of the 14 provinces and for imposing land taxes. Fifteen locally chosen non-Fijian advisory councils work in conjunction with 14 elected Fijian provincial councils.

Fiji, a multiracial country, clearly faces potential racial tension, and every effort is made to create a harmonious atmosphere. The dominant social problems are likely to become the increasing drift from the rural areas to the towns, the wide variations in personal incomes, and the scarcity of land. Although there are no shantytowns, an increasing number of both Indians and Fijians live in overcrowded and insanitary conditions in urban shacks. Social services, although relatively well developed, are increasingly faced with the problem of overcrowding in the towns.

Fiji is a healthy country. Malaria is unknown, and many tropical diseases have been practically eradicated. Education is relatively widespread. About 86 percent of children of primary school age attend school; unfortunately, however, school enrollment has outstripped the present capacity of the country to train enough teachers. Vigorous steps to train more teachers are now being taken both in teacher-training colleges and at the University of the South Pacific.

**Cultural life.** The Fijian way of life is based on a form of society headed by chiefs, and ceremony still plays an important part in it; long and intricate welcome ceremonies are particularly noteworthy. *Yaqona* (kava), a drink prepared from the root of the pepper plant, is the basis of a friendly welcome and is presented with due ceremony. Traditional stories are kept alive by songs and dances; the dancers often wear clothes partly made from

Air  
services

Ceremo-  
nies of  
welcome

*masi* (tapa), a cloth prepared from the bark of the mulberry tree.

Fijian traditional arts include the making of pandanus palm mats, wood carving, and pottery, as well as the preparation of *masi*. A remarkable spectacle is the fire-walking ceremony performed by the people of the island of Beqa, who heat small boulders in a large fire in a pit and then walk barefoot on the white-hot stones.

The Indian population has preserved much of Indian culture from India, including the celebration of *Dīwālī*, the Hindu festival of lights; other Indian traditions also include fire walking. Muslims observe the fast of *Ramādān*. Indian temples and Christian churches are common sights in the towns, and it is rare to find a Fijian village without a church.

Modern sports and a Western form of dancing are often interracial activities. Rugby is the leading Fijian game and football (soccer) the Indian game. The Hibiscus Festival of Suva is interracial in character; it is a week of carnival held in September. Newspapers and magazines are published in Fijian and Hindi; the only daily newspaper, the *Fiji Times*, is published in English. The Fiji Broadcasting Commission broadcasts its national program in English and other programs in Fijian and Hindi.

**Prospects for the future.** Economically Fiji is in a stronger position than many other newly independent countries. The government is pursuing a policy of attracting foreign capital in order to diversify its economy and to develop its mineral and biological resources more fully. Important as these aims are, the attainment of a stable and harmonious future for Fiji ultimately depends on the removal of potential causes of racial tension. This necessitates improving the living conditions of Fijians with lower incomes, permitting Indians to gain easier access to land for farming, and the avoiding by the Chinese and European minorities of any appearance of exploiting the Fijians and Indians. If these aims can be achieved, Fiji can look forward to a bright social and economic future.

## Finance, Business

Business finance is concerned with the raising and managing of funds by business firms. The scope of business finance may also include the making of policies that affect a firm's financial status—that is, its ability to raise funds through the sale of its securities.

Because of the importance of the planning, analysis, and control operations for which he is responsible, the financial manager is usually close to the top of the organizational structure of a firm. Typically, he is a member of the first level of the corporate staff in a large organization. In very large firms major financial decisions are often made by a finance committee. In small firms, the owner-manager himself usually conducts the financial operations. Much of the day-to-day work of business finance is conducted by lower level staff; their work includes handling cash receipts and disbursements, borrowing from commercial banks on a regular and continuing basis, and formulating cash budgets.

Financial decisions affect both the profitability and the riskiness of a firm's operations. An increase in the cash position, for instance, reduces risk; but, since cash is not an earning asset, converting other types of assets to cash reduces the firm's profitability. Similarly, the use of addi-

tional debt raises the profitability of the firm, but more debt means more risk. The task of finance is to strike a balance between risk and profitability that will maintain the long-term value of the firm's securities.

### SHORT-TERM FINANCIAL OPERATIONS

**Financial planning and control.** Short-term financial operations are closely involved with the financial planning and control activities of the firm. These include financial ratio analysis, profit planning, financial forecasting, and budgeting.

**Financial ratio analysis.** A firm's balance sheet contains many items that taken by themselves have no clear meaning. Financial ratio analysis is a way of appraising their relative importance. The ratio of current assets to current liabilities, for example, gives the analyst an idea of the extent to which the firm can meet its current obligations. This is known as a liquidity ratio. Financial leverage ratios (such as the debt-asset ratio and debt as a percentage of total capitalization) are used to make judgments about the advantages to be gained from raising funds by the issuance of bonds (debt) rather than stock. Activity ratios, relating to the turnover of such asset categories as inventories, accounts receivable, and fixed assets, show how intensively the firm is employing its assets. The firm's primary operating objective is to earn a good return on its invested capital, and various profit ratios (profits as a percentage of sales, of assets, or of net worth) show how successfully it is meeting this objective.

Ratio analysis is used to compare a firm's performance with that of other firms in the same industry or with the performance of industry in general. It is also used to study trends in the firm's performance over time and thus anticipate problems before they develop.

**Profit planning.** Ratio analysis applies to the firm's current operating posture. But the firm must also plan for future growth. This requires decisions as to the expansion of existing operations and, in manufacturing, to the development of new product lines. The firm must choose between productive processes requiring various degrees of mechanization or automation—that is, various amounts of fixed capital in the form of machinery and equipment. This will increase fixed costs—that is, costs that are relatively constant and do not decrease when the firm is operating at levels below full capacity. The higher the proportion of fixed costs to total costs, the higher must be the level of operation before profits begin, and the more sensitive will profits be to changes in the level of operation.

**Financial forecasting.** The financial manager must also make overall forecasts of future capital requirements to assure that funds will be available to finance new investment programs. The first step in making such a forecast is to obtain an estimate of sales during each year of the planning period. This estimate is worked out jointly by the marketing, production, and finance departments: the marketing manager estimates demand; the production manager estimates capacity; and the financial manager estimates availability of funds to finance new accounts receivable, inventories, and fixed assets.

For the predicted level of sales, the financial manager estimates the funds that will be available from the company's operations and compares this amount with what will be needed to pay for the new fixed assets (machinery, equipment, etc.). If the growth rate exceeds 10 percent a year, asset requirements are likely to exceed internal sources of funds, so plans must be made to finance them by issuing securities. If, on the other hand, growth is slow, more funds will be generated than are required to support the estimated growth in sales. In this case, the financial manager will consider a number of alternatives, including increasing dividends to stockholders, retiring debt, using excess funds to acquire other firms, or, perhaps, increasing expenditures on research and development.

**Control through budgeting.** Once the firm's general goals for the planning period have been established, the next step is to set up a detailed plan of operation—the

Analysis  
of the  
balance  
sheet

budget. A complete budget system encompasses all aspects of the firm's operations over the planning period. It may even allow for changes in plans as required by factors outside the firm's control.

Budgeting is a part of the total planning activity in the firm, so it must begin with a statement of the firm's long-range plan. The long-range plan includes a long-range sales forecast. This forecast requires a determination of the number and types of products that will be manufactured in the years encompassed by the long-range plan. Short-term budgets are formulated within the framework of the long-range plan. Normally, there is a budget for every individual product and for every significant activity of the firm.

Establishing budgetary controls requires a realistic understanding of the firm's activities. For example, a small firm purchases more parts and uses more labour and less machinery; a larger firm will buy raw materials and use machinery to manufacture end items. In consequence, the smaller firm should budget higher parts and labour cost ratios, while the larger firm should budget higher overhead cost ratios and larger investments in fixed assets. If standards are unrealistically high, frustrations and resentment will develop. If standards are unduly lax, costs will be out of control, profits will suffer, and morale will drop.

**The cash budget and management of cash.** One of the principal methods of forecasting the financial needs of a business is the cash budget. The cash budget forecasts the combined effects of planned operations on the firm's cash flow. A positive net cash flow means that the firm will have surplus funds to invest. But if the cash budget indicates that an increase in the volume of operations will lead to a negative cash flow, additional financing will be required. The cash budget thus indicates the amount of funds that will be needed or available month by month, or even week by week.

A firm may have excess cash for a number of reasons. There are likely to be seasonal or cyclical fluctuations in business. Resources may be deliberately accumulated as a protection against a number of contingencies. Since it is wasteful to allow large amounts of cash to remain idle, the financial manager will try to find short-term investments for sums that he will need later. Short-term government or business securities can be selected and balanced in such a way that he obtains the maturities and risks appropriate to the financial situation of his firm.

**Managing accounts receivable.** Accounts receivable are the credit a firm gives its customers. The volume and terms of such credit vary among businesses and among nations; for manufacturing firms in the United States, the ratio of receivables to sales ranges between 8 and 12 percent, representing an average collection period of approximately one month. The basis of a firm's credit policy is the practice in its industry; generally, a firm must meet the terms offered by competitors. Much depends, of course, on the individual customer's credit standing.

To evaluate a customer as a credit risk, the credit manager considers what may be called the five C's of credit: character, capacity, capital, collateral, and conditions. Information on these items is obtained from the firm's previous experience with the customer, supplemented by information from various credit associations and credit-reporting agencies. In reviewing his firm's credit program, the financial manager should regard losses from bad debts as part of the cost of doing business. Accounts receivable represent an investment in the expansion of sales. The return of this investment can be calculated as in any capital budgeting problem.

**Managing inventories.** Every company must carry stocks of goods and materials in inventory. The size of the investment in inventory depends on various factors, including the level of sales, the nature of the productive processes, and the speed with which goods perish or become obsolescent.

The problems involved in managing inventories are basically the same as those in managing other assets, including cash. A basic stock must be on hand at all times. Because the unexpected may occur, it is also wise to have

safety stocks; these represent the little extra needed to avoid the costs of not having enough. Additional amounts—anticipation stocks—may be required to meet future growth needs. Finally, some inventory accumulation results from the economies of purchasing in large quantities: it is always cheaper to buy more than is immediately needed, whether of raw materials, money, or plant and equipment. There is a standard procedure for determining the most economical amounts to order, one that relates purchasing requirements to costs and carrying charges. While carrying charges rise as average inventory holdings increase, certain other costs (ordering costs and stock-out costs) fall as average inventory holdings rise. These two sets of costs comprise the total cost of ordering and carrying inventories, and it is fairly easy to calculate an optimal order size that will minimize total inventory costs.

**Short-term financing.** The main sources of short-term financing are (1) trade credit, (2) loans from commercial banks, and (3) commercial paper.

**Trade credit.** A firm customarily buys its supplies and materials on credit from other firms, recording the debt as an account payable. This trade credit, as it is commonly called, is the largest single category of short-term credit. Credit terms are usually expressed with a discount for prompt payment. Thus the seller may state that if payment is made within ten days of the invoice date, a 2 percent cash discount will be allowed. If the cash discount is not taken, payment is due 30 days after the date of invoice. The cost of not taking cash discounts is the price of the credit. (The effective rate of interest in this case is 36.7 percent annually.)

**Commercial banks.** Commercial bank lending appears on the balance sheet as notes payable and is second in importance to trade credit as a source of short-term financing. Banks occupy a pivotal position in the short-term and intermediate-term money markets. As a firm's financing needs grow, banks are called upon to provide additional funds. A single loan obtained from a bank by a business firm is not different in principle from a loan obtained by an individual. The firm signs a conventional promissory note. Repayment is made in a lump sum at maturity (when the note is due) or in installments throughout the life of the loan. A line of credit, as distinguished from a single loan, is a formal or informal understanding between the bank and the borrower as to the maximum loan balance the bank will allow at any one time.

In the United States, the role of commercial banks in the financing of business is somewhat unusual. The Banking Act of 1933 required the separation of investment banking and commercial banking functions, whereas in most other countries commercial banks are a source of long-term as well as of short-term financing.

**Commercial paper.** Commercial paper, a third source of short-term credit, consists of promissory notes of well-established firms sold primarily to other business firms, insurance companies, pension funds, and banks. Commercial paper is issued for periods varying from two to six months. The rates on prime commercial paper vary, but they are generally slightly below those on prime business loans.

A basic limitation of the commercial paper market is that its resources are limited to the excess liquidity that corporations, the main suppliers of funds, may have at any particular time. Another disadvantage is the impersonality of the dealings; a bank is much more likely to help a good customer weather a storm than is a commercial paper dealer.

**Use of security in short-term financing.** Most short-term business loans are unsecured. It is ordinarily better to borrow on an unsecured basis, but frequently a borrower's credit rating is not strong enough to justify an unsecured loan. The most common types of collateral used for short-term credit are inventories and accounts receivable.

Financing through accounts receivable can be done either by pledging the receivables or by selling them outright (called factoring in the U.S.). When the receivables

Cash and  
credit  
manage-  
ment

Working  
capital

are pledged, the borrower retains the risk that the person or firm who owes the receivable will not pay; this risk is typically passed on to the lender when factoring is involved.

When loans are secured by inventory, the lender takes title to them. He may or may not take physical possession of them. Under a field warehousing arrangement, the inventory is under the physical control of a warehouse company, which releases the inventory only on order from the lending institution. Canned goods, lumber, steel, coal, and other standardized products are the types of goods usually covered in field warehouse arrangements.

**Intermediate-term financing.** Whereas short-term loans are repaid in a period of weeks or months, intermediate-term loans are scheduled for repayment in one to 15 years. Obligations due in 15 or more years are thought of as long-term debt. The major forms of intermediate-term financing include (1) term loans, (2) conditional sales contracts, and (3) lease financing.

**Term loans.** A term loan is a business credit with a maturity of more than one year but less than 15 years. Usually the term loan is retired by systematic repayments (amortization payments) over its life. It may be secured by a chattel mortgage on equipment, but the larger, stronger companies are able to borrow on an unsecured basis. Commercial banks and life insurance companies are the principal suppliers of term loans. The interest cost of term loans varies with the size of the loan and the strength of the borrower.

Term loans involve more risk to the lender than do short-term loans. The lender's funds are tied up for a long period, and during this time the borrower's situation can change markedly. To protect themselves, lenders often include in the loan agreement stipulations that the borrower will maintain his current liquidity ratio at a specified level, limit his acquisitions of fixed assets, keep his debt ratio below a stated amount, and in general follow policies that are acceptable to the lender.

**Conditional sales contracts.** Conditional sales contracts are a common method of obtaining equipment by agreeing to pay for it in installments over a period of up to five years. Until payment is completed, the seller of the equipment continues to hold title to the equipment.

**Leasing.** It is not necessary to purchase assets in order to use them. Railroad companies in the United States, for instance, have acquired much of their equipment by leasing it. Whether or not leasing is advantageous depends—aside from tax advantages—on the firm's access to funds; leasing provides an alternative method of financing. A lease contract, however, being a fixed obligation, is similar to debt and uses some of the firm's debt-carrying ability. It will generally be advantageous to a firm to own its land and buildings, because their value is likely to increase, but this consideration does not apply to equipment.

The statement is frequently made that leasing involves higher interest rates than other forms of financing, but this need not always be true. Much depends on the firm's standing as a credit risk. Moreover, it is difficult to separate the money costs of leasing from the other services that may be embodied in a leasing contract. If the leasing company can perform nonfinancial services, such as maintenance of the equipment, at a lower cost than the lessee or someone else could perform them, the effective cost of leasing may be lower than for funds obtained from borrowing or other sources.

Although leasing involves fixed charges, it enables a firm to present lower debt-to-asset ratios in its financial statements. Many lenders, in examining financial statements, give less weight to a lease obligation than to a loan obligation.

#### LONG-TERM FINANCIAL OPERATIONS

**Use of bonds.** Long-term capital may be raised either through borrowing or by the issuance of stock. Long-term borrowing is done by selling bonds, which are promissory notes that obligate the firm to pay interest at specific times. Secured bondholders have prior claim on

the firm's assets. If the company goes out of business, the bondholders are entitled to be paid the face value of their holdings plus interest. Stockholders, on the other hand, have no more than a residual claim on the company: they are entitled to a share of the profits, if there are any, but it is the prerogative of the board of directors to decide whether a dividend will be paid and how large it will be.

Long-term financing involves the choice between debt (bonds) and equity (stocks). Each firm will choose its own capital structure, seeking the combination of debt and equity that will minimize the costs of raising capital. As conditions in the capital market vary (e.g., changes in interest rates, the availability of funds, and the relative costs of alternative methods of financing), the firm's desired capital structure will change correspondingly.

**Long-term debt.** The larger the proportion of debt in the capital structure (leverage), the higher will be the returns to equity. This is because bondholders do not share in the profits. The difficulty with this, of course, is that a high proportion of debt increases the firm's fixed costs and increases the degree of fluctuation in the returns to equity for any given degree of fluctuation in the level of sales. Leverage increases the returns to owners if used successfully but decreases the returns to owners if used unsuccessfully. Indeed, if leverage is unsuccessful, the result may be the bankruptcy of the firm.

**Forms of long-term debt.** There are various forms of long-term debt. A mortgage bond is one secured by a lien on fixed assets such as plant and equipment. A debenture is a bond not secured by specific assets but accepted by investors because the firm has a high credit standing or obligates itself to follow policies that assure a high rate of earnings. A still more junior lien is the subordinated debenture, which is secondary to all other debentures and specifically to short-term bank loans.

The use of long-term debt will be encouraged when: sales and earnings are relatively stable; profit margins are large enough to make more leverage advantageous to the stockholders; an increase is expected in profits or the general price level; the existing debt ratio is relatively low; the price-earnings ratios on common stock are low in relation to the levels of interest rates; management is concerned with maintaining voting control over the company; cash-flow requirements under the bond agreement are not burdensome; and the restrictions on management written into the bond indenture are not onerous.

**Stock.** Equity financing is done with common and preferred stock. Preferred stock usually has priority over common stock with respect to earnings and claims on assets in liquidation. Preferred stock is usually cumulative—that is, the omission of dividends in one or more years creates an accumulated claim. The dividends on preferred stock are usually fixed at a specific percentage of face value. A company issuing preferred stock gains the advantages of limited dividends and no maturity—that is, the advantages of selling bonds but without the restrictions of bonds. Companies sell preferred stock when they seek more leverage but wish to avoid the fixed charges of debt. The advantages of preferred stock will be reinforced if a company's debt ratio is already high and if common stock financing is relatively expensive.

If a bond or preferred stock issue was sold when interest rates were higher than they are at present, it may be profitable to call the old issue and refund it with a new, lower cost issue. This depends on how the immediate costs and premiums that must be paid compare with the annual savings that can be obtained.

**Earnings and dividend policies.** The size and frequency of dividend payments are critical issues in company policy. Dividend policy affects the financial structure, the flow of funds, corporate liquidity, stock prices, and the morale of stockholders. If earnings are paid out as dividends, they cannot be used for company expansion. Some stockholders are interested in receiving maximum current returns on their investment, while others prefer reinvestment of earnings so that the company's capital will increase.

Companies tend to reinvest their earnings to a higher

Financing  
equipment

Managing  
the capital  
structure

degree when there are chances for profitable expansion. Thus, at times when profits are high, the amounts reinvested are greater and dividends are smaller. For similar reasons, reinvestment is likely to decrease when profits decline, and dividends are likely to increase.

Companies having relatively stable earnings over a period of years tend to pay high dividends. Well-established large firms are likely to pay higher than average dividends because they have better access to capital markets and are not as dependent as other firms on internal financing. In the same way, if a firm has a strong cash or liquidity position, it is likely to pay higher dividends than if it has not. A firm with heavy indebtedness has implicitly committed itself to paying relatively low dividends and retaining earnings to service the debt. It may decide, however, to continue with high dividends in order to facilitate a stock issue or a refunding of its debt. If the directors of a company are concerned with maintaining control of it, they may retain earnings so that they can finance expansion without having to issue stock. Some companies favour a stable dividend policy rather than allowing dividends to fluctuate with earnings; the dividend rate will then be lower when profits are high and higher when profits are temporarily in decline. Companies whose stock is closely held by a few high-income stockholders are likely to pay lower dividends in order to permit the stockholders to avoid personal income taxes.

In Europe, until recently, company financing tended to rely heavily on internal sources. This was because many companies were owned by families and, also, because a highly developed capital market was lacking. In the less developed countries today, firms rely heavily on internal financing; they also tend to make more use of short-term bank loans and other forms of short-term financing than is typical in other countries.

*Convertible bonds and stock warrants.* Companies sometimes issue bonds or preferred stock that give holders the option of converting them into common stock or of purchasing stock at favourable prices. Convertible bonds carry the option of conversion into common stock at a specified price during a particular period. Stock purchase warrants are given with bonds or preferred stock as an inducement to the investor; they permit him to buy common stock in the company at a stated price whenever he chooses. Such option privileges make it easier for small companies to sell bonds or preferred stock. They help large companies to float new issues on more favourable terms than they could otherwise obtain. When bondholders exercise conversion rights, the company's debt ratio is reduced because bonds are replaced by stock. The exercise of stock warrants, on the other hand, brings additional funds into the company but leaves the existing debt or preferred stock on the books. Option privileges also permit a company to sell new stock at more favourable prices than those prevailing at the time of issue, since the prices stated on the options are higher. They will be most popular, therefore, at times when stock prices are expected to have an upward trend.

#### GROWTH AND DECLINE

Growth  
by combi-  
nation

**Mergers and consolidations.** Companies often grow by combining with other companies. One company may purchase all or part of another; two companies may merge by exchanging shares; or a wholly new company may be formed through consolidation of the old companies. From the financial manager's viewpoint, this kind of expansion is like any other investment decision: the acquisition should be made if it increases the acquiring firm's net present value as reflected in the price of its stock.

The most important term that must be negotiated in a combination is the price the acquiring firm will pay for the assets it takes over. Present earnings, expected future earnings, and the effects of the merger on the rate of earnings growth of the surviving firm are perhaps the most important determinants of the price that will be paid. Current market prices are the second most important determinant of prices in mergers: depending on whether or not asset values are indicative of the earning

power of the acquired firm, book values may exert an important influence on the terms of the merger. Other, nonmeasurable, factors are sometimes the overriding determinant in bringing companies together: synergistic, or "two-plus-two-equals-five," effects may be present to a sufficient extent to warrant paying more for the acquired firm than earnings and asset values would indicate.

A merger may be treated as either a purchase or a pooling of interests. In a purchase, a larger firm generally takes over a smaller one and assumes all management control. The amount actually paid for the smaller firm is reflected in the acquiring firm's balance sheet; if more was paid for the acquired firm than the book value of its assets, the difference is reflected in the acquiring firm's financial statements as goodwill. In a pooling of interests, the merged firms are usually about the same size; both managements carry on important functions after the merger; and common stock, rather than cash or bonds, is used in payment. The total assets of the surviving firm in a pooling are equal to the sum of the assets of the two independent companies, and no surplus remains to be written off as a charge against earnings.

The basic requirements for the success of a merger are that it fit into a soundly conceived long-range plan and that the resulting firm have performance characteristics superior to those attainable by the previous companies independently. In the heady environment of a rising stock market, mergers have often been motivated by superficial financial aims. Companies with stock selling at a high price relative to earnings have found it advantageous to merge with companies having a lower price-earnings ratio; this enables them to increase their earnings per share, thus appealing to investors who purchase stock on the basis of earnings.

Some mergers, particularly those of the "conglomerate" kind, which bring together firms in unrelated fields, owe their success to economies of management. In the 1950s certain large-scale changes in managerial technology occurred. The role of the general management functions (planning, control, organizing, information) and other functions centralized at top management levels (research, finance, legal services) increased in importance. The costs of managing large, diversified firms were substantially reduced. This explains generally the spread of conglomerate mergers in the United States in the 1960s.

In mergers, one firm disappears. An alternative is for one firm to buy all or a majority of the voting stock of another and to run it as an operating subsidiary. The acquiring firm is then called a holding company. There are several advantages in the holding company: it can control the acquired firm with a smaller investment than would be required in a merger; each firm remains a separate legal entity, and the obligations of one are separate from those of the other; and stockholder approval is not necessary, as it is in the case of a merger. There are also disadvantages to holding companies, including the possibility of multiple taxation and the danger that the high rate of leverage will amplify the earnings fluctuations of the operating companies.

An important source of financing in developing countries is through "financial groups." These are groups of enterprises centred around a nucleus of a commercial bank or an industrial finance company. They are not conglomerates or holding companies; they are held together primarily by personal and financial ties between the principals involved.

**Reorganization.** When a firm cannot operate profitably the owners may seek to reorganize it. The first question to be answered is whether the firm might not be better off by ceasing to do business. If the decision is made that the firm is to survive, it must be put through the process of reorganization. Legal procedures are always costly, especially in the case of business failure; both the debtor and the creditors are better off if matters can be handled on an informal basis rather than through the courts. The informal procedures used in reorganization are (1) extension, which postpones the settlement of outstanding debt, and (2) composition, which reduces the amount owed.

If voluntary settlement through extension or composition is not possible, the matter must be taken to court. If the court decides on reorganization rather than liquidation, it appoints a trustee to control the firm and to prepare a formal plan of reorganization. The plan must meet standards of fairness and feasibility: the concept of fairness involves the appropriate distribution of proceeds to each claimant; the test of feasibility relates to the ability of the new enterprise to carry the fixed charges resulting from the reorganization plan.

**BIBLIOGRAPHY.** Comprehensive introductions to business finance include J. FRED WESTON and EUGENE F. BRIGHAM, *Essentials of Managerial Finance*, 2nd ed. (1971), and *Managerial Finance*, 3rd ed. (1969); JAMES C. VAN HORNE, *Financial Management and Policy*, 2nd ed. (1971); and ROBERT WILLARD JOHNSON, *Financial Management*, 3rd ed. (1966). Examples of the case approach are EUGENE F. BRIGHAM *et al.*, *Cases in Managerial Finance* (1970); J. KEITH BUTTERS (ed.), *Case Problems in Finance*, 5th ed. (1969); and PEARSON HUNT and VICTOR L. ANDREWS, *Financial Management* (1968). Collections of basic readings include EUGENE F. BRIGHAM (ed.), *Readings in Managerial Finance* (1971); J. FRED WESTON and DONALD H. WOODS (comps.), *Basic Financial Management: Selected Readings* (1967); and EDWARD J. MOCK (ed.), *Financial Decision-Making* (1967).

(J.F.W.)

## Finland

Now an independent republic in northern Europe, Finland (Finnish Suomi; in full, Suomen Tasavalta) was a part of Sweden from the 12th century until 1809. It was a Russian grand duchy until, following the Russian Revolution, the Finns declared their independence, on December 6, 1917; independence was formally recognized by the Soviet Union on October 14, 1920. Ahvenanmaa (Åland Islands), an archipelago at the entrance to the Gulf of Bothnia, forms an integral, although autonomous, part of Finland.

Finland is bordered on the north by Norway, on the northwest by Sweden, on the west by the Gulf of Bothnia, on the south by the Gulf of Finland, and on the east by the Soviet Union. Its area is just over 130,000 square miles (337,000 square kilometres), of which Ahvenanmaa comprises just over 581 square miles. Finland's area was reduced by about one-tenth in 1944, when it ceded to the Soviet Union a large part of southeastern Karelia (an autonomous region within the Russian S.F.S.R.) and the Petsamo (Pechenga) area, which had provided a corridor to the ice-free Arctic coast. About one-third of Finland lies north of the Arctic Circle.

The most remote of the Scandinavian countries, Finland seems little known outside that area. But its trading and cultural relations with other countries have steadily increased in the last decades. It has close ties with the Scandinavian bloc, sharing a free labour market and participating in various economic and scientific projects. Finland shares with these countries a common law and since 1955 has sent representatives to the Nordic Council, which makes suggestions to member countries on coordination of policies. Finland is a member of the Organization for Economic Co-operation and Development (OECD) and an associate member of the European Free Trade Association (EFTA). In July 1972 Finland initialled a free trade agreement with the Common Market (EEC). Finland's trade with the Soviet Union represents less than 15 percent of the total. Politically, Finland is carefully neutral; although its 1948 treaty of friendship with the Soviet Union requires Finland to repel any attack on the Soviet Union through its own territory, Finland has no other military obligations to the Soviet bloc. (For related information, see SCANDINAVIA, HISTORY OF; RUSSIA AND THE SOVIET UNION, HISTORY OF; HELSINKI; and BALTIC SEA.)

### THE LAND

**The natural environment.** *Topography.* Finland, heavily afforested, mainly with conifers, and containing about 55,000 lakes, numerous rivers, and an extensive area of marshland, looks from the air like an intricate blue and green jigsaw puzzle. Except in the northwest, relief fea-

tures do not vary greatly, and a traveller on the ground or on the water will rarely see beyond the trees in his immediate vicinity. The landscape, nevertheless, possesses a striking—if sometimes bleak—beauty.

Finland's underlying structure is a huge worn-down shield composed of extremely ancient rock, mainly granite, dating from the Precambrian Era (4,600,000,000 to 570,000,000 years ago). The land is low-lying in the southern part of the country and higher in the centre and the northeast, while the few mountainous regions are in the northwest, adjacent to Finland's borders with Sweden and Norway. In this area there are several high peaks, including Haltiatunturi, at 4,357 feet (1,324 metres), Finland's highest mountain.

The islands comprising Ahvenanmaa are mainly low-lying, especially around the central Bay of Lumparen, but toward the northern coastline rise to upland heights such as Orrdalsklint (423 feet). The islands, like mainland Finland, are heavily wooded.

*Drainage and soils.* Finland's inland waters occupy nearly 10 percent of the country's total area; there are about 150 lakes of about eight square miles (2,000 hectares) in area and innumerable smaller ones. The largest lake, Saimaa, in the southeast, covers 1,699 square miles. There are many other large lakes near it, including Päijänne and Pielinen, while Oulujärvi is near Kajaani in central Finland, and Inari is in the extreme north. Away from coastal regions, many of Finland's rivers flow into the lakes, which are generally shallow: only three lakes are deeper than about 300 feet. Saimaa itself drains into the much larger Lake Ladoga in Soviet territory, via the Vuoksi River. Drainage from Finland's eastern uplands is through the lake system of Soviet Karelia to the White Sea. In the extreme north the Paatsjoki and its tributaries drain considerable areas into the Arctic. On Finland's western coast a series of rivers flow into the Gulf of Bothnia. These include the Torniojoki, which forms part of Finland's border with Sweden, and the great Kemijoki (343 miles), Finland's longest river. In the southwest the Kokemäenjoki, one of Finland's greatest rivers, flows out past the city of Pori. Other rivers flow southward into the Gulf of Finland.

Soils include those found in eskers, remarkable winding ridges of stratified gravel and sand laid down subglacially. There are extensive marine and lake postglacial deposits in the form of clays and silts; these provide the country's most fertile soils. The northern third of Finland has thick layers of peat, the humus soil of which is being steadily reclaimed. Such marshland still covers as much as 30 percent of the countryside. In Ahvenanmaa the soils are mainly clay and sand.

*Climate.* Approximately one-third of Finland lies north of the Arctic Circle and suffers extremely severe and prolonged winters. Temperatures can fall to  $-22^{\circ}$  F ( $-30^{\circ}$  C). In these latitudes the snow never melts from the north-facing mountain slopes; but in the short summer (Lapland has 73 days of the midnight sun) from May to July, temperatures can reach as high as  $80^{\circ}$  F ( $27^{\circ}$  C). Further south the extremes are slightly less marked. Annual precipitation, about one-third of which falls as sleet or snow, is about 24 inches in the south and a little less in the north. All Finnish waters are subject to some surface freezing during the winter.

*Vegetation and animal life.* Much of Finland is dominated by conifers, but in the extreme south there is a zone of deciduous trees, comprising mainly hazel, aspen, maple, elm, lime, and alder. The conifers are mainly pine and spruce. Pine extends to the extreme far north, where it can be found among the dwarf Arctic birch and pygmy willow. Lichens become increasingly common and varied in kind toward the north. In autumn the woods are rich in edible fungi. More than 1,000 species of flowering plants are recorded. The sphagnum swamps, which are widespread in the northern tundra or bogland area, yield harvests of cloudberries and, less happily, plagues of mosquitoes.

Finland is relatively rich in wildlife. Seabirds, such as the black-backed gull and the Arctic tern, nest in great

Ancient  
underlying  
rocks

Glacial  
influences  
in soil  
formation

The  
character  
of the  
country

The three principal regions

Urban settlement in the south

numbers on the coastal islands; waterfowl, such as the black and white velvet scoter duck, nest on the internal lakes. Other birds include the Siberian jay, pied wagtail, and, in the north, the eagle. Many birds migrate southward in winter. Native woodland animals include bear, wolf, wolverine, lynx, and Finnish elk. Wild reindeer have almost disappeared, and those remaining in the north are domesticated. A noticeable feature, attributed by some to climatic change, is the recent northward advance of flora and fauna.

Salmon, trout, and the much esteemed *siika* (whitefish) are relatively abundant in the northern rivers. Baltic herring is the most common sea fish, while the crayfish is caught during a brief summer season. Pike, char, and perch are also found.

The vegetation and wildlife of Ahvenanmaa is much as that of southern Finland.

**The human imprint.** *Traditional regions.* Three principal regions may be distinguished in Finland: a coastal plain, an interior lake district, and an interior tract of higher land that rises to the fells (*tunturi*) of Lapland. The coastal plain comprises a narrow tract in the south, sloping from Salpausselkä to the Gulf of Finland, the southwest plain lands of Turun ja Porin Lääni (province), and the broad west coastal lowlands of the region of Pohjanmaa facing the Gulf of Bothnia. The coastal region has the most extensive stretches of farmland, the most continuous settlement, and the largest number of urban centres. Associated with it are the offshore islands, which are most numerous in the archipelago off Turku on the southwest coast. Further north in the Gulf of Bothnia another group of islands lies off Vaasa.

The "lake district," with its inland archipelagoes, is the heart of Finland. It has been less subject to external influences than the coastal region, but recently its population has increased, and it has become considerably industrialized. The northeast and north comprise what may still be called "colonial" Finland, areas of expansion and development, where many economic and social interests conflict. This area includes, in the far north, the area of *saamelaisalue*, or Lapp territory, the upland fells.

Ahvenanmaa is naturally a region entirely distinct from Finland, not only because of its geographical separateness but because of its seagirt situation. The islands—whose inhabitants are almost entirely Swedish speaking—are autonomous and fly their own flag.

*Settlement patterns.* Although increased industrialization in Finland, as elsewhere, has steadily raised the proportion of the population living in towns, about 25 percent of the population are still engaged in farming and forestry, and rural settlement therefore remains intensive. Most farms are small holdings, usually owner occupied. Farms are more frequent in the meadowland regions of the southwest, where land is most fertile and where the 9 percent of agricultural land that is used for crop rearing is mostly found. In these areas mixed farming is practiced, whereas in the north farmers usually concentrate on small dairy herds and forestry. In Finnish Lapland there is some nomad life, based mainly on reindeer husbandry.

Major urban settlement is all in the southern third of the country, with a large number of cities and towns on the coast, either on the Gulf of Finland, as is Helsinki, the capital, or on the Gulf of Bothnia, as are Vaasa and Oulu. The only fair-sized town in the north is Rovaniemi, capital of the *lääni*, or province, of Lappi. Helsinki is by far its largest city, with a population in the early 1970s of more than 500,000, as against the 150,000 plus of Tampere, its nearest rival in size. The other largest cities or towns are Turku, the country's capital until 1812, with a population rivalling that of Tampere; Espoo, Lahti, Oulu, and Pori, with populations in the 70,000 to 90,000 range; and Jyväskylä, Kuopio, Lappeenranta, and Vaasa, with populations varying between 30,000 and 60,000.

On Ahvenanmaa farming is a more usual occupation than fishing; there are mixed farms, as in the southwest of Finland, but fruit is also grown. The population of Mariehamn, Ahvenanmaa's capital and only large town, is about 10,000.

THE PEOPLE

**Racial, linguistic, and religious groups.** There is evidence of settlement in Finland for fully 5,000 years. Archaeological remains suggest that early people came from or had contact with what was to become Russia and also Scandinavia and central Europe. Peoples of Finno-Ugric stock dominated two settlement areas. Those who entered southwest Finland across the Gulf of Finland were the ancestors of the Tavastlanders, the people of Hämeen Lääni; those who entered from the southeast were the Karelians. The proto-Lapps probably retreated northward before these colonists. Scandinavian peoples occupied the western coast and archipelagoes and also Ahvenanmaa. Present-day Finns, therefore, belong to the Scandinavian and Baltic races.

Finland has two official languages, Finnish and Swedish. The Swedish-speaking population, found mainly in the southwest, in the islands, and especially in Ahvenanmaa, is gradually declining and comprises somewhat more than 7 percent of the total. More than 90 percent of the population speaks Finnish, and the language is an important nationalist feature, although it is spoken in strong regional dialects. The Lappish-speaking minority in the extreme north numbers about 3,800.

Christianity entered Finland from both the west and the east as early as the 12th century. About 93 percent of the population belong to the Evangelical Lutheran Church, a national church the bishops of which are nominated by the head of state. There are one archbishop, whose see is at Turku, and seven bishops; the country is divided into nearly 600 parishes. Just over one percent of the population belong to the Greek Orthodox Church of Finland. The Finnish Orthodox Church was granted autonomy from Moscow in 1920, and in 1923 it was transferred to the jurisdiction of the patriarch of Constantinople. It has one archbishop, with his see at Kuopio, one other bishop, and 25 parishes.

No other Christian denomination in Finland claims more than about 7,000 members. In 1970 just over 5 percent of the population regarded themselves as having no church affiliation.

The two official languages

\*Where two figures are given, the first is the land area, the second the total area. †De jure. ‡Preliminary. §Figures do not add to total given because of rounding.

Source: Official government figures.

**Demographic trends.** The population, numbering about 421,500 in 1750, 1,636,900 in 1850, and 2,655,900 in 1900, had risen to 4,029,800 in 1950 and to over 4,600,000 in the early 1970s. This figure includes the ap-

proximate 21,000 of Ahvenanmaa. In the early 20th century the decline in the birth rate exceeded that in the number of deaths, but in the 1930s the birth rate increased and did spectacularly so during the years immediately following the war. Although the birth rate is now less high again, the death rate rose slightly over the 1960s. In 1971 there was 13 births per 1,000 of the population, as against 10 deaths.

Emigration from Finland was heavy in the first decade of the 20th century, when an estimated 159,000 people

left the country. In the 1960s an increasing number of Finnish workers were employed in Sweden. The figure rose from 42,000 in 1960 to 107,000 10 years later. This movement was in part simply a reflection of mobility of labour, but, with unemployment problems continuing in Finland, the majority of these workers were expected to remain in Sweden. Immigration rates are much lower; between 1961 and 1970 just over 3,600 foreigners became naturalized Finns. Internal movements of population have been steadily toward the towns; in 1800 more than

94 percent of the population were rural, but this figure had dropped to about 49 percent in the 1970 census. Because most of the towns are in the south, the drift is in that direction, but the development of Finland's "frontier" areas always keeps a small trickle of population moving in the opposite direction.

With a slightly falling birth rate and a changing death rate, the proportion of elderly people in the population is bound to increase. In fact, while in 1930 some 30 percent were under 15, more than 63 percent between 15 and 65, and more than 6 percent elderly, it was estimated that in 1975 the respective proportions would be 26, 64, and 10 percent. Out of a 1972 employed population of 2,100,000, agriculture and forestry accounted for 408,000 persons; industry for 572,000; the construction branch for 165,000; and the service branches for 911,000. The number of unemployed was almost 75,000. In all demographic fields it seems likely that present trends will continue.

#### THE NATIONAL ECONOMY

Finland is not one of the world's (or Scandinavia's) richest countries; its productivity is relatively low, but, because its population is low also, the share per head of the country's gross national product is above that of the United Kingdom, Austria, and Italy. Wages are lower than in adjacent Sweden (which, as has been noted, draws Finns into its labour market) but higher than in Eastern bloc countries. Finland was for many years a predominantly agricultural country, and some of its low productivity is attributable to the infertility of the terrain. By the 1970s, however, industry had surpassed agriculture and forestry in terms of numbers employed. Reparations payable to the Soviet Union after World War II, at first a desperate burden, eventually proved a boon to Finland, necessitating the development of heavy industry, which later found markets in western as well as in eastern Europe. Subscribing to the General Agreement on Tariffs and Trade since 1949, Finland is the one associate member of the European Free Trade Association, and in 1969 it became a member of the Organization for Economic Cooperation and Development.

**The resource background and sources of national income.** *Mining and quarrying.* Finland is not rich in mineral resources; it has neither coal nor oil. A diversity of minerals occurs in the Precambrian bedrock, but mining output is modest. Outokumpu, in the east, Finland's largest copper mine, produces large quantities of copper, zinc, and iron sulfides annually. Limited amounts of iron, vanadium, and titanium are produced at Otanmäki, near Kajaani, and there are new iron-ore developments at Äkäslompolo in the northwest. Some granite is quarried, and cement output is increasing at Pargas and Lohja in the southwest and at Lappinranta in the southeast.

*Agriculture, forestry, and fishing.* About 20 percent of Finland's population work in agriculture and forestry; most farms include some forest land. Of about 300,000 holdings, more than one-third have less than 12 acres of cultivated land. The main crops are sown grasses and clovers, oats, barley, potatoes, wheat, rye, sugar beet, and rape. In the early 1970s Finland had about 85,000 horses, 889,000 milch cows, 984,000 other cattle, 189,000 sheep, 1,002,000 pigs, 145,000 reindeer, and about 8,000,000 poultry. Animal husbandry has been concentrated on dairy cattle, but there has been serious overproduction, involving a subsidized export of dairy goods and, in 1970, a severe culling of dairy herds. At the same time (between 1968 and 1970) about 200,000 acres of land were taken out of production.

Finland is nearly 65 percent forest covered, and wood remains its most important raw material. But forest resources are running out, especially in the north, and marshland is not being reclaimed quickly enough to provide adequate restocking. The costs of transporting timber from remote areas can often eliminate all profit; adequate exploitation depends on accessibility, and sleigh ways, roadways, and lake and river flotage ways are being steadily developed. The latter can be used only in the summer months. In the late 1960s timber and wood

products comprised about two-thirds of Finland's total exports.

In 1970 Finland's total fish catch amounted to 87,000 metric tons. Fish caught include salmon, sea and rainbow trout, whitefish, pike, and char. Some degree of river pollution and also dams built for hydroelectric works have adversely affected natural spawning habits, especially of salmon and sea trout, and there are now more than 200 fish-breeding stations at which artificial spawning is induced. Dry fodder is used. There is some trawling for Baltic herring, which are also taken in the winter by seine fishing (dragging nets under the ice) around the offshore islands.

*Hydroelectric and nuclear power stations.* Most of Finland's power comes from hydroelectric plants, but the low fall of water makes dam building necessary. In 1971, total production was 23,500,000,000 KWh. The loss in 1944 of Karelian hydroelectric resources turned attention to the north, where seven plants were due to be built on the Oulujoki by 1975, and nine were also in progress on the Kemijoki. Finland's electricity grids are linked with those of Sweden, from where electricity is also imported.

Two nuclear power stations with a capacity of 440 megawatts each will be erected at Loviisa, east of Helsinki, and will be ready for commercial cooperation in 1976 and 1978. The Soviet Union will deliver the reactors, equipment for the turboalternator plant, and nuclear fuel for a 20-year period. Large deliveries of equipment are made by Finnish industries, notably in the case of ice condensers made under a license agreement with Westinghouse Electric Corporation, the international conglomerate.

*Manufacturing.* The dominant basis of industry is softwood. In the course of time the manufactures of tar and pitch have given way to sawn goods, pulp (mostly chemical), and paper. Mills are situated on lakes, rivers, and estuaries, while integrated plants produce wallboard, plywood, and veneer. A further sophistication of the wood industry is the manufacture of furniture, which is exported to Sweden, West Germany, and the United States, as well as to the Soviet Union. The iron and steel industry is developing, and in the 1960s a new plant was built at Raahel, south of Oulu. The number of engineering and shipbuilding establishments greatly increased after 1944. Railway rolling stock and locomotives are manufactured at Tampere, while shipbuilding is centred at Turku and Helsinki, icebreakers and luxury liners being a specialty. Electrical goods are mainly produced at Helsinki. There are oil refineries, of which the largest are at Porvoo and Naantali, and there are various chemical works where nitrogen and phosphates are made. There are textile factories at Turku, Tampere, Vaasa, Forssa, and Hyvinkää. Helsinki is said to have Europe's largest porcelain factory, while Riihimäki, Karhula, Iittala, and Nuutajärvi have international reputations for glass. Leather and pewter goods are also made. Beer is brewed and vodka distilled, and liqueurs, soft drinks, and various sweets are made from cloudbberries, currants, gooseberries, and lingonberries.

*Finance and foreign trade.* Finland is seriously short of capital and since World War II has, in common with most other countries, suffered from inflation. Responsibility for financial stability is a task of the Bank of Finland (Suomen Pankki), established in 1811 and guaranteed and supervised by Parliament since 1868. The bank controls the circulation of the national currency, which Finland has had since 1860. The markkaa (made up of 100 pennia) was devaluated in 1949, 1957, and 1967. The bank fixes interest rates, which are usually high. It provides a clearinghouse for commercial banks and in fact is one itself, although it has no private customers and grants few private loans. Finland is a member of the International Monetary Fund.

During the period of reparations (1944-52), the Soviet Union made inroads into Finland's trade, but the United Kingdom has been the main export market since 1921. It kept that position also in the early 1970s, followed by Sweden, West Germany, and the Soviet Union. Among

The role of nuclear energy

International economic standing

other export markets are the United States, The Netherlands, and France. The main imports are from Sweden, followed by West Germany, the United Kingdom, the Soviet Union, and the United States. Trade relations with the Soviet Union are maintained by a series of five-year agreements, the fifth of which covered the period 1971 to 1975. In 1969 a total of 65 percent of Finland's trade was with countries of the European Economic Community (EEC) and of EFTA. The most valuable exports are wood and wood products, but heavy machinery and transport equipment were growing in importance in the early 1970s.

**Economic policies and taxation.** Beside maintaining internal financial stability, the government needs to achieve a healthy external balance of payments position. Attempts to counter inflation included the introduction of wage and price controls from 1968. Fluctuations in external trade (Finland had deficits in 1967, 1969, and 1970 but a surplus in 1968) have led to the imposition of some import controls. Increasing investment is made, especially in the public services, industry, and agriculture, but much more is required.

Finland derives its highest revenue from sales duties, followed by income tax and taxes on property, inheritance, and gifts. Of current expenditure, about one-third goes to education and social services. State business enterprises include an alcohol monopoly and softwood processing plants, and the state holds substantial share capital in commercial organizations.

**Transportation.** Until comparatively recently, the problems posed to internal communications and transport by Finland's difficult terrain and weather conditions had hardly been tackled, and communities were very isolated. External communications were mainly by sea and, especially as a result of the period of Swedish rule, account for the series of well-developed ports on the Gulf of Bothnia and the Gulf of Finland.

In 1971 there were just over 45,000 miles (about 73,600 kilometres) of roads in Finland, of which about 66 miles were major motorways. There is a quite good network of major and minor roads, but the lakes tend to make routes indirect in the southeast, while north of the Arctic Circle the roads are still few. One-third of the public roads are paved. Bridges and car ferries are beginning to assist road travel in the lakeland areas and in the island archipelagoes, as, for instance, off Turku.

With only about 5,500 miles (about 8,800 kilometres) of track, the railway system is much less adequate than

that of the roads: the southwest of the country is the best served area. The railways are state owned, and diesels are replacing steam engines.

Finland has more than 4,000 miles of navigable waterways, comprising lakes, rivers, and canals. A further approximate 26,000 miles of waterways are suitable for the floating down of felled timber. More than 120,000 ships and about 19,000 timber rafts navigate the canals annually. In 1963 the Soviet Union leased to Finland the Soviet end of the canal linking Lake Saimaa with the Gulf of Finland; it was opened in 1968 for ships with a draft of 13 feet or less and not more than 255 feet long and 36 feet wide. Most of Finland's overseas cargoes are carried in its own merchant marine, which in 1970 amounted to nearly 1,400,000 gross tons. There are passenger liners, and car ferries operate to Denmark, Sweden, and East Germany.

Beside Helsinki, where a new air terminal was built in the late 1960s, Finland has about 16 airports, the most northerly of which is at Ivalo, at Lake Inari. In addition to providing for internal flights, Finnair, the national airline offers international service to various places in the Soviet Union and western Europe and also to New York City.

#### ADMINISTRATION AND SOCIAL CONDITIONS

**The central government.** Finland adopted a republican constitution in 1919. Legislative power rests in the unicameral Parliament (Eduskunta) of 200 members elected for a four-year term and in the president of the republic, whose term of office is six years. Executive power is shared by the president and the Council of State, or Cabinet, at the meetings of which he takes the chair. A clause in the constitution specifically stresses that government ministers are responsible to Parliament.

The president's six-year term of office and the possibility of his re-election enhance his powers and provide the country with an important source of stability, in view of the frequent changes of government caused by the multi-party system. In cases of complete deadlock, the president can appoint a nonpolitical caretaker government. Government bills are introduced into Parliament in the president's name; he can refuse to sign a bill, but, if it is passed in a subsequent Parliament, he must then endorse it. The president can dissolve Parliament at any time. He has certain decree-making powers and is the head of the armed forces. The president conducts his country's foreign policy, but decisions on major treaties and questions of war and peace must be validated by Parliament.

**Regional and local government.** Finland is divided into 12 *läänit* (provinces), each under a governor (*maaherra*) appointed by the president. The provinces are, in the order of density of population, Uusimaa, Häme, Kymi, Turku ja Pori, Vaasa, Kuopio, Keski-Suomi, Ahvenanmaa (which is autonomous), Mikkeli, Pohjois-Karjala, Oulu, and Lappi.

The provincial governor is in charge of the provincial office (*lääninhallitus*) and of the local sheriffs (*nimisies*); in the early 1970s there were almost 240 sheriff districts. Ahvenanmaa, in addition to having a provincial governor, has its own local council, elected by universal suffrage, and a county executive board. The provinces are divided into communes, which may be rural or urban in character. The commune councils, elected for a four-year term, each choose their executive board. Communes, of which there were over 520 in the early 1970s, are responsible for local health, education, and social services and for such amenities as roads in their particular areas.

**Elections, political parties, and trade unions.** At the start of the present decade, every citizen of Finland who had reached the age of 20 was enfranchised and was regarded as eligible for election to any position. A bill to reduce the voting age to 18 was passed by Parliament in 1972. Presidential elections are indirect; they are arranged by means of the general electorate choosing a college of electors of 300 members, who then conduct the election proper. In Finland there are always more

The prevalence of coalition governments

than two candidates for the presidency and sometimes as many as six. Parliamentary elections are conducted by a system of proportional representation. There are 15 electoral districts. The same system is used for the election of the communal councils.

The use of proportional representation in elections invariably leads to a proliferation of political parties, and this is the case in Finland. In the election held in 1970, for example, eight parties won representation in Parliament. Governments are mostly coalition ministries. In 1970, in the first election of the decade, the Sosialidemokraattinen Puolue (Social Democrats) won nearly 24 percent of votes cast; the conservative Kansallinen Kokoomus Puolue, the Centre, formerly Agrarian Party, the Keskusta Puolue, and the Communist People's Democratic League (SKDL) won between 16 and 18 percent; the Rural Party won more than 10 percent, while the liberal Kansan Puolue and the particularist Swedish party, Svenska Folkpartiet, won just over 5 percent each. The Christian League won considerably less than 1.0 percent of votes cast. The Centre and Social Democratic parties have always played an important role in Finland's political life, and have been included in almost every government. The Communist People's Democratic League is also influential.

Finland has both a Finnish Employers' Confederation and a Federation of Finnish Trade Unions, the latter having a membership of more than 700,000. There are also a Confederation of Salaried Employees (with more than 200,000 members) and a smaller Confederation of Academic Professional Associations. Monetary and inflationary troubles have caused periodical unrest and have resulted in disruptions of industry through major strikes. A few of the important unions show strong Communist influence.

**Justice and the armed forces.** The Finnish judiciary is independent of the legislature and executive; judges are removable only by judicial sentence. There are district courts, held in towns by the burgomaster and his assessors and in the country by a judge and 12 jurors. Appeal from these courts lies to courts of appeal in Helsinki, Turku, Vaasa, and Kuopio. The Supreme Court, in Helsinki, appoints the district judges and those of the appeal courts. The chancellor of justice (*oikeuskansleri*) is the supreme judicial authority and also acts as public prosecutor.

By the Treaty of Paris (1947), made with the Allied Powers after World War II, Finland may maintain an army of 34,000 men, an air force of 3,000 men and 60 aircraft (bombers being forbidden), and a navy of 4,500 men with ships to a total tonnage of 10,000. All male citizens between the ages of 19 and 60 are liable for military service. Most undergo training lasting from 240 to 330 days, and the total trained reserve is about 650,000. In the early 1970s the army consisted of one armoured brigade, six infantry brigades, and four artillery regiments, the total manpower amounting to just over 34,000. The navy possessed two frigates, a training ship, two corvettes, two minelayers, and more than 50 diverse smaller vessels. Its total manpower was about 2,500. The air force had three operational groups, a transport squadron, and various training establishments. The combat units possessed 38 Soviet MiG-21 fighters, as well as various training and transport aircraft. Its personnel numbered about 3,000.

**Education.** In Finland it is compulsory for children to attend school for seven years from the age of seven. A child may move to a secondary school between the ages of 10 to 13. The state meets a large part of primary school costs, but fees are charged in both state-controlled and private secondary schools. There are a large number of schools or institutions providing vocational training for many professions or trades, including navigation, all branches of agriculture, domestic science, and social science. Additional adult education is provided in worker's institutes.

The only higher education institutions in Finland that were founded before the country achieved independence are the University of Helsinki, founded at Turku in 1640

and transferred to Helsinki in 1828, and the Helsinki Institute of Technology, founded in 1849. The latter was always subject to considerable state control, but the university played an important part, historically, in fostering Finnish nationalism, and the Finnish constitution specifically guarantees its traditions of self-government. There are also universities at Jyväskylä, Oulu, and Tampere and two (one Finnish- and one Swedish-speaking) at Turku. Of these universities and other institutes, including five schools of economics, the majority are privately run, although receiving some state aid.

**Health and welfare services and housing.** Social security in Finland comprises a system of pensions and care for the aged, unemployment benefits, and family welfare schemes. The state pays disability pensions and old age pensions to those persons 65 years of age and older. The cost of these pensions is met from premiums originally paid by the beneficiaries, payments by employers, and by the central and local government. The Central Pensions Security Institute administers a further, earnings-related old age pension, available also to farmers and other self-employed people.

The Health Welfare Department provides care and attention for the elderly and in 1971 opened recreational centres to provide social amenities for them. Unemployment benefits and compensation for industrial accidents are paid. Maternity benefits were first introduced in 1937 and family allowances for all children under 16 in 1948.

The state does not supply free medical services but reimburses the patient to an average of 60 percent of his medical costs. From 1946 students have had a comprehensive medical care and insurance scheme.

The National Board of Housing supervises problems of supply and development in its area. There is a general housing shortage, acute in the towns and especially so in Helsinki. Property values and rents are high. Low-income families are eligible to obtain state-subsidized flats, and government loans for mortgages are also obtainable. Houses, whether of traditional Nordic style or of imaginative new architectural form, are still usually timber built, although such material as concrete is used for apartment blocks.

The police authorities are subordinated by the Ministry for Internal Affairs. The cities pay to the state a part of the expenses for the local police force.

**Social conditions.** Finland shares many of the economic problems of the developed countries, notably balance of payment deficits and steady inflation. Between 1960 and 1966, for example, the cost of living rose by an average of nearly 5 percent each year; during 1967 it was nearly 6 percent and in 1968 nearly 9 percent. A slowing down of the process to something under 3 percent was achieved in 1969 and 1970, largely by means of imposing wage and price controls, and has been more or less maintained. But, despite strikes, real wages have not kept up with price rises, and in 1971 the President proposed a general wage increase of 10 percent during the 15 months ending in March 1972.

Class distinctions, based on economic status, are clearly discernible in Finland. Statistics show that the majority of the working population are manual workers, although the trend since World War II has been toward a slight increase in the upper classes (landowners, industrial entrepreneurs, professional men) and the middle classes (government employees, business personnel, white-collar workers generally).

#### CULTURAL LIFE AND INSTITUTIONS

Finland's national epic, the *Kalevala*, compiled in the 19th century by the scholar Elias Lönnrot from old Finnish ballads, lyrics, and incantations, played a vital part in fostering Finnish national consciousness and pride. Indeed, the development of almost all Finland's cultural institutions and activities has been involved with and forced on by nationalist enthusiasm. This theme can be demonstrated in the growth and development of Finnish theatre and opera, in writing and music, in art and architecture, and also in sport. The festivals of various arts, held annually at places such as Helsinki, Kuopio, Vaasa,

University of Helsinki

The *Kalevala*, Finland's national epic

and Kaustinen, and the recent proliferation of museums in Finland show an awareness of the individuality and importance of Finland's contribution to world culture. Savonlinna, in particular, is celebrated for its annual opera festivals.

**Theatre, opera, and music.** Drama in Finland is truly popular in the sense that vast numbers act in, as well as watch, theatrical productions. Beside the 40 or so theatre companies in which all the actors are professionals, there are some in which a few professionals or even the producer alone are supplemented by amateur performers. There are amateur theatrical companies in almost every commune.

The most important theatre is the National Theatre of Finland, established in 1872 with the dynamic enthusiast Kaarlo Bergbom as producer and manager; its granite building in Helsinki was put up in 1902. There are also seven municipal theatres. One of the most exciting in the country is the Pyynikki Summer Theatre of Tampere, the auditorium of which revolves in a complete circle. There are innumerable institutions connected with the theatre, including the Central Federation of Finnish Theatrical Organizations, which runs a drama school. There is a wide repertory of Finnish as well as of international plays. The theatre receives some degree of state assistance.

The Finnish National Opera, housed in the empire-style opera house built in Helsinki in 1879 as a Russian theatre, opened in 1919 with a performance of Verdi's *Aida*. There are about 250 members of the company. Finnish as well as foreign opera is performed, often on modern themes, as in Tauno Pykkänen's *Opri and Oleksi*, set at the time of the war of 1939 to 1940.

Finland's most famous composer, Jean Sibelius (1865–1957), brought Finnish music into the repertoire of international concert halls; in the other direction, the work of foreign composers has influenced those in Finland. For instance, among 20th-century composers, Uuno Kallervo Klami has been influenced by Ravel and Einö Juhani Rautavaara by Shostakovich and Bartók. Yrjö Kilpi perpetuated traditional folk themes in his *kanteletar* songs, and Tauno Martinen's *Kokko, Bird of the Air* takes themes from the *Kalevala*. The centre for higher musical studies is the Sibelius Academy at Helsinki. An international Sibelius violin competition is held every five years.

**Writing, art, and architecture.** Literature has contributed particularly to Finnish nationalism. The first novel written in Finnish was *Seitsemän veljestä* (1870; *Seven Brothers*), by Aleksis Kivi. In the 1880s an important group of liberal writers developed. Calling themselves Young Finland (Nuori Suomi), they included Arvid Järnefelt, Eino Leino, and Teuvo Pakkala. The works of Johannes Linnankoski and Aino Kallas were translated into various other languages, including English, in the 1930s.

Gradually writing became more self-critical, and modern techniques were practiced, such as the use of monologue and flashbacks in *Alastalon Salissa* (1933; "In the Parlour at Alastalo"), by Volter Kilpi, who died in 1939. In poetry, free verse and exotic themes became usual. Among its exponents were Katri Vala and Lauri Viljanen. Later followers are Paavo Haavikko, poet and playwright, the humorist Veikko Huovinen, and novelists Antti Hyry, Veijo Meri, and Hannu Salama, whose novel *Juhannustanssit* (1964; "Midsummer Dance") aroused much critical interest.

Literature in Swedish also has a long tradition in Finland. Among 19th-century writers, J.L. Runeberg and Zacharias Topelius are nationally known and loved. A later group of authors having a strong influence on modern poetry both in Finland and Scandinavia included Edith Södergran, Gunnar Björling, and Rabbe Enckell. Representing a still younger generation are the poet and playwright Bo Carpelan and the novelists Christer Kilhman and Jörn Donner.

From the time that the *Kalevala* inspired the paintings of Akseli Gallén-Kallela, there has been a distinctive school of Finnish painters, but the Finnish artistic genius

seems more drawn to three-dimensional work. Sculpture is important, highly abstract, and experimental; Eila Hiltanen's monument to Sibelius in Helsinki is composed of chrome, metal, and steel tubes.

Modern Finnish architecture is among the most imaginative and exciting in the world. Its development was closely allied to the nationalist movement, and among its pioneers were Eliel Saarinen, whose work is exemplified by the National Museum and Helsinki's railway station, and Lars Sonck, whose churches in Helsinki and Tampere are particularly notable. Both these men used huge granite blocks.

In the 20th century, functionalism was developed by Gustaf Strengell. In the 1920s Alvar Aalto and Eric Bryggman were partly inspired by the work of the Swiss-born Le Corbusier. Among the most striking of Aalto's work are the Paimio Sanatorium, the library at Viipuri, and Finlandia House, a concert and congress hall in Helsinki. There is general experimentation, using concrete and metals, in industrial buildings and flats and in environmental design, as at the garden town of Tapiola outside Helsinki.

Finnish imaginative design is also shown in furniture, glass, porcelain, and jewelry.

**Sport.** In Finland the basic national sport, originally a necessity for getting about, is skiing. Nationalism again encouraged the development of special proficiency, which was fostered by ski fairs and competitions held at Oulu from the late 1890s. Finns soon began to compete successfully in Scandinavian competitions.

Nationalism also encouraged an interest in athletics, developed from the time that the Finns took part in the interim Olympic Games held in Athens in 1906. At Stockholm in 1912 Hannes Kolehmainen won three gold medals, and in 1920, 1924, and 1928, Paavo Nurmi, a Finnish national hero, won six gold medals for his middle- and long-distance running. At the 1972 Olympics Lasse Viren won two gold medals. The Finns, and especially Timo Makinen, have kept Finland's name well to the fore in international automobile rallying. Popular sports also include water-skiing, riding, fishing, and shooting.

**Newspapers, radio, and television.** Newspapers in Finland, immediately after independence, were mainly organs of the various political parties, but an increasing number are now independent. There are more than 200 newspapers published in Finnish, of varying sizes, and about 20 published in Swedish. Of periodicals, appearing once a week or monthly, there are about 400 in Finnish, about 50 of mixed language, and fewer than 20 in Swedish.

The state has a monopoly in radio broadcasting. The Finnish Broadcasting Corporation, which broadcasts in Finnish and Swedish, receives its income from the revenue derived from license fees. There has been television service since 1958 and colour television since 1969. There is one commercial television company, operating from Helsinki.

#### THE OUTLOOK

Finland shares with most other developed countries numerous economic problems—inflation, unemployment, shortage of investment capital, and trade deficits. But the diligence and enterprise of the Finns, coupled with their sense of national purpose, equip them to deal with their difficulties. Finland's cultural impact on the world, especially through its arts and architecture, is meanwhile steadily increasing; the actual country, too, is becoming better known, tourism growing by about 10 percent each year.

Poised delicately between East and West, Finland has had a difficult political position to maintain. But the establishment, in 1969, of Helsinki as the initial venue of the strategic arms limitations talks (SALT) between the United States and the Soviet Union suggests that Finland is gaining acceptance of its status as a neutral state; and in the foreseeable future the role of mediator and conciliator is clearly one of the most valuable that any nation can perform.

Modern

ure

**BIBLIOGRAPHY.** Good general books on Finland are WALTER BACON, *Finland* (1970); HILLARD KALLAS and SYLVIE NICKELS, *Finland: Creation and Reconstruction* (1968); and WILLIAM R. MEAD, *The Delineation of Finland* (1968). *The American-Scandinavian Review* (quarterly) regularly contains articles on Finland. For the geography of Finland and general traveller's impressions, HENRY M. BELL, *Land of Lakes* (1950), is an outstanding personal account, by the first British representative in independent Finland. B. PIHLSTROM, *Finland* (1970), is an efficient travel guide; while R.R. PLATT, *Finland and Its Geography* (1955), is a serious geographer's account of the country. Books on special aspects include WILLIAM R. MEAD, *Farming in Finland* (1953); and NILS E. WICKBERG, *Architecture in Finland* (1959). The standard English translation of the *Kalevala* is by W.F. KIRBY (1907), but A.K. JOHNSON produced a new prose version in 1950. See also URHO KEKKONEN, *Neutrality: The Finnish Position* (1970); MAX JAKOBSON, *Diplomacy of the Winter War: An Account of the Russo-Finnish War, 1939-40* (1961) and *Finnish Neutrality* (1968). The Ministry for Foreign Affairs has also published a number of useful publications on Finnish affairs.

(Ed./C.F.S.)

## Finno-Ugric Religion

The religion of the Finno-Ugric peoples, who inhabit regions of northern Scandinavia, Siberia, the Baltic area, and central Europe, is an admixture of agrarian and nomadic primitive religion and of Christianity and Islām. This article is concerned primarily with the pre-Christian and pre-Islāmic elements of Finno-Ugric religion.

**Geographical and cultural background.** *The Finno-Ugric peoples.* The area inhabited by the Finno-Ugric peoples is extensive: from Norway to the region of the Ob River in Siberia and southward into the Carpathian Basin in central Europe and the Ukraine. The history of their geographical dispersion is based almost entirely on linguistic criteria, since historical knowledge is recent and archaeological finds are scanty and interpreted variously.

The Finno-Ugric languages and the Samoyed languages together form the Uralic family of languages, which began to split up about 4000 BC. The original Uralic people are thought to have lived in the region between the Ural Mountains and the middle reaches of the Volga River. Their descendants in the north are the Samoyeds (four tribes of about 25,000 people, living on the shores of the Arctic Ocean between the Taymyr and the Kanin peninsulas). In the south, the original speakers of the parent Finno-Ugric language probably began to disperse between 3000 and 2500 BC, when the Ugrians formed their own group. One branch moved northeast, behind the Ural Mountains: the Ostyaks (who in their own language call themselves Hanti), numbering about 19,000 and living east of the Ob River, and the Voguls (who call themselves Mansi), numbering about 6,000 and living west of the Ob River. The other branch spread southward and made contact with the Bulgar Turks and the Khazars; in the year 895 this branch (the Magyars), together with certain Turkish tribes, conquered what is now Hungary. In this way, the largest (numbering over 10,000,000), but at the same time linguistically the most isolated, Finno-Ugric nation came into existence. Other Magyars (over 2,000,000) live in the countries of Romania and Czechoslovakia.

The Permyak branch of the Finno-Ugric populations living in central Russia split from the other groups between 2000 and 1500 BC; the linguistic differentiation is not very great between the present-day Permyaks, who are divided into Votyaks (called Udmurt, now numbering about 400,000 and living between the Kama and Vyatka rivers) and Zyryans (called Komi, now numbering about 600,000 and living in the region between the upper reaches of the Western Dvina River, Kama, and Pechora)—the differentiation only occurred a little over 1,000 years ago.

Further to the south, the differentiation of the Volga Finns probably began about 1000 BC. The Volga Finns consist today of 1,500,000 Mordvins (including the Mokšas [Mokshas] in the southeast and the Erzas in the northwest) living in a rather large region near the middle reaches of the Volga River and 500,000 Cheremis

(the Mari) living in the vicinity of the confluence of the Volga and the Kama.

When the Baltic Finns came to the regions bordering on the Baltic Sea is not certain. The latest possible date would be c. 500 BC (the evidence being the Baltic loan words in proto-Finnic), when the "proto-Finns" still maintained contact with the Mordvins and the Lapps. A much earlier date is possible, however, as there must have been many and repeated migrations by the Finno-Ugric populations westward from the Ural Mountains toward the Baltic regions. Initially, settlement was sparse, as is always the case with hunting cultures, but language differentiation sped up with the change to stable agriculture. The Lapps (called the Sábme, numbering about 31,500) have been the slowest of the Finno-Ugric peoples to relinquish the hunting culture—which has withdrawn slowly towards the north, and they themselves have moved from the direction of Lakes Ladoga and Onega (northeast of Leningrad, U.S.S.R.) to the northern parts of Fennoscandia and the Kola Peninsula (northeast Soviet Union).

After separating from early proto-Finnic about 2,500 years ago, the Lappish language became divided into a number of very different dialects. The oldest population settlements of the Baltic Finns were to the south of the Gulf of Finland and to the south of Lake Ladoga. The most westerly group, the Livonians (now numbering 700, in the north of Courland), is disappearing. In Estonia there are approximately 900,000 Estonians, and they are one of the three most advanced of the Finno-Ugric peoples, the others being the Finns and the Hungarians. Small but interesting cultures are represented by the Votes and the Ingrians (today these are nearly extinct Greek Orthodox groups) in Ingria (near the head of the Gulf of Finland), the Veps (numbering about 16,000 and living between Lake Onega and Belozero), and the Karelians (numbering about 200,000 in Karelia and Finland), as well as the Ludes in Olonets, who speak a transition dialect. The population moved into Finland from the south and southeast; there are at present 4,500,000 Finns.

**Ecological and intercultural factors.** To attain a proper understanding of the history and phenomenology of the religion of the Finno-Ugric peoples, two basic influences must be borne in mind: the ecological factors and the pressure of alien cultures on the original religious tradition. The result of both factors has been a very great variation in the religious atmosphere in different places.

The Lapps, Samoyeds, Voguls, and Ostyaks—who all have been associated with a nomadic and hunting culture in Arctic regions—retain a religious life that has many primitive elements. The Finns, Karelians, and Zyryans have practiced hunting up to the present, but they have been familiar with agriculture for thousands of years. The peoples on the south side of the Gulf of Finland, such as the Estonians, have long practiced agriculture and cattle breeding as well as fishing, but hunting has not been as important to them. The Finno-Ugric peoples of the southeast, like the Votyaks and the Cheremis, have practiced agriculture and cattle breeding only. The agrarian economy of the Hungarians, with its seminomadic features, is the outcome of a complicated history.

Habitat, climate, and other ecological factors have had an important influence on economy and social organization and on traditional religion. Some of the differences between the various Finno-Ugric peoples, however, can be traced to outside cultural influences. The eastern Finno-Ugric peoples have been marked by Turko-Tatar influence. In the 8th century the Votyaks and the Cheremis came under Bulgar domination; the conversion of the Bulgars to Islām in 922 and the subsequent Tatar domination in eastern Russia (1236-1552) gave added significance to the Arab-Islāmic tradition. In the 16th and 17th centuries, the Volga Finns, the Permyaks, the Ob Ugrians, and the Samoyeds finally came under the domination of Moscow; before this, Orthodox missionaries had worked, for example, among the

graphic  
distri-  
bution

Influences  
on Finno-  
Ugric reli-  
gion

Zyryans (St. Stephen, 14th century) and the Baltic Finns.

The influence of Slavic tradition on the Finno-Ugric peoples has been considerable—from the point of view of both folk religion and the more institutionalized Orthodox faith, though some of this influence in many places is late and superficial. Pre-Christian practices were still alive in the early 20th century, and among the Votyaks, the Ob Ugrians, and the Samoyeds there were still people who were unbaptized. Roman (Catholic) and Byzantine (Orthodox) traditions met one another in Finland and Estonia, but the Orthodox groups remain established only in the eastern regions. Most of Finland was converted to Christianity by way of Sweden, beginning in the 12th century, and the country remained Catholic until Lutheranism was established in the 16th century. The position of the Hungarians, who formed a pocket surrounded by alien cultures, resulted in an extremely mixed array of contacts at different levels.

Thus, each of the Finno-Ugric peoples has its own cultural history, habitat, and level of civilization. In considering their religion, all this must be borne in mind. The Hungarians, Finns, and Estonians have the longest literary traditions, while a number of the other peoples are only now becoming literate. Ancient popular belief, preserved in oral tradition, has for the most part developed more freely on the periphery, but near centres of culture it has become a minor growth alongside institutional religions.

*The problem of the concept of a Finno-Ugric religion.* Since it is not possible to find a single formula to cover Finno-Ugric cultures and religions and since the relationship between the peoples is often distant both geographically and historically, it may well be asked whether there is any utility in attempting, by means of comparative methods, to discover some common or basic substratum in Finno-Ugric religion. Many earlier scholars attempted this enthusiastically, but today there is general agreement that a hypothetical reconstruction representing the "original religion" of a single language family is virtually impossible. That ancient tradition may have been preserved in different regions, although fragmented and adapted to new conditions, is, of course, possible, and indeed seemingly trustworthy discoveries have been made that substantiate this view. One must, however, be extremely circumspect in projecting hypotheses applying to the entire linguistic group. Genetic-historical considerations are of great importance when dealing with those areas of the language family where a cultural connection has subsisted long and late.

The search for a common historical tradition is not, however, the most rewarding aspect of the study of Finno-Ugric religions. The religio-phenomenological approach is equally interesting and significant. In the course of conducting nonhistorical studies of similarities and differences in Finno-Ugric religious material, scholars have uncovered a spectrum running all the way from Arctic hunting and fishing cultures to southern cattle breeding and agriculture.

**Mythology.** *Creation, cosmography, and cosmology.* The most widely spread account of the creation among the Finno-Ugric peoples is the earth-diver myth. In the north it is known in an area extending from eastern Finland to the Ob River, and in the south it is found, for example, among the Mordvins. This myth, which is well-known in North America and Siberia, is fairly constant in form among the Finno-Ugric peoples; in the Mordvin variant, God sits on a rock in the middle of the primeval sea and spits into the water; the saliva begins to grow and God strikes it with a staff, whereupon the devil comes out of it (sometimes in the form of a goose). God orders the devil to dive into the sea for earth from the bottom; at the third attempt, he succeeds but tries to hide some of the earth in his mouth. While God scatters sand, the earth begins to grow and the devil's deceit is unmasked, and the earth found in his cheek becomes mountains and hills. The eastern Finnish myth contains an interesting detail; God stands on the top of a golden statue and orders his reflection on the water to rise, and this becomes the devil.

Etiological (causal) continuations are common; the devil demands for himself a piece of earth the size of the end of a stick, and from the hole that results vermin emerge—mice, fleas, mosquitoes, flies, and other such living things. Indo-Iranian influence has been seen in the dualism of the myth—setting God against the devil—since religious dualism is most significant in Indo-Iranian religion. A water bird may be older than the devil; it also occurs, however, without the dualistic emphasis. Thus, in an account by the Yenisey Ostyaks, the great shaman (a medicine man with psychic abilities) Doh glides above the primeval sea among the water birds, asks the red-throated loon to dive for earth from the bottom of the sea, and with the earth makes an island. A rarer, but apparently ancient, myth is found among the Voguls; the god of the skies lets earth come down from heaven and places it on the surface of the great primeval sea.

The world made from an egg is a myth best known in equatorial regions, though the most northerly points of its distribution are in Finland and Estonia. A water bird or an eagle makes its nest on the knee of the creator (Väinämöinen), who is floating in the water; it lays an egg, which rolls into the water, and pieces of it become the earth, the sky, the moon, and the stars. Myths concerning the creation of man are found in the north among the Voguls and in the south among the Volga Finns. The common element among all such myths is that man, on the brink of achieving perfection, had his hairy covering transferred to the dog by the devil, whose spit blighted man and made him subject to disease and death. In Finland the variant of yet another anthropogonic (origin of man) myth has been found; a hummock rises from the sea, a tree stump thereon splits open, and the first human couple steps forth.

Finno-Ugric cosmographic (world description) concepts include the following well-known mythological themes: a stream or sea encircling the round world; a canopy of the heavens, the central point of which is the North Star (a kind of nail on which the sky rotates); a world pole supporting the sky; a world mountain and a world tree rising in the middle of the earth; animals carrying the earth; and the nub of the earth and the nub of the sea (an abyss that swallows ships). From these and from other materials more or less coherent cosmographies have been formed in different places; the central components are the sky, the earth, and the underworld. Among the Ob Ugrians and the Samoyeds is found a myth of the seven- or nine-storied heaven.

The cosmogonic (origin of the world) and cosmographic myths have had important ritual functions and have provided the basis for cosmology (the order of the world). When, in incantations and prayers, numerous natural, cultural, and social phenomena derive from these basic myths, it is not a matter of giving an explanation but of finding the connection with the decisive primeval events that gave the world its lasting order. A pillar representing the world pole has been worshipped by the Lapps and the Ob Ugrians, especially as a symbol of the world order.

**High gods.** The semantic elements "sky" and "god of the sky" are found to be so close in the terminology of certain of the Finno-Ugric peoples (for example, Cheremis Jumo, Finnish Jumala, Votyak Inmar, Zyryan Jen, Samoyed Num) that the association cannot be a recent phenomenon. The tradition of the god of the sky is many layered, and the influence of monotheism, especially of Christianity and Islām, is widely exhibited. This influence was evidently preceded by that of ancient southern high cultures. Thus the Cheremis Jumo has a real court with servants in his heaven, and these servants act as intermediaries between men and the god of the sky. This indicates a Turko-Tatar influence, which can also be seen in the Votyak Inmar; Christian elements, however, are also found (Inmar's mother is related to the Virgin Mary). "Great," the most common epithet for Inmar and Jumo, reminds one of Allāh. The Mordvin god of the sky (Škaj, "creator, birth giver," among the Mokša people, and also Nišké-pas, "the great inseminating god") is the chief of the gods, all knowing and all seeing, who is not approached for trivial things. He appears, however, very

the study  
of Finno-  
Ugric reli-  
gion

## Sky gods

concretely in a festival connected with the beginning of the spring ploughing. In this festival an old man represents the god of the sky and from an attic or a tree answers questions put to him by people who pray about health, the grain harvest, the weather, and other matters. The gods of the sky of the Arctic Finno-Ugric peoples (Samoyed Num; Ostyak Num-Turom, Sängke; Vogul Num-Tarom; Lappish Tiermes, Horagalles, and Radien) are the high gods of hunting and nomadic cultures, which sometimes appear in myths as creator gods and culture heroes (often as *dei otiosi*, or "inactive gods," without a cult) and sometimes as venerated gods of the economy (as the promoters of fishing, hunting, and reindeer herding), especially as weather gods. Originally the Finno-Ugric peoples probably had no concept of a hierarchic family of gods with its supreme god acting as chief man; the attribute found in many places, "lofty" or "high" merely means "being above"—that is to say, a god appearing in the sky.

The concept of a begetting sky is stressed in southern agricultural cultures, in which an increasing importance of the "earth mother" may be observed; it is no longer a mere local field spirit but rather has the role of a great birth giver. "The god of the sky is our father, and the earth mother is our mother," say the Mordvins. The earth mother's function is not limited to field sacrifices, but also includes child giving; she is the begetter *par excellence*.

*System of spirits.* The high gods are usually encountered in connection with a rite; they are distant, invisible, and do not make surprise visits. With the guardian spirits, however, matters are different. They are first and foremost supranormal beings that appear in definite visions, auditory experiences, and other such occurrences. They appear especially when a social norm involving a guardian-spirit sanction is broken. The guardian spirits—along with the spirits of the dead—are significant as important regulating factors in daily behaviour and normally are solitary local spirits, believed to "govern" and "own" a particular area: a cultural locality (e.g., household spirits), a natural region (e.g., guardian spirits of forest or water), and a natural element or phenomenon (e.g., fire spirits or wind spirits). There are also special guardians (of man or of treasure) and various demonic beings that—though similar to the guardian spirits—are not worshipped.

The names of guardian spirits are normally compounds of words, the first element of which indicates the sphere of action, the second being a name such as "man" or "master" (Votyak Korka-murt, "house-man," Vu-murt, "water-man"), "old man" or "old woman" (Cheremis Pört-kuguza, "the old man of the house," or Pört-kuwa, "the old woman of the house"), or "father" or "mother" (Mordvin Jurt-at'a, Jurt-ava). The system of social values is revealed by the system of guardian spirits; the home spirit protects the luck of the home; the cattle spirit watches over the cattle during the winter (in the summer the cattle come under the forest spirit); the barn spirit looks after threshing luck. In representing these values the spirit may appear in a number of roles. Thus, the Ingrian house spirit appears as "owner," the original owner of the plot on which a house is built; "moralist," punisher of crimes against norms that may endanger the luck of the house; and "sympathizer," one who warns in advance of catastrophes threatening house or family. With some peoples—the Mordvins, for example—the guardian-spirit system is very specific and there is a very large number of spirits; with others, such as the Arctic Lapps, the Samoyeds, and the Ob Ugrians, there are fewer of them, and Herr der Tiere (Master of Animals) game spirits predominate.

*Sacred ancestors.* The oldest form of Finno-Ugric religion is thought to be ancestor worship. Some of the main terms (e.g., "grave," "hades," and "soul") go back several millennia. The cult concerned only dead members of the family; other dead beings were experienced as restless haunters, and aggressive expelling rites were used to dispel them. The worship of ancestors must be understood as a family institution in which intercourse between the

living and the dead is the internal activity of a social primary group. The dead belong to the family, and they have both rights and duties; they protect the happiness of the family, assist it in its means of livelihood, and receive their share of the produce; they are also considered to be counsellors, moralists, and judges. The cult of the dead can be divided in the following manner: (1) rites at the moment of death; (2) funeral preparations (washing the corpse, attiring it, and watching by it; making the coffin); (3) the committal; (4) celebrations in memory of a single dead person; (5) annual memorial ceremonies for the dead; (6) offerings and prayers to the dead in connection with earning the means of subsistence; and (7) occasional rites (e.g., when moving to a new place or during illness).

The most important of the ritual ceremonies for a dead person are those that take place during the transition period, which may last for six weeks and may include addressing the departed euphemistically and in dirges. The departed person remains in the dwelling place, separated from his body; agreements are made with him about the distribution of property; he is given advice about how to live on the other side; he is invited to return for the celebration of his anniversary; and so on. The most important matter is the ensurance of harmony between the newly departed and his relations in the graveyard. Of central importance in the collective worship of the dead is the visit of the departed members to their old home; among the Eastern Finno-Ugric peoples this approximates with the Christian feast of Easter, and among the Western it is in late autumn (e.g., the Finnish *kekri*, November 1, an ancient festival to celebrate the seasonal change). Living members of the family also visit the graves on the anniversary days of the departed. Customs among the Arctic Lapps, the Samoyeds, and the northern Ostyaks differ somewhat from the above; among the Lapps, the departed person is represented by a clothed log and among the Ostyaks and the Samoyeds by a doll-effigy that is kept for as long as three years.

The other world is viewed as two-storied and consists of (1) a graveyard, hades, or underground village of the dead in a holy forest near the village; and (2) a distant hades, far in the north behind the burning stream (with an admixture of paradise concepts). Name-giving rites suggest continuity and reincarnation; a child is given the name of a dead relative, and the child thereby is believed to receive the personality of the deceased relation. If the result is unsuccessful, a name-changing rite can be performed.

*Divine heroes.* Hero worship in Finno-Ugric religion does not point to culture heroes who are described in myth and whose actions are located in cosmogonic contexts. In general, culture heroes are not worshipped. The matter is otherwise when dealing with divinized historical figures, the cults of which are found among several of the Finno-Ugric peoples. Mardan of the Yelabuga Votyaks is viewed as the progenitor of 11 villages and the one who led the dwellers therein from the north to their present habitations. There is a sacrificial ceremony in his honour every year. Also, there are signs of the worship of tribal chiefs, for example in the forest sanctuary worship of the Votyaks (*lud*) and the Volga Finns (*keremet*). The best known of the Cheremis princes, called "the old man of the Nemda mountain," is a great ancient warrior under whose rule the people were strong and united. According to this myth, he promised to return when war threatened; once he was called for unnecessarily and after discovering the betrayal, he ordered an annual propitiation sacrifice, a foal. The Ob Ugrians have a large number of "local gods" of whom pictures have been made and who are sometimes associated with ancient mighty men or Christian heroes and saints. A death doll made from a shaman may also have been the origin of a hero cult; the Samoyeds have been known to cherish and feed such a doll for as long as 50 years.

*Sacred animals.* In the "hunters' religion" preserved among the northern Finno-Ugric peoples, bear ceremonies are central. The Ostyaks, Voguls, Samoyeds, Lapps, Finns, and Karelians have all been acquainted with myths and rites connected with the bear. The myths recount that the bear is of heavenly origin and is the son of the god of

## Ancestor-cult rites

## Bear ceremonies

the sky; it descends from heaven and, when it dies, returns there. There is also a story about a marriage between a bear and a woman from which a tribe of the Skolt Lapps (in Finland) is said to be descended. The bear-killing ceremony is divided into two acts—the killing itself and the feast afterward. Killing a bear that was protected by a forest guardian spirit involved a complicated ritual, which ended with bringing the bear home. Women believed that they had to keep at a distance so that the bear would not make them pregnant. The feast to celebrate the killing of the bear lasted two days and was full of marriage symbolism. The bear was addressed euphemistically, and a young man or woman was chosen to be its mate. A large meal made of the meat of the bear was consumed. Finally, the skull of the bear was carried in procession to the branch of a pine tree on the top of a mountain. This was the custom in Karelia. A number of miniature dramas were connected with Ob Ugrian bear rites. Masked participants tell the bear that members of a strange tribe have killed it.

The exogamic patrilineal clans (involving marriage outside a particular group) of the Ob Ugrians are often known by animal names—"bear," "falcon," "frog," or "dog." The animal is regarded as the manifestation (*epiphania*) of the family guardian spirit and is not allowed to be killed or eaten. Evidence of totemistic systems, in which animals are associated with blood-related groups, has been found among the Lapps and the Samoyeds. Some scholars consider the names of relations (animal names) found among other Finno-Ugric peoples, such as the Hungarians and Karelians, as evidence of a lost totemism.

**Institutions and practices.** *Cult authorities.* The male head of the family has long had a central role in leading different home and family cults. In the *lud* sanctuaries of the Votyaks, for example, worship was performed by members of the family; the head of the family had the responsibility of organizing the cult and the task was hereditary. Women also were able to supervise certain minor home rituals—such as those performed in connection with cattle breeding (offerings to the guardian spirit of the cattle shed and the forest). In hunting and nomadic cultures, the head man (*e.g.*, the oldest of the hunting party or the reindeer chief) supervised the rites. The official authorities of the rites (*i.e.*, the religious specialists) among the Finno-Ugric peoples were of the following types: shamans (among the Samoyeds and the Lapps); seers (the counterparts of the shaman among southern peoples); sacrificing priests (the leaders of the annual rites, especially in cattle-breeding cultures and agricultural communities); guardians of the sanctuary (the protectors of holy groves, buildings, and other places and the controller of the rites); professional weeping women (the "vocalists," especially of the cult of the dead but also of weddings, who were the verbal expressers of the content of the ritual); the masters of ceremonies at weddings; and many more. The shaman had many and various tasks in Arctic regions, but further south particular tasks were undertaken by various cult authorities: the seer (healing and counselling) and the weeping woman, or psychopomp (*i.e.*, "conductor of souls"), guiding the soul to the other world. The two last-mentioned are verbal ecstasies; the task of the seer, especially in solving critical problems, was of the utmost importance. The task of the sacrificing priest was more of a routine affair, but among the Volga Finns and the Permyaks, for example, the long and skillful prayers as well as the complex ceremonies performed by the priests required great professional competence.

*Cult centres.* The home sanctuary of the Votyaks is a *kuala*, a primitive log cabin near the dwelling house. In a corner at one end of the *kuala* is a shelf, at the height of a man, on which there are branches of deciduous trees and conifers, and on top of them a *voršud* (a box with a lid). A weekly offering is made here. Another Votyak sanctuary is the *lud*—a fenced-off area in an isolated place in the forest. In the middle is a primitive table for sacrificial gifts. In the *lud* regular animal sacrifices are offered and occasional crisis rites performed (sacrifices to dispel accidents or disease). The cult group in both *kuala*

and *lud* is the family; the office of the sacrificing priest of the *lud* is hereditary, and in the principal house of the family there is a great *kuala*, which is visited three times a year in addition to the offerings made in the small *kuala* at home. The small *kuala* is built on a foundation of earth and ashes brought from the big *kuala*. The system is exogamous—the woman visiting the *kuala* of her own father and not that of her husband's father. The Votyaks also have large groves near a spring or a brook in the vicinity of a village, where common sacrifices for the whole village are made. There are, in addition, larger sacrificing groups, which may include dozens of villages and which meet every third year for a festival lasting many weeks. The Volga Finns also have fenced-in *kere-met* groves for the family cult and places of worship common to the whole village. Evidence also exists concerning sacrificial groves among the Baltic Finns and from group villages in Karelia and Ingria. In the thinly populated parts of Finland, the family cult took place either at cup stones (sacrifice stones with shallow cup-like depressions) or at holy trees. Among the nomadic Lapps (those involved in reindeer herding and fishing) *seita* (sacrificial stone) places for worship arose near a reindeer migration route or a good fishing place, and for such a place an outstanding stone generally was chosen. The Ob Ugrians had a kind of "mobile temple" for the wooden idols (normally kept in the corner of the house) that were placed on special sledges.

*Cult practices.* All the main categories of rites are found among the Finno-Ugric peoples: cyclic rites (concerning the means of livelihood), rites of passage (the transition of the individual from one status to another), and crisis rites (concerning threats of disaster). The character of these rites varies considerably, depending on ecological factors and cultural contacts. Generally, an agrarian culture produces a cult system that is more stable and formal than that produced by a mobile hunting culture or a nomadic way of life. In the latter, sacrifice rites tend to be more improvised and the cult group smaller. An example of a formal system is the distinction "upward" and "downward" in worship found among the Votyaks and the Cheremis; sacrifices of white animals are made in deciduous groves to the god of the sky and to certain nature gods, the direction of prayer being to the south; sacrifices of black animals are made to the departed and to the guardian spirits of the earth near conifers, the direction of prayer being to the north.

**Conclusion.** Two phenomena may be consistently observed with regard to the religious customs of the Finno-Ugric peoples. These are the ecological adaptation of religion and the stratification of tradition in connection with acculturation. A number of examples of the former have already been given. As far as acculturation is concerned, it may be said that the "syncretism" it produces does not result in any conflict in the religious field, except perhaps for short periods of adjustment. Old and new elements of different origins are moulded into an active system, and choice and adaptation take place according to practical religious need. Christianity and Islām have in many places provided a religious superstructure, but they have not been accepted as such; certain elements from them have been adapted to the depth structure of a primitive religion. The best example of this is the preservation of folk religion in Hungary, Finland, and Estonia, where Christianity, supported by a literate culture, is ancient. Popular belief has become intertwined with the religious tradition because it has always had a function that no Christian practice has replaced. Only mass media and urbanization have jeopardized the ancient belief tradition.

**BIBLIOGRAPHY.** A comprehensive presentation of "Finno-Ugric Mythology" by UNO HOLMBERG-HARVA is published in the *Mythology of All Races*, vol. 4 (1927, reprinted 1964). More recent surveys with extensive bibliographies are "Die Religionen Nordeurasien" by IVAR PAULSON in *Die Religionen der Menschheit* 3 (1962); and "Religion der finnisch-ugrischen Völker" by LAURI HONKO in *Handbuch der Religionsgeschichte*, vol. 1 (1971). References to standard monographs on the religion of various Finno-Ugric peoples are available in these sources.

Fire Prevention and Control

Fire protection, undertaken in order to safeguard human life and property, includes preventing, detecting, and extinguishing fires. It is also concerned with: improving the methods of prevention and suppression by research into the causes of fire; the study of engineering data leading to establishment of standards in building design and construction that will limit fire hazards; the education of the public as well as professional fire-fighting personnel to take prompt and correct emergency action; the maintenance and improvement of fire-fighting equipment; and the inspection of buildings for compliance with established fire-preventive practices.

Until after World War I little official attention was given to fire prevention, for most departments were thinking of fire extinguishment only; today nearly all large cities have at least a small staff exclusively concerned with it. Modern engineers and architects have discarded the fictitious notion of fireproof construction; their fire-safe designs seek to limit interior combustibles so that fires will be slower, to build cutoffs and compartmentalize structures so that fires will be smaller, to minimize the probability of a source of ignition coming in contact with combustible material, to include facilities for rapidly detecting and extinguishing fires, and to provide space around buildings, thus giving easy access to fire fighters. Once a building is built, periodic inspection helps to insure compliance with fire codes.

Modern fire-safe designs

FIRE PREVENTION

A specific fire-prevention program of a company, institution, or government has as its goals the creation of employee and public interest; the planning of safe buildings, equipment, and processes; the elimination of the causes of fire and explosion; the provision and maintenance of protective equipment such as automatic sprinklers and portable fire extinguishers; and the organization of professionals, volunteers, or employees for emergency action.

**Policy formulation.** A company-policy statement typically stresses the importance of safety, prevention of loss, and the responsibilities of supervisory employees. A city or other governmental ordinance details the duties of fire-prevention personnel, methods of storage and use of explosives and flammables, installation and maintenance of alarm and protection systems, maintenance and regulation of fire escapes and exits, investigation of causes and circumstances of fires, and conducting of fire-prevention campaigns.

**Public awareness.** Public-awareness campaigns in many cities have had notable results in the removal of fire hazards in homes, places of business, and institutions; the better maintenance of equipment; the better prepara-

tions for fire emergencies; and the better public support for the needs of the professional fire-fighting force. In the United States many such efforts are related to National Fire Prevention Week, held during the week in which October 8-9 falls—these being the dates on which, in 1871, both the Chicago Fire and the Peshtigo, Wisconsin, forest fire raged.

**Building design.** City building codes usually contain strict building-design requirements aimed toward fire prevention and safety. Every area of a building will have at least two separate exits, for example, arranged to minimize the possibility of a fire blocking both. Often an exterior stairway of open iron or an interior stairway enclosed in fire-resistant construction will be provided from roof to street.

Any fire, especially one involving explosions or structural collapse, may cause panic, a major cause of loss of life; intelligent construction plans consider all such potential circumstances. Exit stairs, for example, are separated from floors by heavy, metal, self-closing and self-latching fire doors rated by established fire-testing laboratories to resist fire of a specified intensity for a specified number of hours. Plans also include alarm systems, signs indicating exits, safeguarding of unusual hazard areas such as rooms in which highly flammable or explosive materials are stored, and design of interior finish and contents to inhibit rapid spread of flame. Glass with wire embedded in it may be used in exterior windows to prevent fires from spreading to or from adjoining structures and in fire doors to allow users to see through the door.

Fire-retardant coatings, paints with good heat-insulating qualities, have been developed for application over combustible surfaces and have shown excellent results in reducing surface combustibility. Such coatings, often applied in older structures, help to smother small fires and slow the progress of large blazes long enough for the building to be evacuated and for fire fighters to confront the fire. Another development is fire-retardant lumber, produced by impregnating wood with fire-retardant chemicals—water-soluble inorganic salts including ammonium bromide, borax, boric acid, phosphates, and sodium salts—under high pressure. The treatment of fabrics used for curtains and draperies to reduce their combustibility, while frequently referred to as fireproofing, actually only retards the development and spread of flame. Regulations in practically all countries require that fabrics used in theatres and other buildings where large numbers of people congregate must be either incombustible (as fibreglass) or treated to reduce combustibility. A problem common to such treatments is that many impregnating chemicals are water soluble; thus, each time the fabric is washed, the treatment must be renewed. To minimize holiday-season fires in the homes, Christmas trees are often sprayed with fire-retarding chemicals, a process called flocking. Trees may also be dipped into fire-retardant solution or the trunk may be immersed in chemicals that act to preserve the tree and keep it moist.

**Fire-safe construction.** A broad range of structures are capable of withstanding fires of specified intensity and duration without failure. Although the structures are relatively safe, combustible materials used in interior furnishings, ceilings, or trim, can contribute fuel to a fire. For this reason, sprinkler systems (described below) are indispensable, particularly in such buildings as factories and warehouses in which large amounts of combustible materials are handled or stored.

Several types of construction are basically fire-resistive. Heavy-timber construction, with masonry walls, timber columns and beams, and heavy plank floors, is not immune to fire, but the mass of wooden members slows the burning; the char that forms on wooden surfaces serves to insulate the wood within. Exposed steel-beam construction with masonry, metal, or asbestos panel walls is commonly termed noncombustible. Under moderate fire exposure, the steel may warp, buckle, and collapse; therefore sprinkler systems are required except where occupancy is low hazard. Ordinary construction, consisting of noncombustible masonry bearing (supporting) walls and

Planning to avert panic

Preventing holiday-season fires

combustible interior framing, floors, and roofs—the bulk of which is less than that of heavy-timber construction, is less fire-resistant. Protected ordinary construction has floor and roof construction of one-hour fire-resistance rating (*i.e.*, it will resist fire, as defined by standard test procedures, for one hour), and all openings through floors, including stairways, are enclosed by partitions with one-hour ratings, the minimum permitted or recommended in most places. This type of building predominates in congested areas of many of the world's largest cities. In wood-frame construction, exterior walls, as well as partitions, floors, and roofs are wood, but exterior walls may be sheathed with brick or other fire-resistant siding. This construction can be made reasonably safe for light-hazard, low-density occupancy if enough exits are provided, and combustible interiors are minimized. Sprinkler protection, however, greatly improves safety.

**Protection of hazardous equipment.** Electrical equipment, internal-combustion engines, storage tanks, pipelines carrying liquids or gases at high temperature, and debris are potential hazards in all buildings. The best protection against most of these hazards is sound basic design, but frequent inspection and good housekeeping practices are always necessary. Flammable-liquid storage requires approved pumps and containers. Where hazards are unavoidable, extinguishers must be provided.

High-hazard processes such as chemical production must be isolated and protected in building design, and personnel facilities planned to minimize danger.

**Study of causes of fire and explosion.** It is important to ascertain likely causes of fire so that they can be eliminated. A study of more than 25,000 fires of all kinds in the United States over a ten-year period showed the following principal causes: electrical, 23 percent; smoking, 18 percent; friction (from such industrial sources as hot bearings and misaligned machines), 10 percent; overheated materials, 8 percent; hot surfaces (resulting from defects or heat from boilers, furnaces, flues, lamps, and other appliances or processes), 7 percent; burner flames, 7 percent; combustion sparks (released from incinerators and other equipment), 5 percent; spontaneous ignition (sometimes called spontaneous combustion), 4 percent; and cutting and welding, 4 percent. Other causes include exposure to neighbouring fires, incendiarism, mechanical sparks, molten substances, chemical action, and static electrical sparks, including lightning.

Spontaneous  
ignition

Spontaneous ignition sometimes occurs when combustible solids or liquids are stored loosely enough so that large areas of surface are exposed to oxidation but with inadequate air circulation to dissipate heat. As the combustible material slowly oxidizes (unites chemically with atmospheric oxygen), it releases enough heat to raise the temperature of the stored material perceptibly. As additional air seeps in, the temperature is gradually raised until the ignition temperature is reached. Soft coal tends to spontaneous ignition. Spontaneous ignition can also occur in hay, which should be stored in a cool, dry, well-ventilated barn. In the home, this phenomenon most often occurs among oily rags. Prevention of spontaneous ignition is accomplished either by total exclusion of air or by good ventilation.

#### CLASSES OF FIRES

The system or classification described below, based on types of combustible, is very widely used throughout the world.

Class A fires involve paper, wood, cloth, trash, and other ordinary combustibles and are by far the most common class of fire. They are most effectively extinguished by cooling until combustion can no longer be supported. Extinguishers for such fires, called Class A extinguishers, may use water, soda-acid, loaded stream (*i.e.*, solution of fire-extinguishing chemicals), foam, or multipurpose dry chemical. (Operation of these extinguishers is explained below under *Fire-extinguishing materials*.)

Class B fires involve flammable liquids such as gasoline, oil, paint, and tar. Because the flames are on the surface, the extinguishing agent must not cause the liquid to flow

and spread; this condition explains why water is not suitable for such fires. The best Class B extinguishing agent smothers the fire by cutting off its oxygen supply or interrupting the combustion process; if a suitable cover is available a Class B fire can be smothered.

Class C fires involve electrical equipment and pose the special hazard of electrocution. The oxygen-exclusion principle is used against them. Nonconductive agents in Class C extinguishers include carbon dioxide, dry chemicals, or certain compounds containing halogen elements (fluorine, chlorine, etc.), called Halons (described below).

Class D fires involve such burning metals as magnesium, aluminum, zinc, potassium, and sodium and newer metals of the nuclear age. Class D fire extinguishers employ special extinguishing agents such as the dry powder (described below, under *Fire-extinguishing agents*), and require special training for their use.

Large fires usually involve more than one class of combustibles, and very large fires involve all four. The term conflagration is usually reserved for very large fires that involve many buildings and which cross natural or prepared barriers, such as streets or fire walls. Fires that are extensive in damage but not in area, as in a single industrial complex or group of warehouses, are generally called group fires.

The conditions described as fire storms in cities attacked with incendiary bombs in World War II were conflagrations in the sense of fires burning over large areas, but they differed from peacetime conflagrations because multiple fires were started in such numbers that the flame from the individual fires merged into a single convective column producing so much heat that all the buildings beneath were set on fire. Whereas a conflagration spreads along a defined path, and population can retreat, the fire storm is an area phenomenon and the population is trapped. Life loss in fire storms is likely to be far greater than in conflagrations.

#### FIRE CONTROL EQUIPMENT

**Alarm and signalling systems.** A protective-signalling system is designed to accomplish several objectives. First, it must alert building occupants to permit prompt evacuation of the premises; to do this it must be distinctive and take precedence over all other signals, such as paging or music, and it must be appropriate—*i.e.*, visual signals for deaf people or signals limited to custodial personnel only in an institution where a general signal might create panic. Drills are of critical importance in practicing orderly evacuation; the alarm for a drill must be the same as that for an emergency. Second, an alarm system must notify the fire-fighting agency and signal the location of the fire. The system must be designed to minimize accidental or malicious interference. A third function of a comprehensive alarm system is to monitor automatic extinguishing facilities and signal failures. A fourth function is to monitor building functions and industrial processes and signal any dangerous phase, such as a boiler or furnace failure, or breakdown of electrical or air-conditioning equipment.

Signal systems may be classified as manual or automatic and with respect to the scope of their function. Local systems simply warn occupants of the protected area; these often have separate auxiliary systems to notify the public fire-fighting force. The familiar fire-alarm box seen in many cities all over the world notifies the local fire station by means of signals carried over wire lines. Remote-station systems may register alarms in an office or fire department located away from the premises. Proprietary systems may transmit signals to a central location, usually in a large complex, such as a major industrial facility. Central-station systems serve a number of unrelated communities or industrial plants.

**Heat-sensitive devices.** Automatic fire-detecting systems employ a variety of detecting devices, of which the most common are simple thermostats set to a certain fixed temperature. Bimetallic-strip types operate against a fixed contact; the distance the strip must travel to close against the contact determines the temperature rating. A difficulty is that as the strip approaches the contact, a

Special  
signalling  
systems

Use of  
bimetallic-  
strip  
detectors

slight jar may cause a false alarm. In the United States and some other countries, thermostats are nonadjustable (that is, they are responsive to heat only at the rated temperature). In the United Kingdom and some European countries, however, the unit is fitted with movable stops and can be adjusted to lower or higher temperatures.

The snap-action disk, also of bimetallic construction, flexes from concave to convex when its rated temperature is reached. The greater mechanical force required to make the electrical contact greatly reduces the possibility of a false alarm.

The fusible link and quartzoid bulb use the same principle; they restrain the operation of an electrical switch until a certain temperature is reached. The solder-type link melts at this temperature; the quartzoid bulb breaks. Both are replaced after operation. In the thermostatic cable system, two steel cables are held apart by heat-sensitive insulating material. At the rated temperature, the covering melts and the two wires come into contact to initiate the alarm.

Rate-of-rise detectors usually combine two functioning elements, one to trigger the alarm on a rapid rise in temperature, the other on a slow rise. These detectors combine a number of advantages: they usually operate faster than fixed-point devices; they can be used in high- and low-temperature areas; they recycle rapidly and, thus, are more quickly available for continued service than fixed-point devices; and they can tolerate a slow increase in room temperature without triggering an alarm. They have two disadvantages: they may sound a false alarm if the room temperature rises rapidly and they may fail to signal a fire that propagates very slowly.

Rate-of-rise detectors are of two types. (1) Pneumatic-tube detectors use a tubing circuit filled with air. Pressure is built up in the detector diaphragm (bellows-like chamber) when heat reaches the tubing and causes the air inside to expand. When the temperature reaches the set point, the pressure expands the diaphragm to close the alarm circuit. The system contains breathing vents to compensate for small temperature changes. (2) Thermoelectric detectors have two sets of thermocouples (devices for measuring temperature that depend upon the electrical current produced when two different conducting metals are joined) mounted in a single housing. One set points outward to sense heat transferred by convection or radiation; the other set is shielded to sense only ambient (surrounding) heat. When one set of thermocouples gets hotter than the other, an electrical voltage difference is produced. When this difference becomes great enough, a detector circuit signals the alarm.

Combined rate-of-rise and fixed-temperature detectors are being used increasingly because they have the advantages of both types.

Rate  
compensa-  
tion  
devices

Rate-compensation devices operate on the rate-of-rise principle but also compensate for intermediate changes in this rate. Their construction is based on a cylinder containing thin struts held in compression, on which electrical contacts are mounted. Because of the difference in rates of expansion between the cylinder and the struts, a signal is given for both low- and high-temperature rise. They also actuate the alarm signal at a predetermined maximum temperature.

The following two devices are used to actuate fire extinguishing equipment; however, any other detecting device can be used to actuate extinguishing equipment.

Pneumatic rate-of-rise actuating devices consist of one or more thin-walled, bulb-shaped chambers or tubing connected to a releasing mechanism. Heat expands air in the system, and this expanded air actuates a mechanical or electrical release. Small air vents prevent tripping caused by slow, normal temperature changes.

Metal-expansion rate-of-rise actuating devices use two metal rods of different size to trigger a small valve at each detector; this valve action, in turn, trips a release that controls a sprinkler system.

**Smoke detectors.** Smoke detectors are used where the materials stored are likely to create much smoke before generating enough heat to activate a heat-detection system. Some are designed to be placed in heating and cool-

ing ducts. Some are backed up by a heat-sensing unit set at a fixed temperature. Smoke detectors are best located after an engineering survey determines the effects of air velocity, ventilating and air-conditioning facilities, and existing dust or vapours that could affect their operation. All detectors must be kept clean.

The photoelectric type of smoke detector measures the change in current caused by smoke as it partially obscures the transmission of a beam of light. An alarm is tripped when the density reaches a critical value. Lamps usually run on six volts of current and last 5,000 hours. The ionization smoke detector employs a chamber that is bombarded by particles from a minute amount of radioactive material. Oxygen and nitrogen molecules in the air are ionized by the radioactive particles and carry a very small electric current across the chamber. Combustion particles in the air attach themselves to the oxygen or nitrogen ions and slow them down to reduce current flow and increase the voltage applied across the chamber. A sensing element triggers the alarm when the current flow drops below (or voltage increases above) a predetermined level. The amount of nuclear radiation emitted by the radioactive material in some units is large enough to require licensing by the appropriate government agency.

The refraction smoke detector uses the principle that particles of smoke can reflect and scatter light. A small chamber, open to the atmosphere, contains a light source set at an angle to a photoelectric cell. When smoke particles enter the chamber, some of the light reaches into the cell. This light changes the electrical resistance of the photoelectric cell and a signal is given.

Light-  
sensitive  
devices

Other types include a flame detector that is responsive to the changes of light intensity caused by the flickering of flames; a unit that measures variations in wire tension as a result of heat expansion; and a balanced (Wheatstone bridge) circuit in which products of combustion bring about fast impedance (electrical resistance) changes that upset the balance of the circuit to trigger an alarm.

**Single-station alarms.** Single-station alarm units composed of a self-contained sensing element, power supply, and sounding mechanisms are of three types. In the gas-powered-horn type, a metal softens from heat and releases gas to sound the horn. Several heat-sensitive mechanisms can be connected to one gas-operated horn. The mechanical type is powered by a spring. When triggered by a heat-sensitive mechanism, the spring is released to sound a bell. The photoelectric (or optical) smoke detector type is powered by house circuit. Several ionization type home alarm units now marketed are powered by flashlight cells. Not having been tested by recognized fire-testing laboratories, these have no established proof of reliability.

**Spacing of sensing devices.** In most countries, established fire-testing laboratories and safety organizations recommend spacing for fire detection devices. Where there are smooth ceilings and large open areas in the structure, sensing devices are spaced about 10 to 15 feet (3 to 4.5 metres) apart. Devices are installed in all parts of a building, including unused and service areas. Because it takes time for heat to be transferred to reach the heat-sensitive device and its signal-actuating part, the temperature of the surrounding air in case of fire is higher than the operating temperature of the device itself. This is called thermal lag.

**Fusible links.** In addition to triggering alarms, fusible links, consisting of two metal parts held together by a solder that melts at low temperature, are used as a release element for fire doors, tank and hatch covers, and extinguishers. Once the fusible link melts, electro-mechanical elements take over to close doors or perform other work. Power for operation is usually an electric solenoid or a weight tripped by the system.

**Extinguishing systems as detectors.** Automatic sprinklers also can be used for fire detection, signalling through a water-flow alarm switch. To overcome the possibility of a false alarm as a result of water-system pressure fluctuations, a retarding device delays transmission of the alarm signal until the flow has persisted for some specified time.

Sprinkler-system effectiveness

**Automatic sprinkler installations.** Automatic sprinkler systems can be designed to extinguish or control virtually every type of fire. Sprinkler protection involves the automatic discharge of water in density sufficient to control or extinguish a fire before it can build up. Four factors are involved in the effectiveness of a sprinkler system: the system design itself, the building construction, special hazards of occupancy, and the water supply.

Records from cities throughout the world show that from 1925 to 1969 automatic sprinklers proved 96 percent effective, with 65 percent of alarms resulting in complete extinguishing and 32 percent in control until other equipment could be mobilized. The few failures were generally attributable to insufficient water supply or an inadvertently shut-off water valve.

Water damage has been cited as an objection to installing automatic sprinklers. In the great majority of recorded cases, however, fire damage would have been more severe. Precautions must be taken to prevent unnecessary discharge of water as a result of mechanical injury, freezing, overheating, or corrosion.

There are five major types of sprinkler systems in wide use: wet pipe, dry pipe, preaction, deluge, and on-off. In the wet-pipe system, water stands in the pipes at all times ready for discharge. Where the possibility of freezing exists, a dry-pipe system, in which the pipes are filled with air under pressure, with the water held back by a valve, is preferred. Water is released to the sprinkler pipes when the actuated sprinklers cause a loss of air pressure. The preaction system is a dry-pipe system with a smaller time lag between the tripping of the dry-pipe valve and the release of water from the sprinklers. A separate detector sends a preliminary warning signal to the valve, which opens to let the line fill with water. An alarm may be sounded, permitting an attempt to suppress the fire with hand extinguishers. If the fire increases in intensity, the individual sprinklers open to release water. These systems are used primarily to protect properties such as computer areas where there is danger of serious water damage as a result of defective pipes or sprinkler operation. Deluge systems have open sprinklers with the water held back by a central valve. When fire is sensed by the detector system, a signal is sent to the central valve and water is released to all the sprinklers at once. Wetting down an entire floor is an advantage in extra-hazard occupancies, such as where flammable liquids or rocket propellants are handled or stored and where there is a possibility that a flash fire may spread ahead of the operation of ordinary sprinklers, or in an area such as an aircraft hangar, with a very high ceiling where air drafts may deflect the heat of a fire and confuse an individually activated sprinkler system. On-off multicycle sprinkler systems are heat-actuated in both directions—turning on water to the sprinklers when fire strikes and off when the fire is under control. If fire redevelops, the control again turns the water on. Detectors actuate the individual sprinklers as in a conventional system. The on-off cycle can be repeated any number of times. The valves can also be operated manually.

Extra-hazard areas

Variations in building contents and materials determine proper sprinkler spacing. Minimum spacing is normally six feet (two metres); closer spacing is sometimes used with baffles to keep an operating sprinkler from wetting (and thus cooling) an adjacent sprinkler. Sprinklers are positioned close to the ceiling if they are designed to operate fast, because hot gases rise quickly to the ceiling.

Where occupancy hazards are classed as light, effective protection can be anticipated from water supplies and sprinklers; most apartments, churches, hotels, public buildings, offices, and schools are in this class. Occupancy hazards classed as ordinary (kitchens, stores, or manufacturing plants) or extra (oil, chemical, or explosive plants) may require increased protection.

**Water supply.** Sprinkler systems can be supplied with water from one or more sources: street mains, gravity tanks, reservoirs, fire pumps, pressure tanks, rivers and lakes, and wells. Both a primary and one or two secondary supplies must be considered, because a single supply may be temporarily low or disabled.

Major sources of sprinkler-water supply include direct connections to municipal mains; connections to mains through private water-supply systems; gravity tanks; fire pumps (usually automatic); pressure tanks; and fire-department connections, designed to match fire department hose fittings.

The minimum water flow for adequate sprinkler supply is about 250 gallons (1,000 litres) per minute for light-hazard occupancy and up to six times as much for ordinary-hazard occupancy. Water pressure must suffice to overcome system-pressure losses. The discharge rate of a sprinkler is proportional to the pressure of the water at the sprinkler. As the discharge rate rises, however, the pressure required rises faster. A typical relationship for a sprinkler head of one-half inch (12.7 millimetres) orifice diameter is 10 pounds (4.5 kilograms) per square inch at a discharge rate of 18 gallons (72 litres) per minute, rising to 25 pounds (11.4 kilograms) for 28 gallons (102 litres), 50 pounds (23.5 kilograms) for 41 gallons (164 litres), 75 pounds (34 kilograms) for 50 gallons (200 litres), and 100 pounds (45 kilograms) for 58 gallons (232 litres). Other orifice sizes are available where different flow rates are needed.

**Sprinkler mechanism.** The discharge of water from an automatic sprinkler is restrained by a cap or valve held tightly against the orifice by a system of levers and links anchored by struts (see Figure 1). The linkage is de-

Figure 1: Parts of a soldered-link automatic sprinkler.

signed to give way at a certain temperature. There are three types of automatic sprinklers: (1) The common soldered-link automatic sprinkler is held closed by the smallest safe amount of metal and solder possible, so that operation will be rapid. It usually takes a minute or two before a sprinkler begins to operate over an ordinary fire. This interval allows time for use of a hand extinguisher or early smothering of the fire. (2) Frangible-bulb sprinklers use a brittle glass bulb containing a liquid and a small air bubble. As the liquid is expanded by heat the bubble is compressed and, finally, absorbed by the liquid. At this point, the pressure in the bulb rises rapidly and shatters the bulb to release the valve cap. (3) Frangible-pellet sprinklers use a fusible pellet in a cylinder containing a sliding plunger. When heated, the plug melts and the plunger moves to release the valve cap. Because solder (used in the first type) starts to lose its strength somewhat below its actual melting point, the maximum safe room temperature can be closer to the sprinkler's operating temperature in these last two types.

Temperature ratings

Temperature ratings of all soldered-link sprinklers are stamped on the link; for other types, temperature rating heads are used where room temperatures do not exceed 100° F (38° C), as in schools, hospitals, offices, hotels, and apartments, and if they are not exposed to direct rays of the sun. Intermediate ratings are used for ordinary occupancy in industrial and commercial properties. Higher ratings are specified in hotter areas, such as foundries, and in areas in which a fast-developing high-heat-release fire can be anticipated. This difference reduces the number of sprinklers that would otherwise operate outside the fire area.

**Water distribution.** The most widely used sprinkler (Figure 1) has a deflector that directs the water horizontally and downward in a uniform umbrella pattern. At a distance of four feet (1.2 metres) below the deflector, the spray covers a 16-foot- (4.8-metre-) diameter area when discharging at a rate of 15 gallons (57 litres) per minute. Other sprinklers for specialized uses include ceiling or flush-type sprinklers, whose minimum projection of working parts makes them suitable for installations in ceilings where appearance is important; sprinklers for corrosive conditions with protective wax coatings; picker trunk sprinklers with smooth deflectors that reduce collection of lint and fibre in such locations as air ducts; side-wall sprinklers used near the junction of walls and ceilings, equipped with a deflector that distributes the water toward one side in a quarter-sphere pattern; sprinklers without operating elements used in deluge systems in which the water supply is controlled by an independently actuated automatic-control valve; small and large orifice sprinklers used for special installations in which special discharge capacities are required; and the dry pendant automatic sprinkler with an extension nipple equipped with a valve at the top to prevent freezing because of condensation of water in the drop pipe; this type is also useful in a wet system in which sprinkler lines are extended to protect unheated areas.

Manually operated sprinklers

Manually operated sprinklers include window and cornice sprinklers that protect windows and combustible cornices against fire outside the building and full-release sprinklers designed to protect the interior of ducts, air filters, or other enclosed spaces.

**Fire-extinguishing equipment.** The simplest and oldest type of extinguisher is the pail, or bucket. A common assembly is a large covered cask or drum, holding 25 or 50 gallons (100 or 200 litres), and three buckets.

**Fire extinguishers.** Pump-type extinguishers are operated by pumping liquid from a tank. Chemical-reaction extinguishers, such as soda-acid and chemical foam, acquire their pressure from the chemical reaction; turning the unit over causes the chemicals to mix. Invert-and-bump extinguishers have a carbon dioxide cartridge that must be punctured to create pressure. After the unit is inverted it must be bumped on the floor to puncture the disk on the cartridge. Lever- or wheel-operated types use stored pressure from compressed air, carbon dioxide, nitrogen, or other gas. They are activated by a trigger, lever, or wheel that opens a valve or punctures a disk.

The type, size, number, and location of extinguishers is a matter of engineering judgment, involving the type of fire anticipated, including heat and smoke. Most modern buildings require more than one type of protection. A hospital, for example, needs Class A extinguishers for patients' rooms, corridors, and offices; Class B extinguishers in laboratories, kitchens, and in places where flammable anesthetics are used and stored; and Class C extinguishers to protect electrical switchgear or emergency-generator rooms. Class A and B extinguishers are normally located on walls (that are marked with a red square or other indication) in places that limit travel distance to reach them to about 75 feet (23 metres). In general, the area protected by each extinguisher does not exceed 3,000 square feet (about 300 square metres). For Class B exposures, the maximum travel distance is usually limited to 50 feet (15 metres).

**Fire engines and other motorized equipment.** In practically all modern communities, the basic fire-fighting ve-

hicle is the fire engine, a gasoline- or diesel-engine truck that carries hose, water tanks, pumps, ladders, and portable tools and other appliances. Normal life of motorized equipment is about 15 to 20 years, depending on use and maintenance. Normally a third or a fifth of the fire-fighting manpower is on duty at one time. Most cities keep extra equipment available for emergencies and as a reserve when first-line equipment is undergoing repairs or service. The four major standards to which fire apparatus throughout the world conform are National Fire Protection Association Standard No. 19 (North America), DIN-14530 Standard in West Germany, the British National Standards, and the National Fire Service Bureau in Japan. German and British fire-equipment manufacturers supply a large proportion of the world's equipment outside North America.

Apparatus-carrying pump trucks have pump capacities of up to 2,000 gallons (8,000 litres) per minute for high-hazard and industrial service. Most trucks carry a water tank for supplying water before hydrants or suction sources can be brought into use. Much hose is carried. (See discussion under *Hose and Transportable Equipment*, below.)

Ladder and rescue trucks are equipped with ladders, forcible-entry tools, generators, lights, and rescue equipment. Pumpers are positioned at the fire for best use of available water; rescue equipment is placed for most expedient use. About one-third of the labour at a fire is in truck and rescue work. Aerial-ladder units and elevating-platform trucks usually are employed for this service; their power-operated equipment reaches higher than manual ladders and can provide effective water-tower service. Besides aerial ladders, manually raised ladders, often aluminum, are also carried. A common arrangement is a booster pump, water tank, and small hose on an aerial-ladder truck. Less common is a pumper-ladder combination. Because pumpers of 1,000 gallons (4,000 litres) per minute capacity or larger seldom carry enough hose to use their capacity fully, some fire departments provide a hose truck or a second pumper with additional hose, called a hose-carrier wagon. Other fire departments have trucks carrying 5,000 feet (1,500 metres) or more of extra hose and heavy, water-stream equipment. Multiple lines often are required to bring enough water across a long distance. Two 2½-inch-diameter (64 millimetre) hoses will move 500 gallons (2,000 litres) per minute over 1,000 feet (300 metres).

Staff and command officers usually are provided with separate transportation in fire-chiefs' vehicles, equipped with warning lights and sirens, radio-communications equipment, protective clothing, water-distributions system, and with fire extinguishers and self-contained breathing apparatus.

In outlying areas, water-tank units, mobile water-supply apparatus, are commonly provided. Units have a pump for filling tanks, suitable discharge hose, manpower space, and a minimum of fire-fighting tools, in addition to their 1,000 to 1,500 gallon (4,000 to 6,000 litre) tank.

Fire trucks with hydraulically operated elevating-platform apparatus, sometimes called snorkels, have become standard equipment (see Figure 2). These vary from 50 to 90 feet (15 to 27 metres) maximum elevation. Equipped with a standpipe, they can throw an 800-gallon- (3,200-litre-) per-minute stream through one or more turret nozzles on the basket at the maximum elevation. Because they can lift a 700-pound (315-kilogram) load in addition to equipment normally carried on the boom or basket (such as emergency lights, short ladders, axes, and communications equipment), the units can be used to hoist men and equipment or for removing endangered persons. Controls are located in both the basket and at the turntable base. Most large fire departments use elevating platforms and aerial ladders as complementary equipment.

Hydraulically operated water towers, capable of elevating a nozzle at least 50 feet (15 metres) above ground level, can provide a stream of water up to 1,000 gallons (4,000 litres) per minute. Towers may be installed on pumpers or on squad (ladder and rescue) trucks.

Characteristics of snorkels

Figure 2: Elevated-platform fire apparatus, known as a snorkel, consisting of a hydraulically operated boom attached to a truck-mounted turntable and equipped with a turret nozzle.

By courtesy of the Seattle Fire Department

Specialized squad-truck units carry emergency equipment to supplement pump and ladder trucks. Crews are trained in emergency work as well as in general fire fighting. Units carry respiratory-protective equipment, resuscitation equipment, and first-aid and rescue equipment. Sometimes a pumping engine is used as the basic squad truck. Rescue trucks, usually completely enclosed, provide shelter for first-aid and emergency work during inclement weather and are manned by especially trained personnel. Trucks for forest, grass, and brush-fire control carry a water tank, water-type extinguishers, and much light-weight, small-diameter hose. Light plant or floodlight trucks carry a large-capacity electric generator, cables, flood and spot lights, and various power-operated tools. Such trucks usually are found only in the largest cities, because auxiliary lights are also carried on standard ladder trucks and on squad and rescue trucks. Salvage trucks are used in large cities to reduce water damage. Salvage equipment includes covers and runners (large pieces of canvas used to cover furnishings in a building to protect against water damage), sprinkler stoppers, brooms, shovels, squeegees, buckets, dewatering pumps, and sometimes smoke ejectors.

**Fireboats.** Fireboats (see Figure 3) vary from large seagoing tugs to fast, jet-propelled fire-rescue craft. Their principal services include protecting vessels in harbour; protecting piers and cargoes on the waterfront; protecting yacht basins and marinas; serving in marine rescue operations; acting as pumping stations for fires within reach of hose (often in combination with fireboat-tender trucks); and breaking ice in harbours and rivers.

Fireboats carry much the same equipment as motorized land equipment: pumps, ladders, and rescue equipment. In addition, they have considerable foam-making capacity and special extinguishing agents, such as carbon dioxide systems. Speed is a minimum of ten knots (ten nautical miles per hour); pumping capacity ranges from 500 gallons (2,000 litres) per minute for a very small craft, to over 10,000 gallons (40,000 litres) per minute.

**Airport trucks.** Airport crash trucks, used for aircraft rescue and fire-fighting service, are equipped with foam or other extinguishing agents. They are usually capable of providing continuous protection, for about five minutes, before backup apparatus arrives. These lightweight vehicles (up to about 8,000 pounds or 3,600 kilograms) are designed to reach the crash site quickly and get rescue operations started in a few seconds; the backup equipment, weighing up to 30 tons (27,000 kilograms) per vehicle, is designed and positioned to arrive before the crash trucks have exhausted their foam.

**Hose.** Fire hose is designed to be rugged and dependable, capable of carrying water under substantial pres-

Figure 3: Fireboat in action.

By courtesy of the U.S. Coast Guard

sure, yet flexible and easy to manage. Properly maintained hose lasts a minimum of ten years. After use, hose is dried thoroughly. Hose is usually tested annually, for three to five minutes at working pressures. The nozzle is closed so that the hose must take the full pressure.

Suction hose is used on the supply side of the pump. It is of larger diameter (two-and-one-half inches, or 63 millimetres, and up), furnished in ten-foot (three-metre) lengths, and reinforced to prevent collapse from atmospheric pressure. The cover is woven of mildew-resistant cotton, cotton polyester, or all polyester.

If infrequent use is anticipated, unlined linen hose may be provided on pin-racks inside buildings, and connected to wet standpipe systems. Unlined hose leaks water, which makes it useful in fighting forest fires. It has twice the pressure loss of rubber-lined hose. Lightweight rubber-lined hose is favoured for use inside buildings and in connection with sprinkler systems.

**Transportable equipment.** Other apparatus is carried on motorized equipment. Pumper trucks carry suction and fire hose of various size, such as 1,200 to 2,000 feet (360 to 600 metres) of double-jacket 2½-inch (63-millimetre) to four-inch (100-millimetre) large-diameter suction hose, 400 to 1,000 feet (120 to 300 metres) of 1½-inch (38-millimetre) hose, and 200 to 300 feet (60 to 90 metres) of three-quarter-inch (18 millimetre) or one-inch (25-millimetre) hose, if reels are provided. The 1½-inch and smaller hoses are for use inside buildings. Solid-stream, spray, or combination nozzles are also carried. A monitor nozzle can be attached to two or three hoses to combine their output in situations where additional "throw" is required; and a distributor nozzle, which produces a powerful stream of water for use in cellars or roof spaces, and a bayonet nozzle for directing a thin stream of water behind a plaster wall may be included. Various tools and fittings for connecting to hydrants and nozzles and for handling hose are carried.

Rescue equipment includes a first-aid kit, wool blankets, and self-contained breathing units. Lighting and power equipment and portable extinguishers also are carried. In rural areas, back-pack manual pumps, rakes, and long-handled pointed shovels may be carried. Salvage equipment described above, may also be carried.

Ladder trucks, so-called because ladders are their most prominent feature, carry a large inventory of equipment, including axes, shovels, picks, rope, pitchforks, six- to sixteen-foot (two- to five-metre) pike poles, sledges, battering rams, bolt and wire cutters, hydraulic spreaders, power saws and blades, blocks and tackles, hooks, gas

Uses of  
unlined  
hose

Ladder-  
rescue  
equipment

and water shut-off wrenches, and a complete assortment of hand tools. Considerable rescue equipment is also carried, including stretchers; a resuscitator; a life gun (for firing lifelines 100 to 650 feet, or 30 to 195 metres, for water rescue); a life net; and pompier, or scaling, ladders that can be hooked over window sills. The crew is especially trained for search and rescue service and the use of self-contained breathing apparatus and gas masks.

All trucks carry portable Class A, B, and C extinguishers. A small pump and hose is often carried. Emergency electric power (at least 2,000 watts), floodlights, and cables are standard equipment.

Ladders are available in many types: folding; pompier; roof; wall; and extension ladders from 16 to 45 feet (5 to 15 metres) in length and from two- to six-man capacity. Ladder steps are designed for placement of the ladder at a distance from the building of one-fourth the distance from the base to the top support.

Nozzles are available for spray or straight stream for one-inch (25-millimetre), 1½-inch (37-millimetre), and 2½-inch (63-millimetre) hose and in a variety of other special types with various flow characteristics. Adjustable, combination, and high-pressure spray nozzles are used, in addition to monitor and other nozzles already described, depending on the specific type needed and the amount and pressure of the water supply. Hose couplings have been standardized by national or other authorities. Where fittings require it, adapters are added to the couplings.

Smoke ejectors are used to move smoke and blow in fresh air in order to reduce smoke damage from minor fires. Heat and flames from large fires can sometimes be channelled through a smoke ejector if this seems advisable. Smoke ejectors are of at least 5000 cubic feet (140 cubic metres) per minute capacity.

**Fire-extinguishing agents.** These include foaming agents, wetting agents, fog, carbon dioxide, dry chemical systems, Halons, and steam and inert-gas systems.

**Foaming agents.** Foam apparatus may be fixed or portable and may be automatically or manually operated. Discharge rates vary from low to high volume; the larger systems are employed to protect areas in which paint, oil, or asphalt is used. Foam systems can extinguish oil-tank fires by subsurface injection of foam that rises both to cool and smother the fire. Shutting off the fuel supply as quickly as possible is important.

There are two types of foam: chemical and mechanical. Chemical foam is formed by a chemical reaction in which masses of bubbles of carbon dioxide gas and a foaming agent produce an expanded froth. There are four general types of equipment: self-contained units; closed generators; hopper generators; and stored-solution systems. The self-contained unit has two solutions, both stored separately and mixed before use. Closed generators have chemical-foam powder stored in large hoppers. When the hopper is opened, the powder is added to a generator that mixes it with water to make foam, which is forced through outlets. It is used mainly on flammable-liquid storage-tank farms, where a single foam-making unit can service a number of tanks. Hopper generators, either permanent or portable, permit continuous refilling if needed. Lines or towers permit foam application to burning oil-storage tanks. Stored-solution systems have large, permanently installed tanks that contain two foam-producing solutions stored separately. To make foam, pumps force the solution to outlets where they mix and discharge as foam.

Mechanical foam is made by adding a liquid concentrate to water in a 2 to 6 percent (by volume) ratio and by then mixing air into the solution. These concentrates are of two types: protein and nonprotein, or synthetic. Protein types (especially the fluoroproteins) are used to put out fires of hydrocarbon compounds such as oil or gasoline. They can be used with a special stabilizer on substances such as alcohol and ether, which mix with water. Nonprotein compounds, similar to synthetic detergents, are proportionately fed to water flowing through a hose. The proportion can be varied to create foam or foamless liquid as needed. Nonprotein compounds are

used to extinguish certain types of alcohol fires against which unstabilized protein foam is ineffective. Low in viscosity, these compounds spread quickly over the surfaces of burning liquids. They are not effective against burning liquefied petroleum gas and are not recommended for class A (ordinary) combustibles or class C (electrical) fires.

High-expansion foam uses wetting agents in ratios from 100 to 1 to as high as 1,000 to 1, with a very low water content. This foam is mechanical; *i.e.*, it is formed by passing air or other gas through a screen wetted by an aqueous solution or surface-active (acting to reduce the surface tension of a liquid) foaming agent. Principally a smothering agent, it is used to fight fires in inaccessible places such as coal mines and on ships, as well as in ordinary combustibles. It causes minimum water damage. It is not recommended for petroleum fires.

**Wetting agents.** Wet water contains a chemical that reduces its surface tension, thereby increasing its penetrating, spreading, and emulsifying properties and, thus, its cooling ability. It can be applied as a liquid or as a foam. As a clinging foam it is often used to protect structures from exposure fires (which might spread from a structure that is already burning), the foam acting as an insulating blanket. As heat breaks down the foam, hot water flows away from the protected surface. If a fluorochemical wetting agent (*i.e.*, one containing the element fluorine) is used to make the foam, the foam can be used on certain flammable liquids. Known as light water, this substance was developed by the U.S. Navy.

Slippery water is formed when a polyethylene oxide polymer is added to water in a proportion of 30 pounds per 120,000 gallons (13.5 kilograms per 480,000 litres). It flows more smoothly than ordinary water at high velocity; by reducing friction, slippery water increases the capacity of small-diameter hose.

Tests in Great Britain indicate that the time required for sprayed-on foam to extinguish a fire is reduced by polyolefin plastic balls floating on the surface of a flammable liquid in a tank. In addition to inhibiting evaporation of the flammable liquid, these plastic balls permit the foam layer to form more easily once it is applied to the burning tank.

Ablative water is formed by mixing water with additives, usually high-molecular-weight polymers, which convert it into a thick film that flows like honey, egg white, or even wet sand. Much thicker than foam, these films provide more insulation and act in a manner similar to the ablators (heat shields) on spacecraft that char, consuming thermal energy as they decompose.

**Fog.** Conventional sprinklers deliver a rather coarse spray, but with a special head a fog pattern can be developed. Flame is a burning vapour or gas about one-third thousandth the weight of water and sometimes only a fraction of an inch or a few millimetres thick. The amount of heat that water will absorb depends on the amount of water surface in contact with the fire. The more droplets that the water divides into, the more surface produced for a given amount of liquid water. Water fog is quickly evaporated by flame or superheated air. Because a small amount of water can be made to vapourize into a large volume of steam, a fire can be extinguished both by cooling and by smothering, with very little water damage to premises.

Fog nozzles have been tested and found suitable for use on electrical-equipment fires. At a minimum distance of ten feet (three metres), equipment up to 25,000 volts can be protected. Fog is also effective in controlling oil fires, which a conventional stream might stir into a fiercer blaze. Fog nozzles protect fire-fighting personnel who might be entering a gas fire to shut off a valve, by providing a curtain of water, and they neither kick under high pressure nor whip if dropped.

**Carbon dioxide.** Carbon dioxide systems are used to protect areas in which water must not be used, areas in which fire can be extinguished by diluting the oxygen, and areas containing electrical equipment, flammable materials, or hazardous processes. The compressed gas is stored in high-pressure cylinders at normal temperature,

water

Foam-  
powder  
hoppers

Liquid  
carbon  
dioxide

or in an insulated pressure vessel kept at 0° F (−18° C) so that pressure can be reduced. Low-pressure systems permit storage of large quantities more economically than high-pressure systems. Liquid carbon dioxide is delivered through pipelines to nozzles that can deliver up to 2,500 pounds (1,125 kilograms) per minute. Release may be manual or automatic but is delayed until integral warning alarms alert persons working in the area. After a fire is extinguished, the area must be ventilated thoroughly because there may not be sufficient oxygen present to sustain life. Fixed tanks of carbon dioxide with hose reels permit a limited range of fire fighting. Some units may be transported by hand trucks. Hand units are available for small electrical and laboratory fires. Care must be taken not to spray a hot steam line with carbon dioxide, because the sudden chilling could rupture the line.

**Dry-chemical systems.** Dry-chemical piped systems quickly extinguish flammable liquid or electrical fires; they are operated either automatically or manually. Extinguishing action results mainly from the chemical agent's interruption of the flame chain reaction. (See COMBUSTION AND FLAME.) This chemical agent usually is a powdered mixture of sodium or potassium bicarbonate or ammonium phosphate base chemical. Potassium chloride (KCl) and KCl/urea are also used against flammable liquid and electrical fires, except where delicate electrical contacts are present. Ammonium phosphate also is suitable for fires of ordinary combustible materials. Dry chemicals are designed to be stored in a tank that is pressurized by an inert-gas cylinder or in a pressurized container. Dry-chemical systems can also be mounted on vehicles or in portable extinguishers. The dense stream of a dry chemical has a range of six to 15 feet (two to 4½ metres). The portable extinguisher takes ten to 17 seconds to discharge. Wheeled and stationary units require from 30 to 90 seconds.

**Dry powder.** Designed to extinguish burning metal, such as magnesium, alkali metals, or nuclear-reactor fuel metals, dry powder is usually dispensed by a special extinguisher or can be simply applied with a shovel. No single powder is successful on all metal fires. G-1 powder, graded granular graphite with organic phosphate added to improve effectiveness, one of the oldest approved powders, is used against magnesium and magnesium-alloy fires and is applied with a scoop. Met-L-X, sodium chloride (common salt) with tricalcium phosphate added to improve flow characteristics and metal stearates for water repellency, is used in pressurized extinguishers from 30- to 2,000-pound (12.5- to 900-kilogram) capacity on sodium, potassium, sodium-potassium alloy, and magnesium fires. X-8, a dry granulated shale-like material mixed with pitch or tar and crystalline ammonium chloride, is effective on almost all combustible metals. Other materials include dry sand, talc, asbestos powder, powdered limestone, graphite powder, and sodium carbonate (soda ash).

Powders  
for metal  
fires

**Halons.** Halons, or halogenated hydrocarbons, are created when methane or ethane have some or all of their hydrogen atoms replaced with atoms of halogen elements such as bromine, chlorine, or fluorine, which change them from flammable substances to fire-extinguishing agents. Chemically they resemble the higher-molecular-weight fluorocarbons used for refrigerants and plastics (e.g., Teflon). The presence of fluorine in a molecule usually increases its inertness and stability; other halogen elements, particularly bromine, increase its fire extinguishing effectiveness. These compounds extinguish a fire by inhibiting the flame chain reaction and ion formation. The U.S. Army Corps of Engineers devised a system for numbering the Halon compounds, which is used worldwide. The first digit of each identifying number represents the number of carbon atoms in the molecule; the second digit, the number of fluorine atoms; the third, the number of chlorine atoms; the fourth, the number of bromine atoms; and the fifth, the number of iodine atoms. Terminal zeros are dropped. Any atoms unaccounted for are hydrogen.

All the Halons are either vapourizing liquids or liquefied

gases at room temperature. A very large number exist, but only seven are of importance:

Halon 104 (carbon tetrachloride) appeared in fire extinguishers in the U.S. and Europe early in the 20th century. Unfortunately, the vapours are highly toxic; also, when exposed to flame or hot metal, it can form phosgene, a poisonous gas. Halon 104 is no longer approved as a fire-extinguishing agent for general use.

Halon 1001 was used during World War II by both the United Kingdom and the United States in fixed systems protecting engine nacelles (enclosed shelters for the engine of an aircraft), and aircraft wheel wells. It is extremely toxic, and is not approved for general use.

Halon 1011 is seldom used because it endangers life in places from which people can not evacuate quickly, or in which operators of extinguishing equipment can not avoid the vapours. Developed in Germany during World War II, its present major use is for extinguishing ground and aircraft-engine fires under well-ventilated conditions.

Halon 1211 has been used in Europe and Australia since 1955. It is approved for use in both fixed and portable equipment by governmental authorities in the United Kingdom, The Netherlands, Germany, Switzerland, Australia, and some other countries.

Halon 1202 has been used in only a few types of applications, including fixed systems on aircraft.

Halon 1301, a promising agent to eliminate the smoke and heat damage of a fire, has been used as the agent in explosion-suppression systems, in full-flooding systems where both Class A and Class B fire hazards are present, in museums and libraries, as well as in some passenger aircraft.

It is a liquefied gas, extinguishing in extremely low concentration; only 3.3 percent by volume in air is required to put out a butane fire. Properly used, it has no harmful effects, and if detection is early enough, it acts rapidly. Halon 1301 is quite expensive, but is about 10 times more efficient than carbon dioxide.

Halon 2402, used in Italy and other countries, has proved effective in combination with foam or dry-chemical agents. A vapourizing liquid, it can be expelled as a liquid stream. The higher density of its vapours generates an inhibiting atmosphere that renders flashbacks or re-ignition unlikely.

**Steam and inert gas.** Automatic or manually controlled steam-jet systems are used to smother fires in small rooms or in closed containers such as heaters, drying kilns, smokehouses, asphalt-mixing tanks, and drying-cleaning tumbler dryers. These systems require a large supply of steam and pose a personal-injury hazard from burns.

Inert gas is used to replace a specified percentage of the oxygen in air; carbon dioxide, nitrogen, helium, argon, or flue gas (gases resulting from combustion in a furnace, mostly nitrogen, carbon dioxide, and water vapour) may be used. Depending on the type of combustible material involved and the type of inerting gas used, the amount of oxygen is reduced from about 21 percent to between 2 and 16 percent. The system is used to prevent gas, vapour, or dust fires and explosions, because when the oxygen content of the atmosphere is less than 16 percent, many common materials will not burn.

## FIRE DEPARTMENT ORGANIZATION AROUND THE WORLD

In Paris, the Brigade des Sapeurs-Pompiers, founded in 1811 by Napoleon I, looks after the fire protection needs of the entire metropolitan area of about 6,000,000 persons. Marseilles has 640 marine fire fighters, administered by the navy. The rest of France is divided into sectors, each having a maximum radius of about 7½ miles or about 11 kilometres, covered by about 3,600 paid firemen and 236,000 volunteers. West Germany has 59 professional fire brigades with a total of more than 12,000 men; these cover the central areas of cities greater than 100,000 population. There are also 23,500 voluntary fire brigades with about 775,000 men and 500 work brigades with about 15,000 men. A major activity of city fire departments in West Germany is ambulance service. Every fire fighter is trained in first aid, and most fire sta-

tions have at least one ambulance. Italy has a single national fire service (Corpo Nazionale-Vigili del Fuoco) of 8,500 paid and 17,000 to 20,000 part-time and volunteer fire fighters. These are organized into 92 provincial commands, coordinated by inspectors from 12 regional centres. These centres have mobile units that can cope with large-scale disasters. In the United Kingdom, the fire service is placed under the authority of 146 counties, boroughs, and special districts—all under the supervision of the Chief Inspector of Fire Services. There are about 23,500 fully paid personnel, helped by about 17,000 part-time fire fighters. Eighteen of Switzerland's 22 cantons have fire-police forces and official fire-insurance establishments. Professional fire brigades exist in six cities. There are about 220,000 fire fighters, paid, volunteer, and industrial. In Denmark, local authorities responsible for municipal fire protection can contract with private firms for fire fighting service; the firms are supervised by the national Ministry of Justice. Forty-four towns and 800 rural communities have contracts; 60 towns have municipal fire brigades.

In the Russian Soviet Federated Socialist Republic, one of 15 republics that make up the Soviet Union, which contains a little more than half of the entire country's population and covers about 17,000,000 square kilometres, there are 72 administrative regions, each with a council controlling a fire-protection department, which administers both paid and volunteer fire brigades.

The Soviets stress fire prevention. As a result, the number of fires per thousand population is a small fraction of the number in the United Kingdom and the United States. The Soviet people are deluged with fire-protection propaganda. The reasoning is that with state ownership, it is only good citizenship to protect communal property. Schools often have their own fire brigades, and children are encouraged to join junior brigades outside of school in which they are provided with helmets, uniforms, belts, and badges—even a fire engine with hose (and an adult driver).

The Melbourne, Australia, Metropolitan Fire Brigade has 45 fire stations and more than 1240 officers and men to protect 353 square miles of land and a population of 2,350,000. The remainder of the state of Victoria is protected by the Country Fire Authority, headquartered at Malvern. One of the greatest problems in Australia is grass and forest fires, especially in midsummer (January through March). Great efforts are made to combat this menace.

Japan has 43 regional and three metropolitan fire departments under national supervision, staffed with about 35,000 paid fire fighters; 9,200 part-time, industrial fire fighters; and 1,600,000 volunteers. Fire Prevention Week is in November, at the start of the dry season. Hong Kong has a severe fresh water shortage, aggravated by hilly terrains that cause water-pressure problems even where sufficient water is present. Hence, fire departments must often pump seawater onto fires.

Fire protection of life and property in Canada is a provincial or territorial government responsibility. Fire marshals or commissioners are appointed by these governments and are responsible for all property within their respective areas of jurisdiction, with the exception of properties under the administration and control of the federal government, which are the responsibility of the Dominion Fire Commissioner (except for national defense and aircraft-crash fire fighting). The Canada Emergency Measures Organization has developed a proposed fire defense plan for use in the event of a nuclear emergency.

In the United States, fire protection is under local jurisdiction. It is estimated that there are 25,000 fire departments, operating approximately 110,000 pumpers and 10,000 aerial ladder and elevating platform trucks. There are approximately 250,000 full-time professional fire fighters and about 1,250,000 volunteers and paid-on-call men. In 1971, there were 147 colleges and universities offering 200 programs in fire service education. Approximately 13,700 students were enrolled.

All industrial countries have extensive facilities for

training professional fire fighters. Several weeks or months of indoctrination for recruits are followed by continued in-service study by all fire fighters, practical fire training of units on special grounds or on condemned structures, or courses for command personnel working toward promotion. Germany provides full college engineering training for ranking officers. The Soviet Union has fire technical schools at Moscow and Leningrad in which full-time students receive about 4,000 hours of instruction, about half of which is practical work. Sweden has a Fire Service College; Denmark, a school in Charlottenlund; and London has a fire-brigade training centre in which 16-year-old boys are given a two-year course covering all phases of fire-brigade activity. Yugoslavia's Workers' University offers a two-year work-school course in safety engineering, which includes fire protection.

#### FIRE-FIGHTING TECHNIQUES

Alarms received by the devices described earlier, and direct calls for help are quickly transmitted. Mobile teleprinters and computers are now being used for dispatching. Volunteer or off-duty personnel are called when needed. The location and nature of the fire must be determined quickly, and the proper agencies and manpower mobilized; many fire-fighting forces have regional mobilization and mutual-aid plans worked out in advance. Once a fire starts, the key factor is time.

In cities, a full-time, professional fire-fighting force is available. In rural and sparsely populated areas, however, volunteer fire departments, composed of local residents who serve when needed, are formed. When a fire alarm is received, these volunteers assemble at the scene. To contact them, radio is generally used. If possible, each volunteer fire fighter carries a small, portable radio receiver, tuned to pick up fire calls. When an alarm is received, the radio sounds a loud alerting tone followed by a voice message stating the location of the fire. Telephone hookups have also been developed in which a single telephone call alerts all volunteers.

*Urban fires.* Though operational plans vary, in most cities of the world the safe response to a fire in a low-hazard (well-spaced) residential area is at least three pieces of equipment: two pumpers and either a ladder, squad, or rescue unit. For fires in larger structures, including schools, at least double this minimum response is needed. In high-hazard business or industrial districts, an additional task force is required to attack the rear of the structure and to reduce the possibility of exposure fires in adjoining structures. Additional pumpers and tanks may also be called.

After a fire situation is surveyed, rescue operations commence. Prompt placement of hose streams and ladders is essential. The next steps are to reduce exposure, confine and extinguish the fire, and to assure that the fire does not rekindle. Ventilation and salvage may be required at any time. The first areas attacked are those that threaten adjoining structures. A coordinated attack from front and rear is usually made.

Communications at the scene of a fire are effected by means of hand signals, loudspeakers, rope signals, and two-way radio. When the noise level is high, hand signals may be preferred to loudspeakers. Rope signals are employed when two or more men (often rescue workers) are connected together by means of a life line. Two-way portable radio is used also; some firms offer such devices fitted into the face masks of life-support equipment. Mobile repeater units are used to relay messages from men inside a building or in a "dead spot." Fire departments also install two-way radios in their trucks for communications with headquarters.

Fires generally are controlled by applying cooling agents to absorb heat or reduce fuel temperatures and by using insulating agents to separate the fuel from the oxygen, smothering the fire. Because heated gases expand and are lighter than air, fires set up thermal columns that can move with drafts or air currents. As combustion products rise, air (oxygen) is drawn to the base of the fire. The unburned vapours rise with the heat and smoke

Training facilities

Alerting volunteer firemen

Over-  
and-under  
operation

and spread or mushroom at the highest level. If fire continues without ventilation, heat and smoke may bank down and fill the entire structure to a point where introduction of oxygen in large amounts can cause a smoke (particulate and vapour) explosion and an intense fire. For this reason, most structural fires are fought by the over-and-under method that involves both ventilation to prevent smoke buildup and hoses placed at the top level of the fire to prevent further upward or horizontal expansion. The main attack comes from below the fire; the front entrance and the main stairway are usually the first attack positions for hose lines. Control of the stairs provides access to the building and a means for rescuing occupants. If the fire is on the lower floor, the aim is to prevent it from moving upstairs; on the upper floors, advantage is taken of the cooler air beneath it.

It usually is bad practice to attack a fire from the outside if interior positions are tenable; such action hinders the advance of crews working inside and may drive the fires into other areas and endanger occupants.

When a fire is in a basement or on a lower floor, the over-and-under operation is important, because lines are needed above the fire to prevent upward extension while other lines move in to extinguish it.

*Fires in sparsely populated areas.* Rural properties usually are quite combustible; they are seldom subject to adequate building and fire-prevention regulations. The fires can be devastating; distance and limited water supplies compound the problem. In addition to the customary fire-company apparatus, response equipment often includes water-tank trucks and portable pumps for placement at ponds, cisterns, and other static water sources. Normally, at least two fire companies will respond, if possible.

Grass, bush, and forest fires involve two types of response. When protected by an organized fire department, such fires usually are handled by the same units that do structural fire fighting. In prolonged dry, windy weather, additional personnel may be mobilized. Special apparatus may include patrol cars with small water tanks and pumps, tankers, bulldozers, reserve water tanks, and small hose. Some communities use aircraft. Backpack units for personnel often are carried on pumpers and trucks for use on grass and brush fires.

Outdoor fires are seasonal, influenced by weather conditions. They present one of the chief hazards in thousands of communities, where dwellings are located in areas with extremely combustible ground cover; combustible roofs often add to the problem.

Woodland-area fires usually are the responsibility of national, state or provincial, and private forest-fire protection agencies. Some districts have mutual-assistance pacts with nearby municipal fire departments. Forestry agencies commonly use labour crews directed by skilled foresters. Crews use lightweight, small-capacity hose and portable pumps, hand tools for cutting and trenching fire lines, and back fires (fires started to check an advancing fire by clearing the area) as controls. Fire-retardant materials, such as bentonite clay and chemical solutions, are used for maintaining fire lines. Fire-retardant slurries (water mixtures) can be dumped from aircraft.

Modern forest-fire-fighting techniques include a carefully organized chain of command, preplanned supply services, aerial reconnaissance, frequent issuance of fire-line maps, and coordinated communications.

Patrols and lookout towers are used during fire seasons to spot incipient fires. Aerial reconnaissance and air drops of fire fighters and equipment are used in rural areas. Evacuation plans are made for residents of woodland areas. Fire trails are maintained along ridges, in valleys, and at other places requiring special access. Fires spread very rapidly up slopes, however, and unpredictably in shifting winds, limiting the value of trails as firebreaks.

*Extinguishing fires in space vehicles and pressure chambers.* Until the Apollo tragedy of January 1967 in which three United States astronauts lost their lives, pressure chambers and chambers with oxygen-rich atmospheres did not include special fire-protection systems or

strict control of combustibles within the chamber. High-pressure chambers have become common in medical, space, and underwater research. Two problems complicate fire-fighting in such environments. First, rapid escape is impossible; a person brought rapidly from high pressure to normal atmospheric pressure is in serious danger from decompression sickness. Second, the combustion rate of materials increases as air pressure increases; materials only slightly combustible under normal atmospheric pressure ignite and burn under high pressure. As in ordinary fire situations, the best protection is prevention. Construction specifications call for sealed electrical circuits, water-turbine motors, minimum electrical wiring in the chamber, and fire-retardant finishes and plastics. Electric motors and combustible materials are kept out of the chamber. Spark-inducing clothing, instruments, or other sources of static electricity are not permitted in the chamber. Workers in the units are trained for emergencies.

Sprinkler systems for such chambers are pressurized to 65 pounds per square inch (29 kilograms per square centimetre) above the pressure in the chamber, and the system is designed to activate within one second. Under pressure, the spray pattern from sprinkler heads is smaller than under atmospheric pressure, even though flow is about the same; usually at least twice as many sprinklers are needed. When sprinklers are actuated, electricity is shut off in the chamber and emergency battery-powered lights go on. The water storage tank has a capacity about double that required to extinguish a fire in any one chamber. For oxygen-enriched atmospheres, water-spray is also effective.

Tests of fires in zero-gravity conditions have demonstrated that ordinary convection (rise) of hot combustion products ceases completely. Ignition of combustibles occurs in a manner similar to that at normal gravity, but the products of combustion refuse to vacate the site of burning, and no new oxygen can displace the combustion gases. Further combustion is starved to a point of self-extinction of the fuel.

## Fiscal and Monetary Policy

Government measures to stabilize the economy

The term fiscal and monetary policy refers to the various measures that governments may take to stabilize their economies at high levels of employment and output. Fiscal policy relates to taxes and expenditures; monetary policy has to do with the financial markets and with the supply of credit, money, and other financial assets. The essential idea is that in a capitalistic economy the public authorities may take action to increase or decrease the level of employment and output and to influence the trend of prices.

**Tools of fiscal policy.** In discussing fiscal policy it is useful to distinguish between actions that affect government spending and those that bear upon revenues. The government may, for example, increase its expenditure on equipment, buildings, public services, or social security. This will tend to have an expansionary effect on the economy through higher investment and consumption. The government may also achieve an expansionary effect through action on the revenue side of the budget; i.e., by reducing taxes. It may reduce personal income taxes or indirect taxes such as sales taxes; alternatively, it may seek to stimulate investment by giving tax abatements to firms that invest—by reducing indirect taxes on capital goods such as machinery and building or by liberalizing depreciation allowances in corporation income taxation.

Correspondingly, when economic activity is at a high level, with a rapid rate of price increase, the government may slow it down by reversing the above measures: by reducing government spending, by increasing taxes, or by stiffening the rules for depreciation allowances.

**Tools of monetary policy.** Another way to manage the aggregate level of demand is to influence conditions in financial markets. In time of unemployment the central bank may stimulate private investment expenditure, and possibly also household spending on consumer goods, by reducing interest rates and taking measures to increase the supply of credit, liquid assets, and money. The customary tools for doing this are: (1) open market operations, (2) the discount rate of the central bank, and (3) reserve requirements for the commercial banks.

In open market operations the central bank buys government securities—bonds and treasury bills—from the private sector. The effect is to reduce interest rates by bidding up bond prices. The sellers of the government securities obtain cash which they deposit in the banks, thus increasing the cash reserves of the banks and enabling them to expand credit to private borrowers; this in turn causes interest rates in the private sector to fall and the terms of credit to become easier. In response, firms are likely to increase their investment expenditures, and households are likely to spend more on consumer goods.

The second tool of monetary policy, often used together with open market operations, is the discount rate of the central bank. This is the interest rate at which commercial banks can borrow funds from the central bank. If the discount rate is reduced, banks become more willing to extend credit to private borrowers because they can obtain funds themselves on easier terms. In many countries, changes in the discount rate tend to be followed by similar changes in the interest rates charged by banks to their borrowers.

The third tool of monetary policy is that of the cash reserve requirements, or liquid asset ratios, under which the banks must maintain money balances (in the form of deposits in the central bank) at a certain proportion of their liabilities. This means that the banks cannot expand their earning assets, such as government securities and private loans, beyond that point. If the government reduces the reserve requirements, the banks can expand their loans further, thus increasing the total volume of credit outstanding. In some countries the required reserves consist of money deposits plus certain types of government securities.

Monetary policy, like fiscal policy, may also be used to combat inflationary tendencies by reversing the above measures: the central bank will then sell government securities (thereby increasing interest rates and reducing the supply of private credit and money), raise the discount rate, or increase reserve requirements.

**Conflicts in fiscal and monetary policy.** The problems of stabilizing an economy are much more complex than the foregoing discussion would suggest. The reason for this is that stabilization involves the pursuit of more than one goal—including not only full employment but reasonably stable prices and an equilibrium in the balance of foreign payments. Measures that help to achieve one may sometimes hinder the achievement of another. Conflicts may also arise between the overall aim of stabilization and other economic aims such as improved income distribution, better allocation of resources, or special political considerations.

The two most obvious conflicts in stabilization policy in recent decades have been the conflict between full employment and price stability and the conflict between domestic policy objectives (the "internal balance") and the balance of payments (the "external balance"). Some of the efforts made to reduce these conflicts are discussed below.

### THE ORIGIN OF COMPENSATORY FISCAL AND MONETARY POLICY

The use of fiscal and monetary policy as a means of stabilizing the economy is relatively recent, for the most part a development of the period after World War II. During the 19th century the only stabilization policy was that associated with the international gold standard. Under the gold standard, if a deficit occurred in a country's balance of payments, gold tended to flow out of the country. To counteract this process, the monetary authorities would raise interest rates and stiffen credit requirements, causing a fall in prices, income, and employment; this in turn led to a reduction in imports and an expansion of exports, thus improving the balance of payments. If a country had a surplus in its balance of payments, gold tended to flow in; this meant that the interest rate fell and the supply of money and credit was increased. As a consequence, imports were stimulated and exports discouraged so that the surplus in the balance of payments tended to disappear. The adjustment mechanism also included another important element: capital movements between countries. When interest rates fell in surplus countries and rose in deficit countries, mobile international financial capital tended to flow from the former to the latter, contributing to the elimination of deficits and surpluses in the balance of payments. The working of this mechanism was partly automatic and partly the result of deliberate actions by the monetary authorities in each country.

In this form of stabilization policy, external stability was achieved at the cost of stability in the domestic economy: fluctuations in domestic prices, incomes, and employment functioned as the levers for bringing about equilibrium in the balance of payments. Occasionally governments attempted to reduce the impact of this mechanism on the domestic economy, particularly on the price level. In particular, governments in some surplus countries took "sterilization actions" to prevent the gold inflow from increasing the supply of money and credit to the maximum extent. This could be done if the central bank offset its purchases of foreign exchange

The complexity of the problems

and 1930s

and gold with sales of government securities on the domestic credit market.

A somewhat more ambitious type of stabilization policy emerged in the period after World War I. During the late 1920s and early 1930s the need to reduce unemployment acquired more urgency. Previously, the exchange rate, the balance of payments, and occasionally the price level had been considered more important than the situation in the labour market. During the 1920s unemployment in Great Britain rose to very high levels (between 20 and 30 percent of the labour force). Consequently, there was much discussion of whether employment could be increased by actions of the public authorities. At first, the discussion in Great Britain centred on the feasibility of public works programs as a means of putting men to work, but there was a growing belief that public works programs might also be a good means of raising the general level of economic activity through their effect on purchasing power. Some also maintained that budget deficits (*i.e.*, a policy of expanding government expenditure without raising taxes to cover it) would also raise the level of economic activity. An active part in this discussion was taken by the economist J.M. Keynes, and also by the Liberal Party, which in 1928 published its proposals for government intervention under the title *Britain's Industrial Future*.

The first countries to adopt the new policies were Sweden and Germany. When the Nazi Party took power in Germany in 1933, its rearmament policies helped to reduce unemployment and to stimulate the economy. In Sweden, the new Social Democratic government attempted in more modest ways to expand the economy and ease unemployment through increased government expenditures in 1932–33. In the United States, some very limited attempts were made by the administrations of Presidents Herbert Hoover and Franklin D. Roosevelt; they were too slight, however, to have any significant effect on unemployment, which persisted at a high level until World War II.

The work  
of J.M.  
Keynes

#### THE THEORETICAL BASIS OF FISCAL AND MONETARY POLICY

The new stabilization policy needed a theoretical rationale if it was ever to win general acceptance from the leaders of public opinion. The main credit for providing this belongs to J.M. Keynes. In his *General Theory of Employment, Interest and Money* (1936) he endeavoured to show that a capitalist economy with its decentralized market system does not automatically generate full employment and stable prices and that governments should pursue deliberate stabilization policies. There has been much controversy among economists over the substance and meaning of Keynes's theoretical contribution. Essentially, he argued that high levels of unemployment might persist indefinitely unless governments took monetary and fiscal action. At that time he believed that fiscal action was likely to be more effective than monetary measures. In the deep depression of the 1930s, interest rates had ceased to exert much influence on the ways in which wealth owners disposed of their funds; they might choose to hold larger cash balances instead of spending more money as the traditional theory had suggested. Nor were investors inclined to take advantage of low interest rates if they could not find profitable uses for borrowed funds, particularly if their firms were already suffering from excess capacity. Keynes's pessimistic view of monetary policy had a strong influence on economists and governments during and immediately after World War II, with the result that monetary policy was not tried very much during the 1940s. It was often forgotten during the policy discussions of the time that Keynes's views on the efficacy of monetary policy were related to the particular situation of the 1930s.

Another influential idea embodied in Keynes's writing was that of economic stagnation. He suggested that in the advanced industrial countries people tended to save more as their incomes grew larger and that private consumption tended to be a smaller and smaller part of the national income. This implied that investment would have to take a continually larger share of the national

income in order to maintain full employment. Since he doubted that investment would rise sufficiently to do this, Keynes was rather pessimistic about the possibility of achieving full employment in the long run. He thus suggested that there might be some permanent tendency to high levels of unemployment. This also had considerable influence on economic policy during the early postwar period; it was some time before those in decision-making positions realized that inflation, rather than stagnation and unemployment, was to be the main problem confronting them.

The desirability of government policies to maintain high levels of employment was generally accepted in most industrial countries after the war. In 1944 the British government stated in its White Paper on Employment Policy that "the government accept as one of their primary aims and responsibilities the maintenance of a high and stable level of employment after the war." One of the most influential British economists at this time was Sir William Beveridge, whose book *Full Employment in a Free Society* had a strong impact on general thinking. Similar ideas were expressed in the United States in the Employment Act of 1946, which stated: "The Congress hereby declares that it is the continuing policy and responsibility of the Federal Government to . . . promote maximum employment, production and purchasing power." The Employment Act was less specific as to policy than the British government's White Paper, but it established a council of economic advisers to assist the president and called upon him to present to every regular session of congress a report on the state of the economy. The president was also required to present a program showing "ways and means of promoting a high level of employment and production." Similar programs were adopted in other countries. In Sweden in 1944 the Social Democrats published a document somewhat similar to the British White Paper, and other such declarations were made in Canada and Australia.

#### EXPERIENCE IN VARIOUS COUNTRIES

The application of full-employment policies after World War II was made more difficult by the fact that the post-war situation was radically different from that of the 1930s, when much of the policy thinking had been done. Most governments and their advisers expected a depression after the war, but it never materialized. One explanation is that the reallocation of resources from military to civilian uses proceeded much more smoothly than had been expected. Another explanation is that the consumers spent a considerably larger part of their disposable income than they had been observed to do in the 1930s; this upset some of the sophisticated statistical projections based on empirical data from those years. A third explanation, which applies perhaps to the years after 1948, was the Cold War between the United States and the Soviet Union, which raised defense spending in many countries.

The period of the late 1940s and early 1950s proved to be characterized by tendencies to inflation rather than to unemployment. Governments were slow to realize this and to shift their emphasis from employment-creating policies to anti-inflationary policies. The fact that governments had accepted to a large extent the belief that monetary policy was not very important made it difficult for them to combat the tendencies to inflation. In most countries a very passive, even expansionary, monetary policy was in effect; interest rates were kept down and the supply of money was allowed to grow faster than would have been consistent with stable prices. Inflationary tendencies were further stimulated by the Korean War and the great increases in raw material prices that accompanied it.

During the 1950s several important developments influenced the attitudes of governments toward stabilization policy. Most of the economic controls engendered by the war were removed, particularly in international trade and finance. The western European countries found themselves in a period of rapid economic growth. With the removal of direct controls on prices, imports, and

monetary  
policy

building investment, governments began to develop and refine the tools of monetary and fiscal policy. In most countries the passive attitude toward monetary policy disappeared during the early 1950s; there was increased interest in more flexible monetary management. Interest also grew in developing a systematic fiscal policy that would offset the cyclical swings in production and employment. The most energetic attempts to devise a countercyclical fiscal policy were made in Britain and Sweden. The United States and continental European countries placed more reliance on monetary policy.

In the United States, a contributing factor in the revival of monetary policy was a theoretical reformulation that took place among monetary and banking experts. This was the so-called availability theory of credit: that monetary policy had its effect on spending not only directly through interest rates but also by restricting the general availability of credit and liquid funds. It was argued that even rather small changes in the rate of interest for government securities could have a considerable impact on the supply of private credit; if the supply diminished, this would induce banks and other financial institutions to stiffen their credit standards and ration credit to their customers; this in turn, it was argued, would tend to curb investment and thus have a braking effect on the economy. Similar ideas were at work in other countries, but with more emphasis on limiting the availability of credit through credit rationing, loan ceilings, control of private bond issues, regulation of installment credit for the purchase of durable consumer goods, and so on.

Serious attempts have been made to put a countercyclical monetary policy into practice in most advanced industrialized countries since the middle of the 1950s. In some, such as the United States, the emphasis has been, as suggested above, on changes in the interest rate and in the supply of money and credit; in others, such as France, Italy, and Japan, the emphasis has been on the rationing of credit by the central bank.

Fiscal policy has found less use than monetary policy in efforts to control cyclical fluctuations in the economy. It has been most favoured in Britain, the Scandinavian countries, and the Netherlands. One can point to specific situations in which fiscal measures have been used to stimulate the economy in other countries, as in Belgium and Germany during the recessions of 1958 and 1962. Another example is the postponement of certain military expenditures in the United States as an anti-inflationary measure during the boom of the mid-1950s, and most notably of all, the tax cut passed by Congress in 1964 on the recommendation of the Council of Economic Advisers as a stimulus to economic expansion. Several countries have taken restrictive fiscal actions to overcome balance-of-payments crises, including France and Finland on various occasions. During the 1960s there was an increasing tendency to employ fiscal policies in the short run, partly in order to assist monetary policy in the solving of cyclical problems.

#### PROBLEMS AND CONTROVERSIES

Discretionary and automatic policies

One may make a broad distinction between two types of stabilization policies: discretionary and automatic. Discretionary policies involve deliberate actions taken by the authorities, such as open market operations, changes in discount rates and reserve requirements, and changes in tax rates or government expenditures. Automatic policies put reliance on built-in stabilizers that function without any deliberate intervention by the authorities. In the monetary field, for example, an increase in commodity prices tends to reduce the real value of financial assets, and if the government does nothing to offset this by increasing the volume of financial assets in the system, private spending will tend to decline. On the fiscal side, the main automatic stabilizer is the relation between tax revenues and cyclical changes in the economy: during booms, tax revenues will rise and the need for expenditures on unemployment compensation will decrease, channelling a larger proportion of the national income into government coffers; these effects are accentuated if the tax system is progressive (*i.e.*, if tax rates are pro-

portionately higher on higher incomes), because tax revenues will rise more rapidly than money incomes. Provided that the government does not raise its expenditures along with the increased revenues, the budget will tend to have a braking effect on private expenditure in boom times; correspondingly, it will have an expansionary effect in times of recession.

**The problem of time lags.** There has been much discussion over the merits of discretionary policies as against automatic stabilizers. One advantage ascribed to automatic stabilizers is that the effects occur without the necessity of any deliberate policy action by the government, which means that there will be no delay because of political controversies, administrative problems, or difficulties in determining whether the time has come to act. The problem of delay, or lag, requires further elaboration. It is usual to distinguish three types of lag in economic policy: the recognition lag, the decision lag, and the effect lag.

The recognition lag is the time it takes for the authorities to discover the need to make a change in economic policy. The reasons for this type of lag are that statistical information is often somewhat behind the event, and that it is sometimes difficult to distinguish between random fluctuations and fundamental shifts in economic trends. Governments prefer to wait until there is certainty that, say, an increase in unemployment is not a passing thing.

The decision lag is the period between the time when the need for action is recognized and the time when action is taken. Although the recognition lag is presumably of about the same duration for both monetary and fiscal policies, the decision lag is usually considerably shorter for monetary policy than for fiscal policy. The central bank can change monetary policy almost overnight, whereas a change in fiscal policy is more complex, both politically and administratively. In many countries changes in income taxes, for example, can be made only at the beginning of a calendar year; such changes are often complicated by political discussions in the nation's legislative body. The recognition lag and the decision lag are sometimes called together the inside lag of economic policy; that is, the lag resulting from delays within the political and administrative machinery.

The third lag, the effect lag, may be called the outside lag because it results from factors outside the policy-making machinery. The duration of this lag will vary. Monetary policy is thought to involve longer delays than fiscal policy; the length of time between a change in monetary policy and its ultimate effect on private investment may be between one and two years.

Some economists argue that the sum of all the lags is so long that the best strategy is not to take any action at all, since by the time the effects occur the economic situation may be radically different from that which the action was designed to correct. Attempts have been made in various countries to shorten the lags in fiscal and monetary policy. One obvious way of reducing the recognition lag is to improve the techniques of forecasting. This has been achieved to some extent by more sophisticated methods of collecting and interpreting economic information; an example is the development of questionnaires for finding out what businesses plan to invest in buildings, machinery, and inventories, and how much consumers intend to spend on durable goods. Another example is the construction of elaborate econometric models consisting of mathematical equations that describe the relationships among different parts of the economy. These have become more practical with the development of electronic computers, and in some countries they are in common use to forecast business conditions in the immediate future.

In order to reduce the decision lag in fiscal policy, attempts have been made in some countries to give the authorities power to take limited action without the prior consent of the legislature. In Britain, the government has the power to change tax rates on durable consumer goods within certain limits. In Belgium and West Germany, the governments also have some discretionary

Difficulties of implementing policy

powers to change tax rates without first asking the legislature. In most countries, however, the legislative bodies have been reluctant to give up their control of the budget.

Attempts to shorten the effect lag of fiscal policy have produced some new policy tools. Some countries now use systems of taxes or subsidies to influence business investment within a relatively short time. Sweden has reduced the effect lag in this sphere to less than a year. Attempts have also been made to reduce the effect lag in monetary policy. Some countries have tried to speed things up by using various tools of credit rationing rather than relying on traditional measures such as open market operations. But the effect lag still constitutes a serious problem for monetary policy.

The multiplicity of goals

**Conflicts among goals.** Perhaps the most serious unsolved problem of stabilization policy is the multiplicity of goals that policy makers must consider. Every government has aims other than stabilizing the economy. First, it must stay in power—a need that is likely to limit the alternatives open to stabilization policy, particularly in periods of prosperity immediately before elections, when it is very difficult to take restrictive measures, such as raising taxes. Second, some monetary and fiscal actions impinge heavily on particular groups in society, and governments may wish to avoid what appear to be discriminatory policies. Third, the goal of stabilization comprises in itself several different goals, such as full employment, price stability, and equilibrium in the balance of payments. A policy designed to achieve one of these goals may prevent the achievement of another.

**Full employment and price stability.** The conflict between full employment and price stability seems to arise in two different sets of circumstances. Sometimes wage increases that are made in the normal collective bargaining process are greater than the increases in labour productivity (or output per man-hour); such wage increases tend to increase the cost of production and to force prices upward. The government is then confronted with a choice between two unpleasant alternatives. One is to allow the general price level to rise approximately in proportion to the increase in production costs; the other alternative is to try to hold prices down by taking measures to restrict aggregate demand, thus making it difficult for firms to shift their increased costs to the consumer through higher prices. The latter alternative means increased unemployment. Many governments have been confronted with exactly this choice of alternatives. Wage gains made in collective bargaining have forced them to choose between allowing prices to move upward or attempting to hold prices stable at the cost of greater unemployment.

Another reason for the conflict between full employment and price stability is the tendency of wage increases to accelerate when the level of unemployment falls and the number of job vacancies increases. In other words, as the economy approaches full employment wages tend to rise at an increasing speed. (This is the so-called Phillips' curve problem, named after the British economist A.W. Phillips, who was the first to demonstrate statistically the correlation between the level of unemployment and the rate of wage change.) As prices begin to rise, the conflict between full employment and price stability may be further exacerbated by the expectation that they will rise still further; this may, for example, induce employees and their organizations to press for greater wage increases than they otherwise would in order to compensate for the expected price increases.

**The balance of payments and price stability.** Another conflict in policy may arise with respect to the balance of payments. When the economy is in a period of boom, there is a tendency for imports to increase, and sometimes for exports to decrease as well, with obvious difficulties for the balance of payments. The crisis may be heightened by short-term capital movements if buyers and sellers of foreign exchange expect that there may be a devaluation of the country's currency. This has caused much difficulty for many countries in the period since World War II. In Britain and Denmark, notably, periods of boom have usually been accompanied by balance-of-

payments problems. When that occurs, the government must sooner or later take restrictive actions that slow the economy down and increase unemployment; if speculation in the currency is already under way, it may be necessary to pursue the restrictive policy far into the next recession. The problem is accentuated if there have been substantial price increases during the boom that have reduced the country's ability to compete with other countries. It is ironic that a temporary improvement in the employment situation may, if it leads to an accelerated increase in the price level, serve to create greater unemployment in the future, when restrictive actions become necessary for balance-of-payments reasons.

**Incomes policy.** Attempts have been made to eliminate these conflicts of policy. One remedy that has been widely discussed is "incomes policy," meaning direct efforts by the government to prevent employers and unions from raising prices and wages. Various methods have been tried. The most moderate is the so-called guideposts system, under which the government announces the need for restraints on wage increases and perhaps also sets targets to guide unions and management; this was attempted in the United States in the early 1960s. In some countries, responsibility for limiting wage increases has been assigned to labour-management organizations, as in Sweden, where bargaining takes place in a very centralized fashion. A more interventionist approach is for the government to enter the bargaining process and try to persuade unions to limit their wage demands. The government may go still further and announce a wage freeze, or even a system of wage and price control. In The Netherlands and Australia, the courts have occasionally been empowered to set wages; but the resulting decisions have often been rather uncoordinated with the rest of stabilization policy.

Incomes policies have sometimes succeeded for short periods. Generally, however, public refusal to accept the restraints has eventually led to their collapse. In the United States, the guideposts broke down during the boom of the mid-1960s, and attempts at incomes policy in Sweden and Britain have not been notable. Even in The Netherlands and Australia the system has failed in recent years to limit the rate of wage increase.

**The question of governmental competence.** Governments have displayed serious deficiencies in their ability to handle stabilization policy. Political leaders often lack economic information and understanding, and their economic advisers find it difficult to explain the economic situation to them and to apprise them of the relevant tools. There are also, as pointed out above, a variety of political inhibitions against taking action. One consequence is that what is designed to be a countercyclical policy becomes a procyclical one; instead of stabilizing the economy it tends to destabilize it. The postwar experience in Britain is held by some to demonstrate the deficiencies of government in handling monetary and fiscal policy. In time of boom the government often followed an expansionary course; when a balance-of-payments crisis developed it then took restrictive action—too late—and pushed the economy into deeper recession than would otherwise have occurred. On the basis of this experience, some economists have argued that a policy that did not attempt to counter the short-run swings in the economy would have been more successful in achieving stabilization. They maintain that the authorities should concentrate on the goal of letting the volume of money and credit increase steadily at a rate dictated by the long-term growth trend of the economy. Those who hold this view believe that capitalist economies are inherently stable, that crises are usually the result of bad policies on the part of the public authorities. Most economists do not share their optimism as to the stability of the economy if left alone; they continue to believe that governments must seek better tools for the purpose of short-run stabilization.

Efforts to control inflation

#### RECENT DEVELOPMENTS

The study of fiscal and monetary policy has become increasingly subtle. It has been established, for example,

The  
various  
effects of  
budget  
deficits

that the size of the budget surplus or deficit is not a good criterion of its effects on the economy. Quite different types of fiscal action may produce the same surplus or deficit, but they will not have the same effects on the economy. Thus a tax increase for poor households will have a different effect than a tax increase for high income groups; and an expenditure on government purchases of goods and services will have a different effect than a tax reduction of the same amount for corporations, even though both may produce the same budget deficit. In short, one cannot cite changes in the size of the budget surplus or deficit as an indication of whether its effects are expansionary or not.

Attempts have been made to appraise budgets in terms of what their effect on the economy would be at high levels of employment. Thus a "full-employment surplus" means that a particular budget would show a surplus if the economy were at full employment, although in fact the budget may be in deficit. The importance of this is that it enables the authorities to distinguish between a budget deficit that will have an expansionary effect in the present state of the economy and one that simply reflects a low level of economic activity.

Selective  
fiscal  
policy

Fiscal policy in recent years has tended to become more selective than formerly, largely because most Western economies have been operating much of the time at levels close to full employment. It is not unusual to have full employment, or even labour shortages, in some sectors of the economy at the same time that there is unemployment in other sectors. The fiscal approach to this problem is to stimulate the economy in areas where there is unused capacity, perhaps through subsidies or tax reductions, and to constrain it in other areas.

Another problem for stabilization policy is the discovery that immediately following a boom there may be a continuing tendency for prices to rise, despite the fact that unemployment is increasing. This has been manifest in a number of countries, most notably perhaps in Britain and the United States at the end of the 1960s. The rate of increase in the price level seems to reach its maximum about 12 to 18 months after the peak of the business cycle. This complicates stabilization policy considerably. It emphasizes the need to check the boom at an early stage in order to avoid price increases in the forthcoming recession.

There has been considerable discussion as to whether the conflict between full employment and the balance of payments might not be reduced by a system of freely fluctuating exchange rates. It is argued that allowing exchange rates to move freely would automatically bring about equilibrium in the balance of payments, whatever the internal situation. On the other hand, such flexibility might make it more difficult to maintain stable prices; a deficit in the balance of payments during a boom would immediately be reflected in a depreciated currency, and this might tend to push prices up because of the higher costs of imported goods. At the same time, fixed exchange rates may also be incompatible with price stability. At fixed exchange rates, international price changes are automatically transmitted to the domestic economy. There is a problem, then, whether the exchange rate should be used mainly to equilibrate the balance of payments, in which case freely fluctuating rates would be appropriate, or to shield the domestic economy from international price changes and to stabilize the domestic price level. In the latter case a flexible exchange-rate policy that would allow for discretionary changes in the exchange rate would be appropriate.

**BIBLIOGRAPHY.** Surveys of the principles of fiscal and monetary policy may be found in standard textbooks on economics. The works listed below are more specialized.

## Fischer von Erlach, Johann Bernhard

Johann Bernhard Fischer von Erlach, architect, sculptor, and architectural historian, inaugurated the style that came to be known as Austrian Baroque, leaving a legacy of significant buildings, notably in Vienna and Salzburg, and in the Habsburg dominions. The development of this artistic style coincided with the rise of the Habsburg Empire after its victories over the Turks at the end of the 17th century. Taking his elements from the architecture of ancient Rome, from that of the Renaissance, as well as from Italian, French, and English Baroque architecture, Fischer created a new style by a lofty intellectual and formal synthesis. His buildings can be considered "total works of art" in which architecture and the figurative arts are united to express a predominant idea—the glorification of God or the patron saint in ecclesiastical architecture; or the allegorical glorification of the ruler or of the noble patron in secular buildings. Not only were they a source of inspiration for later Austrian and south German architects but they also provided the setting in which Austrian Baroque painting and sculpture could unfold.

**Early career in Italy.** Son of a provincial sculptor and turner, Fischer was baptized July 20, 1656, at Graz, Austria. After a craftsman's training in his father's workshop, he went to Rome when he was about 16 years old. He had the good fortune to enter the studio of the great Baroque sculptor and architect Gian Lorenzo Bernini, where he learned the art of designing and making medals as well. In 1679 and 1682 he received his first known commissions as a medallist. In Rome he came into close contact with the circle of archaeologists and antiquarians around Queen Christina of Sweden, who had converted to Roman Catholicism, abdicated, and then settled in Rome. From that association he acquired considerable knowledge of ancient art and of the scientific methods then beginning to be used in archaeology—methods that formed the basis for his own later archaeological reconstructions. He also studied ancient Roman, Renaissance, and Baroque art and architecture and the architectural theory of those periods. About 1684 he went to Naples, then under Spanish rule, probably in the service of the Spanish viceroy. He is reported to have been very active there and even to have acquired considerable wealth, although exactly what work he did is not known.

**Return to Austria.** After some 16 successful years in Italy, Fischer returned to his homeland at an opportune time; after the imperial victories over the Turks, the Habsburg Empire was emerging as a great European power, and the emperor Leopold I wished to emulate King Louis XIV of France by representing his power as an absolute monarch visibly in magnificent buildings. The aristocracy followed his example by erecting splendid palaces, and the Catholic clergy, too, wanted to glorify the victory over the infidel as well as that over the Reformation in ecclesiastical architecture. Moreover, the Turks had destroyed many country seats of the aristocracy and had severely damaged the suburbs of Vienna during the siege of 1683. The need for new buildings as well as the quick economic recovery following the victories brought about a great increase in building and a resultant flowering of art and architecture. In 1687 Fischer embarked on a brilliant career as court architect to three successive emperors, Leopold I, Joseph I, and Charles VI, and also designed buildings for the aristocracy and the Archbishop of Salzburg. In 1689 Leopold I appointed him to teach his elder son, Joseph, perspective and the

to three  
emperors

theory and history of architecture. In 1690 Fischer won public recognition with two temporary triumphal arches erected in Vienna to celebrate Joseph's entry into the city after his coronation as king and future ruler of the Holy Roman Empire in Frankfurt am Main. During the next ten years, Fischer was much sought after as an architect in Vienna and Salzburg and in the Habsburg lands. In 1693 alone he had 14 important buildings in hand; at the same time he was also producing sculpture and designing for the decorative arts—notably goldsmiths' work.

**Fischer's early innovations in secular architecture.** During these years he created a new type of country house, combining the most important achievements in suburban architecture since the 16th century. He united the ideas of the French Baroque country palace made up of many joined pavilions with that of the classically inspired Renaissance villa, typical of Andrea Palladio, surrounded by low detached wings. By using the powerful curving forms of the Roman Baroque architects, especially Bernini, he gave his villas a more dynamic form. One of their outstanding features is the spacious oval hall in the centre of the plan, as in Schloss Neuwaldegg, near Vienna, and in Schloss Engelhartstetten, in Lower Austria. Fischer's country house designs had a decisive influence on the architects of his time. In a similar synthesis of Roman and French Baroque seasoned with Palladian elements, he also created a new type of town palace characterized by impressive form, structural clarity, and the dynamic tension of its decoration. The Winter Palace of Prince Eugene of Savoy, begun in 1695, and the palace of the ban of Croatia, Count Batthyány, begun in 1699, both in Vienna, are notable examples of this type.

The most important of Fischer's palace designs, however, remained unexecuted: his first project for Schönbrunn Palace on a hill near Vienna. His plan was for an enormous residence befitting the ruler of the Holy Roman Empire; it would have surpassed all previous palaces, even Versailles, by combining and harmonizing features from all of them. Fischer deeply regretted the fact that he was allowed to build only a much smaller palace in the valley below, the Schönbrunn Palace of today, begun in 1696 and later radically altered under Maria Theresa.

**Ecclesiastical architecture for the Archbishop of Salzburg.** As architect to Johann Ernst, Graf von Thun, the Archbishop of Salzburg, Fischer displayed his talent in church architecture and town planning. The domes and towers of his churches changed the whole appearance of Salzburg. In their exquisitely proportioned, lofty interiors he tried to achieve a balance between the longitudinal and central schemes, a problem all great church architects had been faced with since Michelangelo's projects for St. Peter's in Rome. All of Fischer's churches have two-towered facades accented by dynamic curves and elegant decoration, but each has its own special quality, determined by its location and by its particular function, as attached to a seminary, a university, or a nunnery. The elegant concave facade of Holy Trinity Church, for example, contrasts to and heightens the effect of the sober front of the adjoining seminary buildings. The almost geometric forms of the University Church surmounted by the undulating forms of its towers crown the university complex, providing a new architectural and symbolic accent to a city dominated by its massive cathedral, as Salzburg had been. Fischer also designed a new facade for the Archbishop's stables and laid out a square in front of it. He changed an old quarry into a summer riding school and built the Archbishop's summer residence, Schloss Klesheim, outside Salzburg.

**Foreign travels and change of style.** At the turn of the 18th century Fischer was at the height of his career. In a visible sign of his success as a court architect, he was raised to the nobility in 1696. The imperial alliance with Prussia, Holland, and England during the War of the Spanish Succession enabled Fischer, in 1704, to visit those countries and to study their architecture, particularly in relation to Palladio. The result was a remarkable change in his architectural style. In 1707 he went to Venice to study Palladian architecture at its source. The

result was his development of a new type of "Palladian" palace facade, classical in its proportions but enlivened with richly sculptured decoration. It consists of a central projection accentuated by a giant order and surmounted by a triangular pediment, and of relatively unarticulated lateral sections. Its models were English and North German Baroque interpretations of Palladian architecture as well as the works of Palladio himself and of his Italian followers. Fischer's most important achievements in this field are the facades of the Bohemian Chancellery and Trautson Palace, both in Vienna, and of the Clam-Gallas Palace, in Prague, which were imitated by architects all over the Habsburg Empire.

During the first ten years of the 18th century, however, Fischer designed fewer buildings than in the years before. His time was taken up by his administrative duties as chief inspector of court buildings and his work on a great history of architecture, *Entwurf einer historischen Architektur*. His book, which reveals the wide range of his learning, was the first comparative history of the architecture of all times and all nations; it included significant specimens of Egyptian, Persian, Greek, Roman, Muslim, Indian, and Chinese architecture, illustrated by engravings with explanatory notes. Some of the archaeological reconstructions that appeared in the book were among the best of Fischer's time. At the end of the historical survey he placed his own achievements, which he saw as a logical continuation of the Roman tradition of architecture. The book was published in 1721.

**Final projects.** When his second imperial patron, Joseph I, died in 1711, Fischer's position as the principal architect at the Viennese court was no longer uncontested. Many preferred the more pleasing and less demanding architecture of his rival Johann Lucas von Hildebrandt to Fischer's lofty conceptions. Yet he was also able to gain the favour of Charles VI, to whom he dedicated his history of architecture in manuscript in 1712, and to obtain commissions for the greatest architectural undertakings in Vienna—the rebuilding of the imperial palace and the building of the Karlskirche (Church of St. Charles Borromeo).

Charles had vowed to build the Karlskirche as an offering to his patron saint for the city's deliverance from an epidemic of the plague. In its imperial grandeur the building Fischer conceived not only glorified St. Charles but was also a monument to the Emperor himself. In this church he attempted to incorporate and harmonize the main ideas contained in the most important sacred buildings of past and present, beginning with the Temple of Jerusalem and including the Pantheon and St. Peter's in Rome, the Hagia Sophia in Istanbul, and also the Dôme des Invalides in Paris and St. Paul's in London. The relatively independent parts of the building—a pair of Roman triumphal columns, low towers, a high oval dome, a central portico modelled after a Roman temple facade, a transept and presbytery—are harmonized to form a visual unity from whatever point they are seen. The complex formal and symbolic structure of the building is the result of its twofold function. For example, the most striking feature of the church, the pair of giant triumphal columns on either side of the portico, is decorated with spiral reliefs glorifying the life of St. Charles. The pair of columns, however, also alludes to the Emperor's emblem, the "pillars of Hercules." As the last Habsburg king of Spain, Charles had in vain dreamed of establishing a worldwide monarchy by uniting the crowns of Spain and the Empire. Yet the columns of the Karlskirche bear the crown of Spain at their summits, flanked by eagles, the heraldic bird of the Holy Roman Empire.

Fischer did not live to see his masterpiece completed. He died in Vienna, on April 5, 1723. His son Joseph Emanuel Fischer von Erlach completed the church with some alterations. He also completed the Imperial Stables and built, according to his father's designs, the Imperial Library, the interior of which was the most imposing library hall of its time.

**Fischer's significance.** The form of Fischer's architecture is determined by its function. Each single form conveys not only aesthetic value but also a symbolic

The  
Karls-  
kirche  
of Vienna

Fischer's  
imprint on  
Salzburg

meaning. Fischer looked to the already existing great works of similar function to find a new, even unique, solution for each task, the best of all possible solutions. All of his works are composed of several different elements or contrasting features that are harmonized in a unified whole and in reference to their natural and artistic environment.

Fischer's contemporaries admired his genius in inaugurating a new artistic period. His strongly individual architectural solutions, however, could neither be taught nor imitated. Only those works which introduced new general types, such as the country houses and palace facades, had a direct influence on the architecture of the period. The universality of his architectural conceptions has been recognized only recently.

#### MAJOR WORKS

**ARCHITECTURE:** Hall of the Ancestors, Frain Castle (1688–95; Vranov nad Dyji, Czechoslovakia); Stratmann Palace (1692–93; Vienna); Schloss Neuwaldegg (1692–97; Vienna); high altar of Pilgrimage Church (1692–1704; Mariazell, Austria); summer riding school, north facade, and horse pond of the Archbishop's stables (1690–94; Salzburg); Schloss Engelhartstetten (Niederweiden; c. 1693; Austria); Dreifaltigkeitskirche (Church of the Holy Trinity and Priests' House; 1694–1702; Salzburg); Johannesspital and Johanneskirche (Hospital and Church of St. John the Baptist; before 1695–1704; Salzburg); Winter Palace of Prince Eugene of Savoy (1695–1700; Vienna); Kollegienkirche (University Church; 1696–1707; Salzburg); Schönbrunn Palace (1696–1711; Vienna); Ursulinenkirche (Ursuline Church; 1699–1705; Salzburg); Batthyány Palace (1699–1706; Vienna); Schloss Klesheim (1700–09; near Salzburg); high altar of Franziskanerkirche (Franciscan Church; 1708–09; Salzburg); Bohemian Chancellery (1708–14; Vienna); Trautson Palace (1710–16; Vienna); Clam-Gallas Palace (begun 1713; Prague); Karlskirche (Church of St. Charles Borromeo; begun 1715; Vienna); Elector's Chapel in Cathedral (1715–21; Wrocław, Poland); Nationalbibliothek (Imperial Library; designed in 1716, built 1723–37 by Fischer's son in Vienna); Hofstallungen (Imperial Stables; 1719–23; Vienna).

**WRITINGS:** *Entwurf einer historischen Architektur* (1721; *A Plan of Civil and Historical Architecture*, 1730).

**BIBLIOGRAPHY.** The most comprehensive account of Fischer and his work is H. SEDLMAYR, *Johann Bernhard Fischer von Erlach* (1956), a German monograph with catalogue raisonné and bibliography. H. AURENHAMMER, *J.B. Fischer von Erlach* (in prep.), a briefer English monograph with a complete list of works and a bibliography, also includes the material and literature published during and after the commemorative exhibition of 1956. G. KUNOTH, *Die historische Architektur Fischers von Erlach* (1956), is a study devoted to Fischer's history of art and its sources.

(Ha.A.)

## Fish

The term fish is applied to a variety of cold-blooded aquatic vertebrates of several evolutionary lines. It describes a life form, rather than a taxonomic group. Modern fishes represent about five classes, as distinct from each other as the four classes of familiar air breathing animals, amphibians, reptiles, birds, and mammals.

The study of fishes, the science of ichthyology, affects everyone although most are not directly aware of it. There are many reasons why fishes are of interest to man, but the most important, his relationship with and dependence on the environment, is not always immediately apparent. A more obvious reason for interest in fishes is their role as a moderate but important part of man's food supply. This resource, once thought unlimited, is now realized to be quite finite, and in delicate balance with the biological, chemical, and physical factors of the aquatic environment. Overfishing, pollution, and alteration of the environment are the chief enemies of proper fisheries management, both in fresh waters and in the ocean. For a detailed discussion of the technology and economics of fisheries, see **FISHING, COMMERCIAL**. Another practical reason for studying fishes is their use in disease control. As predators on mosquito larvae, they help curb malaria and other mosquito-borne diseases.

Fishes are valuable laboratory animals in many aspects of medical and biological research. The readiness of

many fishes to acclimate to captivity has allowed biologists to study behaviour, physiology, and even ecology under relatively natural conditions. In the study of animal behaviour, especially, fishes have provided a broad base for the understanding of the more flexible behaviour of the higher vertebrates.

There are aesthetic and recreational reasons for an interest in fishes. At least 5,000,000 people in the United States alone keep live fishes in their homes for the simple pleasure of observing the beauty and behaviour of animals not otherwise familiar to them. To many, aquarium fishes provide a personal challenge, allowing them to test their ability to keep a small, beautiful section of the natural environment in their often extremely artificial homes. Sport fishing is another way of enjoying the natural environment, also indulged in by millions of people every year. Interest in aquarium fishes and sport fishing support multimillion-dollar industries throughout the world.

#### GENERAL FEATURES

**Structural diversity.** Fishes have been in existence for over 450,000,000 years, during which time they have evolved repeatedly to fit into almost every conceivable type of aquatic habitat. In a sense, land vertebrates are simply highly modified fishes, for when fishes colonized the land habitat they became tetrapod (four-legged) land vertebrates. The popular conception of a fish as a slippery, streamlined aquatic animal that possesses fins and breathes by gills applies to many fishes, but far more fishes deviate from that conception than conform to it. The body is elongate in many forms, greatly shortened in others; it is flattened in some (principally in bottom-dwelling fishes) and laterally compressed in many others; the fins may be elaborately extended, forming intricate shapes, or they may be reduced or even lost; the positions of the mouth, eyes, nostrils, and gill openings vary widely. Air breathers have appeared in several evolutionary lines.

Many fishes are cryptically coloured and shaped, closely matching their respective environments; others are among the most brilliantly coloured of all organisms, with a wide range of hues, often of striking intensity, on a single individual. The brilliance of pigments may be enhanced by the surface structure of the fish, so that it almost seems to glow. A number of unrelated fishes have actual light-producing organs. Many fishes are able to alter their coloration, some for the purpose of camouflage, others for the enhancement of behavioral signals.

Fishes range in adult length from less than 10 millimetres (2/5 inches) to more than 20 metres (60 feet) and in weight from about 1.5 grams (0.05 ounces) to about 4,000 kilograms (8,000 pounds). Some live in shallow thermal springs at temperatures slightly above 42° C (100° F), others in cold Arctic seas a few degrees below 0° C (32° F) or in cold deep waters more than 10,000 metres (3,500 feet) beneath the ocean surface. The structural and, especially, the physiological adapta-

tions for life at such extremes are relatively poorly known and provide the scientifically curious with great incentive for study.

**Distribution and abundance.** Almost all bodies of natural water on the earth bear fish life, exceptions being very hot thermal ponds and extremely salt-alkaline lakes such as the Dead Sea and Great Salt Lake in Utah. The present distribution of fishes is a result of the geological history and development of the earth as well as the ability of fishes to undergo evolutionary change and to adapt to the available habitats. Fishes may be seen to be distributed according to habitat and according to geographical area. Major habitat differences are marine and fresh waters. For the most part the fishes in them, even in adjacent areas, are different, but some, such as the salmon, migrate from one to the other. The freshwater habitat may be seen to be of many kinds. Fishes found in mountain torrents, Arctic lakes, tropical lakes, temperate streams, and tropical rivers will all differ from each other both in obvious gross structure and in physiological attributes. Even in closely adjacent habitats where, for example, a tropical mountain torrent enters a lowland stream, the fish fauna will differ. Marine habitats can be divided into deep ocean floors (benthic), midwater oceanic (bathypelagic), surface oceanic (pelagic), rocky coast, sandy coast, muddy shores, bays, estuaries, and others. Also, for example, rocky coastal shores in tropical and temperate regions will have a different fish fauna, even when such habitats occur along the same coastline.

Although much is known about the present geographical distribution of fishes, far less is known how that distribution came about. Many parts of the fish fauna of the fresh waters of North America and Eurasia are related and undoubtedly have a common origin. The faunas of Africa and South America are related, extremely old, and probably an expression of the drifting apart of the two continents. The fauna of southern Asia is related to that of central Asia and some of it appears to have entered Africa. The extremely large shore fish faunas of the Indian and tropical Pacific oceans comprise a related complex, but the tropical shore fauna of the Atlantic, although containing Indo-Pacific components, is relatively limited and probably younger. The Arctic and Antarctic marine faunas are quite different from each other. The shore fauna of the North Pacific is quite distinct, and that of the North Atlantic more limited and probably younger. Pelagic oceanic fishes, especially those in deep waters, are similar the world over, showing little geographical isolation in terms of family groups. The deep oceanic habitat is very much the same throughout the world, but species differences do exist, showing geographical areas determined by oceanic currents.

#### NATURAL HISTORY

**Life history.** All aspects of the life of a fish are closely correlated with adaptation to the total environment, physical, chemical, and biological. In studies of fish life, all the interdependent aspects of their life such as behaviour, locomotion, reproduction, and physical and physiological characteristics must be taken into account.

Correlated with their adaptation to an extremely wide variety of habitats is the extremely wide variety of life cycles that fishes display. The great majority hatch from relatively small eggs a few days to several weeks or more after the eggs are scattered in the water. Newly hatched young are still partially undeveloped and are called larvae until body structures such as fins, skeleton, and some organs are fully formed. Larval life is often very short, usually less than a few weeks, but it can be very long, some lampreys continuing as larvae for at least five years. Young and larval fishes, before reaching sexual maturity, must grow considerably, and their small size and other factors often dictate that they live in a habitat different than that of the adults. For example, some tropical marine shore fishes have pelagic larvae. Larval food also is different and they often live in shallow, more protected waters.

After the fish reaches adult size, the length of its life is subject to many factors, such as innate rates of aging, predation pressure, and the nature of the local climate. The longevity of a species in the protected environment of an aquarium may have nothing to do with how long members of that species live in the wild. Many small fishes live only one to three years at the most. In a few large species some individuals may live as long as 10 or 20 years or even longer.

**Behaviour.** Fish behaviour is a complicated and varied subject. As in almost all animals with a central nervous system, the nature of a response of an individual fish to stimuli from its environment depends upon the inherited characteristics of its nervous system, on what it has learned from past experience, and on the nature of the stimuli. Compared with the variety of human responses, however, that of a fish is stereotyped, not subject to much modification by "thought" or learning, and investigators must guard against anthropomorphic interpretations of fish behaviour.

Fishes perceive the world around them by the usual senses of sight, smell, hearing, touch, and taste, and by special lateral-line water-current detectors. In the few fishes that generate electric fields, a process that might best be called electrolocation aids in perception. One or another of these senses often is emphasized at the expense of others depending upon the fish's other adaptations. In fishes with large eyes the sense of smell may be reduced; others, with small eyes, hunt and feed primarily by smell (*e.g.*, some eels).

Specialized behaviour is primarily concerned with the three most important activities in the fish's life: feeding, reproduction, and escape from enemies. Schooling behaviour of sardines on the high seas, for instance, is largely a protective device to avoid enemies, but it is also associated with and modified by their breeding and feeding requirements. Predatory fishes are most often solitary, lying in wait to dart suddenly after their prey, a kind of locomotion impossible for beaked parrot fishes, which feed on coral, swimming in small groups from one coral head to the next.

**Sleep** in fishes, all of which lack true eyelids, consists of a seemingly listless state in which the fish maintains its balance but moves slowly. If attacked or disturbed most can dart away. A few kinds of fishes lie on the bottom to sleep. Most catfishes, some loaches, some eels and electric fishes are strictly nocturnal, being active and hunting for food during the night and retiring during the day to holes, thick vegetation, or other protective parts of the environment.

Communication between members of a species or between members of two or more species often is extremely important, especially in breeding behaviour (see below *Reproduction*). The mode of communication may be visual, as between the small so-called cleaner fish and a large fish of a very different species. The larger fish often allows the cleaner to enter its mouth to remove gill parasites. The cleaner is recognized by its distinctive colour and actions and therefore is not eaten, even if the larger fish is normally a predator.

**Locomotion.** Many fishes have a streamlined body and swim freely in the open water. Fish locomotion is closely correlated with habitat and ecological niche (the general position of the animal to its environment).

Many fishes in both marine and fresh waters swim at the surface and have mouths adapted to feed best (and sometimes only) at the surface. Often such fishes are long and slender, able to dart at surface insects or at other surface fishes and in turn to dart away from predators; needlefishes, halfbeaks, and topminnows are good examples. Oceanic flying fishes escape their predators by gathering speed above the water surface, with the lower lobe of the tail providing thrust in the water. They then glide hundreds of yards on enlarged, winglike pectoral and pelvic fins. South American freshwater flying fishes escape their enemies by jumping and propelling their strongly keeled bodies out of the water with their pectoral fins, which function as flapping wings.

Habitats

Longevity

So-called midwater swimmers, the most common type of fish, are of many kinds and live in many habitats. The powerful fusiform tunas and the trouts, for example, are adapted for strong, fast swimming, the first to capture prey speedily in the open ocean, the second to cope with the swift currents of streams and rivers. The trout body form is well adapted to many habitats. Fishes that live in relatively quiet waters such as bays or lake shores or slow rivers usually are not strong, fast swimmers but are capable of short, quick bursts of speed to escape a predator. Many of these fishes have their sides flattened, examples being the sunfish and the freshwater angelfish of aquarists. Fish associated with the bottom or substrate usually are slow swimmers. Open-water plankton-feeding fishes almost always remain fusiform and capable of rapid, strong movement (for example, sardines and herrings of the open ocean and also many small minnows of streams and lakes).

#### Special adaptations of bottom dwellers

Bottom-living fishes are of many kinds and have undergone many types of modification of their body shape and swimming habits. Rays, which evolved from strong swimming, midwater sharks, usually stay close to the bottom and move by undulating their large pectoral fins. Flounders live in a similar habitat and move over the bottom by undulating the entire body. Many bottom fishes dart from place to place, resting on the bottom between movements, a motion common in gobies. One goby relative, the mudskipper, has taken to living at the edge of pools along the shore of muddy mangrove swamps. It escapes its enemies by flipping rapidly over the mud, out of the water. Some catfishes, synbranchid eels, the so-called climbing perch, and a few other fishes venture out over damp ground to find more promising waters than those that they left. They move by wriggling their bodies, sometimes using strong pectoral fins; most have accessory air-breathing organs. Many bottom-dwelling fishes live in mud holes or rocky crevices. Marine eels and gobies commonly are found in such habitats and usually seldom venture far beyond their cavelike homes. Some bottom dwellers, such as the clingfishes (Gobiesocidae), have developed powerful adhesive disks that enable them to remain in place on the substrate in areas such as rocky coasts where the action of the waves is great.

**Reproduction.** The methods of reproduction in fishes are varied but most fishes lay a large number of small eggs, fertilized and scattered outside of the body. The eggs usually remain suspended in the open water in pelagic fishes. Many shore and freshwater fishes lay eggs on the bottom or among plants. Some have adhesive eggs. The mortality of the young and especially of the eggs is very high, and often only a few individuals grow to maturity out of hundreds, thousands, and in some cases, millions of eggs laid.

Males produce sperm, usually as a milky white substance called milt, in two (sometimes one) testes within the body cavity. In bony fishes a sperm duct leads from each testis to a urogenital opening behind the vent or anus. In sharks and rays and in cyclostomes the duct leads to a cloaca. Sometimes the pelvic fins are modified to help transmit the milt to the eggs at the female's vent or on the substrate where the female has placed them. Sometimes accessory organs are used to fertilize females internally; for example, the claspers of many sharks and rays.

In the females the eggs are formed in two ovaries (sometimes only one) and pass through the ovaries to the urogenital opening and to the outside. In some fishes the eggs are fertilized internally but shed before development takes place. Members of about a dozen families each of bony fishes (teleosts) and sharks bear live young. Many skates and rays bear live young. In some bony fishes the eggs simply develop within the female, the young emerging when the eggs hatch (ovoviviparus). Others develop within the ovary and are nourished by ovarian tissues after hatching (viviparous). There are also other methods utilized by fishes to nourish young within the female. In all live-bearers young are born at a relatively large size and are few in number. In one family

of primarily marine fishes, the surfperches from the Pacific coast of North America, the U.S.S.R., and Japan, the males of at least one species appear to be born sexually mature, although not fully grown.

Some fishes are hermaphroditic, an individual producing both sperm and eggs, usually at different stages of its life. Self-fertilization, however, is probably rare.

Successful reproduction and in many cases defense of the eggs and young is assured by rather stereotyped but often elaborate courtship and parental behaviour, either by the male, the female, or both. Some fishes prepare nests by hollowing out depressions in the sand bottom (cichlids, for example), build nests with plant materials and sticky threads excreted by the kidneys (sticklebacks), or blow a cluster of mucus-covered bubbles at the water surface (gouramis). The eggs are laid in these structures. Some cichlids and catfishes incubate eggs in their mouths.

Some fishes, such as salmon, undergo long migrations from the ocean and up large rivers to spawn in gravel beds where they themselves hatched (anadromous fishes). Others undertake shorter migrations from lakes into streams, or in other ways enter for spawning habitats that they do not ordinarily occupy.

#### FORM AND FUNCTION

**Body plan.** The basic structure and function of the fish body is similar to those of all other vertebrates. The usual four types of tissues are present: surface or epithelial, connective (bone, cartilage, and fibrous tissues, as well as their derivative, blood), nerve, and muscle tissues. The organs and organ systems parallel those of other vertebrates: for a more detailed discussion, see **ORGANS AND ORGAN SYSTEMS, ANIMAL**.

The typical fish body is streamlined and spindle shaped, with an anterior head, gill apparatus, and heart, the latter lying in the midline just below the gill chamber (see Figure 1). The body cavity, containing the vital organs,

Figure 1: Internal structure of fishes. (A) Skeleton of a perch. (B) Dissection of perch.

is situated behind the head in the lower anterior part of the body. The anus usually marks the posterior termination of the body cavity and most often occurs just in front of the base of the anal fin. The spinal cord and vertebral column continue from the posterior part of the

Figure 2: Scales of bony fishes.

From T. Storer and R. Usinger, *General Zoology* (1957); McGraw-Hill Book Company

head to the base of the tail fin, passing dorsal to the body cavity and through the caudal (tail) region behind the body cavity. Most of the body is of muscular tissue, a high proportion of which is necessitated by swimming. In the course of evolution this basic body plan has been modified repeatedly into the many varieties of fish shapes that exist today.

#### Skeleton

The skeleton forms an integral part of the fish's locomotion system, as well as serving to protect vital parts. The internal skeleton consists of the skull bones (except for the roofing bones of the head, which are really part of the external skeleton), vertebral column, and the fin supports (fin rays). The fin supports are derived from the external skeleton but will be treated here because of their close functional relationship to the internal skeleton. The internal skeleton of cyclostomes, sharks, and rays is of cartilage; that of many fossil groups and some primitive living fishes is mostly of cartilage but may include some bone. In place of the vertebral column, the earliest vertebrates had a fully developed notochord, a flexible stiff rod of viscous cells surrounded by a strong fibrous sheath. During the evolution of modern fishes the rod was replaced in part by cartilage and then by ossified cartilage. Sharks and rays retain a cartilaginous vertebral column; bony fishes have spool-shaped vertebrae that in the more primitive living forms only partially replace the notochord. The skull, including the gill arches and jaws of bony fishes, is fully, or at least partially, ossified. That of sharks and rays remains cartilaginous, at times partially replaced by calcium deposits but never by true bone.

The supportive elements of the fins (basal or radial bones or both) have changed greatly during fish evolution. Some of these changes are described in the sections below (*Paleontology and evolution; Classification*). Most fishes possess a single dorsal fin on the midline of the back. Many have two and a few have three dorsal fins. The other fins are the single tail and anal fins and paired pelvic and pectoral fins. A small fin, the adipose fin, almost always without fin rays, occurs in many of the relatively primitive teleosts (such as trout) on the back near the base of the caudal fin.

**The skin.** The skin of a fish must serve many functions. It aids in maintaining the osmotic balance, provides physical protection for the body, is the site of coloration, contains sensory receptors, and, in some fishes, functions in respiration. Mucous glands, which aid in maintaining the water balance and offer protection from bacteria, are extremely numerous in fish skin, especially in cyclostomes and teleosts. Since mucous glands are present in the modern lampreys it is reasonable to assume that they were present in primitive fishes, such as the ancient Silurian and Devonian agnaths. Protection from abrasion and predation is another function of the fish

skin, and dermal (skin) bone arose early in fish evolution in response to this need. It is thought that bone first evolved in skin and only later invaded the cartilaginous areas of the fish's body, to provide additional support and protection. There is some argument as to which came first, cartilage or bone, and fossil evidence does not settle the question. In any event, dermal bone has played an important part in fish evolution and has different characteristics in different groups of fishes. Several groups are characterized at least in part by the kind of bony scales they possess.

Scales have played an important part in the evolution of fishes. Primitive fishes usually had thick bony plates or thick scales in several layers of bone, enamel, and related substances. Modern teleost fishes have scales of bone, which, while still protective, allow much more freedom of motion in the body. A few modern teleosts (some catfishes, sticklebacks, and others) have secondarily acquired bony plates in the skin. Modern and early sharks possessed placoid scales, a relatively primitive type of scale with a toothlike structure, consisting of an outside layer of enamel-like substance (vitrodentine), an inner layer of dentine, and a pulp cavity containing nerves and blood vessels. Primitive bony fishes had thick scales of either the ganoid or the cosmoid type. Cosmoid scales have a hard, enamel-like outer layer, an inner layer of cosmine (a form of dentine), and then a layer of vascular bone (isopedine). In ganoid scales the hard outer layer is different chemically and is called ganoin. Under this is a cosmine-like layer and then a vascular bony layer. The thin, translucent bony scales of modern fishes, called cycloid and ctenoid scales (the latter distinguished by serrations at the edges), lack enameloid and dentine layers.

Skin has several other functions in fishes. It is well supplied with nerve endings and presumably receives tactile, thermal, and pain stimuli. Skin is well supplied with blood vessels. Some fishes breathe in part through the skin, by the exchange of oxygen and carbon dioxide between the surrounding water and numerous small blood vessels near the skin surface.

Skin serves as protection through the control of coloration. Fishes exhibit an almost limitless range of colours. The colours often blend closely with the surroundings, effectively hiding the animal. Many fishes use bright colours for territorial advertisement or as recognition marks for other members of their own species, or sometimes for members of other species. Many fishes can change their colour to a greater or lesser degree, by expansion and contraction of the pigment cells (chromatophores). Black pigment cells (melanophores), of almost universal occurrence in fishes, are often juxtaposed with other pigment cells. When placed near iridocytes or leucophores (bearing the silvery or white pigment guanine) melanophores produce structural colours of blue and green.

#### Types of scales

#### Coloration

These colours are often extremely intense, because they are formed by refraction of light through the needlelike crystals of guanine. The blue and green refracted colours are often relatively pure, lacking the red and yellow rays, which have been absorbed by the black pigment (melanin) of the melanophores. Yellow, orange, and red colours are produced by erythrophores, cells containing the appropriate carotenoid pigments. Other colours are produced by combinations of melanophores, erythrophores, and iridocytes.

**The muscle system.** The major portion of the body of most fishes consists of muscles. Most of the mass is trunk musculature, the fin muscles usually being relatively small. The caudal fin is usually the most powerful fin, with the largest amount of direct musculature. Its musculature is really a structural and functional continuation of the main musculature of the body. The body musculature is usually arranged in two rows of chevron-shaped segments on each side. Contractions of these segments, each attached to adjacent vertebrae and vertebral processes, bends the body on the vertebral joint, producing successive undulations of the body, passing from the head to the tail, and producing driving strokes of the tail. It is the latter that provides the strong forward movement for most fishes.

**The digestive system.** The digestive system, in a functional sense, starts at the mouth, with the teeth used to capture prey or collect plant foods. Mouth shape and tooth structure vary greatly in fishes, depending on the kind of food normally eaten. Most fishes are predacious, feeding on small invertebrates or other fishes and have simple conical teeth on the jaws, on at least some of the bones of the roof of the mouth, and on special gill arch structures just in front of the esophagus. The latter are throat teeth. Most predacious fishes swallow their prey whole, and the teeth are used for grasping and holding prey, for orienting prey to be swallowed (head first) and for working the prey toward the esophagus. There are a variety of tooth types in fishes. Some, such as sharks and the piranhas, have cutting teeth for biting chunks out of their victims. A shark's tooth, although superficially like that of a piranha, appears in many respects to be a modified scale, while that of the piranha is like that of other bony fishes, consisting of dentine and enamel. Parrotfishes have beaklike mouths with short incisor-like teeth for breaking off coral and have heavy pavement-like throat teeth for crushing the coral. Some catfishes have small brushlike teeth, arranged in rows on the jaws, for scraping plant and animal growth from rocks. Many fishes (e.g., the Cyprinidae or minnows) have no jaw teeth at all but have very strong throat teeth.

Some fishes gather planktonic food by straining it from their gill cavities with numerous elongate stiff rods (gill rakers), anchored by one end to the gill bars. The food collected on these rods is passed to the throat where it is swallowed. Most fishes have only short gill rakers that help keep food particles from escaping out the mouth cavity into the gill chamber.

Once reaching the throat, food enters a short, often greatly distensible esophagus, a simple tube with a muscular wall leading into a stomach. The stomach varies greatly in fishes, depending upon the diet. In most predacious fishes it is a simple straight or curved tube or pouch with a muscular wall and a glandular lining. Food is largely digested here and leaves the stomach in liquid form.

Between the stomach and the intestine, ducts enter the digestive tube from the liver and pancreas. The liver is a large, clearly defined organ. The pancreas may be imbedded in it, diffused through it, or broken into small parts spread along some of the intestine. The junction between the stomach and the intestine is marked by a muscular valve. Pyloric ceca (blind sacs) occur in some fishes at this junction and have a digestive or an absorptive function, or both.

The intestine itself is quite variable in length depending upon the diet. It is short in predacious forms, sometimes no longer than the body cavity, but long in herbivorous

Figure 3: Digestive tracts of various kinds of fishes.

Lampreys and chimaeras have no stomachs; the stomach of a lungfish is merely an enlargement of the esophagus.

From B. Dean, *Fishes Living and Fossil*, in A.S. Romer, *The Vertebrate Body*, 4th ed. (1970); W.B. Saunders Company

forms, being coiled and several times longer than the entire length of the fish in some species of South American catfishes. The intestine is primarily an organ for absorbing nutrients into the bloodstream. The larger its internal surface, the greater its absorptive efficiency, and a spiral valve is one method of increasing its absorption surface.

Sharks, rays, chimaeras, lungfishes, surviving chondrosteans, holosteans, and even a few of the more primitive teleosts have a spiral valve or at least traces of it in the intestine. Most modern teleosts have increased the area of the intestinal walls by having numerous folds and villi (fingerlike projections) somewhat like those in man. Undigested substances are passed to the exterior through the anus in most teleost fishes. In lungfishes, sharks, and rays it is first passed through the cloaca, a common cavity receiving the intestinal opening and the ducts from the uro-genital system.

**The respiratory system.** Oxygen and carbon dioxide dissolve in water and most fishes exchange dissolved oxygen and carbon dioxide in water by means of the gills. The gills lie behind and to the side of the mouth cavity and consist of fleshy filaments supported by the gill arches and filled with blood vessels, which give gills a bright red colour. Water taken in continuously through the mouth passes backward between the gill bars and over the gill filaments, where the exchange of gases takes place. The gills are protected by a gill cover in teleosts and many other fishes, but by flaps of skin in sharks, rays, and some of the older fossil fish groups. The blood capillaries in the gill filaments are close to the gill surface to take up oxygen from the water and to give up excess carbon dioxide to the water.

Most modern fishes have a hydrostatic (ballast) organ, called the swim bladder, that lies in the body cavity just below the kidney and above the stomach and intestine. It originated as a diverticulum of the digestive canal. In advanced teleosts, especially the acanthopterygians, the

Swim bladder

Types of teeth

bladder has lost its connection with the digestive tract, a condition called physoclastic. The connection has been retained (physostomous) by most relatively primitive teleosts. In several unrelated lines of fishes the bladder has become specialized as a lung or, at least, as a highly vascularized accessory breathing organ. Some fishes with such accessory organs are obligate air breathers and will drown if denied access to the surface, even in well-oxygenated water. Fishes with a hydrostatic form of swim bladder can control their depth by regulating the amount of gas in the bladder. The gas, mostly oxygen, is secreted into the bladder by special glands, rendering the fish more buoyant; it is absorbed into the bloodstream by another special organ, reducing the overall buoyancy and allowing the fish to sink. Some deep-sea fishes may have oil in the bladder, rather than gas. Other deep-sea and some bottom-living forms have much reduced swim bladders or have lost the organ entirely.

The swim bladder of fishes follows the same developmental pattern as the lungs of land vertebrates. There is no doubt that the two structures have the same historical origin in primitive fishes. More or less intermediate forms still survive among the more primitive types of fishes such as the lungfishes *Lepidosiren* and *Protopterus*.

**The circulatory system.** The circulatory, or blood vascular, system consists of the heart, the arteries, the capillaries, and the veins: it is in the capillaries that the interchange of oxygen, carbon dioxide, nutrients and other substances such as hormones and waste products takes place. The capillaries in turn lead to the veins, which return the venous blood with its waste products to the heart, kidneys, and gills. There are two kinds of capillary beds, those in the gills and those in the rest of the body. The heart, a folded continuous muscular tube with three or four sacklike enlargements, undergoes rhythmic contractions, and receives venous blood in a sinus venosus. It then passes the blood to an auricle and then into a thick, muscular pump, the ventricle. From the ventricle the blood goes to a bulbous structure at the base of a ventral aorta just below the gills. The blood then passes to the afferent (receiving) arteries of the gill arches and then to the gill capillaries. There waste gases are given off to the environment and oxygen is absorbed. From there the oxygenated blood enters efferent (exuant) arteries of the gill arches and then into the dorsal aorta. From there blood is distributed to the tissues and organs of the body. One-way valves prevent backflow. The circulation of fishes thus differs from that of the reptiles, birds, and mammals, in that oxygenated blood is not returned to the heart prior to distribution to the other parts of the body.

**Excretory organs.** The primary excretory organ in fishes, as in other vertebrates, is the kidney. In fishes some excretion also takes place in the digestive tract, skin, and especially the gills (where ammonia is given off). Compared with land vertebrates, fishes have a special problem in maintaining their internal environment at a constant concentration of water and dissolved substances, such as salts. Proper balance of the internal environment (homeostasis) of a fish is in a great part maintained by the excretory system, especially the kidney.

The kidney, gills, and skin play an important role in maintaining a fish's internal environment and checking the effects of osmosis. Marine fishes live in an environment in which the water around them has a greater concentration of salts than they can have inside their body and still maintain life. Freshwater fishes, on the other hand, live in water with a much lower concentration of salts than they require inside their bodies. Osmosis tends to promote the loss of water from the body of a marine fish and absorption of water by that of a freshwater fish. Mucus in the skin tends to slow the process but is not a sufficient barrier to prevent the movement of fluids through the permeable skin. When solutions on two sides of a permeable membrane have different concentrations of dissolved substances, water will pass through the membrane into the more concentrated solution, while

the dissolved chemicals move into the area of lower concentration (diffusion).

The kidney of freshwater fishes is often larger in relation to body weight than that of marine fishes. In both groups the kidney excretes wastes from the body, but that of freshwater fishes also excretes large amounts of water, counteracting the water absorbed through the skin. Freshwater fishes tend to lose salt to the environment and must replace it. They get some salt from their food, but the gills and skin inside the mouth actively absorb salt from water passed through the mouth. This absorption is performed by special cells capable (like those of the kidney) of moving salts against the diffusion gradient. Freshwater fishes drink very little water and take in little water in their food.

Marine fishes must conserve water, therefore their kidneys excrete little water. To maintain their water balance marine fishes drink large quantities of seawater, retaining most of the water and excreting the salt. By reabsorption of needed water in the kidney tubules, they discharge a more concentrated urine than do freshwater fishes. Most nitrogenous waste in marine fishes appears to be secreted by the gills as ammonia. Some marine fishes, at least, can excrete salt by clusters of special cells in the gills and intestine.

There are several teleosts—for example, the salmon—that travel between fresh water and seawater and must adjust to the reversal of osmotic gradients. They adjust their physiological processes by spending time (often surprisingly little time) in the intermediate brackish environment.

Marine lampreys, hagfishes, sharks, and rays have osmotic concentrations in their blood about equal to that of seawater so do not have to drink water nor perform much physiological work to maintain their osmotic balance. In sharks and rays the osmotic concentration is kept high by retention of urea in the blood. Freshwater sharks have a lowered concentration of urea in the blood.

**Endocrine glands.** Endocrine glands secrete their products into the bloodstream and body tissues and, along with the central nervous system, control and regulate many kinds of body functions. Cyclostomes have a well-developed endocrine system, and presumably it was well developed in the early Agnatha, ancestral to modern fishes. Although the endocrine system in fishes is similar to that of higher vertebrates, there are numerous differences in detail. The endocrine glands of fishes are the pituitary, thyroid, suprarenals, adrenals, pancreatic islets, sex glands (ovaries and testes), the inner wall of the intestine, and the ultimobranchial bodies. There are some others whose function is not well understood. These organs regulate sexual activity and reproduction, growth, osmoregulation, general metabolic activities such as the storage of fat and the utilization of foodstuffs, blood pressure, and certain aspects of skin colour. Many of these activities also are controlled in part by the central nervous system, which works with the endocrine system in maintaining the life of a fish. Some parts of the endocrine system are developmentally, and undoubtedly evolutionarily, derived from the nervous system.

**The nervous system and sensory organs.** As in all vertebrates, the nervous system of fishes is the primary mechanism coordinating body activities, as well as integrating these activities in the appropriate manner with stimuli from the environment. The central nervous system, the brain, and spinal cord, are the primary integrating mechanisms. The peripheral nervous system, consisting of nerves that connect the brain and spinal cord to various body organs, carries sensory information from special receptor organs such as the eyes, internal ears, nares (sense of smell), taste glands, and others to the integrating centres of the brain and spinal cord. The peripheral nervous system also carries information via different nerve cells from the integrating centres of the brain and spinal cord. This coded information is carried to the various organs and body systems, such as the skeletal muscular system, for appropriate action in response to the original external or internal stimulus. Another

The  
brain

branch of the nervous system, the autonomic system, helps to coordinate the activities of many glands and organs and is itself closely connected to the integrating centres of the brain.

The brain of the fish is divided into several anatomical and functional parts, all closely interconnected but each serving as the primary centre of integrating particular kinds of responses and activities. Several of these centres or parts are primarily associated with one type of sensory perception such as sight, hearing, or smell (olfaction).

**Olfaction.** The sense of smell is important in almost all fishes. Certain eels with tiny eyes depend mostly on smell for location of food. The olfactory, or nasal, organ of fishes is located on the dorsal surface of the snout. The lining of the nasal organ has special sensory cells that perceive chemicals dissolved in the water such as substances from food material and send sensory information to the brain by way of the first cranial nerve. Odour also serves as an alarm system. Many fishes, especially various species of freshwater minnows, react with alarm to the body fluids produced by an injured member of their own species.

**Taste.** Many fishes have a well-developed sense of taste, and tiny pitlike taste buds or organs are located not only within their mouth cavities but also over their heads and parts of their body. The barbels ("whiskers") of catfishes, which often have poor vision, serve as supplementary taste organs, those around the mouth being actively used to search out food on the bottom. Some species of naturally blind cave fishes are especially well supplied with taste buds, these being often over most of their body's surface.

**Sight.** Sight is extremely important in most fishes. The eye of a fish is basically like that of all other vertebrates, but the eyes of fishes are extremely varied in structure and adaptation. In general, fishes living in dark and dim water habitats have large eyes, unless they have specialized in some compensatory way with another sense such as smell being dominant, in which case the eyes will often be reduced. Fishes living in brightly lighted shallow waters often will have relatively small but efficient eyes. Cyclostomes have somewhat less elaborate eyes than other fishes, with skin stretched over the eyeball perhaps making their vision somewhat less effective. Most fishes have a spherical lens and accommodate their vision to far or near subjects by moving the lens within the eyeball. A few sharks accommodate by changing the shape of the lens, as in land vertebrates. Those fishes that are heavily dependent upon the eyes have especially strong muscles for accommodation. Most fishes see well, despite the restrictions imposed by frequent turbidity of the water and by light refraction. Experimental evidence indicates that many shallow-water fishes, if not all, have colour vision and see some colours especially well, but some bottom-dwelling shore fishes live in areas where the water is sufficiently deep to filter out most if not all colours, and these fishes apparently never see colours. When tested in shallow water, they apparently are unable to respond to colour differences.

Colour  
vision

**Hearing.** Sound perception and balance are intimately associated senses in a fish. The organs of hearing are entirely internal, located within the skull, on each side of the brain and somewhat behind the eyes. Sound waves, especially those of low frequencies, travel readily through water and impinge directly upon the bones and fluids of the head and body, to be transmitted to the hearing organs. Fishes readily respond to sound; for example, a trout conditioned to escape by the approach of fishermen will take flight upon perceiving footsteps on a stream bank even if it cannot see the fisherman. Compared with humans, however, the range of sound frequencies heard by fishes is greatly restricted. It is thought that many fishes communicate with each other in a crude way by producing sounds in their swim bladders, in their throats by rasping their teeth, and in other ways.

**Other senses (touch, pain, and special senses).** A fish or other vertebrate seldom has to rely on a single type of

Figure 4: Magnified longitudinal section through a carp's body wall showing lateral line sensory system.

From T. Storer and R. Usinger, *General Zoology* (1957); McGraw-Hill Book Co.

sensory information to determine the nature of the environment around it. A catfish uses taste and touch when examining a food object with its oral barbels. Like most other animals, fishes have many touch receptors over their body surface. Pain and temperature receptors also are present in fishes and presumably produce the same kind of information to a fish as to humans. Fishes react in a negative fashion to stimuli that would be painful to human beings, suggesting that they feel a sensation of pain.

An important sensory system in fishes that is absent in other vertebrates (except some amphibians) is the lateral line system. This consists of a series of heavily innervated small canals located in the skin and bone around the eyes, along the lower jaw, over the head and down the midside of the body where it is associated with the scales. Intermittently along these canals are located tiny sensory organs (pit organs) that apparently detect changes in pressure. The system allows a fish to sense changes in water currents and pressure, thereby helping the fish to orient itself to the various changes that occur in the physical environment.

Lateral  
line  
system

#### EVOLUTION AND PALEONTOLOGY

Although a great many fossil fishes have been found and described, they represent a tiny portion of the long and complex evolution of fishes and knowledge of fish evolution remains relatively fragmentary. In the classification presented in this article fishlike vertebrates are divided into seven classes, the members of each having a different basic structural organization and different physical and physiological adaptations for the problems presented by the environment. The broad basic pattern has been one of successive replacement of older groups by newer, better adapted groups. One or a few members of a group evolved a basically more efficient means of feeding, breathing, swimming, or several better ways of living. These better adapted groups then forced the extinction of members of the older group with which they competed for available food, breeding places, or other necessities of life. As the new fishes became well established, some of them evolved further and adapted to other habitats, where they continued to replace members of the old group already there. The process was repeated until all or almost all members of the old group in a variety of habitats had been replaced by members of the newer evolutionary line.

The earliest vertebrate fossils of certain relationships are fragments of dermal armour of jawless fishes (class Agnatha, order Heterostraci) from the Middle Ordovician Period in North America, about 450,000,000 years in age. Early Ordovician toothlike fragments from the U.S.S.R. are less certainly remains of the class Agnatha. It is uncertain whether the North American jawless fishes inhabited shallow coastal marine waters, where their remains became fossilized, or were freshwater vertebrates washed into coastal deposits by stream action.

Early  
jawless  
fishes

Jawless fishes probably arose from ancient small, soft-bodied filter-feeding organisms much like and probably also ancestral to the modern sand-dwelling filter feeders, the Cephalochordata (*Amphioxus* and its relatives). The body in the ancestral animals was probably stiffened by a notochord. Although a vertebrate origin in fresh water is much debated by paleontologists, it is possible that mobility of the body and protection provided by dermal armour arose in response to streamflow in the freshwater environment and to the need to escape from and resist the clawed invertebrate eurypterids that lived in the same waters. Because of the marine distribution of the surviving primitive chordates, many paleontologists doubt that the vertebrates arose in fresh water.

Heterostracan remains are next found in what appear to be delta deposits in two North American localities of Silurian age. By the close of the Silurian, about 400,000,000 years ago, European heterostracan remains are found in what appear to be delta or coastal deposits. In the Late Silurian of the Baltic area, lagoon or freshwater deposits yield jawless fishes of the order Osteostraci. Somewhat later in the Silurian from the same region, layers contain fragments of jawed acanthodians, the earliest group of jawed vertebrates, and of jawless fishes. These layers lie between marine beds but appear to be washed out from fresh waters of a coastal region.

It is evident, therefore, that by the end of the Silurian both jawed and jawless vertebrates were well established and already must have had a long history of development. Yet paleontologists have remains only of specialized forms that cannot have been the ancestors of the placoderms and bony fishes that appear in the next period, the Devonian. No fossils are known of the more primitive ancestors of the agnaths and acanthodians. The extensive marine beds of the Silurian and those of the Ordovician are essentially void of vertebrate history. It is believed that the ancestors of fishlike vertebrates evolved in upland fresh waters, where whatever few and relatively small fossil beds were made probably have been long since eroded away. Remains of the earliest vertebrates may never be found.

By the close of the Silurian, all five known orders of jawless vertebrates had evolved, except perhaps the modern cyclostomes, which are without the hard parts that ordinarily are preserved as fossils. Cyclostomes were unknown as fossils until 1968, when a lamprey of modern body structure was reported from the Middle Pennsylvanian of Illinois, in deposits almost 300,000,000 years old. Fossil evidence of the four orders of armoured jawless vertebrates is absent from deposits later than the Devonian. Presumably they became extinct at that time, being replaced by the more efficient and probably more aggressive placoderms, acanthodians, selachians (sharks and relatives), and by early bony fishes. Cyclostomes survived probably because they early evolved from anaspid agnaths and developed a rasping tongue-like structure and a sucking mouth, enabling them to prey on other fishes. With this way of life they apparently had no competition from other fish groups.

Early jawless vertebrates probably fed on tiny organisms by filter feeding, as do the larvae of their descendants, the modern lampreys. The gill cavity of the early agnaths was large. It is thought that small organisms taken from the bottom by a nibbling action of the mouth, or more certainly by a sucking action through the mouth, were passed into the gill cavity along with water for breathing. Small organisms then were strained out by the gill apparatus and directed to the food canal. The gill apparatus thus evolved as a feeding, as well as a breathing, structure. The head and gills in the agnaths were protected by a heavy dermal armour; the tail region was free, allowing motion for swimming.

Most important for the evolution of fishes and vertebrates in general was the early appearance of bone, cartilage, and enamel-like substance. These materials became modified in later fishes, enabling them to adapt to many aquatic environments and finally even to land. Other basic organs and tissues of the vertebrates such as the cen-

tral nervous system, heart, liver, digestive tract, kidney, and circulatory system undoubtedly were present in the ancestors of the Agnatha. In many ways, bone, both external and internal, was the key to vertebrate evolution.

The next class of fishes to appear was the Acanthodii, containing the earliest known jawed vertebrates, which arose in the Upper Silurian, over 400,000,000 years ago. The acanthodians declined after the Devonian but lasted into the Lower Permian, a little less than 280,000,000 years ago. The first complete specimens appear in Lower Devonian freshwater deposits, but later in the Devonian and Permian some members appear to have been marine. Most were small fishes, not over 75 centimetres in length.

We know nothing of the ancestors of the acanthodians. They must have arisen from some jawless vertebrate, probably in fresh water. They appear to have been active swimmers with almost no head armour but with large eyes, indicating that they depended heavily on vision. Perhaps they preyed on invertebrates. The rows of spines and spinelike fins between the pectoral and pelvic fins give some credence to the idea that paired fins arose from "fin folds" along the body sides.

The relationships of the acanthodians to other jawed vertebrates are obscure. They possess features found in both sharks and bony fishes. They are like early bony fishes in possessing ganoid-like scales and a partially ossified internal skeleton. Certain aspects of the jaw appear to be more like those of bony fishes than sharks, but the bony fin spines and certain aspects of the gill apparatus would seem to favour relationships with early sharks. Acanthodians do not seem particularly close to the Placodermi although, like the placoderms, they apparently possessed less efficient tooth replacement and tooth structure than the sharks and the bony fishes, possibly one reason for their subsequent extinction.

The first record of the jawed Placodermi is from the Early Devonian, about 390,000,000 years ago. The placoderms flourished for about 60,000,000 years and were almost gone at the end of the Devonian. Nothing is known of their ancestors, who must have existed in the Silurian. The evolution of several other, better adapted, fish groups soon followed the appearance of the placoderms and this apparently led to their early extinction. Their greatest period of success was approximately during the middle of the Devonian, when some of them became marine. As their name indicates (placoderm means "plate skin"), most of these fishes had heavy coats of bony armour, especially about the head and anterior part of the body. The tail remained free and heterocercal (*i.e.*, the upper lobe long, the lower one small or lacking). Most placoderms remained small, 30 centimetres or less in length, but one group, the arthrodires, had a few marine members that reached 10 metres in length. Important evolutionary advances of the placoderms were in the jaws (which usually were amphistylar—*i.e.*, involving the hyoid and quadrate bones) and development of fins, especially the paired fins with well-formed basal or radial elements. The jaws tended to be of single elements with strongly attached toothlike structures. These were too specialized to be considered ancestral to the more adaptable jaws of subsequent bony fish groups. It has been proposed that sharks arose from some group of placoderms near the Stensioelliformes and that the chimaera line (class Holocephali) arose from certain arthrodires; this suggestion, however, is uncertain.

A peculiar, five-centimetre fish, *Palaeospondylus*, from Middle Devonian rocks in Scotland, is probably not a placoderm, although classed with them here. Various suggestions that its relationships are with the agnaths, placoderms, acanthodians, sharks, and even lungfishes and amphibians are unconvincing and its relationships remain completely unknown.

Sharks (class Selachii) first appear in the Middle Devonian about 375,000,000 years ago, became quite prominent by the end of the Devonian, and are still successful today. Two Early Devonian orders of primitive sharklike fishes, the Cladoselachiformes and the Cladodontiformes, became extinct by the end of the Permian, about 230,-

Appear-  
ance of  
bone

Origin of  
sharks

000,000 years ago, while the freshwater order Xenacanthiformes lasted until the Middle Triassic, about 200,000,000 years ago. The final Devonian order, Heterodontiformes, still has surviving members.

Modern sharks and rays arose during the Jurassic Period, about 135,000,000 to 190,000,000 years ago, probably from an older group, the hybodont sharks. Presumably marine cladoselelchians gave rise to the hybodont Heterodontiformes during the close of the Devonian. These had the placoderm amphistylous jaws but had paired fins of a more efficient type. In turn the hybodonts are thought to have given rise to the living but archaic mollusk-eating Port Jackson sharks (heterodonts). The relationships of the surviving (but archaic) hexanchiform sharks are unknown. The two main orders of modern Selachii, the Lamniformes (sharks) and Rajiformes (skates and rays), appeared between 140,000,000 and 180,000,000 years ago during the Jurassic Period. They are characterized by a hyostylic jaw (in which articulation involves only the hyoid bone), an improvement allowing greater mobility of the jaws and an important feature in the methods of predation used by modern selachians.

Skates and rays evolved from some bottom-living shark-like ancestor during the Jurassic. The primary evolution and diversification of modern sharks, skates, and rays

thyologists believe that the two major groups, the Crossopterygii (including the rhipidistians and coelacanth) and the Dipnoi, have independent origins, their present structure being widely divergent. The primitive members, however, show several similarities, supporting the view that they had a common ancestor. The nature of the ancestor or ancestors remains a mystery. The Sarcopterygii probably evolved from unknown Silurian jawed freshwater fishes that may also have been ancestral to the actinopterygians.

The rhipidistian crossopterygians apparently flourished in the fresh waters of the Middle Devonian where, in adapting to a habitat subject to seasonal droughts, some evolved pectoral and pelvic appendages strong enough and flexible enough to enable them to leave drying pools to seek out those ponds that retained water. Paradoxically, terrestrial vertebrate amphibians first rose through the need to survive in water.

The early coelacanth of the Upper Devonian were small freshwater and inshore fishes, and it was not until the Late Permian and Triassic that they became marine and grew larger and more diverse. They are not known as fossils later than the Cretaceous, and it was therefore a great surprise when in 1938 a live, 160-centimetre specimen was taken at 120 metres off the coast of eastern South Africa.

The dipnoans first appeared in the Lower Devonian and were fully differentiated at that time. They flourished until the close of the Triassic, when their numbers became greatly reduced. The modern Australian lungfish differs little from one of the Triassic forms. The living South American and especially African lungfishes are elongated, specialized fishes adapted to live and survive in more or less annual ponds.

The Actinopterygii, or "ray-finned" fishes, is the largest class of fishes. In existence for about 390,000,000 years, since the Lower Devonian, it consists of some 52 orders containing more than 480 families, at least 80 of which are known only from fossils. The class contains the great majority of known living and fossil fishes, with about 20,000 living species. The history of actinopterygians can be divided into three basic stages or evolutionary radiations, each representing a different level of structural organization and efficiency.

The Chondrostei have a 300,000,000-year history. They arose first in the Lower Devonian, increased in numbers and complexity until about the Permian, and thereafter declined, becoming almost extinct by the middle of the Cretaceous, 100,000,000 years ago. The chondrosteian order Palaeonisciformes is the basal actinopterygian stock from which all other chondrosteians and the holosteans evolved. They were the most common fishes of their time, relatively small and typically like later fishes in appearance. In comparison with today's fishes they had peculiar looking jaws and tails. Their tails were heterocercal. On their bodies were thick ganoid scales that abutted each other, rather than overlapping, as in most modern fishes. Palaeonisciformes often had large eyes placed far forward, long mouths with the upper jaw firmly bound to the fully armoured cheek, and a relatively weak lower jaw muscle. They gave rise to a great variety of types, with elongate bodies and jaws (vaguely like the modern pike), bottom-living types that fed on micro-organisms, deep-bodied marine reef fishes and coral-eating reef fishes. Almost all of these were replaced by modern teleosts. Surviving Chondrostei are the bottom-feeding marine and freshwater sturgeons, the strange plankton-feeding paddlefishes of the Mississippi of North America and the Yangtze River of China, and the freshwater bichirs and reed fishes (family Polypteridae) of Africa. The relationship of the polypterids are in some doubt and the group is sometimes placed in the Sarcopterygii.

Several of the chondrosteian orders developed characters that approached the holostean level of anatomical organization, sometimes called subholosteans. One of these orders, the Parasemionotiformes, evolved from the Palaeonisciformes in the Lower Triassic and may have given rise to at least some of the holosteans. This evolutionary

Chondrostei

took place in the Cretaceous Period and Cenozoic Era. Thus, along with the teleost fishes (discussed below) most surviving sharks, skates, and rays are essentially of relatively recent origin, their main evolutionary radiation having taken place within the last 140,000,000 years.

The class Holocephali, the chimaeras or ratfishes as their modern survivors are called, first appeared in the Upper Devonian but were most common and diversified during the Mesozoic Era. Only one of the seven known orders survived beyond the close of the Cretaceous Period about 65,000,000 years ago. Although not many modern species of chimaeras are known, they are sometimes relatively abundant in their deep-sea habitat. The relationships of these fishes are in question. It has been proposed that they are related to the Devonian ptyctodont arthrodires, which had a chimaera-like shape and pelvic claspers. It has also been suggested that they are closely related to the Selachii because both selachians and holocephalians have many characters in common, such as placoid scales, pelvic claspers, and absence of true bone. It has been suggested recently that both holocephalians and selachians are related to the acanthodians on the basis of the gill arch structures. Further evidence is needed to solve the problem.

The class Sarcopterygii are extremely ancient in origin, their first remains appearing in Lower Devonian strata of Germany, about 390,000,000 years old. The most important group, the rhipidistians, which gave rise to the amphibians by the end of the Devonian, became extinct about 120,000,000 years later, near the beginning of the Permian. Two lesser groups, the coelacanth and the dipnoans (lungfishes), have barely survived. Recognition of the class Sarcopterygii is controversial in that some ich-

Figure 6: Phyletic family tree for fishes.

line leads to the Pholidophoriformes, which gave rise to modern bony fishes, or teleosts.

The holosteans are thought to be of mixed origin and to represent a stage in the evolution of a group of chondrosteian orders. If so, the infraclass Holostei does not represent a single lineage. Important holostean characters are the approach of the tail toward the homocercal condition and the equal number of fin rays and basal elements of the fin rays. Both of these conditions make the holostean a more efficient swimmer than the chondrosteian, as does thinning of the holostean body scales. Another important advance of holosteans was the freeing of the upper jaw from the preopercular bone of the cheek, allowing greater movement of the gill chamber and jaws, with more powerful development of the lower jaw muscle.

Five orders of holosteans are known, with their greatest evolutionary radiation occurring during the Triassic, Jurassic, and Cretaceous periods, when the chondrosteians were declining and the teleosts just beginning to expand. Two holostean groups survive today, the bowfin, *Amia calva*, and the several species of gars, *Lepisosteus*, all found in North America.

The modern bony fishes, infraclass Teleostei, include the great majority of living fishes. They first appear in the fossil record about 190,000,000 years ago (as the family Leptolepididae) with their homocercal caudal fin and caudal skeleton already fully developed. They arose from an order of holosteans now extinct, the Pholidophoriformes. This group was intermediate in character between the chondrosteians and the teleosts. Teleosts have reached their fullest extent within the last 50,000,000 years and represent a distinct functional advance over their holostean ancestors. They have greater swimming ability, due to the improvement in the tail structure, and have a still more efficient feeding and gill ventilating apparatus.

The bony fishes represent the culmination of a long evolution toward a body plan with maximum swimming efficiency. Particularly important in this evolution have been changes in fins and in the tail. Some authorities believe that the paired fins arose from a single continuous tail and anal fin that was divided at the vent and extended forward along each side to the head. Later, the sections between the pectoral, pelvic, anal, and caudal fins were lost. The fin rays of sharks and rays are of a horny material, but those of many primitive fossil fishes are of bone. The bony fin rays of sarcopterygians and actinopterygians probably arose from scales lying in the fin folds. Modern teleost fishes have flexible fin rays (called soft rays) of jointed segments of bone, or spiny rays, each of solid continuous bone. The first dorsal fin of acanthopterygian fishes is of the spiny type. The original tail fin of primitive

fishes was not an effective swimming organ, due to its asymmetry. The steady improvement in tail shape over 400,000,000 years is one of the prominent features of fish evolution. In primitive fishes the tail (vertebral) axis turned upward (heterocercal) or downward (hypocercal) and a lobe of flesh projected from it. This form of tail cannot provide a powerful driving mechanism because the driving force is unevenly distributed, relative to the body axis. With an asymmetrical tail, the fish swims by an undulating motion of the body and tail. In some fishes with a diphyccal tail (with the axis of the vertebrae extending down the middle of the fin lobe), developed in both modern and ancient fishes, the tail remains relatively ineffective because it has remained too rigid for proper propulsive action. The development of a true homocercal tail fin, in which powerful muscles move strong fin rays with a very flexible basal joint and in which the upper and lower lobes are about equal, is a development exclusive to teleost fishes.

As suggested by the existence of more than 400 families, teleosts are extremely varied in anatomical form and in the habitat occupied. They can be divided into about nine superorders, each with distinct evolutionary significance. The Leptolepidomorpha, an extinct, relatively primitive group, has uncertain relationships with other teleosts and is as yet poorly understood. The second group, the Elopomorpha, retains some relatively primitive living members, such as the tarpons, but is mostly represented by the large variety of specialized true eels. The Clupeomorpha includes the herrings and anchovies, relatively primitive fishes, mostly specialized for existence near the surface of the open ocean. A few species are anadromous, breeding in fresh water, but spending most of their lives in the sea. The fourth superorder, the Osteoglossomorpha, consists of a group of relatively primitive teleosts, most of which are now extinct. The few surviving members are tropical and worldwide in distribution, but adapted for restricted habitats. The Protacanthopterygii is a varied collection of relatively primitive orders, marine, deep-sea, and freshwater in distribution; trouts, smelts, and argentinids are examples. The sixth superorder, the Ostariophysi, is an important group of primarily freshwater fishes, including the characins, carps, minnows, loaches, suckers, and catfishes.

The remaining three superorders have a complex fossil history and are not yet fully understood, but all seem to possess similar evolutionary trends. Each group shows a tendency to develop spiny fin rays in the dorsal and anal fins (reduced in some) and a shelf of bone under the eye. There is a tendency for the pelvic fins to move forward on the body, with a reorganization of swimming methods

Advent of  
advanced  
bony  
fishes

and a slight gain in manoeuvrability. All three groups probably are related and presumably arose from some early protacanthopterygian ancestor. The Scopelomorpha includes a wide variety of deep-sea open-ocean plankton feeders and predators, some of which bear light organs. The Paracanthopterygii is a rather miscellaneous collection of fishes, the most important to man being the cods. The final superorder, the Acanthopterygii, is the result of the great radiation of modern spiny-rayed fishes and contains the dominant fishes in marine shore habitats, tropical, temperate, and Arctic. They also have penetrated the freshwater environment, especially lakes, slow-moving streams, and ponds. The superorder has some important open-ocean members, such as tunas. The main key to the successful acanthopterygian radiation probably has been their mobile, protractile mouth.

#### CLASSIFICATION

**Distinguishing taxonomic features.** In forming hypotheses about the evolution of fishes and in establishing classifications based on these hypotheses, ichthyologists place special emphasis on the comparative study of the skeleton. There are two primary advantages of this approach. First, direct comparison between extant and fossil groups is possible, the latter usually represented only by bony remains. The second advantage is that the bones of living fishes are relatively easy to observe and to study, compared with other body structures. Proper preservation and special preparation of the nervous system, for example, is difficult and expensive when the fishes compared are from the far ends of the earth. In the study of the relationships of species within a group major use has been made of similarities and differences in the dimensions of external features such as head and body length, and of counts of external characters, such as teeth, fin rays, and scales. Colour pattern is also important. In recent years valuable data on classification of fishes has been obtained from studies of comparative behaviour, physiology, genetics and functional anatomy.

**Annotated classification.** The following classification has been derived primarily from the works of C. Patterson, Miles, P.H. Greenwood and co-workers, D.E. Rosen and C. Patterson, and K.S. Thomson. Fish classification has undergone major revisions in recent years and further modifications can be expected in the future. Ichthyologists frequently disagree on major as well as minor concepts of phyletic relationships. There remains much to learn about both living and fossil fishes. The geographical distribution given for a poorly known fossil group usually represents only the location of fossil finds not necessarily the true distribution of the group. In the classification presented here groups indicated by a dagger (†) are known only from fossils.

#### CLASS AGNATHA

Vertebrates with a suctorial or filter-feeding mouth; no true jaws; 2 (possibly 1 sometimes) semicircular canals; pelvic fins lacking, pectoral finlike structures, when present, lacking fin rays; persistent notochord, without bone or cartilage; bony skeleton, when present, formed in skin; true gill arches absent, gill basket present. Habitat of fossil groups uncertain; earliest probably in fresh water (see AGNATHA).

##### Subclass Monorhina

With 1 nostril.

†*Order Osteostraci.* Late Silurian to close of Devonian. Heavily armoured with bony plates and scales; bony head shield present; bone cells tend to be absent; pectoral appendages present in some; eyes dorsal, close together; no common gill opening; bottom-dwelling with heterocercal tails. Length about 8–75 cm.

†*Order Anaspidia.* Late Silurian to Late Devonian. Heavily armoured with bony plates and scales; head protected by small bonelike plates; bone cells present; pectoral appendages various, spine or fleshy fold; eyes not close together but facing laterally; no common gill opening; probably swam above bottom with tail lobe extending downward (hypocercal). Length about 10–25 cm.

*Order Cyclostomata* (Lampreys and hagfishes). Pennsylvanian and Recent. Freshwater and marine, breeding in fresh water (lampreys); or marine only (hagfishes). Without dermal ossification of any sort; pectoral appendages absent; eyes

more or less lateral or dorsal (poorly developed in hagfishes); gill openings multiple, not common; tail more or less diphy-cercal. Primarily bottom-dwelling fishes, but suctorial, feeding on blood and juices of live fishes (lampreys) or rasping and feeding on flesh of dead or dying fishes (hagfishes); horny teeth present. Length about 15–100 cm.

##### †Subclass Diplorhina

With 2 nostrils.

†*Order Heterostraci.* Ordovician to Upper Devonian. Usually heavily armoured, with a head shield in many species and scales or plates; bone cells absent; thin layer of enamel present over bone surface; no paired fins; eyes lateral and far apart; common gill opening present; tail hypocercal. Some perhaps midwater swimmers, others flattened bottom forms. Length about 5 to at least 30 cm.

†*Order Coelolepida.* Upper Silurian and Lower Devonian. Small, little known agnaths of uncertain affinities. Appear to have had armoured head; body with small bony plates or scales; paired fins uncertain; eyes lateral; gill openings uncertain; number of nostrils uncertain; tail apparently reversed heterocercal. Length up to about 10 cm.

#### †CLASS ACANTHODII

Jaws apparently formed of the 3rd gill arch (as in all jawed vertebrates) but attached to cranium and hyoid (4th) arch (amphistylic); jaws with teeth; pectoral and pelvic fins present, often with additional paired fins or spines between these; all fins except tail with a strong anterior spine; body covered with bony scales of the ganoid type, with bone cells tending to be lost in some members; no head shields but small dermal plates over head; some known with partially ossified vertebral column; cranium partially ossified; gill opening between jaws and hyoid arch apparently reduced to a spiracle; 3 semicircular canals (as in all higher fishes); an opercle (gill cover) present, attached to hyoid arch, followed by a series of smaller opercles, 1 over each remaining gill opening; caudal fin heterocercal. Active, free-swimming fishes with large eyes placed laterally. Small species probably freshwater, some larger species may have gone to sea.

†*Order Climatiformes.* Upper Silurian to Lower Carboniferous. With 2 dorsal fins; 2 or more free spines present between pectoral and pelvic fins; operculum not covering entire gill chamber; supplementary operculae present or in some cases operculum covering entire gill chamber; no extramandibular bone. Mostly small, about 10 cm long.

†*Order Ischnacanthiformes.* Upper Silurian to Middle Carboniferous. With 2 dorsal fins; no free spines between pectoral and pelvic fins; operculum complete; no extramandibular bone.

†*Order Acanthodiformes.* Upper Silurian to Lower Permian. With 1 dorsal fin; no intermediate spines (or with a single pair) between pectoral and pelvic fins; operculum covering all or nearly all of opercular chamber; extramandibular bone present. Length to about 30 cm.

#### †CLASS PLACODERMI (placoderms)

Jaws amphistylic (supported by both the cranium and hyoid arch); pelvic fins present or absent; pectoral fins or finlike structures often present; often with ossified or partially ossified vertebral column and internal cranium; gill arches present; skeletal ossification reduced in some groups; caudal fin most often heterocercal or some modification of this form. Habitat in many cases uncertain, but apparently most later groups were marine (for further information, see PLACODERMI).

†*Order Arthrodiriformes* (arthrodires). Throughout the Devonian, especially common in last half of the period. Head and gill and trunk (thoracic) shields present (the two hinged upon each other in later Devonian forms); entire body more or less fusiform, sometimes flattened; pectoral and pelvic fins usually present and not encased in armour; jaws (when well preserved) of tusklike dermal bony elements. Some early groups freshwater; later groups with giant species (up to 10 m), marine.

†*Order Rhenanidiformes.* Found throughout the Devonian, but more common in first half of the period. Covered with small bony plates, head shield present in some; body flattened, raylike with eyes on top of head; gill chambers typically placoderm in occupying a large area below head; pectoral fins greatly enlarged; transverse jaws armed with teeth; apparently primarily marine. Average length about 24 cm.

†*Order Antiarchiformes* (antiarchs). First known from Middle Devonian, extinct by end of the period. Head and thorax shield present; internal skeleton partially ossified in some; body fusiform but flattened ventrally for bottom living; pectoral fins movable but encased in armour; jaws of small transversely placed bony plates; eyes close together on top of head; well-preserved specimens show intestine with a spiral

valve and lunglike structures; apparently mostly small bottom-dwelling freshwater fishes. Length about 10–40 cm.

†*Order Stensioelliformes*. Lower Devonian. Not well-known but appearing to have a general lack of bone development, isolated tubercles covering skin in some; gill bars and jaws well developed in reasonably well-preserved specimens; marine. Small; length about 25 cm.

†*Order Palaeospondyliiformes*. Middle Devonian. Relationships uncertain, not a typical placoderm. Dermal armour lacking; ring-shaped vertebral centra and neural arches present; jaws apparently present. One genus, *Palaeospondylus*, many specimens, probably of a single species. Length about 4 cm.

### CLASS SELACHII (sharks, skates, rays, and relatives)

Vertebrates with jaws; dermal and endochondral bone absent, cartilage often calcified but no true bone except possibly at base of teeth and denticles (controversial); scales placoid, of dentine and enamel, present over entire body and enlarged to form teeth on jaws; scales and teeth do not grow once fully formed but are replaced when worn out; notochord often reduced, partially replaced by cartilage, which joins the connective tissue covering of the notochord; labial cartilages present in some; spiracle present (sometimes lost); claspers (pterygopodia) often present in pelvic fins of males, used in mating; intestinal spiral valve present in modern forms (condition in fossils unknown); lungs or swimbladder-like structures absent in modern forms (see SELACHII).

†*Order Cladoselechiiformes*. Middle Devonian to close of Permian. Notochord persistent in adult; 2 dorsal fins; each with a spine; no anal fin; basal cartilages or cartilages of pectoral fin remain along base of fin, radial cartilages unjointed; pelvic fins without claspers; tail fin externally almost symmetrical but internally heterocercal; jaws amphistylitic (upper jaw articulates with cranium and hyoid bone); rostral region of cranium small; postorbital process of cranium large; teeth with 1 large median cusp and smaller lateral cusps; 5 gill openings; marine predators.

†*Order Cladodontiformes*. Middle Devonian to about end of Permian. Notochord persistent in adult; 2 dorsal fins each with or without dorsal spine; anal fin absent; basal cartilage or cartilages of pectoral fin remain along base of fin; radial cartilages unjointed; pelvic fins with claspers; tail fin externally equilobate but internally heterocercal; jaws amphistylitic; rostral region of cranium small; postorbital process of cranium large; teeth with 1 large median cusp and smaller lateral cusps; 5 gill openings; marine predators.

†*Order Xenacanthiformes*. Upper Devonian to Middle Triassic. Notochord persistent, but reduced, in adult; some cartilage present; 1 long-based dorsal fin, no spines; postoccipital head spine present; 2 anal finlike structures present; basal cartilages of pectoral fins in series and enter fin as axial element, radial cartilages unjointed; pelvic fins with claspers; tail fin diphycercal; rostral region of cranium small; postorbital process of cranium large; teeth with a small central cusp and a large lateral cusp on each side; 5 gill openings; freshwater predators.

*Order Heterodontiformes*. Upper Devonian to Recent. Notochord persistent in primitive forms, replaced partially in advanced ones; 2 dorsal fins, each with a spine; anal fin present; 3 basal cartilages in pectoral fin or a modification of this condition; fin more mobile than 3 preceding orders, radial cartilages of pectoral fins jointed; pelvics with claspers; tail heterocercal or modified from this; jaws remain amphistylitic but trend toward hyostylic (supported by movable hyomandibular cartilage); postorbital process of cranium large to reduced; rostral region of cranium usually small; teeth cladodont-like to very modified and rounded; 5 gill openings; marine, several modern forms mollusk eating in habit (heterodonts). Includes the more primitive fossil hybodonts and more specialized, living, heterodonts or hornsharks (Heterodontidae).

*Order Hexanchiformes*. Jurassic to Recent. Notochord persistent but in some constricted anteriorly; 1 posterior spineless dorsal fin present; anal fin present; basal cartilages of pectoral fin reduced in number; radial cartilages of pectoral fins jointed; pelvic fins with claspers; tail heterocercal to nearly diphycercal; jaws essentially amphistylitic but contact with hyoid arch absent in Hexanchidae; postorbital process of cranium reduced; teeth trifold in Chlamydoselachidae, many-pointed in Hexanchidae; 6 to 7 gill openings; marine predators; 2 living families, Chlamydoselachidae (frilled shark) and Hexanchidae (cowsharks).

*Order Lamniformes* (typical sharks). Lower Jurassic to Recent. Notochord in adults replaced by calcified cartilaginous centra; 2 dorsal fins present, opened or not; anal fin present or absent; 2 basal cartilages of pectoral fin reduced (except Orectolobidae, which has 2); pelvics with claspers,

and with basal cartilage; tail heterocercal; jaws hyostylic, mobile, shortened and protrusible; postorbital process of cranium reduced; teeth with varied cusps; 5 gill openings; rostral area elongate; about 15 living families, typical sharks, mostly marine predators, free-swimming and bottom-dwelling, few in freshwater. Length to about 20 m.

*Order Pristiophoriformes* (sawsharks). Cretaceous to Recent. Like Lamniformes, but with 6 gill openings. Elongated, flattened snout with sawlike teeth along sides in Recent members; body somewhat flattened but elongated; marine shore fishes and in fresh water, tropics. Length (in modern species) to about 1.2 m.

*Order Rajiformes* (rays, banjo-fishes, and sawfishes). Upper Jurassic to Recent. Notochord replaced with calcified cartilage; 2, 1 or no dorsal fins; spines absent or present; anal fin absent; pelvic fins with claspers; tail heterocercal to modified, whiplike; jaws modified, supported by pseudohyoid cartilage, very mobile; 5 gill openings; rostral area elongate; marine bottom-dwelling sharklike fishes, flattened; spiracle (lateral opening) used for intake of water to gill chamber; eyes on top of head; gills ventral; greatly enlarged pectoral fins extend forward along gill opening, attached to sides of head and even meet in front of head in some; swim by wavelike motions of pectoral fins; 8 extant families, including Torpedinidae (electric rays). Medium to large fishes; maximum width (in manta ray) to 7 m, weight to 1,700 kg; length (in sawfish) to 11 m with weight to at least 2,500 kg.

### CLASS HOLOCEPHALI

Jaws holostylic (the palatoquadrate) supporting the upper jaw completely fused to cranium; hyoid arch complete, unmodified; branchial arches below cranium; internal skeleton of cartilage, often calcified but never of bone; dermal skeleton of dentine or dentine-like tissue (placoid scales), never with true bone; scales do not continue to grow once fully formed; pelvic and cephalic claspers in males of some groups.

*Order Chimaeriformes* (chimaeras). Upper Devonian to Recent. Teeth in a single series of a few tooth plates along each jaw ramus (half); pectoral with 2, and pelvic fins with 1 basal element; pelvic fin claspers present; dermal armour frequently present on head; primitive forms with placoid scales covering body, lost in certain advanced forms; scales specialized in some; dorsal fin spine present or absent; cephalic clasper present in some; marine.

†*Order Copodontiformes*. Devonian to Carboniferous. Known from teeth only; relationship uncertain. Marine.

†*Order Psammodontiformes*. Lower to Upper Carboniferous. Teeth only; little known. Marine.

†*Order Helodontiformes*. Lower Carboniferous to Upper Permian. Teeth numerous, about 10 series on each jaw ramus, some fused into tooth plates; no specialized symphyseal teeth; no cephalic clasper; pelvic claspers unknown; placoid scales cover body; marine.

†*Order Petalodontiformes*. Fossil only; Lower Carboniferous to Upper Permian. Known from teeth only, relationships uncertain; marine; Europe, Asia, North America.

†*Order Edestiformes*. Fossil only; Lower Carboniferous. Known only from specialized symphyseal (fused) teeth; marine; Europe, North America.

†*Order Chondrenchelyiformes*. Lower Carboniferous. Upper jaw with 4 pairs of tooth plates; lower jaw with 3 pairs of tooth plates; dermal plates on skull, cephalic clasper and dorsal fin spine absent, dorsal fin long, continuous along back; marine; known only from Scotland.

### CLASS SARCOPTERYGII (fleshy-finned fishes)

Primitive members of the following 2 orders show certain similarities and so are placed together in this class. Some of these similarities are: Heterocercal tail fin with a small amount of fin development above the vertebral column at the posterior end of the tail fin; 2 dorsal fins present; pectoral fins an archipterygium of variable form (an axial median support with side branches); cosmoid scales present, similar to that in acanthodians; modern freshwater forms have lungs; presumably lungs were present in fossil freshwater forms also. Scales grow throughout life of the individual. The internal nares of the Crossopterygii and the Dipnoi may or may not have the same origin.

*Order Crossopterygii* (coelacanths and fossil relatives). Lower Devonian to Recent. Cranium divided into 2 parts (anterior and posterior) at region for exit of the 5th cranial nerve, these parts movable on each other; choanae (internal nares) present (lost in coelacanths); teeth labyrinthodont (i.e., with complicated unfoldings of the enamel surface); 2 important groups, suborder Rhipidistia, Lower Devonian to Early Permian, mostly shallow freshwater and thought to have given rise to terrestrial vertebrates during the Devonian, and the suborder Coelacanthini, Upper Devonian to Recent,

mostly marine, includes the so-called living fossil, *Latimeria chalumnae*, from South Africa, which lacks lungs. Length of rhipidistians to about 3 m; of coelacanths to about 2 m (see CROSSOPTERYGII).

**Order Dipnoi** (lungfishes). Lower Devonian to Recent. Cranium not divided into movable parts; teeth on upper jaw early reduced and lost in later members; pterygoid bones with fused teeth in plates modified for eating mollusks; 3 surviving types of lungfishes, 1 each in Australia, Africa, and South America (see DIPNOI). Length 60–200 cm.

#### CLASS ACTINOPTERYGII (ray-finned fishes)

Fins supported by rays of dermal bone rather than by cartilage or cartilage bones. A group of jawed fishes so diverse that no single definition for them can be derived; better understood by determining the distinctive characters of the primitive members and then tracing their various lines of evolution. Primitive actinopterygians can be separated from the sarcopterygians by the following characteristics. Scales ganoid; single dorsal fin; pectoral fins with a series of thin radial bones, rather than basal plates and fleshy lobes; no internal nares. Other important characters: skeleton usually well ossified; scales grow throughout life; swim bladder present (occasionally modified to a lunglike structure).

#### Infraclass Chondrostei

A mixed group that has undergone many evolutionary diversifications. The remaining orders of the Chondrostei are specialized, often for special habitats and ways of life, but many of the groups show trends toward the holostean level of organization, especially in median fin structure and the development of hemiheterocercal tail in which externally at least the tail appears nearly homocercal (see CHONDROSTEI).

†**Order Palaeonisciformes**. Lower Devonian to Middle Cretaceous. Mostly fusiform fishes with heterocercal tail; maxillary bone of the upper jaw bound to the preopercle bone space for the muscle restricted to lower jaw, limiting its power and function; many more fin rays than basal elements in the median fins; 37 families of wide distribution, early members freshwater, later marine.

†**Order Tarrasiiformes**. Carboniferous. Palaeoniscid-like, but with elongate body, a diphyccercal tail and dorsal and anal fins continuous with it. One family, Tarrasiidae, Scotland and Illinois.

†**Order Haplolepidiformes**. Upper Carboniferous. Peculiar fishes with stout unbranched fin rays; large gular plates; small opercular apparatus. One family, Teleopterinae; Europe and North America.

†**Order Perleidiformes**. Lower to Upper Triassic. With ganoid scales; fin rays equal number of basal supports rather than exceed them as in Palaeonisciformes and other Chondrostei; tail hemiheterocercal. Three families; worldwide.

†**Order Redfieldiiformes**. Lower and Middle Triassic. Like Perleidiformes but fin rays more numerous than basal elements in dorsal and anal fins. One family, Dictyopygidae, fresh water of South Africa, Australia, and North America.

†**Order Dorypteriformes**. Upper Permian. Similar to Bobasatraniaformes but with very modified skull; scales confined to anterior part of trunk. One family, Dorypteridae; Europe, China.

†**Order Bobasatraniaformes**. Lower Triassic. Body deep, laterally compressed; fin rays slightly more numerous than basal supports; opercular apparatus with small opercle, large preopercle; crushing dentition; pelvis absent. Thought to perhaps have been a coral feeder. One family, Bobasatraniaidae; marine; widely distributed.

†**Order Pholidopleuriformes**. Lower to Upper Triassic. Some relatively long and slender; dorsal and anal fins far back on body, origin of anal fin anterior to dorsal fin; fin rays more numerous than basal elements; tail hemiheterocercal; jaw support almost vertical or moderately oblique, rather than extremely oblique as in most Chondrostei. One family, Pholidopleuridae; marine and freshwater; wide distribution.

†**Order Peltopleuriformes**. Upper Triassic. Large eyes; hemiheterocercal tail almost symmetrical externally; dentition weak. Two families, Peltopleuridae and Habroichthyidae; marine, perhaps some plankton feeding; Italy, China.

†**Order Platysiagiiformes**. Lower Triassic to Lower Jurassic. Elongate, fusiform body, tail hemiheterocercal; median fins holostean, in that rays probably equalled basal elements; teeth large, conical. One family, Platysiagidae; marine; probably predacious; Italy and England.

†**Order Cephaloxeniformes**. Middle to Upper Triassic. Body deep, fusiform; thick head bones and crushing dentition; tail hemiheterocercal. One family, Cephaloxenidae; marine; probably bottom-dwelling mollusk eaters; Italy.

†**Order Laganioiiformes**. Middle and Upper Triassic. Almost holostean in character; body fusiform; head somewhat

flattened in the horizontal plane; some head bones fused; jaw suspension inclined forward; fin rays apparently equal to basal elements in number; tail hemiheterocercal. One family, Laganioiidae; marine; probably predacious midwater fishes; Italy.

†**Order Ptycholepidiformes**. Middle Triassic to Upper Jurassic. Structure near that of holosteans; fusiform body; fin rays of median fins nearly equalling basal elements in number; jaw support almost vertical; teeth small. One family, Ptycholepididae; marine; presumably plankton feeders; Europe.

†**Order Saurichthyiformes**. Lower Triassic to Upper Jurassic. Elongate, slender; snout elongate; single dorsal fin far back on body, opposite anal fin; tail diphyccercal in appearance; number of scale rows reduced, 1 dorsal, 1 ventral, and 1 along each side; jaw suspension almost vertical; teeth large, conical, jaws long. One family, Saurichthyidae; marine and freshwater; predacious; worldwide. Length about 7–150 cm.

†**Order Chondrosteiformes**. Lower Triassic to Upper Jurassic. Body scales and skull bones reduced; snout moderately developed, maxillary and opercular bones reduced; jaw support somewhat inclined backward; median fins paleoniscid-like, rays more numerous than basal supports. Probably gave rise to sturgeons. One family, Chondrosteidae; marine; some were suctorial feeders like sturgeons; England.

†**Order Paraseimionotiformes**. Lower Triassic. Very near holosteans in structure but preopercle large and true suborbital bones still present, as in chondrosteans. Two families; marine; Siberia, Greenland, and Madagascar.

**Order Acipenseriformes** (sturgeons and paddlefishes). Upper Cretaceous to Recent. Almost no internal ossification; scales as large scutes in isolated rows (Acipenseridae); snout enlarged and tactile (Polyodontidae); median fins chondrosteian in having more fin rays than basal elements; tail heterocercal. Marine and freshwater, bottom suctorial feeders (sturgeons, Acipenseridae; Europe, Asia, North America) and plankton feeders (paddlefishes, Polyodontidae; China and North America). Length (sturgeons) up to 9 m, weight to 1,400 kg.

**Order Polypteriformes** (bichirs and reedfish). Pleistocene to Recent. Relationships controversial, placed in own subclass by some and thought related to crossopterygians by others. Typical chondrosteian characters, such as ganoid scales and a paleoniscoid type of preopercle. Fins modified into long continuous dorsal, tail diphyccercal; freshwater; Africa.

#### Infraclass Holostei

Tail hemiheterocercal; maxillary scale free of preopercle; rays of median fins about equal basal elements in number; spiracle lost; vertebral column tended to increasing ossification; trend toward thinning scales and loss of ganoid layer (see HOLOSTEI).

#### Division Holosteans

Preoperculum intimately bound to and supporting the posterior border of the palate.

**Order Amiiformes** (bowfin and fossil relatives). Upper Triassic to Recent. Relatively conservative holosteans with typical holostean characters as given above; some specialized in body shape (elongate); most typical fusiform holosteans. One living member of the family Amiidae, with 1 species, *Amia calva* (bowfin), of North America; marine and freshwater, almost worldwide; 6 families.

†**Order Pachycormiformes**. Lower Jurassic to Upper Cretaceous. Long snout, suggesting the teleost swordfishes, Xiphiidae. Two families; Europe and North America.

**Order Semionotiformes** (gar pikes and fossil relatives). Upper Permian to Recent. Two families of widely divergent fishes; probably independent of the Amiiformes but with typical holostean characters; the fossil Lepidotidae with normal holostean fusiform bodies, which become relatively deep and slab-sided in some members; marine and freshwater, widely distributed. Gar pikes (Lepisosteidae) are elongated, sharp snouted, primarily freshwater predators, still extant in North America; length to about 3.5 m.

†**Order Pycnodontiformes**. Lower Jurassic to at least Eocene. Very deep bodied, with jaws and teeth modified for nibbling; perhaps fed on coral; marine and widespread.

#### †Division Halecostomes

Holosteans but with a preoperculum not buttressing the bones of the palate.

†**Order Pholidophoriiformes**. Upper Triassic to Upper Cretaceous. Difficult to separate from the more primitive of the teleost orders (below). Holosteans with some trends toward teleosts, notably: loss of ganoine from fin rays, scales, and dermal bones; loss of peg and socket joints between scales; loss of bone cells in scales retained in some teleosts; development of intermuscular bones; loss of scalelike bones (fulcra) on leading edges of fins (retained in caudal fin of

some teleosts); loss of some skull bones; a "sinking" of skull bones beneath the skin. The caudal skeleton is the major difference between the pholidophoroids and teleosts. Pholidophoroids have the caudal centra incompletely ossified and lack "splint" bones called uroneurals (modified neural arches) that give ridged support to the terminal 4 or 5 vertebrae in teleosts. About 7 families, of which the Jurassic Pholidophoridae are the most likely ancestors of the teleosts; marine and freshwater, of wide distribution.

#### **Infraclass Teleostei** (bony fishes)

Tail homocercal; caudal skeleton with perichordally (around the spinal chord) ossified centra; neural arches modified into elongate uroneurals extending forward onto the preural centra, "stiffening" the joints between the terminal 4 or 5 vertebrae. Two hypural bones supporting the lower caudal fin lobe. (Note: Although the above statement can be used to define and separate early teleosts from holosteans, many later groups of teleosts have modified the tail structure greatly, so the definition will not "fit" at first sight. It can be readily shown, however, that all teleosts have a caudal structure derived from that described above.) Teleosts never have ganoid scales; typically, their scales when present are thin, overlapping plates of bone that continue to grow throughout life; their lower jaws lack certain bones found in many chondrosteans or at least have some of these bones fused to single elements (see TELEOSTEI).

†**Superorder Leptolepidomorpha.** The recognition of this superorder is highly tentative pending determination of the relationships of these fishes with other teleosts. Sometimes classified with the Halecostomi, these fishes were clearly teleosts in their caudal fin structure. Preopercle supported the palate (as in some holosteans) but with several shifts in this region to a teleost-like preopercular-jaw arrangement and with the adductor muscle of the mandible attached to preopercle; no bone cells in scales; more than 1 supraorbital; gular plate present; apparently no adipose fin; rostral elements with a bone enclosed commissure.

†**Order Leptolepidiformes.** Triassic to Middle or Upper Cretaceous. The characters of the order are those listed above for the superorder. Four families; widely distributed.

**Superorder Elopomorpha.** A diverse group including very primitive fishes and specialized fishes such as eels and therefore difficult to define. Some primitive members with a gular plate (absent in eels), ethmoid commissure present in some forms in a dermal rostral bone (lost in many eels); a leptoccephalus larva; no bone cells in scales of primitive members; pelvic fins abdominal when present.

**Order Elopiformes** (tarpons, tenpounders, and bonefishes). Upper Jurassic to Recent. Body fusiform, typical fishlike shape; bone-enclosed ethmoid commissure present; roofed post-temporal fossae; primary bite a tongue-parasphenoid type; marine; worldwide in temperate and tropical zones (see ELOPIFORMES).

**Order Anguilliformes** (eels). Cretaceous to Recent. Body elongate; fins reduced and gill chamber modified; displaced posterior to much of head; opercular apparatus reduced; pectoral girdle free of skull; caudal and other fins often greatly reduced; bony ethmoid commissure sometimes present; marine and freshwater, worldwide in temperate and tropical regions. Length about 15–300 cm (see ANGUILLIFORMES).

**Order Notacanthiformes** (deep-sea spiny eels). Middle Cretaceous to Recent. Ethmoid commissure present, like that of elopomorphs; body relatively elongate and tail skeleton reduced; opercular apparatus complete. Three marine, deep-sea families, Halosauridae, Lipogenyidae, and the Notacanthidae (deep-sea spiny eels). Average length about 50 cm.

**Superorder Clupeomorpha.** Special type of ear-swim-bladder connection present, consisting of a diverticulum of the swim bladder, forming bulla (cavity) within the ear capsule; head lateral line canals on operculum. A diverse group of mostly oceanic, silvery, compressed fishes, many of great commercial importance.

**Order Clupeiformes** (herrings, anchovies, and allies). Lower Cretaceous to Recent. Characters of the superorder; marine and freshwater, some anadromous; worldwide (see CLUPEIFORMES).

**Superorder Osteoglossomorpha.** A diverse group of freshwater fishes with a relatively primitive jaw suspension and shoulder girdle. The primary bite of the mouth between parasphenoid and tongue (basihyal and glossohyal); paired rods present, usually bony, at the base of the second gill arch; no bony ethmoid commissure; no leptoccephalus larvae (see OSTEOGLOSSOMORPHA).

**Order Osteoglossiformes** (bony tongues, freshwater butterfly fishes, mooneyes, knife fishes). Middle Cretaceous to Re-

cent. Circumorbital bones well-developed; scales with an irregular reticulated pattern (except Pantodontidae); fresh water, almost worldwide except extremely cold regions. Four families.

**Order Mormyriiformes** (mormyrs). Pleistocene to Recent. With electricity-producing organs; orbital bones reduced; the cerebellum greatly enlarged; swim-bladder-ear connection reduced in adult; sometimes with long snouts for feeding in mud; 2 families, the elephant fishes, Mormyridae, and the Gymnarchidae; fresh water, Africa.

**Superorder Protacanthopterygii.** A diverse group of relatively primitive teleosts, mostly related by their lack of the specializations (or, in some cases, primitive features) found in the other teleost superorders. Vertebrae usually more than 24; adipose fin present in many members; mesocoracoid bone usually present; glossohyal teeth usually prominent (lost in some); upper jaw usually not protrusible; proethmoid and a series of several perichondral ethmoid commissure; 1 supra-orbital bone; no gular plate.

**Order Salmoniformes** (salmons, trouts, whitefishes, smelts, pikes, and allies). Cretaceous to Recent. Characters are those given for superorder; endochondral ossification often somewhat reduced; marine and freshwater, worldwide. A large and important order, comprising about 35–40 extant and about 6 fossil families. Length about 4–115 cm; weight to about 50 kg (see SALMONIFORMES).

**Order Ctenothrissiformes.** Mostly Upper Cretaceous, marine fishes of uncertain affinities; possibly close to the basal stock from which the acanthopterygians are derived. The living marine family Macristiidae may belong here.

**Order Gonorhynchiformes** (milkfish and certain deep-sea fishes). Cretaceous to Recent. Toothless; with epibranchial organs and a characteristic caudal skeleton; marine of Indo-Pacific and freshwater of Africa. The anterior ribs and vertebrae show affinities with the superorder Ostariophysi and the group may belong with the ostariophysans rather than with the Protacanthopterygii. Length about 10–150 cm.

**Superorder Ostariophysi.** A group of 5,000–6,000 species, including the majority of known freshwater fishes. Characterized by possession of a Weberian apparatus, (a swim-bladder-internal-ear connection with three movable bones; see OSTARIOPHYSI).

**Order Cypriniformes** (characins, tetras, some knife-fishes, carps, and minnows). Lower Eocene to Recent. Parietal, symplectic, and subopercular bones present; worldwide in fresh water except Antarctica and Australia. A few North Asian forms enter the sea.

**Order Siluriformes** (catfishes). Paleocene to Recent. Parietal, symplectic, suboperculum, and true scales absent; often with dermal plates or little bony spines in the skin. Fusion of the supportive parts of the Weberian apparatus extensive. About 30 families; distribution of the superorder, primarily freshwater but some families marine, with the majority of the 2,000 species in Africa and South America.

**Superorder Scopelomorpha.** This superorder, like the Paracanthopterygii and Acanthopterygii (below), is characterized by a tendency toward fin spines, subocular shelves, and separated exoccipital condyles. Scopelomorphs frequently retain such primitive structures as an adipose fin and an asymmetrical caudal fin skeleton.

**Order Myctophiformes.** Cretaceous to Recent. Characters of the superorder. Distinctive jaw musculature, like that of Paracanthopterygii (below). Two subgroups of this order differ in ecology and structure. One contains several families of deep-sea fishes, often elongated predators with large teeth. The second contains benthic or bottom-dwellers (e.g., Aulopidae), tropical inshore fishes (Synodontidae, or lizard-fishes), midwater deep-sea fishes with light organs (the large family Myctophidae, or lantern fishes), and bottom-dwelling deep-sea fishes (e.g., Bathypetroidae, or spiderfishes). Order contains about 15 families, worldwide; marine. Mostly small fishes 10–15 cm; maximum length about 95 cm.

**Superorder Paracanthopterygii.** Most with a distinctive type of jaw musculature (involving levator maxillae superioris muscle and associated structures); caudal vertebrae with the 2nd ural centrum fused with the upper hypural, 2 or fewer epurals and a full neural spine on the 2nd preural centrum; pelvic fins usually placed anteriorly, thoracic (midbody) or even further forward. In general these fishes have tended to lose primitive acanthopterygian characters. For a more detailed discussion of this suborder see PARACANTHOPTERYGII.

**Order Polymixiiformes** (barbudos). Middle Cretaceous to Recent. Barbels suspended from the hypohyal bones (anterior part of the gill arches); spines on the dorsal and anal fins; pelvic fins subthoracic. Retain some primitive paracanthopterygian characters, such as an antorbital bone, a free

second ural centrum, 6 autogenous hypurals, 2 uroneurals, and Baudelot's ligament to the 1st vertebra. Adipose fin lacking. Deepwater marine fishes; 1 family, probably only 2 species. Adult length about 30 cm.

**Order Percopsiformes** (trout perches, pirate perches, and cave fishes). Eocene to Recent. Mouth gape and buccal dentition reduced; median fin spines reduced or lost; head with spine ornamentation of the head; scale covering of the adipose fin lost. All living species freshwater, North America; length 8–13 cm. Three extant families, 1 fossil family.

**Order Gadiformes**. Lower Eocene to Recent. Early gadiforms were similar in structure to early percopsiforms but almost all remained marine and subsequently specialized into a variety of environments. Reduced caudal skeleton; elongate body; altered head and jaw structure. Primitive gadiforms have 7 branchiostegal rays, primitive percopsiforms 6. All with very reduced fin spines; marine, worldwide. Order includes cods, hakes, cusk eels, pearlfishes, eel pouts, grenadiers, and rattails. Length 7 to about 200 cm.

**Order Batrachoidiformes** (toadfishes). Miocene to Recent. Bottom fishes with short, small, spinous dorsal fins; long soft-rayed dorsal fins; flat heads; 1 family, Batrachoididae; marine, occasionally freshwater, shore fishes of tropics. Length to about 40 cm.

**Order Lophiiformes** (goosefishes, anglerfishes, frogfishes and batfishes). Eocene to Recent. Spinous dorsal fin modified as a movable lure. Some deep-sea forms with light organs and males parasitic on females. Marine, widespread; in shallow-water and deep-sea habitats. About 15 families. Length to about 130 cm.

**Order Gobiesociformes** (clingfishes). Recent questionable fossil from Miocene of California. Flattened, depressed fishes with a ventral sucker formed of the pelvic fin and surrounding tissue; no spiny dorsal fin; 1 family, Gobiesocidae; marine and occasionally freshwater in tropics and along many temperate seacoasts.

**Superorder Acanthopterygii** (spiny-rayed fishes). Spiny fins usually emphasized, rather than reduced (as in paracanthopterygians). Mobile, protractable mouth due to the almost universal lack of the levator mandibula superioris muscle; pectoral fin relatively higher on side of body; Baudelot's ligament almost always attached to basicranium. The 13 orders of the superorder Actinopterygii may be divided into 2 categories (sometimes called series), on the basis of the number of vertebrae, the condition of the fin spines, the position of the pelvic fins, and the presence or absence of ctenoid scales. The series Atherinomorpha contains only the order Atheriniformes, the series Percomorpha the remaining actinopterygian orders.

**Order Atheriniformes**. Eocene to Recent. Fin spines present or absent, but frequently weak when present; vertebral number higher than 24; ctenoid scales rare; pelvic fins abdominal, subabdominal, or thoracic in position. Marine shore fishes, also freshwater, tropical and temperate, worldwide. About 16 families, including the oceanic flying fishes (Exocoetidae), killifishes (Cyprinodontidae), live-bearing topminnows (Poeciliidae), and silversides (Atherinidae). Mostly small fishes (2–10 cm) but some needlefishes (Belonidae) to about 130 cm (see ATHERINIFORMES).

**Order Lampridiformes**. Paleocene to Recent. Intermediate in some ways between polymixioids and acanthopterygians, but all living members very specialized. All lack a subocular shelf and pelvic spine; some have a peculiar condition (hypurostegy) in which caudal rays are expanded. Marine, oceanic, tropic, and temperate regions. About 9 families. Medium to large size; to about 2 m and 300 kg in the opah (Lampridae) and about 10 m, but far less weight, in the more slender oarfishes, Regalecidae (see ATHERINIFORMES).

**Order Beryciformes**.—Squirrelfishes and certain deep-sea fishes. Cretaceous to Recent. Spines present in fins; pelvic fins subthoracic; retained primitive number of caudal branched fin rays (17), primitive number of epurals (3); occipital condyles poorly developed; orbitosphenoid present. About 15 families of small to medium-sized fishes. Length 5–60 cm. Marine, worldwide in tropical and temperate regions (see ATHERINIFORMES).

**Order Zeiformes** (dories, boarfishes, and relatives). Lower Eocene to Recent. Anal fin with 1–4 spines; pelvic fin with 1 spine and 5–9 branched rays; caudal fin with less than 15 principal rays; about 6 families, of which the dories, Zeidae, are best known; marine, deep-sea, widespread. Length to about 1 m (see ATHERINIFORMES).

**Order Gasterosteiformes** (sticklebacks, tubenoses, and sea-horses). Eocene to Recent. Frequently with strong spines in dorsal fin and pelvic fins, spines absent in some; snout often elongate; body often with dermal plates; 9 families, marine and freshwater, widely distributed. Length about 3–200 cm (see GASTEROSTEIFORMES).

**Order Channiformes** (snakeheads). Pliocene to Recent. Elongate bodies; dorsal and anal fins present; depressed head with an accessory air-breathing apparatus in the gill chamber. Snakeheads, Channidae; fresh water, tropical Old World. Length about 15–95 cm.

**Order Synbranchiiformes** (swamp eels). No fossil record. Fins reduced, fin spines absent, pharynx modified for breathing air. Three families, restricted to fresh water, in tropics. Length 20 to about 50 cm.

**Order Scorpaeniformes** (scorpionfishes, sculpins, and relatives). Eocene to Recent. A complex group of widely divergent fishes that may be polyphyletic and is difficult to characterize. Three separate groups may be recognized here: scorpaenoid, hexagramoid-cottoid, and anoplomatoid. United as an order because of a distinctive caudal skeleton and a bony process connecting the 3rd orbital with the preoperculum in most members. Some members with external bony plates. About 21 families; primarily marine, some freshwater, tropical and temperate regions (see SCORPAENIFORMES).

**Order Dactylopteriformes** (flying gurnards). Pliocene to Recent. Bottom-dwelling shore fishes with dermal armoured plates, movable modified pectoral fin rays. Marine. One family, Dactylopteridae (see SCORPAENIFORMES).

**Order Pegasiformes** (dragonfishes). No fossil record. Bottom-dwelling marine fishes with dermal armour and large pectoral fins. One family, Pegasidae (see SCORPAENIFORMES).

**Order Perciformes**. Upper Cretaceous to Recent. Fins usually with spines; pelvic fin with 1 spine and not more than 5 rays, usually below pectoral fins; caudal fin with 15 rays; no orbitosphenoid, mesocoracoid, or intermuscular bones. An extremely varied assemblage of fishes, with a variety of body plans and other adaptations. About 140 families, divided among about 20 suborders. Mostly marine, worldwide. Adult length from about 1 cm (certain gobies) to about 4.8 m (swordfish); weight to about 900 kg (see PERCIFORMES).

**Order Pleuronectiformes** (flatfishes). Eocene to Recent. Both eyes on same side of head, skull twisted and asymmetrical, fins usually without spines. Seven families include flounders, soles, and halibuts; mostly marine; bottom fishes, worldwide in tropical and temperate regions (see PLEURONECTIFORMES).

**Order Tetraodontiformes**. Eocene to Recent. With a beak-like snout, gill opening restricted to a small opening; probably related to acanthuroids. Eleven families; marine, occasionally freshwater, worldwide in tropics and subtropics (see TETRAODONTIFORMES).

**BIBLIOGRAPHY.** Titles listed below pertain to the biology of fishes generally. Works on individual fish classes, subclasses, or orders are cited in the bibliographies accompanying the articles on the appropriate groups.

**General works:** E.S. HERALD, *Living Fishes of the World* (1961), a clearly written and extensively illustrated introduction to fishes; G. STERBA, *Freshwater Fishes of the World* (1962; orig. pub. in German, 1959), a general account of freshwater aquarium fishes; P.P. GRASSÉ (ed.), *Traité de zoologie*, vol. 13, *Agnathas et Poissons*, 3 pt. (1958), a classic and authoritative review in French of the classification, anatomy, and biology of fishes; J.R. NORMAN, *A History of Fishes*, 2nd ed. by P.H. GREENWOOD (1963), N.B. MARSHALL, *The Life of Fishes* (1965), and K.F. LAGLER, J.E. BARDACH, and R.R. MILLER, *Ichthyology* (1962), college-level introductory texts of general ichthyology.

## Fish and Marine Products

Fish and marine products include freshwater and ocean fish, shellfish, ocean mammals, and seaweed as well as plankton. They are a major food source, especially valuable for the protein they provide, and also a source of industrial products.

Ancient heaps of discarded mollusk shells, some from prehistoric times, have been found in coastal areas throughout the world, including those of China, Japan, Peru, Brazil, Portugal, and Denmark. These shell mounds indicate that marine mollusks were among the early foods of man. The predominance of the shells of bivalves shows that consumption of this group, including clams, mussels, and oysters, exceeded that of the gastropods, the group including snails and abalone, in both quantity and variety. As suggested by references in ancient Chinese and Japanese documents, the culture of clams, and the development of farms devoted exclusively to this industry, probably originated in the Far East.

Archaeological evidence shows that man next learned to catch fishes in traps and nets. Limited at first to the lakes and rivers, as he improved his boats and fishing devices he ventured into sheltered coastal areas and river mouths and eventually farther out on to the continental shelves, the relatively shallow ocean plains between the land and the deeper ocean areas. In some shelf areas where seaweed was abundant, this was also incorporated in his diet.

Fishing technology continued to develop throughout history, employing improved and larger ships, more sophisticated fishing equipment, and various food preservation methods. In the middle of the 20th century, man became concerned with greater utilization of the resources of the world's waters to feed an expanding population and especially in filling the need for high protein foods. At the same time, he became aware of the effects of overfishing and the importance of conservation measures (see FISHING, COMMERCIAL).

### ROLE IN THE HUMAN DIET

Aquatic organisms are consumed in almost every area of the world. They may be eaten raw or cooked and may be

**Table 1: Comparison of Protein and Protein Calories Provided by the Foods Commonly Consumed in Various Areas of the World**

	% protein weight	% protein calories
Yams	2.1	8.2
Sweet potato	1.8	6.5
Plantains	1.4	6.2
Taro	1.8	6.1
Cassava	0.9	2.3
Tapioca (cassava product)	1.5	1.8
Rice (polished)	5-8	5.7-8.8
White potato	2	9.4
Chinese cabbage	1.8	19
Beans (dry)	19	23
Fish (flesh)	18-25	48-85
Oysters	10	50
Shrimp	21	87
Pork	16	29
Beef	17	39
Veal	19	45
Poultry	21	56

preserved by salting, smoking, freezing, or other methods. Certain species are undesirable as human food because their flesh is either watery or too dry, contains too many bones, is lacking in flavour, or is extremely oily. However, the flesh of many other species is agreeable in flavour, appearance, and texture.

The muscular tissue of fishes consists of 13-20 percent protein; varying amounts of fat, ranging from under one to over 20 percent; and 60-82 percent water, varying inversely with fat content. Exact proportions vary among different species, and seasonal and feeding variations result in differences among individuals of the same species. The proteins and fats of both fishes and shellfishes are readily digested and compare favourably in food value with other meats.

**Vitamins, minerals, and fats.** The composition of the diet affects nutritive content, as well as flavour, of the flesh of fish. For example, only eels and related species deposit vitamin A in their flesh; it is not adequately synthesized by other species. However, fish liver contains vitamin A as a result of the passing of this nutrient along the food chain, the sequence in which each organism uses the next lower member as food. The halibut, for example, yields rich quantities of this vitamin, because it feeds mainly on *Sebastes*, a redfish found in the deep waters of the North Atlantic that has great quantities of vitamin A in its liver oil. The nutrient originates earlier in the food chain, starting with the drifting plant life called phytoplankton.

In many developing countries, the diet is low in fats, minerals, and vitamins. When fish is among the staple foods in these areas, the fatty species are preferred. In addition to supplying needed fat, such fish also provide the fat-soluble A, D, and E vitamins. The flesh of marine fish also supplies such essential minerals as iodine, fluorine, and calcium, providing two to three times the amount of fluorine obtained from the meat of land animals.

In the 1960s and 1970s medical scientists were exploring the relationship between consumption of polyunsaturated fatty acids and reduction of vascular disturbances in man. These acids, more readily broken down than other fatty acids, are characterized by a chemical composition in which the chains of carbon atoms, low in hydrogen, are connected by double bonds that are susceptible to the addition of oxygen. Because the fats in fish are high in polyunsaturated fatty acids, fish are recommended for the human diet.

**Proteins.** In an adequate human diet at least 12 percent of the caloric intake needs to be proteins, essential constituents of living cells. Table 1 compares the proteins provided by the major foods consumed in various areas of the world with those of seafoods and of meat from land animals. Seafood, usually more readily available and less costly than other meat foods, stands out as an efficient protein source, requiring fewer calories for the amount of protein intake than most other foods.

Evidence  
from  
shell  
mounds

Polyun-  
saturates

Protein  
deficiency  
diseases

Foods from aquatic sources have great potential in helping to alleviate shortages of food, and especially of high value protein, in many of the world's undeveloped areas. In the humid tropics, where diets are dominated by sugars or such low-protein tubers as cassava, taro, and plantain, the addition of aquatic protein can eliminate the common protein deficiency diseases. Kwashiorkor and other protein deficiency diseases do not occur in the coastal areas of Central America, tropical West Africa, or northeast Brazil when adequate supplies of fish are available. Aquatic protein is also valuable in diets dominated by corn (maize) or rice, and together with soybeans, seafood is a major ingredient of the daily diet in Japan and Southeast Asia.

In the period of 1967-68 protein from aquatic sources accounted for 18 percent of total animal protein consumed. Fish and shellfish consumed directly provided 14.5 percent, and fishmeal included in the diets of food animals accounted for another 3.5 percent. Table 2

**Table 2: Direct Intake of Animal Protein by Man (1967-68)**  
(in 000,000 metric tons)

land animal meats		land animal products		fish and shellfish	
Beef and veal	5.5	Milk	8.5	Commercial	3.4
Pork	5.1	Eggs	1.8	Subsistence	0.5
Others	1.7				
Total	12.3	Total	10.3	Total	3.9
Total direct animal protein intake: 26.5					

shows world consumption of animal protein foods in terms of millions of metric tons. In addition to the above figures for direct consumption, 2,200,000 metric tons of fishmeal protein were used as animal feed, rendering about 1,100,000 metric tons of the directly animal protein consumed by humans.

In many countries, especially in Asia, per capita consumption greatly exceeds the overall world average, accounting for as much as one-half to two-thirds of total animal protein consumed. The percentage of total animal protein consumption supplied by aquatic protein is 74 percent in Korea. Portugal, the largest seafood consumer in Europe, averages 44 percent. The Caribbean countries also consume large relative quantities of seafood, with aquatic protein supplying 30-50 percent of total animal protein intake.

Table 3 shows per capita consumption of fish in several countries that are traditionally large consumers of

**Table 3: Per Capita Intake of Fish Protein as a Portion of Total Protein Consumed**  
(1966-69 average)

	fish flesh (kg/year)	fish protein (g/day)	animal protein (g/day)	fish protein as percent of animal protein
Japan	64.1	15.8	28.2	56
Portugal	56.5	13.9	31.7	44
Denmark	44.5	11.0	60.2	18
Norway	38.6	9.5	50.4	19
Korea	34.4	8.5	11.5	74
Jamaica	25.2	6.2	18.7	33

seafood. It can be seen that the actual amount of fish consumed does not indicate its importance in the individual diet. For example, Denmark consumes more fish per capita than Korea, but Korea relies on the protein provided by seafood for a greater percentage of total animal protein.

The significance of fish in the world's food balance and in that of individual countries may be evaluated by computing the acreage required to produce equivalent amounts of animal protein employing agricultural technology in its present state. This calculation reveals that to produce land-animal protein equivalent to the fish protein now harvested, Europe would require 60,000,000 hectares (150,000,000 acres), equivalent to 40 percent of the land area presently under cultivation. The U.S.S.R.

would require 16 percent of its presently cultivated land, China would require 23 percent, and, most dramatic of all, Japan would require 380 percent.

Similar expansion would be required in the dairy industry of each country to equal the value of aquatic protein now consumed. Table 4 shows both sets of figures.

## DISTRIBUTION AND HABITAT

The total registered world aquatic catch in the year 1969 was 63,100,000 metric tons (excluding whales). Of this amount, 7,400,000 metric tons, approximately one-seventh of the total, was made up of fishes originating in the fresh waters of lakes, rivers, and ponds and mainly consumed directly as human food (see Tables 5 and 6).

The greater portion of the catch, 55,700,000 metric tons, was obtained from marine waters, the oceans of the world. Shellfish accounted for about one-tenth of this amount, with the remaining 50,800,000 metric tons made up of ocean fish. Almost two-thirds of the ocean fishes were obtained from the Northern Hemisphere. The Pacific Ocean yielded 55 percent; the Atlantic Ocean accounted for 39 percent; the Indian Ocean, with the adjacent Arabian and Red Seas, supplied 4 percent; and 2 percent came from the Mediterranean and Black seas.

**Oceans.** The oceans constitute the largest factories of living organic matter on earth, both in magnitude and total productive biomass. Average organic production per acre is identical to that on land, although productivity varies greatly from one area to another, ranging from luxuriance to almost barren deserts. Production in any specific area varies with the seasons and is subject to large and sporadic fluctuations.

The primary production area of the oceans is the photic zone, the relatively thin surface layer, 25 fathoms deep (50 metres), that can be penetrated by light, allowing the process of photosynthesis, the use of energy derived from sunlight in the manufacture of food, to take place. All marine life is directly or indirectly tied to this zone, on which both recycling and decomposition, also in other spheres of the ocean, depend. Those few micro-organisms deriving their energy from sources other than light have little significance in the overall productive balance of the oceans.

In the photic zone, growth rate depends on light intensity and available nutrients. Nutrients are constantly depleted by the slow sinking toward the bottom of dead plankton, the floating and mainly miniature plant and animal life, which forms the primary link in the ocean food chain. Simultaneously, fertility is constantly restored as the nutrient-rich deeper waters are brought to the surface. The ocean is ploughed by the action of winds drifting surface waters away from coastal areas, by nutrient-rich waters welling up from the depths, and during the winter season of the temperate regions by cooled surface waters becoming heavier and sinking downwards, forcing nutrient-rich waters to rise.

As a rule tropical surface waters do not interchange with the mineral-supplying waters below as much as those of colder regions and are therefore less productive. However, under certain conditions in some regions of the tropics and subtropics, currents and winds induce a sus-

Photic  
zone

tained upwelling of mineral nutrition from lower strata, producing spectacular results. Such regions include the waters around the west coasts of South and Southwest Africa and South America. Consideration of such conditions demonstrates that the production of fish-supporting plankton is not related to latitude but depends upon the presence of "new water" high in nutrient salts.

The marine food chains, ranging from minute floating phytoplankton, sometimes called the "grass" of the sea, to the large predatory species, have many more links than terrestrial equivalents. Each transfer of food value from a lower to a higher level involves a considerable loss in the amount of recoverable organic matter, and consequently of food, so that the amount of organic matter is much greater at the plankton level than it is in fishes. The daily production in kilograms per square metre of dry organic matter beneath a hectare (2.5 acres) of sea surface in the English Channel is as follows: phytoplankton (plant life) 4-5; zooplankton (animal life) 1.5; pelagic fish (living near the surface) 0.0016; bottom fish 0.0010.

The plankton eaters, although they tend generally to be small in size, include the basking shark, the largest of all fishes. Typical consumers of marine plankton include such species as the herrings, menhaden, sardines, and pilchards. Because of this plentiful food source, these fish exist in tremendous numbers, forming the basis of important fisheries.

Demersal fishes, including such species as haddock and halibut, live primarily near the ocean floor, where they feed on various invertebrate marine animals. Most of the large fish, such as tuna, swordfish, and salmon, feed on smaller fishes.

Fishery biologists generally agree that, with proper control and management, the world's marine fisheries could yield approximately twice the amount of the present harvests, providing a sustained yield of upwards of 100,000,000-120,000,000 metric tons, as against the present marine catch (1969) of around 55,700,000 metric tons. This can only be achieved if nations agree to long-term plans for conserving, developing, and working marine resources. Without such agreement, and with continued uncontrolled exploitation of these resources, the most accessible stock may become overfished, or exhausted, followed by overfishing of the remaining stocks.

**Inland waters.** Fresh water does not support the abundance of fishes to be found in saltwater. Some fishes are most abundant in the transition zone of brackish water

between salt and fresh, as at the mouths of streams, and most of these can also live in either fresh water or salt water. Fishes in the Arctic regions cross the line between fresh water and salt water more freely than fishes in warmer areas, but tropical saltwater fishes freely enter local fresh water that is heavily impregnated with lime.

Because there are various natural barriers to the dispersal of freshwater fishes, and these fishes do not cross salt water, those of one part of the world differ from those of another. Fishery science has devised various methods for improving the quality and yield of inland water fish catches. Fish populations may be increased by stocking with fishes from hatcheries, or reduced to increase poundage in the remaining fishes, and some species can be transplanted to entirely new areas that they did not formerly inhabit. Habitats have been improved by removal of obstructions to migration and by control of predators. The use of artificial farm ponds allows control of production conditions, and such ponds may yield as much as a ton of fish per acre annually.

#### MARINE TYPES

Table 7 includes some of the more important kinds of bony fishes that are commercially fished and used as food. Major species of ocean, or saltwater, fishes consumed as human food include salmon, herring, codfish, flatfish, redfish, jack mackerel, tuna, and mackerel.

**Fishes.** Salmon are anadromous, migrating to ocean waters for growth and returning to fresh water for spawning. Pacific salmon return to the freshwater rivers once, to spawn and die; the Atlantic salmon make several returns. Industrial pollution, silting, and damming of rivers for hydroelectric power have seriously threatened the salmon. Only through such large-scale management measures as bypass streams and hatcheries has it been possible to save the Pacific salmon; similar measures in respect to the Atlantic salmon have been less successful.

The herring is probably the most abundant fish in the near surface waters of the seas. The Atlantic species (*Clupea harengus*) and its Pacific counterpart (*C. pallasii*) travel in immense schools several miles long and wide, containing thousands of millions of individuals. Herring feed on small marine animals and other plankton; in turn, such predators as cod, mackerel, tuna, and sharks, as well as some whales and birds, eat freely from the vast herring schools.

One species of anchovy (*Engraulis ringens*) from the Peru Current constitutes the largest single catch of any marine species, exceeding 11,000,000 tons annually. Together with another fish, the South African pilchard (*Sardinops ocellata*) from the Benguela Current off southwest Africa, it is almost exclusively diverted to the manufacture of fishmeal and fish oil. Menhaden, also important as a source of fishmeal and fish oil, constitutes a large portion of the annual world catch. The abundant herring family accounts for two-fifths of the marine catch.

The codfishes, including cod, hake, haddock, whiting, pollack, and saithe, share with herring the leading place among edible marine fish. The U.S.S.R., with its modern long-distance fishing fleets, emulated by most other Eu-

Table 7: Important Food Fishes

fish	habits	description
Herring ( <i>Clupea</i> species)	northern; inshore; pelagic; schooling; plankton feeders	8 to 17 in.; silvery, rather deep-bodied; compressed; sawlike scales on belly
Pilchard and sardine ( <i>Sardinops</i> and <i>Sardinella</i> species)	temperate; inshore; pelagic; schooling; plankton feeders	6 to 8 in.; silvery, with row of dark spots on side behind head; cylindrical
Menhaden ( <i>Brevoortia</i> species)	temperate to subtropical; inshore; pelagic; schooling; plankton feeders	12 to 15 in.; silvery, with row of dark spots on side behind head; compressed; sawlike scales on belly
Anchovies (family Engraulidae)	tropical; inshore; pelagic; schooling; plankton feeders	to 6 in.; usually cylindrical; piglike overhanging snout
Shad ( <i>Alosa</i> species)	temperate; anadromous; schooling; plankton feeders	12 to 30 in.; silvery, with row of spots on sides; sawlike scales on belly
Atlantic salmon ( <i>Salmo salar</i> )	north temperate; anadromous; loose schooling; fish eaters	24 in. or more; silvery or brown, with many spots on sides; slightly compressed; adipose fin on back
Pacific salmon ( <i>Oncorhynchus</i> species)	north temperate; anadromous; loose schooling; fish eaters	18 in. or more; silvery or dark, with spots on sides; slightly compressed; adipose fin on back
Tuna ( <i>Thunnus</i> species)	tropical; offshore; pelagic; schooling; fish eaters	2 to 10 ft; darkish above; compressed; row of finlets on back and belly
Mackerel ( <i>Scomber</i> species)	temperate; offshore; pelagic; schooling; fish eaters	10 to 30 in.; gray above, silvery below; cylindrical; row of finlets on back and belly
Cod ( <i>Gadus</i> species)	northern; bottom; mollusk eaters	2 to 5 ft; greenish or reddish; cylindrical; three dorsal and two anal fins
Haddock ( <i>Melanogrammus aeglefinus</i> )	northern; bottom; mollusk eaters	10 to 30 in.; grayish, with dark spot on shoulder; cylindrical; three dorsal and two anal fins
Whiting or hake ( <i>Merluccius</i> species)	temperate; inshore; loose schooling; fish eaters	10 to 30 in.; grayish; cylindrical; two dorsal and one anal fin
Drums or croakers (family Sciaenidae)	warm temperate; inshore; on sand bottom	to 2 ft; usually deep-bodied; two dorsal and one anal fin; all make noises
Redfish or ocean perch ( <i>Sebastes</i> species)	temperate; bottom; shrimp eaters	10 to 24 in.; reddish; deep-bodied; with spines on head
Flounders and halibut (families Pleuronectidae and Bothidae)	bottom; most food types northern or temperate	to 3 ft; very compressed; both eyes on one side of the head

ropean countries, has raised the annual catch of Atlantic cod to almost 1,000,000 tons; the total by all nations close to 4,000,000 tons (1968). Japan and the U.S.S.R. have expanded their catch of Alaska pollack, used mainly for fishmeal and fish oil, to 2,552,000 tons (1969).

Flatfish include a great many species, such as plaice, halibut, and sole, living largely at the bottom of the coastal shelves. The stock of each species is quite limited, however, and halibut was one of the first species for which catch quotas were established. In the North Pacific, the U.S.S.R. and Japan have expanded their catch of several kinds of flatfish.

A major change in ocean fishery since World War II is the intense exploitation of redfish (*Sebastes* species), also called ocean perch. The catch reached 500,000 metric tons in 1958 but has since receded to around 350,000 tons. Correspondingly the U.S.S.R. raised the catch of rockfishes in the Pacific to 423,000 tons (1965) since dropped to 79,000 (1969). The related seabream shows significant gains in Spain and the U.S.S.R.

Jack mackerel (*Trachurus trachurus*), one of the earliest fishes used for human food, continues as an important food source. Although it lives in midocean, the catch has increased one-third in the last decade, principally because of the fishing efforts of the U.S.S.R. and the Philippines.

The true tuna fishes include albacore, bluefin, bigeye, yellowfin tuna, bonito, and skipjack. These species represent a significant marine source of human food, hunted

since ancient days. Both Atlantic and Pacific stocks have been heavily fished in recent decades, and signs of excessive harvest have appeared. More than half the global catch is canned or frozen for the U.S. market. Spanish mackerels and swordfish belong in this group but, despite efforts toward bigger catches, remain minor items.

Both the Pacific and Atlantic mackerel have almost trebled in catch during the 1960s to reach 2,500,000 tons (1969) due to special efforts by Japan and Norway respectively. A similar relative gain is shown by the Indian or striped mackerel (376,000 tons in 1969) in Thailand, India, and the Philippines.

There are some 250 species of shark. Like the whale, sharks have a broad range of feeding habits. Although many are predators, some, including two of the largest fishes in the oceans, the basking shark of the northern temperate zone and the whale shark of tropical waters, are plankton feeders. Shark meat is commonly eaten in warm latitudes but elsewhere is little esteemed, except for the fins, high in protein and considered a delicacy, that are frequently used in squid soups.

Since World War II, many new fish species have been exploited. The clearest indication of this is the doubling of the catches of nonidentified fishes, a category that equals the volume of codfishes.

**Shellfish.** The term shellfish is generally applied to all invertebrate marine organisms having visible shells. They may be broadly categorized as crustaceans and mollusks.

The crustaceans include lobsters, crabs, crayfish, and both shrimp and the closely related but larger prawns. The shells consist mainly of a hard, inedible substance called chitin. Crustaceans molt frequently during growth. Blue crabs (*Callinectes sapidus*) are eaten when molting and soft-shelled. Marine lobsters (*Homarus americanus*) are eaten when about five years old and have by then molted about 25 times.

With the development of satisfactory freezing techniques in the 1940s, shrimping expanded considerably, becoming a global operation. The U.S. is a major consumer, importing shrimp, mainly frozen, from more than 60 countries. South Africa and Australia have developed a worldwide market for rock lobster (*Palinurus*), and Japan and the U.S.S.R. dominate the world market for king crab (*Paralithodes camtschatica*).

The major mollusks consumed as food are oysters, mussels, clams, scallops, whelks, and snails. The best known marine snail is the abalone, encountered in many warm waters.

This group also includes the octopus, squid, and cuttlefish, popular seafoods in both Mediterranean countries and the Far East. The annual world catch of cephalopods now exceeds 1,000,000 metric tons, with Japan accounting for about 75 percent.

Sea cucumbers (holothurians), or sea slugs, are usually marketed under the name of trepang or bêche-de-mer. Rich in protein, they are eaten in China, Southeast Asia, Australia, and Italy.

**Reptiles.** Marine reptiles include several species of snakes and turtles. Marine snakes, found mainly in Pacific and Indian Ocean waters from the Persian Gulf to Japan, and especially numerous in the Gulf of Siam, are generally regarded as a nuisance; yet they are a source of food in some regions. The scales and skin are removed and the flesh around the ribs and back is eaten.

Green turtles are the best known of the several marine-turtle species, comprising about a fifth of all the turtles found in the warm seas of the world. In their early years they weigh from 10–90 lbs (4.5 to 40.8 kg) and feed on small invertebrates. Later, they graze on submarine pastures of turtle and eel grass. Although plentiful when Europeans first came to the Caribbean, they have been intensively hunted through the years and have gradually disappeared from the shores of most islands. Since 1959 efforts have been undertaken to save the green turtle from eradication and to redistribute it to the beaches where it formerly thrived in order to increase the food supply of undernourished Latin American countries. Eggs have been protected, and hatchlings airlifted to

create new nesting grounds, with limited success. Turtles in African and Asian waters are equally threatened.

**Mammals.** Ocean mammals include such cetaceans as whales, porpoises, and dolphins, as well as seals and walrus. Whales are a source of meat, fats, and oils, hormones such as insulin, and chemicals. They exist at all levels of ocean food chains. The blue whale mainly devours small reddish shrimp called krill, while the formidable killer whale feeds on salmon, seals, and sharks. The number of species, although still large, has declined considerably. Early hunting of these animals was concentrated on a few numerous and large species, including the blue whale, the sperm whale, and the humpback.

As whale stocks of the North Atlantic and Pacific began to decline, whalers turned to the abundant herds of the Antarctic, which today in turn are showing signs of depletion. Only Japan and the U.S.S.R. are engaged in large-scale whaling operations today.

The hunting of porpoises and dolphins preceded whaling in history. Dolphins were eaten in ancient times around the Mediterranean, and Xenophon and his Greek army found sizeable stores of salted dolphin meat in earthenware vessels on the Black Sea coast. Their use as food there continued until banned recently by the U.S.S.R. in the interest of preserving the animals for biological research. Many tropical islanders still hunt dolphin on a large scale. Freshwater dolphins are caught in many of the world's great rivers, including the Ganges, Indus, and Brahmaputra, the Amazon, the La Plata. The dolphins of Chinese rivers have been eradicated, but a number survive in the lake regions of the upper Yangtze.

Seals and walrus of the Arctic region provide sustenance for many Eskimo tribes. They are also encountered along the northern coasts of the United Kingdom, the southern coasts of South America, and the Antarctic. In Labrador and Newfoundland there are 1,200,000 adult Greenland seals and 500,000 baby seals. Hunted principally for their furs, seals were in danger of extinction in the 1960s and 1970s; many measures were being enforced to protect them.

**Seaweeds and plankton.** Marine plants may be divided into two groups: grasses and algae. There is only one subaquatic grass of any significance, namely eelgrass. Algae that grow in a fixed location, generally called seaweeds, may be categorized according to colour, into green, brown, red, or blue-green. Brown algae, sometimes called kelp, may grow to exceptional sizes; some specimens attain a length of 165 feet (50 m) or more.

Seaweeds are heavily exploited in many parts of the globe for human as well as animal food. Several species are extensively cultivated on the coastal shelves of China, Japan, the Philippines, and elsewhere. Brown species in particular are harvested in Japan and made into a number of food products. Several are used as new material for various thickening agents; see below.

Cultivated red seaweeds belong to the genus *Porphyra*. Their sun-dried, blackish fronds are shaped into sheets and used in the Orient as a wrapping for rice. Harvested along the coasts of Ireland and Scotland, red seaweed is made into a powder and used as the main ingredient of a kind of bread called laver. Seaweeds contribute to the diet accessory nutrients such as vitamins B<sub>1</sub> and B<sub>12</sub>.

Phytoplankton does not offer man a suitable food and can hardly be used even as feed for animals. Many species are toxic; the rest are scarcely digestible. In addition, most plankton finish their life cycle within a few days or weeks and are usually devoured by predators. Consequently, the amount of plankton in the water at any given moment is small, even though total plankton production over a year may, in a particular water, well exceed that of fish. Plankton harvesting is therefore very difficult, because of the volume of water that must be sieved.

To date, no technical devices have been contrived to harvest plankton in adequate quantities, even in waters where they abound. The Japanese, Burmese, and East Indians have managed to develop profitable fisheries for certain tiny shrimp that feed on plankton. The shrimp are dried or fermented into pastes. Elsewhere similar plankton-fed shrimp are sun dried and sold as a snack.

Unicellular green algae, such as *Chlorella* and *Scenedesmus*, have been artificially cultivated, yielding 30 tons per acre per year, compared to the standard wheat yield of 1.0 to 1.5 tons. However, the process is costly, since algae, in addition to harvesting, require decolorization and special processing to remove or break down the cell walls through drying and enzyme action in order to become digestible. It is far more efficient to use such plankton directly as fish feed in cultivation ponds or in the raising of cattle and poultry. Blue-green algae easily create water-blooms, slimy accumulations that may be dried in the sun and molded into small loaves with a nutlike flavour and high in protein. This food is extracted from Lake Chad in tropical Africa, and the Aztecs made a similar product. In China a scum called *lan*, collected from ponds and freshwater lakes, provides sustenance for large numbers of people. A related scum, *keklop*, found in Java, is used chiefly as fish feed. Another species is made into dried sheets in Japan and prepared for food by heating in water. Successful cultivation of some blue-green species has been carried through on a semicommercial scale.

A healthy, adult blue whale needs about 1,000,000 calories a day, corresponding to man's requirement for a year. In terms of the shrimp called krill, this amounts to 3,000 to 5,000 lbs (1350–2250 kg) daily. The lactating female blue whale produces 200 to 500 gallons (800–2000 litres) of milk a day to sustain a daily weight gain in her baby of 60 to 150 lbs (27–68 kg), depending on age. The baby grows to be 65 feet (20 m) long when weaned at the age of two. Krill is obviously quite nourishing.

On the average, there are about 1,000 lbs (450 kg) of krill per acre of Antarctic Ocean, comparing favourably with rich pasture lands yielding about 700 lbs (320 kg) of cattle and sheep per acre each year. As blue whales are threatened with extinction, krill trawling has been suggested. Soviet experimentation in krill processing, however, has encountered considerable difficulties in the removal of the indigestible chitin shells and in making attractive products other than pastes.

#### FRESHWATER TYPES

The freshwater fishes that inhabit ponds, lakes, rivers, and swamps include such major food species as carp, eel, whitefish, pike, pike perch, and catfish. Species differ in characteristics according to the type of water they inhabit. Freshwater fishes currently constitute 13.5 per cent of the global catch, with an annual harvest that has more than doubled since World War II.

Fish culture can be broadly considered as a branch of animal husbandry, as it is concerned with both the cultivation of fish and the harvesting and management of wild fish. Most cultivated fish are freshwater species, such as carp and eel. The common carp, the oldest of the domesticated fishes, has been raised in China since about 2000 BC. Another Chinese species, the grass carp (*Ctenopharyngodon*), with the unique quality among fishes of grazing from higher plants, has been transferred to various countries for the purpose of controlling waterweed infestation. Carp also are grown in lakes, reservoirs, and artificial ponds of temperate regions; several species of tilapia are raised in warm regions; and eels, once raised in ponds of medieval European monasteries, are cultivated widely. Carp and eel also have traditionally been raised in rice fields, a practice called wetland cultivation. This method is increasingly jeopardized by sprays used to control pests and diseases and by toxic agents resulting from industrial development.

Pollution produced by chemical preparations applied for agricultural purposes has also created serious problems for the world's freshwater fisheries; fish cultivation is increasingly restricted to man-made waters. Traditional freshwater fisheries still supply basic protein to China, Southeast Asia, and tropical Africa but have been seriously affected in the U.K., continental Europe, Japan, the U.S.S.R., and the U.S.

#### QUALITY CONTROL

In marketing fishery products, grading and quality standards are essential, and most governments establish ap-

Phyto-  
plankton  
as food

Fish  
culture

appropriate legislation and inspection systems. Requirements regarding species, form, size or unit per package, and distribution are primary considerations. Compliance with product identity standards, fill of container or net weight provisions, assurance of wholesomeness, and proper labelling are normally required. Sanitation requirements are concerned with exclusion or limitation of harmful or toxic micro-organisms and of objectionable material.

Quality of fish is usually assessed by taste and odour. Bacteriological and chemical analysis, although useful, does not always give a true picture of quality and requires special equipment and trained personnel. Objective taste and odour observation tests therefore retain their importance.

**Spoilage factors.** Marine fishes are unfit for human consumption when affected by disease, when carrying parasites, or when showing signs of decomposition. Initially biochemical decomposition is later controlled by micro-organisms originating in slime, viscera, water, or through contamination.

Decomposition induces characteristic changes. The odour becomes sour, rancid, or rotten; the gills turn greyish or brownish, becoming slimy or coated; and the entrails decompose. The belly and cut surfaces turn slimy, often showing yellowish or brownish discolorations and the flesh becomes soft and inelastic. Rancidity begins in fatty fish, particularly mackerel and salmon, even prior to spoilage of the flesh, in particular when the fish are kept cool but insufficiently protected from the air.

Handling procedures influence the rate of natural spoilage of fish and fish products. Rough handling, which breaks the skin, facilitates penetration into the flesh by micro-organisms. Dirty or reused ice, or ice stored for long periods, harbours large numbers of fish spoilage bacteria. Any laxity in temperature control results in accelerated bacterial growth. The exposed flesh of fillets provides a favourable medium for bacterial growth; filleting knives, tables, boards, filletter's gloves, and wash water must be kept clean.

**Preservation methods.** The primary aim of all fish processing is to retard or eliminate the activities of spoilage agents. Partial inhibition is achieved by maintaining the temperature close to 32° F by the use of ice or refrigerated brine.

Chemical preservatives operate in a similar way. Antibiotics of the tetracycline group also produce a temporary remission of bacterial growth, yielding considerable extension of storage life. Smoking may ensure such partial inhibition of bacterial growth but is generally combined with chilling, brining, and drying. By removing water, freezing, salting, and drying create conditions that make bacterial growth impossible. In modern salting the inhibition is only partial and supplemented by refrigeration. Some salt-loving bacteria (halophiles) carry red pigments and cause discoloration by surface growth. Sorbic acid may be used in dips to avert mold growth on smoked fish such as chubs, herring, and others. Microbial growth is checked in most fermented and marinated fish products through acids produced in the fermentation and in pickling by direct addition.

In heat processing, micro-organisms are eliminated by destructive high temperatures in closed containers to achieve practical sterility. Poor sanitation in the handling of the products prior to filling may jeopardize the processing efficiency. Very high standards of plant sanitation and operator personal hygiene are necessary in plants producing ready-made seafood, such as fish sticks or fish dinners, because the extremely heat-sensitive natural flora is largely wiped out and may, under poor sanitary conditions, be replaced by contaminants from human sources.

#### OTHER INDUSTRIAL PRODUCTS

**Fishmeal and oil.** Overwhelmingly important among fish products are oils, manufactured largely by pressing and refining, and meal, manufactured through drying or solvent extraction. Both of these products have attained major significance on the world market. Fish oils are used in the manufacture of margarine and paints. Meal

is employed in making concentrate feeds for livestock, competing in this area with soybean meal.

Fishmeal and oil, as well as condensed solubles, are made from the fish less suited for food. The most important source in the U.S. is the menhaden, today used entirely for such manufactured products. The catch of Alaskan herring, small in volume, is used largely for meal and oil. Wastes from fish industries also are utilized. The meal and oil industries of Iceland, the U.K., and Norway are based mainly on Atlantic herring. Sand eel is used in Denmark. Pilchard, anchovy, Pacific mackerel, and jack mackerel also are used in various countries. Alaska pollock has become an important source for fishmeal manufacture in the North Pacific, both in the U.S.S.R. and Japan. Since 1958 anchoveta from the Peruvian and Chilean coasts has become the major source, currently with an annual catch exceeding 12,000,000 tons.

**Fish protein concentrate (FPC).** Fish meal has repeatedly been upgraded for use as human food and given the designation fish flour. This is accomplished by careful choice of raw material, special sanitary precautions, and carefully controlled manufacturing. A stable, odourless, and colourless final product is made from white-fleshed fish species such as hake. Various extraction procedures remove fat or dissolve the protein for subsequent precipitation, rendering fish protein concentrate, a product that has shown considerable promise as a flexible protein supplement to the diets of underdeveloped countries. FPC may not adapt well to regional diets, however, and serious distribution problems exist. Also, fish catches of adequate volume and concentration may not be available.

**Glue and isinglass.** The large salt-cod industry is the basis for a substantial by-product industry for the manufacturing of fish glue and isinglass, important in Japan. Glue is manufactured from bottom fish skins, and sometimes from heads and bones, in a manner quite similar to that employed in the preparation of other animal gelatin glue. When made carefully from the best skins, it can be used for photoengraving. Glues of lower quality are prepared from bones and other waste. Isinglass may be manufactured from other fish, such as hake.

The word isinglass comes from the German word *Hausenblase*, meaning sturgeon's bladder, the original raw material from which this product was made. It is the purest form of fish gelatin and is employed as a clarifying aid, primarily in the manufacture of wine. One ounce of isinglass will clarify 200 to 300 gallons of wine.

**Leather.** Sharks have been a principal source for fish leather skins. Skin leather is available as a by-product in countries still extracting vitamin A from shark liver. Suitability of such skins for leather depends upon the size of the pieces and the absence of defects. The skins are carefully removed from the shark either aboard the fishing vessel at sea or as soon as the vessel lands its catch. They are then coated with salt, cured in piles, and shipped in bundles to the tannery.

**Pharmaceuticals and additives.** A significant new development is the extraction of drugs from various ocean sources. Marine medicine and pharmacology are emerging as new disciplines. Some marine fungi make potent antibiotics. Virus-killing agents have been extracted from ocean gastropods; other molluscs have rendered anticancer substances. Potent antimicrobial agents originate with sea cucumbers, sponges, and similar sources. Special significance has been attached to the wealth of toxins, appearing in almost all categories of marine animals, several of which are under intensive study.

Valuable new animal compounds extracted from the internal organs and glands of whales include steroids, pituitary hormones, insulins, and enzymes.

Insulin is more easily extracted from fish than from cattle. The insulin-producing Langerhans' islets are separate in some fishes and attached to gall bladder, bile duct, mesentery, etc. Fish insulin is more stable, not being subject to decomposition by protein-splitting enzymes from the pancreas. Viscera of tuna, bonito, and cod, as well as whale, are sources generally used in the U.S.S.R. and Japan. Depending on species, whale pancreases weigh 15–500 kg, as compared with 0.3 kg for that of a cow.

Insulin

A principal constituent of seaweeds is cellulose, usually together with other polymer carbohydrates such as manitol, laminarin, alginic acid, and fucoidin. Many of these are isolated and used as thickeners for pharmaceutical or microbial laboratory work. Phycocolloids of commercial importance are chiefly agar, algin, and carrageenin. Algin is produced from brown seaweeds, agar and carrageenin from red varieties. These compounds are used as thickeners, humectants maintaining water content, coagulants, bulking agents, flocculation agents, and antibiotic carriers. In a number of countries, including the U.S., Canada, France, India, Japan, Norway, New Zealand, the U.K., South Africa, Spain, and the U.S.S.R., these items are manufactured from such seaweeds as Irish moss, dulse, and purple laver. Seaweed meal has successfully been used in feeding cattle.

#### FISH AND MARINE PRODUCTS AS A SOURCE OF MATERIALS FOR OTHER INDUSTRIES

**Scale and shell products.** A number of products are made from the scales and shells of fishes. Herring scales are a source of pearl essence, a suspension of guanine crystals sprayed on beads, textiles, and other articles to impart an iridescent sheen. Marine and freshwater shells, harvested mostly in Australia and the Far East, are used to manufacture buttons, buckles, and similar items. Freshwater mussel shells are taken for the same purpose from the Mississippi River and its tributaries. Many are exported to Japan to be used as spherical core matrices for the artificial cultivation of pearls.

Oyster and clam shells are commonly ground for use in poultry feed. In some locations such as southern California, huge deposits of clam shells in tide flat areas are "mined" by dredging at low tide.

Tortoise shells were first employed for ornamental purposes more than 300 years ago in Japan. The marine hawksbill tortoise (*Eretmochelys imbricata*) has been the favoured source. Other ocean varieties employed are other *Eretmochelys* and *Caretta* species and the river tortoise in South America (*Podocnemis*). The plates of the shell are used in inlaid products, toilet articles, knife handles, cuff links, combs, hairpins, and earrings.

**Pearls.** Natural pearls are formed when some foreign matter accidentally becomes inserted between the shell and the soft body tissues of mollusks. The prevalence of natural pearls has been sharply declining due to the deterioration of harvesting grounds and the expansion of pearl culturing. Natural pearls have been produced up to the present in the Persian Gulf, around the northwest coast of Sri Lanka (formerly Ceylon), in the Bay of Aden in the Red Sea, on the northwest coast of Australia, and in the South Pacific.

Cultured pearls were pioneered by the Japanese and others in the 19th century. Several species of marine and freshwater mussels, oysters, and clams are employed. Pearl farms have most recently been developed in the Kuri Bay area of Australia and in India.

**Corals.** Corals, largely of the genus *Corallium*, have been harvested since ancient days in the Mediterranean and were at one time an article of commerce with the Far East, whose own coral fisheries date only from the 19th century, starting in Malaya Peninsula and moving to waters off Japan.

Coral is divided into three categories according to its colours. Pink and red corals are the most valuable. Black corals, of the genus *Antipathes*, are harvested and worked into various ornamental items in the West Indies, Malaysia, the Red Sea region, southeast India, and Indonesia.

**Sponges.** The skeletons of sponges consist of resilient spongin, making them well suited for cleaning purposes. But sponge fishing, once flourishing in the Mediterranean and the West Indies, where sponge farms were established, is another of the many marine industries threatened with depleted stocks and possible extinction of species due to excessive harvesting.

**BIBLIOGRAPHY.** J.E. BARDACH, *Harvest of the Sea* (1968), a survey of the harvests of the oceans and research related to this aspect, contains ample references; G.A. BORGSTROM (ed.), *Fish as Food*, 4 vol. (1961-65), a comprehensive treatise on

the biochemistry and microbiology of fish and shellfish; F.T. CHRISTY, JR. and A.D. SCOTT, *The Common Wealth in Ocean Fisheries* (1965), a critical analysis of man's handling of the ocean resources; W.J. CROMIE, *The Living World of the Sea* (1966), a semipopular review of all major categories of marine life, with good references to scientific books for each group; F.E. FIRTH (ed.), *The Encyclopedia of Marine Resources* (1969) a comprehensive treatment of ocean resources and their utilization, with emphasis on economic activities; M. GRAHAM (ed.), *Sea Fisheries: Their Investigation in the United Kingdom* (1956), the standard reference book on the biology of the oceans despite its age and geographical restriction; SIR ALLISTER HARDY, *The Open Sea: Its Nature and History* (1965), a profound study of the living world of the oceans; C.F. HICKLING, *Fish Culture* (1962), a key study on traditional fish cultivation; A. MCKEE, *Farming the Sea* (1969), a discussion of recent developments in the raising of ocean fish; R.S. WIMPENNY, *The Plankton of the Sea* (1966), a recent survey of the planktonic world and its utilization; M.E. STANSBY (ed.), *Industrial Fishery Technology* (1963), a survey of methods for harvesting, preserving, and processing fish and shellfish.

## Fishing, Commercial

Fishing, which involves the recovery of food and other valuable resources from bodies of water, is one of the oldest employments of mankind. The commercial fisherman works for profit and to satisfy his own needs, in contrast to sport fishing, which has a recreational purpose. Commercial fishing is carried on in all types of waters, in all parts of the world, except where impeded by depth or dangerous currents or prohibited by law. In seawaters, fishing is the oldest form of marine exploitation, having begun long before man extracted oil or minerals from these areas.

Commercial fishing can be done in a simple manner with small vessels, little technical equipment and little or no mechanization as in small local, traditional or artisanal fisheries. It can also be done on a large scale with powerful deep sea vessels, and sophisticated mechanical equipment similar to that of modern industrial enterprises.

Man takes both plants and animals from the sea. Two types of fish are caught: demersal, living at or near the bottom, although sometimes in midwater; and pelagic, living in the open sea near the surface. Cod, haddock, hake, pollock, and all forms of flatfish are common demersal fish. Herring and related species and tuna and their relatives are examples of pelagic fish. Both demersal and pelagic fish can sometimes be found far from coastal regions. Other aquatic animals that may be the object of commercial fishery include, most notably, crustaceans (lobster, spiny lobster, crabs, prawns, shrimps, crayfish) and mollusks (oysters, scallops, mussels, snails, squid, octopuses). Certain mammals (whale, porpoises, seals), reptiles (serpents, crocodiles), amphibians (frogs), many types of worms, coelenterates (coral, jellyfish), and sponges are also sought by commercial fishermen. Most of these animals are legally regarded as fish in many countries.

The most important water plants commercially obtained in seawater and freshwater are algae. Seaweed is harvested in the water or collected on the seashore. Algae play an important role in many countries, not only as human food but also as fodder for cattle, as fertilizer, and as a raw material for certain industries. Other water plants such as rush, reed, and even edible herbs, fruits and roots, are also harvested. Some of the above animals and plants are cultivated in natural waters or in artificial ponds and lakes.

Fisheries are classified in part by type of water: in freshwater—lake, river, and pond—and in the ocean—inshore, midwater, and deep sea. Another classification is based on the object—as in whaling, salmon fishing, and sponge fishing. Sometimes the fishing method is used as the classifying characteristic: diving, fish poisoning, harpooning, and trawling. (For detailed statistics on the world's fish catch and for information on processing and marketing of fish, see FISH AND MARINE PRODUCTS. See also FOOD PRESERVATION.)

Commercial water plants

## HISTORY

Fishing, like farming, is a form of primary production. Food-gathering people first obtained fish and other aquatic products in the shallow water of lakes and along the seashore, in small ponds remaining in inundation areas, in areas with ebb tides, and in small streams. Some authorities believe that in the earliest times fish were rarely caught because of the inadequacy of fishing gear. Shellfish, however, can be gathered easily by hand and large prehistoric shell mounds indicate their importance as food. Such hills, known by the Danish term kitchen middens, are found in many parts of the world, sometimes also on inland lakes.

In earliest times most foodstuffs were used at once and not stored, but as expanding populations increased food needs, techniques were developed for preserving fish by drying, smoking, salting, and fermentation. It became desirable to catch large quantities, and specialized equipment was devised. Individual fishing was replaced by collective efforts involving larger, more effective gear.

Fishing equipment and methods improved through the centuries, until bulk fisheries were established in Europe. Herring were caught in huge numbers in northern Europe in the Middle Ages. Cod fishery began on the Grand Banks of Newfoundland even before the Italian explorer John Cabot made his voyage there in 1497. Whaling with large fleets began in the 17th century, both in the Atlantic and in the South Pacific.

Mechanization came to fishing in the 19th century. The steamer replaced sailing boats in sea fisheries during the final quarter of that century, and was supplanted in turn by motor vessels. Small fishing boats became motorized at the beginning of the 20th century. In the 1940s, instrumentation—such as the echo sounder (for vertical searching) and, later, sonar (for horizontal searching)—was introduced in sea fisheries and in some freshwaters. The total catch of fish and other living aquatic products tripled from 1948 to 1968. Today, some industrial countries lack sufficient manpower for their fisheries and are attempting to automate, with the help of seaborne computers.

Develop-  
ment  
of fishing  
technique

The development of commercial fishery is linked to the development of fishing techniques that grew in response to various pressures, especially the growth of the market. Larger catches could be obtained by increasing the number or the size of the fishing gear or both. Simple lines armed with one or a few hooks were replaced by longlines with thousands of hooks. Single small traps were combined into systems of hundreds, and pots were set in large quantities. Nets were greatly enlarged; net-making machines were invented that produced netting in large sheets. Mechanical netmaking brought replacement of the old local netting fibres (linen and hemp), with cotton and hard fibres. But all natural fibres, especially those of cellulose, begin to rot in time; thus, the introduction after World War II of rotproof nets made of synthetic fibres represented a major advance. Mechanical netmaking remained unchanged for the most part, though for certain fishing gear the usual knotted netting was replaced by knotless netting.

The development of fishing gear in another direction stemmed from the desire to fish in deep water, where larger fish are more common. Fishing in deeper waters required not only gear adapted to the depth but also suitable vessels, although today properly equipped fishermen in small boats can fish at considerable depths. The fisherman of Madeira, for example, catch espada preto (*Aphanopus carbo*) at depths up to 1,000 metres (3,300 feet) with lines up to 1,000 fathoms (6,000 feet, or 1,800 metres) long. The famous coelacanth of the Mozambique Channel is caught with lines in depths up to 400 metres (1,300 feet). To set and haul lines from such depths by hand, however, is hard work. Labour costs increase significantly with depth, especially for heavy gear. A modern fishing vessel, such as a stern trawler or purse seiner, is a specialized, sophisticated equipage in which vessel, gear, and crew act as a unit. Originally, bottom trawling was done out to the edge of the continental shelf, where the depth is about 200 metres, or 650 feet; today it is

done at depths up to 600 and even 1,000 metres. The time required for shooting and hauling gear, however, is an economic barrier to fishing in great depth.

With the extension of fisheries in noncoastal waters and the development of efficient refrigeration methods, long-distance fishery developed. Trawlers from northern Europe made their first expeditions in the Mediterranean and off the west coast of Africa before World War I. Today some nations, such as Japan and the Soviet Union, fish around the world.

As fishing gear increased in size and weight, more people were needed to handle it. Yet it was not until the end of the last century that mechanization of fishing techniques began with winches and pulley blocks. Power-driven winches were introduced for fishing gear at the end of the 19th century, but it was many years before specialized hauling devices, such as rope-coiling machines and power-driven rollers, facilitated easier hauling of netting. In the beginning of the 1950s, mechanization took a great stride forward in purse seining (see below), when the power block was invented for hauling the gear. Another important hauling device was a power-driven drum to haul and store seine nets, gill nets, purse seines, and even the large trawl nets. The Japanese introduced drums in longline fishing for tuna. Another important innovation was the stern chute for stern trawlers, a development made possible by cooperation between naval architects and fishing-gear experts, which permitted large-scale mechanization of gear handling. A trend in the early 1970s was toward full automation, with the help of shipborne computers that will supply information to the engine room and the on-board fish-processing plant and will influence navigation, fish searching, and gear handling.

Earliest  
mechani-  
zation

Statistical treatment of fishermen varies. According to international law all personnel working on a fishing vessel are considered fishermen, including processors, radio operators, kitchen help, stewards, medical personnel and others. Less official statistical sources often include in the fishing population women who repair nets and other members of a fisherman's family. Not all fishermen work full time the year round; there are many part-time fishermen engaged in seasonal businesses, such as farming. In Iceland a person is statistically a fisherman if he earns more than 50 percent of his income from fishing. The Japanese have a nearly identical definition, adding that, in sea fisheries, he must stay at sea at least 30 days a year. Because of these varying definitions of the term fisherman it is impossible to give a reliable number for the world's fishing population. There are more than 100,000 in the countries of the European Common Market and more than 500,000 in all of Europe. In North America there may be more than 200,000 and more than 500,000 in Central and South America. About 4,000,000 fishermen live in Asia, much smaller numbers in Africa and Australia. The total number of fishermen in all parts of the world may be estimated at 5,500,000. Most of these are men, with the number of women actually engaged in fishing no more than 1 percent. World numbers of fishermen are decreasing because of mechanization, especially in the industrial countries.

## FISHING METHODS AND FISHING GEAR

An international classification of fishing methods recently adopted includes 16 types: (1) Fishing without gear; (2) Grappling and wounding gear; (3) Stunning; (4) Line fishing; (5) Trapping; (6) Trapping in the air; (7) Fishing with bag nets; (8) Dredging and trawling; (9) Seining; (10) Fishing with surrounding nets; (11) Driving fish into nets; (12) Fishing with lift nets; (13) Fishing with falling gear; (14) Gillnetting; (15) Fishing with entangling nets; and (16) Harvesting machines.

The simplest and oldest form of fishing, collecting by hand, is still done today by both professionals and non-professionals along the shore during ebb tide in shallow water and in deeper water by divers with or without diving suits. Even when small tools such as knives or hoes are used, such collecting is classified as without gear. Diving to collect sponges, pearl oysters, or corals belongs un-

der this classification, as does fishing with hunting animals. The Chinese still use trained otters, and the Japanese sometimes employ cormorants.

To extend the reach of the human arm, long-handled tools were invented, such as spears, which can be thrust, thrown, or discharged, and clamps, tongs, and raking devices for shellfish harvesting. A special form is the harpoon, composed of a point and a stick joined together by a rope. Such gear also includes spears, blowpipes, bows and arrows, and rifles and guns, which are used in fish shooting.

The method called stunning may involve poisoning with toxic plants and special chemicals or mechanical stunning by explosions under water. The most modern practice in this field is to stun the fish by means of an electrical shock.

In line fishing the fish can be attracted by a natural or artificial bait or lure devised to catch and hold the fish. Generally, the bait is combined with a hook or with a gorge, as is used in France in line fishing for eels. There are handlines, as in pole-and-line fishing for tuna; set-lines, such as bottom longlines with hundreds of hooks, used for cod or halibut; drift lines with a single hook and drifting longlines for tuna, shark, and salmon; and troll lines for mackerel and some game fish. Another method of fishing with hooks is done without bait, by raising and lowering arrays of hooks to gig (hook in the body) such large species as cod and sturgeon.

Genuine mechanical traps, which close by a mechanism released by the prey, are seldom employed for fishing. Most commercial fishing traps are chambers entered easily by the prey but from which escape is prevented by labyrinths or retarding devices, such as gorges or funnels. Fish traps can be simple hiding places, such as bushes or tubes, into which fish or shrimps swim for shelter but cannot escape later when the device is hauled in. The octopus pot used on the Italian coast and by the fishermen of South and East Asia is an example. Other types include small basket-like or cage-like traps made of wood, netting, wire, or plastic pots and fyke nets (long bag-shaped nets kept open by a series of hoops; Figure 1, bottom); and large pound nets (Figure 1, top) used in the Mediterranean for tuna, off the western Baltic coast

Figure 2: Seine net.  
From R. Graumont, *Fisherman's Knots and Nets*

for eels, herring, and other species, and off both coasts of the northern Pacific for salmon. A special class are aerial traps for catching flying fish and shrimps. The fish are stirred up, then caught in the air with the help of special gear called veranda nets. South Sea islanders catch flying fish at night by attracting them with torches.

(The uses of specific nets in seawater and freshwater fishing are covered in those sections of the article.) Bag nets are kept vertically open by a frame and held horizontally stretched by the water current. There are small scoop nets that can be pushed and dragged and big stownets, with and without wings, held on stakes or on anchors with or without a vessel. There is also a special winged type with boards or metal plates (otter boards) that keep it spread open. Stownets, larger than scoop nets and held in place against a current, are used in many rivers and by the Koreans for sea fishing in the strong current off the southwest coast of their country. In this case the stownet is anchored with a vessel.

Dragged gear includes dredges, used mostly for shellfish and operated by hand in shallow waters, and trawls. Bottom trawling is done with different types of gear that vary in design according to the way in which the bottom of the trawl is horizontally stretched. A modern development is the midwater trawl that drags the fishing gear through the water midway between the bottom and the surface. Trawls are the most important fishing gear of the commercial fisheries of northwest Europe and are second only to purse seines in total catch of the world.

The seine net (Figure 2) has very long wings and towing warps (tow lines), with or without bags for the catch.

Purse seines (Figure 3), also lampara, and other types of surrounding nets, capture the highest percentage of the total annual yield of the world. Pelagic fish are surrounded not only from the side but also from underneath, preventing them from escaping by diving downward. Purse seines can be operated by a single boat, with or without auxiliary skiff, or by two vessels. Many sardine-like fishes—herring, tuna, mackerel, cod, and salmon—are commercially fished in this manner.

Another class of fishing methods involves driving the fish into a net or gear. A drive-in net may be one of those already mentioned or may be specially made, such as the dustpan-shaped stationary gear used in some fisheries in south Asia.

A further fishing method employs lift nets, which are submerged, then raised or hauled upward out of the water to catch the fish or crustaceans above them, often attracted by light or natural bait. This group includes small hand-operated lift nets, such as hoop and blanket nets, as well as large, mechanically and pneumatically operated lift nets. Some of these employ levers, or gallows, and are installed on the beach or on a vessel. The fish wheels used on the Tiber, Rhône, and Columbia rivers can be considered as mechanized lift nets. The most important examples of this fishing method are the stick-held dip nets of the Japanese. In contrast to the lift nets are

Nets

Figure 3: (Top) Gill net, (centre) otter trawl, (bottom) purse seine.

Gill nets (Figure 3), which catch the fish in their meshes, are mostly used in long rows. As setnets they are anchored or fixed by stakes; as drift nets they are allowed to drift freely or with a fishing craft. Before the invention of midwater trawls, drift nets, with surrounding nets, were the principal gear for fishing pelagic fishes.

Sometimes gill nets do not catch by meshing but by entangling the fish, especially those too large for the mesh size or provided with spines or hard fins. Single-walled tangle nets are widely used to catch sturgeon, salmon, and shellfish, such as the king crab. Some tangle nets are double walled; most are triple walled, such as the trammel nets used especially for flatfish.

Harvesting machines include comparatively new types of gear that may separate the fish or shellfish from the water by pumps (pump fishing) or by mechanized dredges, as well as floating machines that dig out mollusks by means of underwater jets and transport them out of the water with the help of conveyor belts.

#### FRESHWATER FISHERIES

Freshwater fishing is carried out in lakes and rivers and to some extent in natural and artificial ponds. In tropical

areas, swamps with shallow water, sometimes overgrown with vegetation, are important inland fisheries. Before transportation and distribution of ocean fish was organized, freshwaters were the only resource for fish and other aquatic products for the inland population. Their importance decreased with the growing bulk fisheries of the seas. Today, freshwater fish comprise only 11 percent of the total catch of water products of the world. Nevertheless, in some countries the production of freshwater fish is still very high, more than 300,000 tons in Indonesia, more than 200,000 tons in Bangladesh and the Soviet Union, and more than 100,000 tons in Uganda, Egypt, Burma, and Chad. Widely different species—feeding on bacteria or detritus, plants or plankton, or living as predators—are used for human consumption. Well-known species include trout and whitefish, carp and other cyprinids, catfish, murrals, and tilapias. The desirability of some anadromous fishes—those, such as salmon and sturgeon, that spawn in freshwater but live in the sea—and catadromous fishes—those, most notably the eel, that spawn in the sea but live in freshwater—has led to specialized fisheries in inland waters.

The kind and quantity of fish found in lakes and rivers vary greatly with the physical and chemical condition of the water. Limnologists, scientists who study conditions in freshwater, classify freshwaters by the quantity of oxygen and essential nutrient salts (nitrates, phosphates, and potash) they contain. Fishermen classify waters by the principal fish to be caught therein. Rivers, for example, are divided into different zones beginning with the source, which is often good trout water, and ending in the estuary, where many coastal varieties of ocean fish can be caught. In like manner, fishermen classify lakes by expected catch (*e.g.*, eels, tilapias, or crayfish).

The great variations in the productivity of inland waters are explained by differences in their physical and chemical properties. Though some rivers may produce as much as 200 kilograms per hectare (180 pounds per acre) each year and some lakes may yield 160 kilograms per hectare (140 pounds per acre), the world average is about eight kilograms per hectare or seven pounds per acre.

Management of freshwater fisheries in small bodies of water is easier than management in large bodies or in the oceans, because it is easier to control fish stocks for maximum production. For this reason, increased production is expected in the future in smaller lakes, irrigation tanks, and dams. Management is accomplished by stocking, habitat control, feeding, fertilizing, controlling fish diseases and predators, cultivation of the shoreline, and regulation of the methods and intensity of fishing. A freshwater fishery is best managed by one man or by a cooperative and has a minimum economic size that varies depending upon local conditions. In an area with many lakes, like Schleswig-Holstein in northern West Germany, the minimum size of an economic lake fishery was considered 50 to 75 hectares (125–185 acres) at the beginning of the 20th century and about 150 hectares (370 acres) after World War II.

The inland fisherman's dwelling house may have special rooms for storing and drying professional clothes and boots. There are rooms or special buildings for assistants and helpers, for storing fishing gear, and for making and mending nets. Facilities are also needed for drying and preserving nets. On the shoreline are jetties, sheltered places to keep fish alive, and boathouses. Rooms are also needed for sorting and packing fish, for cooling, deep-freezing, and storage. Some fishermen have a small ice-making plant. Frequently, houses include facilities for fish processing, such as smoking, and a room for local marketing. A garage is needed for trucks and tanks with fuel for motor vessels and cars.

*Fishing methods.* Many techniques are employed to catch fish in inland waters, some appropriate to lakes alone, some to rivers only, and some to both. Of the many methods employed worldwide, only a few are economical for large-scale operation. Commercial line fishing, which uses many hooked and baited branch lines tied to a single main line, is widely practiced. A simpler technique is handlining, in which single lines with baited

Freshwater  
fish  
production

Passive  
and  
stationary  
fishing  
gear

hooks are tied to small sticks or trees along the shore or to special devices set along the side of a hole in ice. Handlining is used for deep fishing or for catching in rocky areas. Drifting lines with one or more hooks can also be used on lakes, though seldom in rivers. Lines may also be trolled (trailed) behind a moving boat. On some rivers in tropical and temperate areas, fish are caught by fouling with sharp-pointed hooks. The main difficulty in line fishing is to keep the lines clear and to obtain baits in needed quantity.

Passive and stationary fishing gear is so important in many lakes and rivers that some fishermen specialize entirely in trapping. Since deep and rocky shores, however, do not favour the use of traps, these devices cannot be used in all areas. Fish seeking shelter may be caught in simple brushwood devices when the brushwood is lifted quickly. More important are traps, such as wooden baskets made of wickerwork or of split bamboo, with retarding devices such as funnels or valves at the entrance. Wooden baskets, generally used in rivers with strong currents, can be set according to the longline system in which the baskets are tied with branch lines on a main line lying across the bottom of the river. Such baskets are usually baited, with the bait sometimes held in small bags or boxes. Today, in river fisheries as in coastal sea fisheries, traps, especially those used for eels, are made of plastic.

A more modern type of trap is the bag-shaped fyke net, held open by hoops; linked together in long chains, these are used to catch eels in rivers. When equipped with wings and leaders, fyke nets are employed in lakes where there are sheltered places with abundant plant life. Hundreds of such nets can be combined into systems where it is not economical to build large traps. (Wings are short leading netwalls at both sides of the opening of a fyke net, see Figure 1 bottom; leaders are long leading walls of netting guiding the fish to the trap, Figure 1, top.)

Another fishing method important in freshwater fisheries employs small scoop nets or large net bags (stow nets). Such gear is known on many European and Asian rivers. The net bag is fixed to the river bottom to catch migrating or drifting fish. Some human control may be necessary; sometimes a watchman lives on a vessel or raft next to the stownet or on a special platform. Though stownets are especially popular in European rivers for eel fishing, their importance is lessening due to increased boat traffic and to pollution. Moreover, the gear can be too large to be moved easily. In Indonesia stownets up to 100 metres (330 feet) long and up to 40 metres (130 feet) across the mouth are used. Small scoop nets can be operated by hand, pushed or towed over the bottoms in shallow waters. Sometimes this is done by fishnetting parties, in which all the men of a village form a line across the river, with a scoop net in each hand. Sometimes the fisherman stands on a platform built on the side of the stream and simply scoops up fish as they pass; this is done by some African fishermen in Malawi and was done by American Indians on the Columbia River in Oregon.

Seining

One of the most common fishing methods in freshwater lakes and rivers is seining, which is done in temperate zones especially in autumn and winter when fish are concentrated in deeper parts of the lakes. Because part of the seine must be dragged over the lake bottom while it surrounds the fish, seining is practicable only where the lake bottom is smooth and where favourable areas (*i.e.*, with fish concentrated near the bottom) are known. In some lakes such areas have been known for a long time and may be named and marked on fishing maps. Seine nets in lake fisheries can be very large with wings of 1,000 metres (3,300 feet) each. Since traditional seining required considerable labour, mechanization became desirable. A modern mechanized seine-net fishery requires only a small number of men. In northern countries seine nets are used under ice. For this purpose a number of ice holes are needed for guiding the towing warps with the net on the underside of the ice sheet. Here also manpower is saved by motorized towing and coiling lines and by drilling the holes in the ice with power drills.

Some success has been achieved in increasing the efficiency of seine nets by electric light. Fish trying to evade the net can be caught by stunning or eels lying in the mud during the cold season (generally a time when eel fishing is poor) can be attracted out of the mud by an electrical current. The disadvantage of all seine nets is that they are not selective; many undersized fish which should be preserved cannot escape.

Trawls and purse seines are used in large lakes only and are discussed below with sea fisheries. But lift nets are often used in freshwater, not only to catch bait fish for line fishing but also to catch crayfish or other freshwater crabs. There are small hand-operated lift nets tightened by frames and larger ones lifted from a gallows or with one or two vessels. Unframed blanket nets are used in rivers in Italy, each corner held by a gallows placed on the banks. Cover pots and cast nets also have some importance in commercial freshwater fisheries. Cover pots are especially used in rice fields or shallow waters with rich vegetation. Cast nets are more used in clear waters in lakes and in rivers; considerable skill is required to cast these. In the Soviet Union shooting mechanisms are employed to cast larger nets. Much more important in freshwater fisheries, however, are gill nets. The mesh size of the net can be used to regulate the size of the fish caught; thus smaller, undesired species escape. Lake fishermen use mostly stationary gill nets, anchored near the bottom or floating. River fishermen use gill nets that drift with the current, with one side tied to the boat and the other to a drifting buoy. With entangling two-walled nets and trammel nets, yield can be increased by frightening the fish into the netting; this is accomplished by beating the water or throwing stones.

*Sources of extra income.* Freshwater fisheries often must double as other types of enterprise in order to be economically successful. Many harvest water plants, collect shellfish or frogs, sell gravel, or, in areas with cold seasons, sell natural ice. Some freshwater fishermen have tried to combine fishing with the breeding of mink or other fish-eating animals.

#### SALTWATER FISHERIES

Fishing in salt water ranges from small traditional operations involving one man and a rowboat to huge private or governmental enterprises with large fleets for deep-sea and distant fisheries. Because industrial fishery grew from traditional beginnings, many similarities exist between the two.

Coastal waters and freshwater are demarcated by law in most countries. Inshore and coastal fisheries are separated from sea fisheries by the frontier limit, traditionally three miles or about five kilometres in most countries. This area is reserved for fishing vessels with small gear; trawling is often forbidden. Some traditional fishing vessels also fish in the deep sea, however. Small traditional vessels from the French Atlantic coast operate seasonally off the Irish coast and off the west coast of Africa. Small Portuguese vessels fish in the northwest Atlantic from Newfoundland to Greenland, and small Canadian and American vessels operate along the Pacific coast of North America. The best example of far distant sea fishery by artisans on a small scale is the fishermen of Ghana, who pilot their open, often unpowered canoes along the West coast of Africa from Senegal to Gabon.

*Objects of sea fishery.* Generally speaking, shellfishes (mollusks and crustaceans), seaweed, sponges, corals, and small coastal fish are objects of traditional fishery. Most other commercial fish are caught both by traditional and industrial vessels. In the United States, sports fishing also has an important effect on the stocks of commercial fish. Nevertheless, some species may be considered typical prey of industrial fishermen. Among these are all larger species of tuna.

The most important sea fish are herring-like fishes—such as anchovies, herring (in the North Atlantic), and pilchard (off the coasts of South Africa). In second place are representatives of the cod family, such as the Atlantic cod, the Alaska pollack, and the haddock. The third group includes such fish as the horse mackerel and the

Demarca-  
tion  
of coastal  
waters

mackerel. In estimating the importance of species, both quantities and market values of landings are considered. From this point of view, different species of tuna (especially yellowfin tuna and skipjack); salmon and capelins; milkfish; flatfishes (especially plaice and halibut); hake; croakers and redfish; mullets and sauries; menhaden and the North Pacific herring; many mollusks (especially squid, clams, scallops, and abalones); a large number of crustaceans—such as king crabs, lobster and spiny lobster, prawns, and shrimps—are important. Sea mammals, such as whale and seals, also have or had substantial economic value.

**Sea-fishing methods.** As noted above, purse seining for pelagic fish and trawling for demersal fish are the most important methods in the sea fisheries of the world. Other methods, widely in use, include diving for oysters and sponges; using spears and harpoons to catch tuna, whale, and seals; and using suction methods to remove clams from the bottom of the sea.

**Whaling.** Grappling and wounding gear used to catch sea fish includes spears and harpoons employed for whaling and sealing and for catching big fish, such as swordfish and sharks. The symbol of fishery, the trident of Neptune, is the old Mediterranean spear for fishing tuna. Harpooning is still important for whaling in the Arctic and Antarctic. Originally small whale were hunted from the shore in open sailboats and rowboats (a practice still current in the Azores) or by driving the animals toward shallow water as is done today in the Faroe Islands. (The whale are then killed with hand harpoons and lances.) Fishermen of the Basque country (southern France and northern Spain) hunted whale from the 14th century off Newfoundland and from the 16th century off Iceland and Greenland. In the year 1660 the Dutch introduced blunderbusses for whale shooting. For flensing (stripping the blubber), the whale was towed ashore, where oil cooking was also done, if the salted blubber was not transported home. Later on, flensing was done at sea outside the vessel, a practice continued up to the beginning of this century. Large whalers were used to transport hunting boats and to carry the blubber home. Old-style whaling reached its peak between 1650 and 1750. In 1731 the whale gun was invented. The Americans organized prosperous whaling in the South Seas between 1820 and 1850. They fished in other seas also; the last sailing vessels from New Bedford, Massachusetts, visited the Azores in 1913. The old whaling industry was destroyed by the introduction of petroleum for illumination, but new industrial uses for whale were found, and the modern era began with important innovations. In 1903 the Norwegians sent the first floating oil cookery to Spitsbergen and in 1924 the first mother ship or factory vessel with a chute on the stern was built. In this vessel the whale could be processed on board with nothing lost. Such a mother ship is accompanied by eight to 12 high-powered catching vessels, characterized by a long gangway connecting the bridge with a harpoon gun on the bow. This gangway enables the operator of the gun to assume his position very quickly. Catching vessels have a crow's nest for observation or are accompanied by airplanes or helicopters. The harpoon is connected with a line more than 1,000 metres (3,300 feet) long. This line is wound on a special winch and, to avoid its being broken by the struggles of the whale, it is run over a block hung on strong springs. The head of the harpoon contains a high-explosive shell that kills the whale instantly. Some species of whales sink rapidly when killed; to keep them afloat until they can be taken by the factory vessel, they are inflated with air. The peak of modern whaling was reached in the season of 1930–31, when more than 30 mother ships caught more than 40,000 whales. Since this time the catch has diminished; in 1946 a maritime convention protected whale stocks by limiting catches (see WHALING).

**Pole fishing and line fishing.** Line fishing at sea is very popular, not only in traditional fisheries with small boats employing a limited number of hooks but also in industrial operations with large vessels or fleets using thousands of hooks. For centuries, line fishing was carried on

in coastal waters and far at sea in the dory fishery famous today. A sailing mother ship carried the dories from Portugal, France, Canada, and the United States to the Grand Banks for cod. The one-man dory operated near the carrier setting longlines and sometimes fishing with handlines. In the evening the catch was carried back to the mother ship where each man prepared his catch for salting. The Portuguese still use dory carriers today, in the Davis Strait between Newfoundland and Greenland. Some large-scale modern enterprises also fish with hooks and lines, sometimes in far distant waters, as for tuna and halibut.

Pole-and-line methods are used in tropical Pacific and Atlantic waters to catch young bluefin and yellowfin tuna, and smaller tuna species—such as albacore, skipjack, bonito, and little tunny. The pole, generally bamboo, ranges in length from two to ten metres (seven to 33 feet), with a line of roughly the same length. Hooks of various sizes are barbless to facilitate baiting and removing the captured fish. To hold onto the pole a "rod rest" is generally used, which is made of canvas, leather, or old rubber tires. Depending on the size of the vessel, the crew may number 30 or more. A large crew is needed, since fishing time may be limited and the maximum possible number of rods must be worked. If larger and heavier fishes are sought, two, three or even four poles may be linked to a single hook. In this case the fishermen must cooperate closely. The tuna is attracted and kept near the vessel by chumming, throwing live bait overboard. The bait is kept alive on board in special tanks in which seawater circulates constantly. Bait can be an expensive problem for tuna fishermen; to catch one metric ton of tuna, roughly 100 kilograms (220 pounds) of live bait fish are needed. Sometimes the hooks are baited, sometimes artificial lures are used with hooks hidden in feathers. When the tuna is "hot" (very eager to take the bait), a naked hook is sufficient. Pole-and-line fishing for tuna is done in daytime from slow-moving vessels. Since considerable space is needed for the angling crew to stand side by side on the lee side of the vessel, Japanese vessels for pole-and-line fishing have a long extended bow. To simplify hauling in the catch these boats also have a low freeboard (*i.e.*, their sides ride low above the water). American tuna vessels hang special racks outside the ship over the water; water spraying helps to attract the tuna; it also serves to camouflage the shadows of boat and crew.

**Drifting longlines.** Used for tuna—especially in Japan, Taiwan, and Korea and to a limited extent in South Africa, Cuba, and French Oceania—drifting longlines are particularly successful in the tropical Atlantic for big fish in depths from 60 to 250 metres (about 200 to 800 feet). More than half the fish caught in this manner are yellowfin tuna, one third are albacores, and the remainder bigeye and bluefin tuna. Sharks, marlins, swordfish, and sailfish, also caught with drifting longlines, are sometimes included in the tuna statistics. Sharks can cause serious losses by damaging hooked tuna. Originally longlining for tuna was a Japanese inshore fishery. At the end of the 19th century, the Japanese were fishing 30 to 40 miles (50–65 kilometres) off their coasts. This fishery was extended when sailing boats were replaced by motorized craft, and by 1926 the Japanese began longlining for tuna off Taiwan, by 1929 in the Indian Ocean, by 1930 in the South Pacific, by 1938 in the eastern Pacific, by 1952 off the southeastern coast of Australia, and since 1955 in the Atlantic. Longlining for tuna is the most important Japanese fishing method by value. A longlining crew must be willing to do a hard, though lucrative, job and remain far from home for long periods. The gear is a line composed of 400 to 450 sections, each section with a length of 150 to 400 metres (500 to 1,300 feet) stored in a basket. The total line can have a stretched length of up to 180 kilometres (about 110 miles). Each section is composed of subsections of different length. The branch lines with the hooks are composed of three sections that vary in number and length. From one to 12 (generally five) branch lines with hooks form one section; 2,000 hooks are considered the greatest

Attracting  
the tuna

Flensing  
whales

Labour-  
saving  
technology

number that can be operated in one set by a vessel. With decreasing catches, attempts have been made to increase the number of hooks; Korean fishermen are said to operate as many as 3,000. The shooting of the line from the stern of the vessel begins early in the morning before sunrise, when the vessel is moving at a speed of about five knots (five nautical miles per hour) or more. During shooting the lines have been tied together and the hooks are baited with frozen Japanese sauries. Each section is tied with a float line and a buoy. Depth of the gear can be regulated by the length of the float lines and the distance of the floats. Ten to 14 men require four hours to perform the task. Hauling from the forepart of the vessel begins in the early afternoon with the help of a line hauler. Depending on the quantity of the catch, hauling can take more than ten hours with a crew of eight to ten. With preparing and sorting the catch, the usual working day of a crew member totals some 18 hours. Because of this and the fact that vessels stay at sea more than 200 days per year, the Japanese and Taiwanese have experienced difficulty in procuring crews; this problem has led to the development of new technology to simplify the work and reduce manpower. One such improvement is the reel system, made especially for larger vessels. The total line is set, hauled, and stored on a drum. Though the floats and branch lines must still be tied by hand, research is being done on a coupling apparatus to do this automatically. Another invention is a line-winder system practicable for small vessels. In this a single line is used, hauled and coiled by a line winder in special tanks in the aft part of the vessel. Though such ideas can be considered first steps in the modernization of longlining, catches have been decreasing since their peak in 1963, so the future is uncertain.

*Bottom longlines.* More popular in commercial sea fisheries are bottom longlines mentioned above with the dory fishery. These catch many species of the cod family, including cod, haddock, coral fish, hake, and pollack, as well as rays, and many flatfish, such as halibut. There are also longline fisheries for groupers, hairtails, croakers, and sea breams. Bottom lines are not as long as the more easily controlled drift lines. The hooks do not always lie on the bottom but may hang above it to protect the bait against unwanted bottom predators, such as starfish, snails, or crabs. Typically, bottom lines are used for halibut in the northern Pacific. A relatively heavy main line is divided in sections of approximately 50 fathoms (300 feet or 90 metres). The branch lines, each about five feet (1.5 metres) long, are tied at intervals of 13 to 18 feet (four to 5.5 metres). Modern synthetics, with their greater strength and lighter weight, have replaced natural fibres for main lines. Fishing depth usually ranges between 45 and 150 fathoms (270 feet or 80 metres and 900 feet or 275 metres), depending on the grounds and season. The setline is anchored on both ends, marked by a floating keg and a lighted flag buoy at night. Originally only two-man dories fished this way, but today special mechanized boats with small crews and high yield per man do longline fishing. In Norway, for example, machines cut fish for bait, and, in the Faroe Islands special machines are used to bait the hooks.

Setting  
traps

*Traps.* There are only a few areas in the world where water or weather conditions prohibit the use of traps. A single small vessel can operate hundreds of traps, though lack of storage space may cause difficulties. Thus collapsible traps of netting on a wire framework are preferred not only for fish but also for crustaceans. Many plastic traps are made today, especially for lobster. Some can be dismantled for easy transportation. Water snails, such as whelk in England and other species in Korea, are also trapped, as are cuttlefish and octopuses. As in freshwater, fyke nets can be set in long rows or in connected systems. Commercial sea fisheries set long rows of pots or framework traps by the longline system; *i.e.*, single pots are tied with a branch line to a main line. Hauling is accomplished with small hand-operated or motor-driven winches. More important for catching fish in commercial sea fisheries are the big wooden corals, or weirs, and the large pound nets. The oldest type may be the

Italian tonnara, used in the Mediterranean for tuna from the Bosphorus to the Atlantic. Very large pound nets are also used by the Japanese on the Pacific coast, by the Danes and their neighbours off the eastern coasts of the Baltic, and for salmon fishing off the Pacific and Atlantic coasts of North America. The difficulty in setting large traps lies in placing them on the bottom. If the water is not deep and the bottom is not hard, the weirs can be held by sticks or piles. Where the water is deeper and the ground is hard or rocky, the weirs must be anchored.

*Dragged gear.* Dredges and trawls are of great importance in commercial sea fisheries. Dredges are generally used in shallow water by small vessels, although a deep-sea dredge is operated by research vessels at depths of up to 1,000 metres (3,300 feet). The simplest dredges in sea fishery are hand operated. Fitted with a stick up to five metres (16 feet) long, they resemble rakes combined with a bag for collecting the catch—usually mollusks or crustaceans. Heavier dredges with a triangular or quadrangular iron frame may be towed along the sea floor by small vessels or pulled some distance from the shore or from an anchored vessel and then towed back with a winch. For digging out mollusks, some dredges have iron teeth on the lower edge of the frame. They may also have a pressure plate on the upper part and chains on the lower part, depending on the catch sought. The bag of the dredge is made of wire rings that have good resistance to friction and of hard fibre netting. Usually more than one dredge is operated by a vessel, and they are towed with the help of outriggers. The great disadvantage of dredging is that much of the catch is damaged, wasting effort and needlessly killing fish.

Trawling

Trawling in sea fishery can be done by small vessels or even rowboats (as in the estuary of the river Tejo near Lisbon, Portugal). More important, however, are fleets of highly mechanized trawlers whose gross registered tonnage may reach 5,000 and whose horsepower approaches 6,000. The trawl is a towed net bag with a wide opening at the mouth and an end closed by a special knot. The mesh size of the opening can be large—600 millimetres (two feet) from knot to knot—to diminish water resistance during towing. The closed end can have meshes of six millimetres (one-quarter inch) according to the species of fish or shrimp sought. The trawl is designed in a smooth funnel-like shape to guide the fish into the closed end. To keep the mouth of the trawl open, a large horizontal beam may be used. Up to 12 metres or 39 feet long, the beam is based on two guides that glide over the bottom. The Dutch catch flatfish with beam trawls that have heavy chains, called tickler chains, dragging on the sea floor in front of the net opening between the two gliders to frighten the fish from the bottom into the trawl. Though beam trawls were the original gear of deep-sea steam trawlers, today they are used by smaller vessels only. Beam trawls are usually towed in pairs, one on each side of the vessel. Such an arrangement can considerably decrease the stability of the vessel and is dangerous except in craft specially designed for the purpose. Another method involves two vessels stretching the horizontal opening of the trawl between them. Two vessels have more power to tow a bigger trawl at greater speed. Spanish pareja fishing is an example of this method, called bull trawling in some countries. The skippers of the two vessels must cooperate very closely. The most recent and presently the most important method for spreading a trawl opening employs two large boards or metal plates (otter boards), rectangular or oval in shape, which are attached to each side of the net and caused to flare apart by the pressure of the water.

Midwater trawling involves dragging the trawl with one or two vessels in the area between the ocean bottom and its surface to catch pelagic fish and crabs. Depth of the trawl is regulated by the length of the towing warps and speed of the towing vessel. With longer warps and lower speed, the trawl sinks; it rises with shorter warps and higher speed. The fisherman attempts to trawl at the depth where fish are observed. A special type of midwater trawl is the semipelagic trawl, originally invented

in Iceland and now operated primarily by French fishermen. In this technique the otter boards remain in touch with the bottom but the trawl floats at some distance above it. Semipelagic trawls were constructed because fish often are concentrated at a short distance from the bottom outside the range of the usual bottom trawl with a low vertical opening. To overcome this difficulty, a higher opening of the trawl is needed. Though the opening of a bottom trawl can be stretched vertically by various means, such stretching decreases the horizontal width of opening. Some modern bottom trawls are constructed with a high vertical and horizontal opening, and many consider them the best available gear for bottom trawling.

**Seine nets.** Mentioned above as important large-scale gear in freshwater fisheries, seine nets are similarly employed in beach seining, where fish shoals are near to beaches. Large beach-seining operations for sardine-like fishes and other species are carried on in the Indian Ocean. The importance of this method has decreased as pollution has cut the available stocks of fish in this region and as manpower costs have risen: not all fishing methods lend themselves to mechanization. More successful are boat seines, better known (because of their origin in Denmark in 1849) as Danish seines. The gear consists of a typical seine net with a large bag and long wings connected with long towing ropes. The ropes act both to keep the net open and to herd the fish toward the net bag. One of the ropes (about 100 metres or 330 feet long) is tied to an anchored buoy. The other rope is tied to the vessel, which steams in a wide circle, returning to the buoy and capturing fish in the wings and bag of the net. Next, the vessel drops anchor and hauls both ropes together until the net bag is taken on board. Special winches and coilers for the long ropes are situated in fore-and-aft position on the deck. These coilers, together with large quantities of coiled rope, typify vessels used for Danish seining. This method is used in northern Europe for flatfish and cod and in Japan has become the most important method of inshore fishery for bottom fish, after two-boat trawling.

**Surrounding nets.** The most important sea-fishing gear is the surrounding net, represented by the older lampara nets and the more modern purse seines. Both are typical gear for pelagic fish schooling in large and dense shoals. When these nets are used, a shoal of fish is first surrounded with a curtain or wall of netting that is buoyed at the surface and weighted at the bottom. The lampara net has a large central bunt, or bagging portion, and short wings; the school of fish is worked into the bunt and captured. With the purse seine, once the school is surrounded, the bottom of the net is closed by drawing a line through purse rings attached to the lead line; the fish are then concentrated and removed by a brail (dip net) or are pumped aboard the fishing vessel.

Surrounding nets are used for tuna, herring, sardines and related species, salmon, mackerels, and even cod (when they come to spawn in the pelagic zone). For these nets to be successful, the fish must be in large and dense shoals; light and bait are sometimes used as lures to produce such shoaling.

**Lift nets.** Fish can also be caught, in limited quantities, by lift nets: stationary types operated along the shoreline, movable ones from rafts and boats, and large blanket nets held on each corner by a small boat. The Soviets operate a large commercial lift-net fishery on the Caspian Sea to catch sardine-like fish attracted by light. Each vessel operates two conical nets, setting one while the other is being lifted. Another effective lift net is the large, boxlike *basnig* of the Philippines, operated with a luring light during the night beneath a single outrigger vessel; sardines, mackerels, hairtails, squid and other pelagic prey are caught. The Japanese have a special kind of lift net for sauries; the fish, attracted by light, swim over the netting lowered into the water and are caught when the netting is hauled.

**Gill nets and drift nets.** Quite important in commercial sea fisheries, gill nets are sometimes operated in large sets thousands of metres long. These generally drift

with the vessel or are set as anchored nets in long rows at or near the bottom of the sea. Gill nets are used for many pelagic fishes, such as herring, pilchards, sardines and related species, mackerels, croakers, salmon, and tuna. They also are used for many bottom fishes—cod, Alaska pollack, and others. For cod, Icelandic fishermen set up to 90 nets, each about 50 metres (160 feet) in length, in depths up to 180 metres (600 feet). About 15 nets are generally set in combination, anchored on each end and marked by floating buoys. Though these nets are checked daily some have been lost in storms, leading to complaints of damage to cod in the area.

Drift nets are widely used to catch pelagic sea fishes. In northern Europe, before the introduction of trawling, drift nets were the most important method of deep-sea fishery. In the old herring fishery of northwestern Europe, drifters commonly set more than 100 nets, each about 30 metres (100 feet) in length. Thus a fleet of drift nets might measure three or even four kilometres (10,000–13,000 feet). The nets are set in the late afternoon to catch the herring as they ascend in the evening from ocean bottom to higher water levels. During the night the vessel drifts with the nets like a buoy. Hauling, done by hand or with mechanical aids, begins at midnight and, when big catches are taken, can continue until late morning. The fish are shaken out of the meshes by hand or with shaking machines.

**Entangling nets.** Similarly operated are entangling nets, single or double walled, and three-walled trammel nets. These are used in sea fisheries for hake, shark, rays, salmon, sturgeons, halibut, plaice, shrimps, prawns, lobster, spiny lobster, king crabs, and turtles. Single-walled nets are used in the southern part of the Caspian Sea and in the Black Sea to catch sturgeons by entangling. Iranian fishermen set about 150 sturgeon nets in one row perpendicular to the shoreline. Setting requires much labour; between each two nets a line is tied, which is connected to a short wooden peg driven into the bottom. The Turkish Black Sea fishermen sometimes set sturgeon nets in another form. Two nets always form an angle open to the sea. The nets are held by sticks rammed into the bottom. Sturgeon nets are checked once or even twice each day, depending on weather. For this purpose an Iranian fisherman lies on the bow of his sailboat, towing the vessel along the float line of the net. The sturgeons are taken from the water by hand or with a gaff. In the Soviet portion of the Caspian Sea sturgeon fishery is forbidden, because the sturgeons are caught for caviar when descending the rivers. The Iranian fishery is a government-operated large-scale fishery, in contrast to the traditional private sturgeon fishery in Turkey.

The most important sea fishery for crustaceans is the king-crab fishery in the northern Pacific. For the Japanese, who use entangling nets, this is a very important distant fishery ranking with whaling and tuna and salmon fishing. Originally carried on close to shore, king-crab fishing was extended in the northern Pacific after its beginnings in the 1870s. The old land stations for processing were replaced by floating factories that accompanied the fishing vessels. The entangling nets are set on the bottom, sometimes 200 nets with a total length of ten kilometres (about six miles) in one row. Larger catching vessels set 1,200 to 1,300 nets a day, usually in parallel rows about 500 metres, or 1,600 feet, apart. Nets stay in the water from five to seven days and are hauled by small open vessels with motor-driven reels, which can take from 2,500 to 3,000 nets per day out of the water. When hauling, the floats and sinkers are untied and the entangled king crabs are taken from the netting. The catch and nets are then transported to the mother ship, where the catch is processed and the nets cleaned, an operation that may require 30 minutes per net. Large racks for drying and cleaning the entangling nets are characteristic of this type of vessel. A single fishing unit may own a permanent set of 15,000 to 30,000 nets.

**Harvesting machines.** A relatively new type of fishing gear is the harvesting machine combined with a pump, used by the Soviets in the northern part of the Caspian for sardine-like fish and by the Americans for squid off

Historic importance of drift nets

Squid fishing

Decline of beach seining

the California coast. In both cases the prey is attracted by light. Squid fishing can be done near the surface, but in the Caspian the fish are sucked on board with pumps from depths up to 110 metres (360 feet). In pumping, the suction nozzle is moved up and down with attracting lamps. Once on board the fish or squid are strained from the water. The difficulty in fish pumping is to avoid damage to the catch. Only small objects can be pumped without injury.

Another type of harvesting machine is the hydraulic dredge, with pumps and conveyors. These dredges wash out deeply buried mussels with jets of water under high pressure. The Americans operate such hydraulic dredges to harvest soft clams, and the British use similar machines for cockles. Harvesting machines also are used to cut kelp off California. Giant kelp is harvested by cutting to a maximum depth of 1.2 metres (four feet) below the surface of the water and is transferred by conveyor belt into the open hold of the vessel.

**Fish finding.** Traditionally, sea fishermen have known the time and place to find their catch, but the history of fishing has demonstrated more than once that even old and rich fishing places can become exhausted quite suddenly. This is especially true with pelagic fish like herring, pilchards, or sardines. The herring yields of the Schonen fishery and later on of the Bohuslaine fishery (1744–1809) in the Baltic fell so severely that the very existence of the Hanseatic League was compromised. This sudden change did not result from overfishing but was caused instead by natural fluctuations in the development of stocks. Recently, the herring fishery in the North Sea and off the Norwegian coast has decreased very quickly. Sardine fishing collapsed off the California coast in 1952. Similar disasters have occurred in other parts of the world not only because of overfishing but also for natural reasons. When this happens new fishing places must be found. It is difficult to explain how good fishing places in great depths were found in ancient times, but fish in shallow waters, fjords, or small bays can easily be seen. Even on the high seas, fish can be located when they surface temporarily. Fish searching by direct observation from a vessel is important even today. But in modern times fish, whale, or seal searching is done in many areas by airplanes or helicopters. Both commend a wider range of vision than a boat, and an experienced air-spotting pilot can detect fish under the surface. Identification by species is accomplished by observing the shoal's form or colour or behaviour and sometimes by the presence of accompanying birds. During the night, fishes can be located through the phenomenon of bioluminescence; *i.e.*, when their passage through the water causes tiny marine organisms to luminesce. Accompanying birds have played an important part in fish searching for centuries, because a concentration of birds can be seen from a distance. Very often the birds are not attracted by the fish sought but by smaller fishes and squid, which may have taken refuge from large species by swimming to the surface. Other animals may also indicate fish concentrations by their presence. Porpoises, for example, are known companions of tuna. With the help of porpoises, fish in deeper water can be detected. According to the Inter-American Tropical Tuna Commission, 62 percent of the yellowfin catches with purse seines were accompanied by porpoises in 1962. To find fish in deeper waters by other means was difficult if not impossible in the past. Herring fishermen used signal lines to find their prey in deep waters. These were long wires dropped from a boat; the fisherman holding the line in his hand could feel the vibration caused by the fish touching the line, which was named the herring's telephone. Other fish were also found by signal lines, often tied with fishing gear. In modern industrial fisheries, experiments have been made with direct listening for fish, but this method has been found impractical. Sea fishermen have also learned to judge where fish can be expected by observing environmental conditions. The colour of the water and the presence of current or of a borderline between different water bodies are some common fish indicators. One of the most important physical

Identifying  
fish in deep  
waters

properties for fish finding is the temperature of the water. The use of thermometers was one of the first practices fishermen learned from oceanographers, not only for fish finding but also for forecasting availability of the desired species.

All these direct and indirect observations can be made by vessels or airplanes. Today, some research is being carried on to find how and to what extent such observations can be made by satellites.

It is possible to judge the vertical distance between the bottom of the ocean and the hull of a vessel by transmitting sound waves and measuring the time required for the reflected wave to return. A shoal, of fish registers on such equipment (echo sounder) as an obstacle. An experienced operator can locate fish with such equipment and can even judge their quantity. Some fish give typical signals, so that even the species can be identified. Horizontal sounders (sonar) are also employed: indeed, echo sounding has become decisive for success in fishery, especially in purse seining and midwater trawling. A sonar transducer can be tied on the headline of a trawl in midwater and bottom trawling. This implement, called a netsonde, signals the distance of the trawl from the bottom or from the water surface, registers the size of the trawl mouth, and signals if fish are entering the trawl. A multi-netsonde has been constructed that alternatively measures and records the water under or over and in front of the gear. New types of netsonde have been combined with a device for temperature measuring, enabling the captain to choose the most favourable environmental temperature during trawling. Effective operation of fish-finding devices requires considerable experience. Fish behaviour can change unpredictably, and fishing captains study each new situation in order to interpret correctly the signals of their equipment.

**Fishing vessels and fleets.** In the past, fishing vessels constituted a much neglected sector of the fishing industry. Naval architects, boat designers, builders, and engineers took little account of fishing methods and the industry's special requirements at sea. Today conditions have changed. The fishing vessel has become the largest single item of investment in the industrial fishery of developed countries, greater than harbours, cannery plants, and retail stores. There exists, therefore, a strong incentive to produce highly efficient fishing vessels.

For a long time fishery followed the general lines of vessel development. Even today, rafts of bamboo or light wood are important in coastal areas of Southeast Asia. Simple wooden boats, such as canoes, are still important for fishing in many parts of the world, including the African coast. Raftlike boats are employed in Guinea and in South America. Wooden boats such as pirogues, with or without outriggers, are used off the Malagasy Republic, Indonesia, and the Philippines. There are also small vessels made of a skin-covered framework—the kayaks of the Eskimos, British coracles and Irish curraghs (both the latter now canvas covered), and the bitumen-coated guffa of Iraq. These small vessels are easy to carry and to navigate during fishing. In the traditional coastal and inshore fisheries of industrial countries, most of the smaller boats are made of wood, which means they can be repaired by the fishermen. Many smaller vessels today are made of aluminum, plastic, or reinforced concrete. Modern cutters and all bigger vessels are now made of steel.

It has been found in sea fisheries that the size of a vessel, its horsepower, and its age are decisive for efficiency. The size of a fishing vessel can be characterized by the number of the crew; the overall length; vessel capacity in terms of fresh, frozen, or filleted fish; the capacity of the fishhold in cubic feet or metres; and the gross registered tonnage of the vessel. Judged on this basis, the size of vessels in sea fisheries has increased considerably in the recent past. There are active fishing vessels today of more than 5,000 gross registered tons; the number of vessels at sea is decreasing but the total tonnage is rising. For statistical purposes, fishing vessels are very often classified according to tonnage, and then broken down into subcategories.

Fishing  
rafts

Its means of propulsion also determines a fishing vessel's efficiency. Rowboats and sailboats are still common in small inshore fisheries. Some fishermen, like those of Ghana, can be seen in open sailboats 30 kilometres (20 miles) or more off the coast of West Africa. Most of the old sailing vessels of the whaler and bank fishermen were replaced by steamships in the last quarter of the 19th century, but the latter were supplanted in turn by motor-driven vessels, the lighter engines of which take less space, require less maintenance, and run longer between refuelings. Though motorization of fishing vessels began in the first decade of the 20th century, progress was slow until after World War I. Horsepower has increased steadily since that time. The first experiments with atomic propulsion were made in the fisheries of Japan after World War II.

Vessel efficiency decreases, of course, with age. Statistics generally show the average age of the total fleet. In West Germany, for example, average age of the deep-sea fleet in 1961 and 1962 was 7.4 years, a marked improvement from 1949 when it was 18.4 years.

There are also many large differences among fleets according to the type of vessel engaged in fishery. There are true fishing vessels and auxiliary craft. Fishing vessels, strictly speaking, are only those that use their own gear to catch fish or other marine products. Moreover, the statistics for fishing vessels include craft such as mother ships and carriers, which permanently accompany a fleet or which visit the fleet to carry catches away and to bring supplies. There are also factory vessels that process catches on board. Included also in the statistics for fishing vessels are the protection or inspection vessels, which are mostly government owned. Originally, these vessels were naval craft.

Fishing vessels employing a particular method often have characteristic shapes and deck arrangements. A typical example is the whaler's catching boat with a gangway, or catwalk between the bridge and the whale gun, allowing the harpoon gunner to reach his place quickly even while high seas sweep the main deck. Another conspicuous feature is the high crow's nest for spotting whales. Vessels for harpooning swordfish or sharks, such as used by the swordfisherman of New England, have a pulpit for the harpooner built forward on the bow of the vessel. The Chinese have harpooning boats with a lengthened bow allowing one or two harpooners to stand high over the water surface. American tuna clipper from which linefishing is practiced have a low stern with fishing platforms or racks hanging outside the vessel and a high bow for increasing the seaworthiness of the vessel in rough weather. For line fishing, Portuguese dorymen ride a ship that may carry 50 to 100 one-man dories piled up on deck like plates. Another typical line-fishing vessel is the troller, which tows a lure or baited hook from its stern. Typical for these vessels are the long outriggers for the lines and a high bridge where the captain can watch for strikes on the trolled gear.

One of the most significant advances in ship design was the development of the stern trawler from the once universal side trawler. Gear is much easier to handle on the stern trawler, account need not be taken of the wind in setting out (shooting) the trawl, and catches of up to 100 tons can be handled without difficulty.

**Fishing harbours and port markets.** For small vessels, landing places are not difficult to find, when the sea-coast is neither too unsheltered nor too rocky. But even coasts with high-breaking waves have been no barrier to fishermen with small beach-landing vessels. The boats are towed ashore manually or with winches. Small boats, with or without motors, can land without special facilities in many areas, allowing easy distribution of marine products to the consumer. Groups of fishermen called water nomads operate in Tierra del Fuego, south of the Malagasy Republic, in Ghana, and along the African coast, travelling from one coastal town to another to sell their catch. For fishermen with heavier vessels, such as motorized cutters, safe water is needed which must be sought in natural or artificial harbours. Such fishing harbours are often commercial ports as well. A fishing har-

bour provides safety for boats, vessel maintenance, and facilities for storage, processing, and marketing of fish.

Small harbours are often built by governmental authorities in the hope that such places will become fishing centres. Such installations may be small landing places, as in Ireland, or a system of jetties built on unsheltered coasts. The main objective of a fishing harbour is to transfer the fish as quickly as possible to the market or consumer and to speed the vessel's landing, departure, and maintenance. Thus, not only landing quays are needed but also facilities for unloading, sorting, and weighing, as well as auction halls, merchants' buildings, ice plants, and cold-storage warehouses. For vessel repair a shipyard is needed or at least a slipway. Service should be available for fishing gear, engines, and electronic equipment. Fuel is supplied by floating or stationary stations. Freshwater is needed both for drinking and for cleaning, and electric power is required. Finally, waste disposal arrangements must be made to prevent harbour pollution.

Planning for the special facilities required for a fishing harbour must be careful to avoid loss of money and time. Fishing ports and the incorporated port markets are often planned, constructed, and administered by governments. The government may lease the harbour and market to special organizations, often private companies. Or sometimes a special authority is set up, consisting of a partnership between the government, which has built the harbour, and the local community, which owns the land. The authority is responsible for the facilities of the fishing harbour and of the market. Customers of the harbour pay dues for moving a vessel, for mooring it at a quay, and for unloading. These dues are often set quite low in order to attract vessels to the harbour and to supply the market with sea products. A greater profit is made from auction sale commissions, rents for land and buildings, and from various service charges. Often such facilities are operated by port or market authorities themselves. These arrangements differ widely from one place to another, according to the political and economic situation.

Port-market organization

#### FISH-FARMING AND AQUACULTURE

A very ancient method for catching fish involves driving the prey toward a beach and closing off the area with a wall of mud or stone or with a wicker fence. Netting was later employed for this purpose, and today fishermen are experimenting with air-bubble screens and electric fences for restraining fish in bays or fjords. By this method, the catch can be kept alive if not needed immediately. There are definite limits however, to the length of time a captured fish can survive; lack of oxygen, unfavourable temperature, and disease are the main hazards. In freshwater, fish may be stored in mesh boxes that float or hang near the landing place in a lake or river. When large quantities of fish must be kept alive, they may be confined in temporary cages of netting or wire. Small quantities are stored in baskets or keep nets similar to those used by sportsmen.

Fish may be stored in order to comply with market regulations, or to stabilize supply. In some cases, fish caught in polluted waters may be transported to clean water to allow them to rid their bodies of readily excretable pollutants. If the fish are stored for some time, they usually lose weight, although some success has been achieved in feeding stored catches. If the fish do eat and are kept under good conditions, they often gain weight faster than under natural conditions. This, of course, amounts to a primitive form of fish-farming.

**Farming and rearing in hatcheries.** Fish-farming as originally practiced involved capturing immature specimens and then raising them under optimal conditions in which they were well fed and protected from predators and competitors for light and space. Carp have been raised in ponds for several thousand years in China and India. Other species were cultivated before 1400 BC, as Egyptian drawings attest. It was not until 1733, however, that a German farmer successfully raised fish from eggs that he had artificially obtained and fertilized. Male and

First artificial fertilization

The whaler's catching boat

female trout were collected when ready for spawning. Eggs and sperm were pressed from their bodies and mixed together under favourable conditions. After the eggs hatched, the fish fry were taken to tanks or ponds for further cultivation. Recently, methods have been developed for artificial breeding of saltwater fish, and it now appears possible not only to rear sea animals but to have the complete life cycle under hatchery control. Some authorities claim that the time is coming when farming the edges of the sea could solve the protein and hunger problems of the world's growing population. Currently, however, saltwater fish-farming emphasizes the higher priced and luxury varieties such as lobster, shrimps, and oysters.

**Carp.** Carp raising, practiced worldwide, is a good example of advanced techniques. For the whole life cycle at least three different types of ponds are used in Europe. Special shallow and warm ponds with rich vegetation provide a good environment for spawning, a process which today is often aided by hormone injections. After spawning, the parent fish are separated from the eggs and taken to a second pond. The fry, which hatch after a few days, are transported to shallow, plankton-rich nursing ponds, where they remain until the fall of the year or the next spring. In tropical areas, such as India, carp spawned from wild fish can be collected by experts in natural waters. To collect eggs or fry from wild fish is disadvantageous, however, because the breeder cannot influence the breeding stocks in a desired direction. In Asia, therefore, the fry of common or golden carp are generally bred under culture conditions in hatcheries. Bigger ponds are needed for rearing the fish in the second year of life. There are large carp ponds in Czechoslovakia, while in Asia common carp are often cultivated in rice fields. For feeding carp in ponds, soybean meal, rice bran, and similar agricultural products are used. Concentrated food in the form of pellets has also been successfully introduced. During the winter season in the temperate zone, the carp are kept in deeper winter ponds with a dependable flow of water to protect them against freezing. In Central Europe, carp are ready for the market after the third summer. In southern Europe, Hungary, and Yugoslavia, carp may be sold after the second summer. In tropical areas the fish grow even faster. To accelerate growth, warm-water ponds now exist in the temperate zone. The first experiments of this sort showed that carp could be kept in small aquariums with a permanent circulation of warm water of 23° C (73° F). Under these conditions they grew rapidly, attaining a marketable size and weight after two years. Similar results were obtained in warm-water ponds fed by heated industrial waters. In the temperate zone an average harvest of 400 to 500 kilograms per hectare (about 360 to 400 pounds per acre) is normal in intensive cultivation of carp. By scientific management and careful selection it is now possible to obtain yields as high as 3,500 kilograms per hectare (3,100 pounds per acre) for carp in warm-water ponds. Other fish, such as Chinese carp or grass carp, may be similarly raised in ponds, as are decorative species, such as golden and silver carp.

**Trout.** Although trout was the first fish to be artificially fertilized, trout cultivation in Europe and North America is much younger than carp cultivation. Trout are cold-water fish and must have a constant supply of sufficient oxygen, making cultivation more difficult. Though trout ponds can be smaller than carp ponds, good year-round water circulation is essential. Trout farms are therefore often located in mountainous areas where plentiful pure water is available. The young fish are obtained exclusively by artificial fertilization; thus, hatchery buildings with low-temperature fountain water and good filters are the centre of this type of pond fishery. Here the eggs are kept under control during breeding in special small tanks. As soon as the hatched fry can swim and eat on their own, they are transplanted to rearing ponds for feeding.

Trout are carnivores; meat-packing by-products are used for feed. Formerly, these and similar products were

also used to feed more mature trout. A special refrigerated feed house for keeping and cooking the food was the second main building typical in trout farms. Dry fodder is now preferred, however, and synthetic pellet-type feeds have been developed that require no refrigeration. Such food may be released into the ponds at predetermined intervals by automatic compressed-air dispensers. Though many authorities claim that trout should have as much natural foodstuff as possible and therefore should be raised in natural ponds only, in many countries rearing is done in concrete-lined ponds or concrete tanks, which are easy to keep clean and permit disinfectant application. The length of time necessary to rear fish and the yield per hectare depend on feeding. Some trout farms not only sell their fish fresh and frozen but also smoked and filleted.

With trout, a new system of fish cultivation has been introduced in recent years. Instead of ponds, enclosures of netting or other materials are placed in natural waters, such as lakes, and also in brackish waters. By this means, areas formerly of low value can be farmed intensively. Farming trout in brackish water or seawater was of especial interest. Since the period preceding World War II, trout farming in seawater has grown tremendously. Keeping trout and other fish in such cages is much easier, construction costs are far lower, and surprisingly dense populations can be raised.

Many other fish are raised artificially by various methods. Among these are salmon, sturgeon, eels, milkfish, mullet, and tilapias.

**Other types of aquaculture.** *Mollusks.* Other important objects of cultivation in many parts of the world are mollusks. Though few water snails are cultivated, bivalves, especially oysters, are quite important in Asia, Europe, and North America. For centuries French fishermen cultivated oysters by placing twigs in the water to which free-swimming oyster larvae could attach. In northern Europe, oysters have been cultivated on the ocean bottom, but low winter temperatures limit the extent of this activity. In the Mediterranean, the Romans are said to have been the first to farm oysters. Today, oysters are cultivated on the Pacific coast of North America, as well as on the southern Atlantic coast and the Gulf of Mexico. Australia, the Philippines, and South Africa also possess farms, and the Japanese grow edible oysters from Hokkaido in the north to Kyushu in the south. Japanese farms are divided into two classes: some cultivate seed oysters only, while others raise them for food, especially for export. The Japanese cultivate oysters on the sea bottom (horizontally) and on sticks (vertically). To collect the larvae, which affix themselves to any firm object, such as an old shell or a stone, fishermen place various devices in the water. These may be bamboo sticks with shells attached or a rope with shells hanging from it; limed tiles and wooden plates have been used for the same purpose in Europe. Production is greatest in places with good shelter against rough seas, a tidal current to carry food to the larvae, adequate salinity, and optimum temperature.

After some growing time, the larvae are loosened and transported to other areas for maturation under the best conditions. While growing to marketable size, the oysters must be protected against predators, such as starfish and oyster drillers. Starfish are removed from growing areas by lowering a device that resembles a mop, in which the predators entangle themselves. As starfish damage cannot be completely avoided when growing oysters on the bottom, a vertical system of culture is preferred in many areas; the oysters hang in clusters or in baskets, or are fixed on poles in sheltered bays. In an alternative system, the oysters remain in horizontal trays kept at some distance from the bottom. Though such tray-raised oysters are expensive, they generally survive better than those reared directly on the bottom.

Blue mussels are cultivated in Italy, Spain, France, the Netherlands, and near West Germany in the North Sea and the Baltic. Here, too, horizontal bottom methods have been replaced by vertical culture. Originally, the young mussels, collected from wild stocks, were spread

on controlled banks leased by a fisherman from the government. Their capacity to grow in very extensive and dense beds is highly advantageous. Before full-grown mussels are sent in sacks to the market, special purification methods are employed to wash out sand. Today vertical culture is practiced with sticks pushed into the ocean bottom or with lines hanging from rafts. Unfortunately, line cultures may be damaged in winter; thus, experiments have been made with polyethylene net bags and endless tubes of polypropylene netting. These bags must be strong enough to carry the mussels until harvesting.

Many other mollusks are cultivated, including soft clams and scallops. The Japanese even raise octopuses and squid. For bivalves, the problems are roughly the same as mentioned above: collecting the larvae; raising the young mussels under good conditions; protecting them against predators; harvesting the adults without injury; and sometimes cleaning for the market.

Among inedible bivalves, pearl oysters deserve mention. Pearl farming is one of the most famous industries of Japan, dating to 1893, when a Japanese first succeeded in cultivating pearls. Under the skin of an oyster, the pearl farmer inserts a pearl nucleus (a small spherical shell fragment wrapped in a piece of living oyster tissue). The treated oyster is placed in a culture cage on a floating raft, and after a period of some months or years, the cultured oyster produces a pearl. Japan's pearl producing centres, once scattered along the coast, are today concentrated in the Inland Sea.

**Crustaceans.** Crustaceans, mainly shrimps, are also cultivated. In traditional Japanese practice, immature shrimps are caught in coastal waters and transferred to ponds. Today, mostly in the United States and Japan, shrimps are cultivated by catching adult egg-bearing females. The presence of eggs can be detected by examining the ovaries, usually visible through the shell. The female shrimps are transferred to large seawater ponds adjacent to the sea or to tanks. After hatching, the shrimps are fed in indoor tanks with cultivated plankton. After ten days they are brought to shallow ponds for further cultivation or for distribution to other farms.

Americans and Europeans have shown interest in commercial lobster culture. Current methods are not yet economical, however, because the animals grow slowly and have a high mortality rate, often dying during molting of the shell. Lobsters must molt in order to grow and are quite vulnerable during this period.

**Seaweed.** A final important item in aquaculture is seaweed. Laver, a red alga, is a traditional part of the Japanese diet. The Japanese first cultivated this plant in the late 17th century in the brackish water of Tokyo Bay. Originally, a vertical method was used, with bushes placed in the water. A horizontal method is now employed: large meshed netting made of rough materials is hung horizontally between poles at the proper depth. The algae grow there by themselves and the owners harvest them from the nets by hand. Harvesting begins early in November and continues until about March. After the season is over, the gear is removed and stored. Part-time fishermen or land farmers often engage in such algae culture. Though other algae are used for food and in industry today, commercial farming has yet to begin.

#### PRODUCTION

According to the statistics of the Food and Agriculture Organization of the United Nations (FAO) most fish are caught in the sea, with only about one tenth coming from freshwater. Since the late 1930s, the total world catch has been increasing at a rate of some 7 percent per year and recently seems to double each decade. During this time, the world total catch in tons has been as follows:

1938 23,000,000  
1948 21,600,000 (a decrease of 7% because of the war)  
1958 36,600,000 (an increase of 69%)  
1968 71,000,000 (an increase of 93%)

The next year, 1969, showed a decrease of 2 percent, but the world catch in 1970 of approximately 74,000,000 tons represented an increase of 6 percent. Nevertheless,

there have been doubts that fishery alone can solve the world's food problem. It has been found that the natural fluctuations in fish stocks caused by climatic changes are not always predictable events. Fish with short lives and pelagic fish in general are especially affected. It has also been found that the fishing industry can damage stocks, sometimes permanently, if it takes large catches when fish stocks are low due to these natural fluctuations. Some authorities estimate that the total world catch should not exceed 61,000,000 tons per year. Others calculate, however, that annual yield of all edible products of the water all over the world could range up to 4,000,000,000 tons. Many scientists think that 100,000,000 to 200,000,000 tons is realistic for the 1970s. Yet the increasing pollution of the world's freshwaters and oceans causes uncertainty, not only because entire stocks of fish and other products can be destroyed, but also because an increasing number of living organisms are contaminated at harvest with poisons, such as DDT and mercury.

**BIBLIOGRAPHY.** Most literature about commercial fisheries deals only with local or small areas. Reports are regularly published by the United Nations Food and Agriculture Organization (FAO) or edited by members of its Department of Fisheries, such as the annual *Yearbook of Fisheries Statistics*; and J.A. GULLAND (ed.), *The Fish Resources of the World*, FAO Tech. Pap., no. 97 (1970). A worldwide study of commercial fisheries (in German) is F. BARTZ, *Die grossen Fischereiräume der Welt*, 2 vol. (1964-65). Summary reports about fishing gear, methods, and tactics may be found in the reports of two FAO congresses: H. KRISTJONSSON (ed.), *Modern Fishing Gear of the World*, 2 vol. (1959-64, vol. 3 in prep.); and A. VON BRANDT, *Fish Catching Methods of the World* (1964), on all types of fishing gear. Integration of commercial fisheries in modern exploitation of the sea is considered in J.F. BRAHTZ, *Ocean Engineering* (1968). Fishing vessels are discussed in J.O. TRAUNG (ed.), *Fishing Boats of the World*, 3 vol. (1955-69); fish farming in freshwater in M. HUET, *Traité de pisciculture* (1970); and aquaculture in seawater in the *Proceedings of the FAO World Symposium of Warm-Water Pond Fish Culture*, no. 44 (1967- ). A new summary was given by E.S. IVERSEN in *Farming the Edge of the Sea* (1968).

(A.v.B.)

## Fishing, Sport

Fishing is one of man's oldest activities; in earliest times in all parts of the world he fished, as he hunted, to obtain food. Even when his existence depended on success in catching fish or hunting animals, he found pleasure in both pursuits, and the desire to hunt and fish is still strong today in men of all nations and races.

Evidence of the excitement man has found in pitting his wits against fish and animals is found in his artistic expressions. Paleolithic man drew on cave walls the animals he hunted and the fish he caught. Two thousand years before the birth of Christ an Egyptian angling scene depicted figures fishing with rod and line and with nets. About the 4th century BC there is reference in Chinese writings to fishing with a silk line, a hook made from a needle, and a bamboo rod, with cooked rice as a bait. There is reference, too, to fishing in ancient Greek, Roman, Assyrian, and Jewish writings. In modern times man's infatuation with rod and line is shown by angling's vast literature, which is the finest and fullest of any sport.

Today, fishing, often called angling or sport fishing to distinguish it from commercial fishing, is, despite the growth of towns and the increase of pollution from many sources, one of man's principal relaxations and in very many countries is the largest participant sport. Despite—and probably because of—the stresses of modern life, modern man, like his ancestors, still finds excitement in “tempting the unknown with a fishing line.”

## I. History

Early  
fishhooks  
and rods

One of man's earliest tools was the fishhook. To begin with this was a gorge—a piece of wood, bone, or stone an inch or so in length, pointed at both ends, and secured off-centre to the line. The gorge was covered with some form of bait. When a fish swallowed the bait, a pull on the line wedged the gorge across the gullet of the fish.

When skill in the use of metals was achieved, a hook was one of the first tools made. This was attached to a line of animal or vegetable material. Such a combination is efficient only when used from a boat, and early man all over the world must soon have seen the advantage of a rod, a stick or tree branch, which allowed him to fish from the bank and over vegetation.

For thousands of years, for reasons unknown, the fishing rod remained short, only a few feet in length. It was not until Roman times that reference is made to a longer rod and one that was jointed, that is, made in several parts that could be fitted together for use and taken apart for easy transport. Historians have long argued whether this was a fishing rod or a fowler's rod: the likely answer is that it would be both, for a nation so advanced and with many forms of hollow bamboo in its empire would surely have seen how simple and convenient it would be to fit different-bore sections together. In Roman times, too, Aelian (c. AD 170–235) wrote of how the Macedonians caught trout on artificial flies and even gave the "dressing" of the fly; that is, the materials and methods of making it. The rod used was only six feet (two metres) long and the line the same length, so the method used must have been dapping (see below *Dapping*).

The history of fishing as a sport can be said to have really started with the printing at Westminster by Wynkyn de Worde in 1496 of the *Treatyse of Fysshynge With an Angle*, part of the second edition of *The Boke of St. Albans*. This was the first fishing manual and is thought to have been written by Dame Juliana Berners.

## BASIC METHODS

The four basic methods of angling that were then practiced, some of which already had been practiced for thousands of years and all of which are still practiced today, are as follows.

**Bait fishing.** In bait fishing, a bait of meat, a small fish, an insect, worm, grub, piece of bread—anything, in fact, edible by fish—is placed on the hook and cast onto the bottom of the water or suspended at a required depth.

**Fly-fishing.** In fly-fishing either a natural fly—or more frequently an artificial fly, insect, or other natural food—is used to lure the fish.

**Bait casting, or spinning.** Bait casting, or spinning, is fishing with a live or dead fish or a lure that, when drawn

through the water, looks like a small fish. This method is used for predatory fish.

**Trolling.** In trolling a mounted dead fish or an artificial lure imitating a small fish is trailed behind a boat. Again, this method is used to catch fish that feed on other fish.

## FISHING TACKLE

At the time of the publication of the *Treatyse* the tackle used had altered little in many hundreds of years. The artificial flies described were surprisingly modern (six of the dozen mentioned are still in use), but the rest of the equipment was crude, comprising a very long (18 to 22 feet [five to seven metres]) rod with a line of plaited horsehair tied to the end. The development of angling as a popular sport has depended to a great extent on the development of fishing tackle, and the history of improved fishing methods is broadly the history of the equipment that made these methods possible.

The first great improvement came in the middle of the 17th century, the period when Izaak Walton was writing his immortal *The Compleat Angler* and Col. Robert Venables and Thomas Barker were making considerable contributions to early fishing literature. Until that time the line was tied to the rod end, limiting the distance that could be cast and allowing a hooked fish to be controlled only within the limits of the joint length of rod and line. Some unknown angler attached a wire loop, or ring, to the end of his rod. This simple invention permitted a running line to be used, giving much greater casting distance and allowing the playing of a fish with much greater efficiency.

This invention meant that fishing lines became much longer (Barker in 1667 mentions a salmon-fishing line of 26 yards [24 metres]), and there was in consequence a need for some form of winder on which to hold the line when fishing and prevent it becoming tangled, and thus the fishing reel was born. To begin with it was simply a wooden spool with a metal ring that fitted over the angler's thumb. The line was wound and unwound by hand.

There are many other mentions of improvements in tackle in the mid-1600s. Although horsehair remained the most common material for lines and for the hardly visible link between line and hook, experiments with other materials were being made. In 1667 Samuel Pepys mentioned in his *Diary* the use of a gut string, and nine years later Robert Venables wrote of using a lute string. The use of a "landing hook"—now termed a gaff—a large hook on a shaft used for lifting large fish from the water, was mentioned by Barker in 1667.

Very important was the perfecting of improved methods of fishhook making by Charles Kirby in 1655. Kirby, a London hook maker, also invented the Kirby bend, a distinctive shape of hook with offset point, and hooks of this type are still in common use all over the world. Kirby, like many other hook, fishing-tackle, and needle makers, lived and worked near Old London Bridge. This cottage industry was dispersed by the plague and the Great Fire of London in 1666 and eventually resettled in the small Worcestershire town of Redditch about 70 years later.

Anglers, it would appear, were slow to see the advantages of the end ring and running line. In 1726 there is reference in the *Gentleman Angler* to rods with rings or guides all along their length and to the use of "Winch or wheel." The reference suggests, however, that such rods and reels were not in common use.

Around 1730, as previously mentioned, British needle makers resettled themselves in Redditch and set about changing the nature of the industry from a cottage type to a factory type, powered by water mills. From needles they extended their interests to a kindred product, the fishhook, and from hooks moved on to other articles of tackle. By 1780 John Mills was exporting his hooks to America and Jamaica, and 30 years later most of the world's fishhook trade was based on Redditch. The availability of efficiently made, factory-produced tackle was, over the next hundred years, to have a profound effect on angling all over the world.

Improved  
fishhooks

### Development of bait-casting and centre pin reels

By 1770 the rod with guides along its length and fitted with a reel came into common use. The first reel to find favour was a multiplying reel, geared for fast line retrieve and in appearance remarkably similar to the modern American bait-casting reel. These reels, which were used under the rod, never won favour in Great Britain. They were, however, to act as models for American craftsmen, notably the Kentucky watchmakers George Snyder and Jonathan Meek, who in the early 1800s pioneered the bait-casting reel. Indeed, from this period, the development of tackle, which heretofore had been entirely confined to Britain, was now shared by the United States.

While the bait-casting reel was being developed in Kentucky, another type of reel, the centre pin, was being developed in the ancient English lacemaking town of Nottingham. Based on the wooden lace bobbin, it was a wide-drum, ungeared, very free-running reel, ideal for allowing float tackle to float downstream with the current in the style known as long trotting (see below, *Long*

Figure 1: Early centre-pin fishing reels. (Left) Nottingham centre-pin reel (1840-50); (Right) Malloch turntable reel (1884).

*trotting and stetting*). The Nottingham reel was also suitable for the casting of dead fish and lures for predatory fish, for various forms of sea fishing, and it had no small influence on the design of reels for fly-fishing.

While great improvements were being made in fishing reels, progress was likewise being made in rods. Heavy native woods were superseded by straight-grained, tough, elastic woods, imported from South America and the West Indies and known as lancewood and greenheart, and by various sorts of bamboo. By the end of the 18th century experiments were in hand to glue several strips of bamboo together, retaining the strength and pliancy of the cane but greatly reducing the thickness. By 1847 rod tops were available in this form, and between 1865 and 1870 complete hexagonal rods, made by laminating six triangular strips of bamboo, variously known as split bamboo, split cane, and built cane, were produced on both sides of the Atlantic, with the Americans winning the race by a short head.

From 1880 on progress in tackle design was rapid. The fly-fishing line, made for centuries of horsehair, was replaced by lines made from silk and covered with coats of oxidized linseed oil. Such lines were heavy, easy to cast, sank deeply if ungreaed or floated if greased. They trebled the distance the average angler could cover and made possible many new methods of fly-fishing, notably dry-fly fishing and sunk-line fishing (see below *Wet and dry fly-fishing*). Fly reels became lighter and the Nottingham reel, originally made in wood, became available in ebonite (vulcanite, a hard rubber) or metal. These reels also became easier to use. They were very free spinning and, unless controlled during a cast, revolved faster than the line runoff, resulting in a considerable tangle. Various types of governor were fitted to Nottingham reels to make them easier for average anglers to use.

During the same period the American bait-casting reel was being improved and made more free running, so that

light lures could be cast. As with the Nottingham reel, control of the drum speed during the cast was a problem and various mechanical aids were added to prevent what Americans call a backlash and the British an overrun. In 1896 William Shakespeare of Kalamazoo, Michigan, invented the level-wind, which automatically spread the line evenly on the spool and made using these reels much easier.

The difficulty in using the Nottingham reel led in 1880 to the invention of the first turntable reel by the firm of Malloch in Perth, Scotland. In this reel one side of the spool was open, and, to cast, this was turned 90°, so that it was in line with the rod guides. During the cast the line slipped off the end of the spool with a minimum of inertia, making casting extremely simple. To recover line the spool was turned back 90°.

The Malloch reel was principally used for casting relatively heavy lures for salmon fishing, but it must have had some influence on the thinking of Holden Illingworth, a Bradford, Yorkshire, textile magnate who in 1905 invented what the British call a fixed-spool reel and the Americans a spinning reel. In this type of reel the open spool is permanently facing up the rod and the line peels off in the cast as on the Malloch. Retrieve, however, was operated first by a hook in a revolving flyer and then, as the reel was improved, by various pickup mechanisms.

The improvements in the various casting reels led to great improvements in artificial lures in metal and wood, which, when drawn through the water, spun or wobbled, represented the struggles of a wounded fish and thus attracted the attention of predators.

Throughout the 20th century tackle has improved at a rapid rate. Rods have become shorter and lighter without losing any power. Split-bamboo rods, which superseded those in greenheart and lancewood, have been almost superseded in their turn by rods in fibre glass, and these in turn may well be replaced by rods in carbon fibre. Reels have become lighter and stronger with more parts being made from reinforced plastics. The fixed-spool reel, which was little used outside Great Britain until the 1930s, spread first to Europe, then, after World War II, to North America, causing the spinning boom, and thence to all parts of the world. The stationary-drum principle also has been adopted in America for spin casting, or closed-face, reels in which the spool is enclosed in a cone-shaped hood. The fixed-spool principle was greatly aided by the development of nylon monofilament line in the late 1930s. Although this material did not become freely available in continuous length until after World War II, it coincided with the boom in spinning and gave the fixed-spool reel the lively, smooth line it needed for ultimate performance. It also superseded silkworm gut, which from 1722 on had been the best nonvisible link between line and hook. Braided lines in other synthetic materials—nylon, Terylene, Dacron—have given the angler many advantages, especially when used with revolving drum reels. Fly lines now have plastic coverings and either float without the use of grease, or sink slowly or quickly as desired. Plastic also is being greatly used for artificial lures and for various tackle containers.

The modern angler has excellent tackle and it will, as always, continue to improve. Despite its excellence, his problems are still those of his ancestors. He must know where to find his fish and how to approach them without being seen. He must know what they are feeding on or what they can be tempted with. He must understand wind and weather. Fishing remains what it has always been, a problem in applied natural history.

## II. Freshwater fishing

### BAIT FISHING

Bait fishing is commonly called still-fishing in North America and bottom fishing in England. Fishing with different types of bait is certainly the oldest form of angling and is practiced in most countries of the world. This style of fishing has been brought to a high degree of efficiency in England, where, in particular, it is used to catch the species classed as "coarse fish." The methods

Fixed-spool reels and monofilament lines

used in England, therefore, will be described, and other types used elsewhere will be discussed as variations.

**General method.** As previously explained, the method broadly is to impale a bait on a hook, which the fish swallows; it is then hooked and eventually landed. Common baits are worms, the maggots of various flies, small fish, bread paste, and cheese. Less common baits are slugs, caddis flies, stewed wheat, hempseed, and fruit. The bait is either fished on the bottom, weighted down by some form of lead weight called a ledger (in America, a sinker), and fished on the bottom, or close to it, or at any depth, suspended by a buoyant object called in England a float and in America a bobber. The float, which is usually made of bird or animal quill, cork, wood or a combination of all three, or of plastic, suspends the bait at a required depth, acts as an indicator that a fish is taking or has taken the bait, can be used to allow the bait to follow the current of river or stream and thus to "search" the water, and is sometimes used as a casting weight to allow a long cast to be made.

**Ledgering.** When a ledger but no float or bobber is used, the general method is known as ledgering. Selection of the right sort of water is important in all types of angling and, when fishing with a ledger, selection will depend greatly on the species sought. If bream (*Abramis brama*) were the quarry, slow, deep water would be chosen; if barbel (*Barbus barbus*), faster, streamy stretches would be fished. On a lake the shallow or deep areas would be chosen according to the time of year and the type of fish sought.

It is always important in fishing to avoid unnatural movement of the bait or lure and also to ensure that the fish has the minimum indication that the bait or lure contains a hook and is attached to a line. With a ledger this latter provision is sometimes difficult to achieve, because, as the fish takes the bait, it may feel the weight of the ledger. For this reason ledgers are made either with a hole drilled through them, or with a metal ring. The line is passed through either hole or ring, and the ledger is prevented from running right down the line to the hook by attaching a split shot to the line. Split shot is commonly used in bottom fishing. It is, as its name indicates, lead shot as used with a shotgun, which has been partially split. The "V" of the split is placed over the line and clamped tight. With the line running free through the ledger the fish will not feel an unnatural weight as it takes the bait.

**Ground bait or chum.** The ledger angler then selects the type of water where he expects fish of a certain species to be, selects what he considers will be the right bait, and casts his bait to the part of the water he believes will contain fish. In order both to concentrate the fish around his bait and to encourage them to take his bait, he throws in what the British call ground bait, and the Americans, chum, in the area close to his hook bait.

Ground bait consists mainly of soaked bread or meal to which various constituents may be added, including frequently a certain amount of the bait used on the hook. The constituency of the ground bait will depend on the water fished—light for still or slow water, heavy for deep or fast water, in which, in order to take full advantage of the current, it obviously needs to be introduced well above the area fished.

**Feeling the bite.** Once the ledger and bait have been cast to the correct area, the main problem in this style is knowing that a fish has taken the bait. Some anglers hold the line between their fingers, feeling the bite in this way. Others watch the line or the rod top. Various bite indicators are used. A piece of silver paper can be placed on the slack line between reel and first ring. If it moves the angler strikes; that is, he raises his rod sharply, tightening the line and setting or driving home the hook.

In recent years bite indicators called swing tips and quiver tips have been developed. These are short lengths (six to eight inches [15 to 20 centimetres]) of pliable plastic attached to the rod's end, the line passing through guides on the tip. Any movement indicates a bite.

**Ledgering tackle.** Tackle for ledgering varies considerably. The rod may be any length from seven feet up

to 14 feet (two to four metres). Nine-foot (three-metre) rods are popular for one style of swing tipping and those around 12 feet (four metres) for another. All are made of hollow fibre glass. The reel used is invariably of the fixed-spool type, loaded with line from 1½- to 6-pound (680- to 2,700-gram) breaking strain (test). Hook size varies according to the size of the species sought; the length of "trail"—the line between ledger and hook—is a matter of personal preference.

Although the main purpose of the ledger is to hold the bait on or near the bottom, particularly in moving water, another style has been developed, known as the rolling ledger. The weight selected is too light to anchor the bait on the bottom. It is cast across the current and allowed to roll along the bottom until it comes to rest under the bank and below the angler. In this way much water can be searched.

**Float ledgering.** A float is sometimes used in conjunction with a ledger, so that the bite can be clearly seen. This method is called float ledgering.

**Float fishing.** For float fishing in the English style no ledger is used. The rod is of fibre glass and long, somewhere between ten and 15 feet (three and six metres). The length is needed because deep water is often fished, and if the distance between float and hook is longer than the rod, casting and landing a fish become most difficult. A long rod also gives good line control and allows hooking fish at a distance.

The reel used is usually a fixed-spool model, although some types of closed-face (spin-casting) reels are becoming more popular. The Nottingham reel is now little used. The line is of nylon monofilament, from about one-pound to six-pound (450- to 2,700-gram) breaking strain. Floats vary greatly in size and design, from small (two-inch [five-centimetre]) models in quill, to large ones (13-inch [33-centimetre]) in wood (called zoomers or darts) that are designed for long casting. Below the float there is a length of nylon monofilament to which the hook is tied or whipped, and it is to this that one or more split shot are fixed. The purpose of this "shotting" is to give casting weight, to "cock" the float—that is, to cause it to float upright in the water with the right amount of tip showing—and, most importantly, to control the speed at which the bait sinks in the water. In fast, heavy water, for example, where the bait needs forcing down to reach the required depth quickly, the tackle is heavily shotted. Alternatively, in fishing slow water, the bait is often required to sink very slowly and one tiny shot is used.

**Selecting the swim.** The depth at which the bait is fished is crucial in all types of float fishing. Some species such as bream and tench (*Tinca tinca*) feed mainly on the bottom and the bait should be placed there. Others, like the dace (*Leuciscus leuciscus*) and the grayling (*Thymallus thymallus*), will take the bait in midwater. The angler establishes the depth and varying depths of his "swim"—the area he is fishing—by the use of a plummet, a lead weight that he attaches to his hook. With this aid he takes soundings and adjusts his float accordingly to give him the depth he requires.

In still water, or very slow-flowing water, the successful angler selects his swim, fishes in the right place at the right depth, and attracts and conditions the fish to take his hook bait by skillful groundbaiting. Indication of a taking fish is given by movement of his float, which may be pulled under the water, or, because bottom-feeding fish often lift the bait off the bottom, by an upward movement.

**Long trotting and stetting.** In faster water different and more active methods are necessary, for the current can be used to carry the float a long way, thereby searching the water and taking the bait to far-off fish. This style of fishing is known as long trotting or swimming the stream. The art in this style is to present the bait in the most natural way, so that it moves with the current. Control of the line, so that the float is not pulled across the current, causing the bait likewise to be pulled, is essential. Another successful manoeuvre is to hold the float back for a few seconds, so that the bait is raised in the water, a movement that has long proved attractive to

Use of  
ledgers  
or sinkers

Use of  
floats or  
bobbers

fish. Conversely, in one method of float ledgering that is sometimes used, called stretting or stret-pegging, the distance between float and bait is considerably in excess of the depth of water. The cast is made across the current and the bait is allowed to rest on the bottom for perhaps 30 seconds. Then it is allowed to move a little further downstream and again is allowed to remain on the bottom. In this way the swim is thoroughly searched.

**Match fishing.** All the methods described are used for what is called match fishing in England. Competitions between a few dozen up to several thousand anglers are held, both on a club and an individual basis. There are large cash prizes, sweepstakes, and a great deal of betting. Several thousand pounds can be won in a match of four or five hours' duration by the angler or team catching the greatest weight of fish. Unlike most other countries, in particular those in Europe, the coarse fish in England are not eaten. As they are caught they are put in a large sack-like net, called a keep net, which is lowered into the water. At the end of the match or at the end of the day's fishing, the fish are returned to the water.

The basic methods described are used in Europe for similar fish, but the tackle there is different from that used in England. Rods are often much longer, sometimes being well over 20 feet (six metres) in length and made usually from hollow fibre glass. Frequently no reel is used and the line is tied to the rod end. Fishing with this tackle is known as *le moyen classique*—the classic method, and it is quite often used for matches, even the "World Championship," which is fished between certain European countries. On the Continent matches are not won on weight alone but on a combined weight and number-of-fish basis, which puts the emphasis on catching small fish.

**Still-fishing in North America.** In North America, where most fish are predatory rather than insectivorous and herbivorous, the emphasis has always been on types of fishing best suited for fish of this nature. Bait fishing, commonly called still-fishing, is practiced on basically the same lines with much less specialized tackle: when bait fishing, Americans generally use the type of tackle used for bait casting, spinning, or fly-fishing. The traditional gear, however, is a long—ten or 12 feet (three or four metres) or more—one-piece, bamboo-cane pole (now often of fibre glass and in sections) with a line tied to the tip. Such gear is still commonly used in fishing off piers, breakwaters, and bridges, from rowboats on small inland lakes, and from the banks of small streams. The most popular quarry are perch, crappies, bluegills, and other pan fish, which also are caught on small flies and lures. In some places the object of still-fishing is catfish, carp, sucker, or other species.

**Ice fishing.** This winter sport is especially popular in the northeastern United States and the Upper Mississippi-Great Lakes-St. Lawrence Valley region of the United States and Canada. Holes are cut through the ice to fish; one fisherman often tends several holes. Minnows, grubs, and nymphs are favoured baits, usually used with a very small jig or ice spoon. Equipment commonly includes a short (three feet [one metre]) whippy, fibre glass rod with a simple centre-pin reel or a cleat-like device to hold a nonfreezing monofilament line and a tip-up or tilt that signals when a fish has taken the bait; it is allowed to run before the hook is set. For larger fish the tip-up may hold the reel, in some models below water to prevent freezing. Many pan fish (mostly crappies, bluegills, and perch) are caught, but also caught are northern pike (especially in the Great Lakes region), walleye, pickerel, bass, and lake trout, with occasional catches of other species.

Ice fishing is little practiced elsewhere, but is becoming more popular in Scandinavia and in some European countries (not Great Britain, where it is rarely cold enough). Methods are as in the United States.

#### TROLLING

Trolling is the style of fishing in which a live or dead fish or other bait, mounted on a tackle that allows it to spin or wobble as it is drawn through the water (or an artificial lure that moves similarly) is trailed behind a slow-

moving boat. In theory it is a simple form of fishing that permits covering a large area, but in practice there is a great deal of skill involved in it.

**Locating the fish.** Used mostly on very large lakes and reservoirs, where fish are difficult to locate and where they may be at a considerable depth, it has been brought to a high degree of efficiency in North America. Much of the skill lies in locating the fish and presenting the bait or lure at the right depth and the right speed. Originally much depended on the water sense of the angler, who, by studying the topography of the lake and by taking soundings, would know where shallows, shoals, deep water, and very deep water occurred. Allying this with his knowledge of the habits of the fish sought, he would be fishing in the right place, with the right bait, at the right time. Electronic aids that show the depth of the lake and its contours as well as in some cases actually locating the fish have greatly simplified the problem, but even with such aids, there is still much skill in taking fullest advantage of them, and the experienced fisherman will still outfish the less experienced.

**Tackle.** In trolling for fish that are feeding near the surface, the type of tackle used for spinning, bait casting, and even fly-fishing can be used perfectly effectively, but when greater depth is needed, specialized equipment is essential. Sometimes heavy sinkers are used, but nowadays the weight is mostly contained in the lines, which may be metal (*e.g.*, Monel Metal) or braided lines (*e.g.*, of Dacron) with a lead core. Such lines allow the lure to fish in a more lifelike way besides giving the hooked fish a more sporting chance. The amount of line out controls the depth at which the lure is worked. Rods in North America are usually short, five to seven feet (about two metres) and are used with a multiplying trolling reel for fast retrieve. The rod is held at right angles to the direction of the boat to take advantage of its resilience when and if a fish strikes.

Trolling is little practiced in Great Britain, on the Continent, or in Scandinavia. Salmon (*Salmo salar*) and big trout (*Salmo trutta*) are sought in this way on the Scottish lochs, the Irish loughs, and on big lakes in Norway, as are pike (*Esox lucius*). Trout and pike are also trolled for on big waters in other European countries.

**Harling.** A form of trolling called harling is also used to catch salmon in big rivers in Scotland and Norway. The lure is fished from the stern of the boat while the boatman holds the boat in the current, allowing the bait or lure to hang over the areas known to hold fish, and the flow of the stream causes the bait or lure to behave like a small fish.

Apart from mounted live or dead fish most of the lures described for spinning and bait casting are suitable for both trolling and harling.

#### BAIT CASTING, SPINNING, SPIN CASTING

The terms bait casting, spinning, and spin casting describe the same method of fishing carried out with different outfits and in particular with different types of reel. In Great Britain all three are termed spinning, although the spin-casting reel is hardly known. In the United States, bait casting usually denotes the use of a bait-casting reel mounted on top of a short (five to six feet [about two metres]) bait-casting rod, spinning means fishing with a fixed-spool reel, and spin casting means using a spin-casting (*i.e.*, fixed-spool, closed-face) reel with a spin-casting rod. Monofilament line is generally used, although on the bait caster braided nylon or Dacron is often preferred. When fishing for certain predatory fish with sharp teeth, a wire "leader" (called a trace in Great Britain) is used between line and lure.

The purpose with all three outfits is to cast out a bait or one of a vast number of artificial lures, so that when retrieved in still water or when it is subject to the current in running water, the bait or lure behaves like a small, wounded, or sickly fish. In nature the desire to kill infirm creatures is strong among predators, be they bird, fish, or mammal, and the erratic movement of a natural or artificial lure has long been known as an effective means of catching many species of fish.

Bait-fishing  
contests

Trolling  
at depth

Casting  
artificial  
lures

Figure 2: Types of bait-casting, or spinning, lures.

The number of artificial lures available to the angler is enormous. Popular all over the world is the metal spoon, so called because many somewhat resemble the broad, dished end of the domestic spoon. Also popular are lures in a vast variety of shapes and colours that spin, wobble, and flicker in the water. Most popular in Great Britain is the Devon minnow, which is a cylinder-shaped lure with two fins near the head to make it spin. In North America the plug—in wood and even more now in plastics—in a bewildering number of shapes, imitates the behaviour of almost everything that swims in or on water. These lures can be fished at all levels, from close to the bottom to right on the surface, representing deep-swimming fish or swimming mice or frogs.

In still or very slow running water the method of fishing is to cast the lure where fish are thought to be and to impart movement to it by retrieving line by winding the reel. Speed of retrieve sometimes cannot be too slow; again, the angler can hardly wind too fast.

On running water the current imparts movement to the lure and frequently the angler does not wind until it has moved across the stream and is under his own bank. An effective method of fishing is to cast upstream and wind the lure down as fast as possible.

Spinning rods in Great Britain are rather longer than those in North America. Single-handed rods, used with the fixed-spool reel, are usually about seven feet (two metres), and double-handed ones, used for salmon or pike with a fixed-spool or bait-casting reel, run between eight and ten feet (two and three metres) in length.

#### FLY-FISHING

**Trout fishing.** The methods used to catch trout (*Salmo* species) all over the world are also used to catch other

freshwater species such as char (*Salvelinus* species), grayling (*Thymallus* species), whitefish (*Coregonus* species), and many others. In some cases a natural fly is used, but much more frequently an artificial lure, made usually from silk, fur, or feathers, is at the end of the angler's line.

**Dapping.** With the natural fly a style of angling known as dapping is the most common method. Two different techniques are employed. The first is used along the well-bush sections of river, brook, or lake. A natural fly, usually a bluebottle fly or a daddy longlegs spider, is impaled on the hook. The angler approaches the water with great caution and, keeping well out of sight, lowers the insect into the water surface, where its struggles attract a fish. Sometimes an artificial lure is used, being lowered to and raised from the surface, creating a slight disturbance that attracts the fish.

Much more common is the method used on Scottish lochs and Irish loughs, in particular during a hatch of mayflies or when crane flies (daddy longlegs) are blown onto the water. A very long rod, 14 to 16 feet (four to five metres), is used from a boat. The line is very light, with silk or nylon floss (embroidery floss) tied near the end. A breeze is essential for this method, and the natural insect is carried out well away from the boat by the action of wind on floss. Sometimes a large, fuzzy artificial fly is used. This is an effective method of catching large trout and sea trout, the latter of which is a migratory form of brown trout that spends part of its life in the sea and returns to fresh water to spawn.

**Midge fishing.** In the Maritime Provinces of Canada a style known as midge fishing is used in the spring. One or two natural up-winged flies (*Ephemeroidea*) are hooked on and cast like an artificial fly.

The use of natural flies is very limited, and fishing with artificial flies is practiced on a much wider scale. The artificial fly represents anything that the fish sought may feed on—aquatic or terrestrial insects, small fish, freshwater shrimps, and snails. In many cases a "fancy" fly is used that imitates nothing, but that over the years has proved attractive to trout and other fish.

**Fly casting.** The first problem in any form of fishing with an artificial fly is presenting it to the fish, for unlike so many other baits and lures the fly has virtually no weight. A flexible rod usually of hollow fibre glass is used, its length somewhere between seven and ten feet (two to three metres), with around seven to eight feet (two to two and one half metres) most popular in North America and eight to nine feet (two and one half to three metres) in Europe. A thick, heavy line is used to give casting weight; it is usually made with a nylon or Dacron core with a plastic covering. The thickest part of these lines will be usually between 50 and 60 thousandths of an inch (0.13 to 0.15 centimetre), but normally they are made in tapered form and the end nearest to the fly will be much finer to allow for delicate presentation. The reel is of simple single-action construction, its sole purpose being to contain the line and, as will be explained, to assist in tiring the hooked fish.

Attached to the line is a length of nylon monofilament called in North America a leader and in Britain a cast. Normally this will be some three yards in length and either tapered to a fine end or level throughout its length. The fly or flies are attached to this link.

The fly is cast by a combination of the springlike action of the rod and the weight of the line. A proficient caster will be able to lay down his fly 60 feet (18 metres) away, and distances of 120 feet (37 metres) are attainable with slightly specialized tackle when necessary.

**Wet and dry fly-fishing.** There are a number of different methods of fly-fishing, but broadly they are based on the behaviour of certain insects that spend their lives mostly in the water but have a short life in the air close to lake or river. The varying styles will be described in relation to these flies.

The three most important species of flies to the fly fisherman are the up-winged or mayflies (*Ephemeroptera*), the caddis or sedge flies (*Trichoptera*), and the midges (*Diptera*; in particular the genus *Chironomus*). All these

Fishing with natural flies

Casting artificial flies

Life cycles of flies

flies spend most of their life in water as nymphs, caddis grubs, bloodworms, and pupae and form a substantial part of the diet of trout and other insectivorous fish. At the appropriate time of year they swim to the surface, where they shed their underwater skins and emerge as winged insects. As soon as their wings are strong enough, they make for dry land. Mating takes place in the air, generally overland, and the females later return to the water to lay their eggs either in or on it. Trout feed on these insects during all these stages when the insect is available to them, and the angler seeks to imitate their appearance and behaviour in order to deceive his quarry. He is therefore either fishing his fly in the water at various levels, known as wet-fly fishing, or on the surface, in the style known as dry-fly fishing.

The wet-fly fisherman uses a line that is designed either to sink rapidly, to sink slowly, or to float. With the first named he will be fishing close to the bottom of river or lake and on a river will make his cast across the stream and allow the current to make it swing round. On a lake he will move the fly by pulling in line by hand. His fly will imitate some insect, aquatic creature, or small fish that spends most of its time on the bottom. The speed at which the fly is allowed to move is important. Frequently more than one fly is attached to the leader by means of short (two-inch [five-centimetre]) links called droppers.

With the slow sinker the angler will be exploring mid-water and his fly will probably imitate an ascending nymph or pupa. On running water the cast will be made across and the flies allowed to swing around with the stream. With the floating line he will be fishing high in the water and his fly or flies will most likely be representing the nymph or pupa just prior to its emergence as a winged insect or during its emergence. On such occasions the cast may be made across, or may be made upstream.

There are many different sorts of wet fly, but always they are made so that they sink quickly through the surface film. Most have feather hackles, which move in the water and thus give a semblance of life.

Indication of a trout taking a fly fished on sinking lines is a firm pull on the line, causing the angler to "strike" or "set his hook" by raising his rod. With the floating line the fish may be felt, but more often than not the fish disturbs the water as it takes and at this sign the angler pulls home the hook. This water disturbance to either a natural or artificial fly is called a rise.

The dry fly is designed to float on the surface and in consequence is fuzzy. It is always used with a floating line and between casts requires whisking through the air, frequently several times, called false casting, to shake the water off it.

The most effective time to fish the dry fly is when trout are rising to flies as they emerge and as they float on the surface before becoming airborne, although "fishing the water"—casting to likely places even though the fish are not rising—can at times produce good sport. During a hatch of fly the angler will select a fly that imitates the fly on the water and on such occasions correct imitation can be important, as fish become very selective. On running water the cast is generally made upstream and the fly allowed to float down with the current, although at times a cast across and down, in which the fish sees the fly before the leader, can be very successful. On still waters the fly is cast out and allowed to remain still for some time.

Another effective time to fish the floater is when the female flies return to the water, usually in the evening, to lay their eggs. After doing so, they die and float on the surface, offering the fish an easy meal.

As with all types of fishing, it is vital that the fly behave in a perfectly natural manner, and one of the problems with the dry fly on running water is to prevent the push or pull of current on line or leader from pulling the artificial so that it moves unnaturally—a circumstance called drag. The angler prevents drag by casting a slack or curved line that delays the pull of the current.

Of all types of fishing, the dry fly is probably the most interesting, for the fish can be seen feeding, the natural fly identified, the correct artificial mounted, cast delicate-

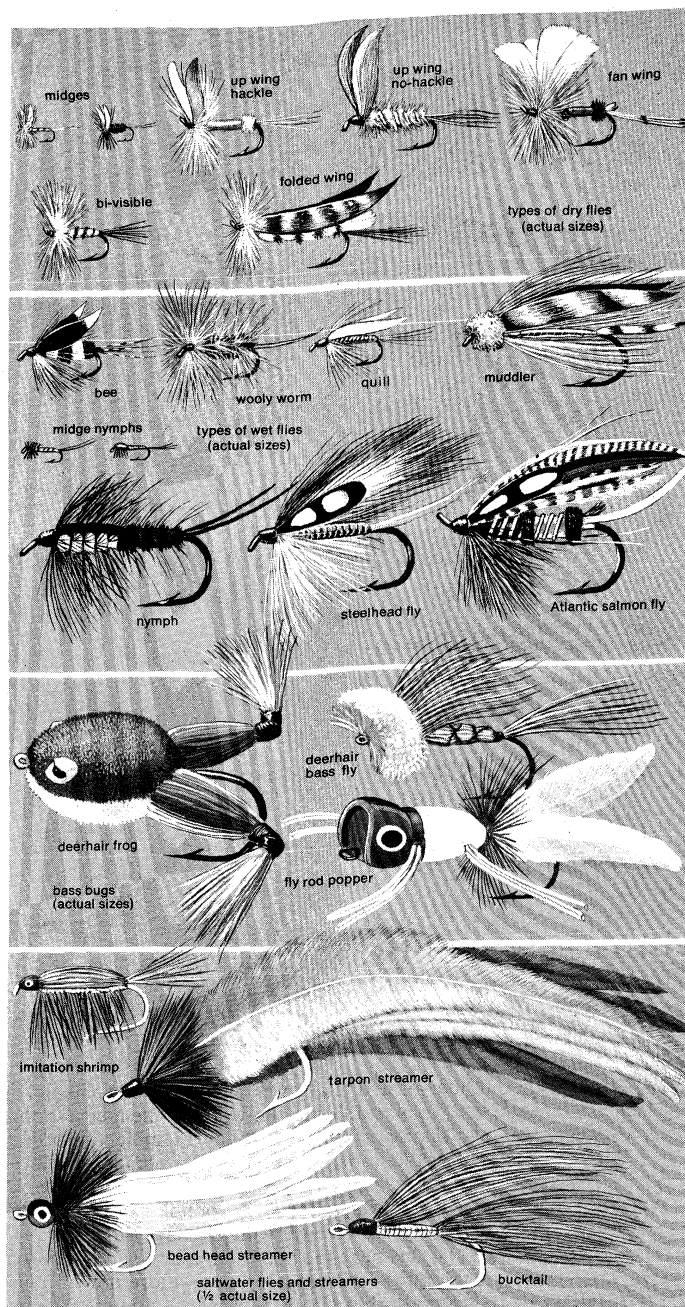

Figure 3: Types of flies.

ly and accurately to the rising fish with the likelihood either of an exciting rise or the fish clearly seen taking the angler's offer into its mouth.

**Salmon fly fishing.** The difference between fly-fishing for Atlantic salmon (*Salmo salar*) and other fish is that the former, which hatches from an egg in a river, where it spends usually two years, thereafter migrating to the sea, again usually for two years before returning to freshwater to spawn, does not feed at all after it enters the river. The angler therefore is not seeking to offer an imitation of any particular insect but rather some lure in fur or feather that appeals to the salmon's latent predatory nature.

Atlantic salmon are caught in eastern Canada (and Maine), in Iceland, Scandinavia, Great Britain, France, and Spain. The methods are broadly similar, but the North American angler uses a short rod, single-handed, of eight to ten feet (two to three metres), whereas the others use a double-handed rod from 12 to 15 feet.

There are three basic methods of catching salmon on artificial flies. In cold water conditions at the start of the season—that is, February and March in Great Britain;

The three basic methods of catching salmon

Conditions for dry fly-fishing

April, May, and early June in North America; and June and July in Norway—a sinking line is used with a big (sometimes three-inch [eight-centimetre]) fly. This is cast across the current and allowed to swing around as slowly and deeply as possible. The indication of a “take” is a firm pull on the line. This method is also used in the autumn, often, however, with a small ( $\frac{3}{4}$ -inch to 1-inch [2-2½-centimetre]) fly.

When the water temperature rises to 45° F (7° C) a much smaller ( $\frac{1}{2}$ -inch to 1¼-inch [one- to three-centimetre]), slimmer fly is used, with a floating line. The cast is made across the stream and the fly allowed to swing fairly quickly with the current. Unnatural movement is prevented (as in dry-fly fishing) by line control. This is a particularly exciting form of fishing as the salmon frequently rises, as does the trout to the dry fly.

In Canada, the salmon take a dry fly larger than that used for trout but fished in basically the same way. It is rare for salmon to be taken on the floating fly elsewhere because, it is believed, the temperature does not rise high enough.

The two sporting varieties of Pacific salmon, the coho or silver (*Oncorhynchus kisutch*) and to a lesser degree the chinook, tyee, king, or spring (*Oncorhynchus tshawytscha*), can be taken on flies. The flies are either cast or trolled in saltwater, or cast in rivers. The methods used are those broadly described for trout wet-fly fishing. Transplanted coho and other salmon in Lake Michigan are taken mainly on spoons and other bait-casting or trolling lures.

#### CASTING TOURNAMENTS

World casting championships are held annually by the International Casting Federation, which also recognizes world records in ten official accuracy and distance events.

Both single- and two-handed distance events are held for fly casting and for bait casting with revolving spool reels using  $\frac{5}{8}$ -ounce (18-gram) plugs and fixed spool reels using  $\frac{3}{8}$ -ounce (11-gram) and (two-handed) 30-gram (one-ounce) plugs. Highly specialized rods and reels are used and few restrictions are imposed on techniques for attaining distance or hitting the target, a floating ring of 30 inches (76 centimetres) or less.

Accuracy events include skish, a refined version of tournament casting that limits the bait-casting line to not less than nine pounds (4,100 grams) and the reel to standard design, although not the rod and not the fly rod, reel, or line. All casting in the skish events, however, must be performed as in fishing and without exaggerated windup.

Casting competitions are especially popular in North America, and annual tournaments are held by member clubs of the American Casting Association. In addition to fly and bait-casting events, American tournaments include a bass-bug accuracy event. (For world records and world champions see SPORTING RECORD in the *Ready Reference and Index*.)

#### FRESHWATER FISH SOUGHT BY ANGLERS

A great variety of freshwater fish furnish sport to anglers around the world. Some of these fish are common to more than one area, while others are limited to particular waters in North America, Africa, and Europe, and a few are limited to one particular region in a single country. A number of the more desirable sporting species have been successfully transplanted outside their native habitats to other areas and countries. Table 1 lists the principal freshwater fish sought by anglers and includes the species for which official records are kept for specimens caught by rod and reel.

### III. Saltwater fishing

The basic methods of fishing in freshwater described above are likewise used in saltwater. Bait fishing and trolling are widely used; casting and spinning are used much less but are rapidly growing in popularity, especially in U.S. waters. Fly-fishing, although also growing in popularity, is practiced only in a few areas and for only a few species of fish. Whereas the methods are basically the same as those used in freshwater, the tackle used

is often very different because of the size of the quarry and the conditions of greater depths, wider areas, rocks, and tides and currents.

#### BAIT FISHING

The various methods of fishing with natural bait are commonly used for sea fish, irrespective of whether the angler is fishing from a beach, off rocks, from a pier, or from a boat. The baits used are those that form a normal part of the diet of sea fish—worms that live in sand or mud, marine shellfish, and small sea fish, either whole or cut up.

The most commonly used methods are those similar to the freshwater methods of bait fishing. A lead sinker, or ledger, sometimes one pound in weight, though more normally four to eight ounces, is used. Shapes and weights vary greatly according to the type of bottom, the depth of the water, and the number of hooks, which may be held away from the line and leader by wire or plastic booms, a rig known to British fishermen as paternoster.

Such tackle can be cast out from beach or rocks, cast or lowered into the water from a pier or jetty, or lowered from a boat to where the fish are known or suspected to be.

**Handline fishing.** Bait fishing, or still-fishing, in its basic form includes the primitive handline or throw line. Closely related to this method is the use of a cane pole. The methods are usually, but not always, associated with fishing from bank or pier. The throw line, clumsy by rod-and-reel standards, is stored on a spindle or frame. It is fitted with one or two hooks and a lead weight of several ounces. In throwing, line is stripped from its frame and coiled at the feet of the thrower, who whirls weight and baited hooks over his head, releasing them when they have gained sufficient momentum. Once the bait has been deposited in the water, the free end of the line is held by the angler, or it may be clipped to a bell or rattle that has been secured to a piling or plank. When the bell sounds to the movements of a biting fish, it is time for the angler to go to work. Warning bells enable an angler to fish three or four lines.

Whereas the rudimentary handline is normally the instrument of the shore caster seeking small species, it is successfully used against such giants of the sea as marlin and sharks by commercial fishermen of several countries. Resistance to the fish is applied by quick and momentary hand pressure on the sliding line. Despite the obvious threat of friction burns, an experienced handline fisherman suffers little but callouses from his role.

**Pole fishing.** In many situations it is necessary to use a pole, sometimes a very long one, to clear rocks, pilings, or other obstacles beyond the reach of the handliner. This may be a version of the old-fashioned bamboo-cane pole, with the line tied to the tip. But in most situations casting or spinning the weighted line and bait out with rod and reel permits the fisherman to fish a larger area, provides more sport when a fish is hooked, and enables him to play and land a larger fish with lighter tackle than is possible without a reel.

**Float fishing.** Fishing with a float or bobber is practiced all over the world for fish that can be caught close to the surface, and because very light tackle can be employed it is a particularly sporting way of catching saltwater fish. Freshwater tackle is often used; a very popular outfit is a seven-foot, light spinning rod and a fixed spool reel. Many species of fish are caught by such means, and members of the bass, mullet, and mackerel families are taken on float tackle all over the world.

**Chumming.** The use of ground bait, called chum in the United States and rubby-dubby in Great Britain, whereas not so frequently and extensively practiced as by the British freshwater bait fisherman, is still used in many parts of the world. Chum consists of bits of fish, fish chunks, even whole live fish or shrimp; pulped-up oily fish such as the North American menhaden or the Cornish pilchard are widely used. Bags containing the crushed fish are either trailed behind a boat or placed so that the current or tide carries out a slick to draw fish to the bait on the angler's hook. Sometimes minced fish or

Table 1: Fresh-Water Fish Sought by Anglers

species	where caught*	weight of good catch		comments
		lb	kg	
Barbel ( <i>Barbus barbus</i> )	most European countries except Norway, Sweden, Finland, Ireland	8-10	4-5	mostly caught bait fishing but will take spinner, particularly in June after spawning
Bass, black, largemouth ( <i>Micropterus salmoides</i> )	all North America, South Africa, and Kenya (both very successful), Cuba, France, Spain	2-5	1-2	one of the most popular North American game fish; caught by all methods but especially on surface lures
Bass, black, small-mouth ( <i>Micropterus dolomieu</i> )	North America, in colder waters, transplanted from northern United States and northeastern Canada; South Africa, Kenya, Sweden	1.5-3	0.7-1.4	one of the world's great sporting fish, excellent eating; caught on fly, spinner, plug, and bait
Bass, redeye ( <i>Micropterus coosae</i> )	central and southern United States	2	1	popular pan fish in its range; good eating; caught on bait, small flies, and lures
Bass, spotted ( <i>Micropterus punctulatus</i> )	southern two-thirds of eastern United States	2-5	1-2	much like largemouth black bass
Bass, white ( <i>Roccus chrysops</i> )	southeastern United States			see spotted bass
Bluegill ( <i>Lepomis macrochirus</i> )	all North America, South Africa	1	0.5	very popular pan fish; caught on bait, also very small surface lures and flies
Bream, common ( <i>Abramis brama</i> )	most European countries except Scandinavia	2	1	caught on float and ledger tackle
Bream, silver ( <i>Blicca bjoernka</i> )	as common bream	6-8	3-4	caught on float and ledger tackle; name sometimes given to several pan fish in North America
Bullhead, black ( <i>Ictalurus melas</i> )	Mississippi Valley and watershed	1-1.5	0.5-0.75	caught on bait and spinning, spin-casting lures
Carp ( <i>Cyprinus carpio</i> )	all European countries except Norway, North America, southern Africa	20	9	caught on a variety of baits including boiled potato and bread; highly valued on the Continent as a food fish; in parts of North America considered a pest
Carp, crucian ( <i>Carassius carassius</i> )	all Europe except Switzerland, Spain, southern Italy, northern Finland	2	1	caught by bait fishing
Catfish, blue ( <i>Ictalurus furcatus</i> )	Mississippi Valley	10	5	mostly caught bait fishing
Catfish, channel ( <i>Ictalurus punctatus</i> )	Mississippi Valley	5	2	mostly caught bait fishing
Char, arctic ( <i>Salvelinus alpinus</i> )	northern Canada, northern Europe, Scandinavia, Iceland, Greenland	15	7	ranks with other <i>Salvelinus</i> (trout) as great game fish; occur in Great Britain, but are too small to be of sporting value
Chub ( <i>Squalius cephalus</i> )	central Europe except Denmark, Sicily, northern Scotland, Ireland	5	2	caught on bait, fly, or spinner
Crappie, black ( <i>Pomoxis nigromaculatus</i> )	North America	1	0.5	popular pan fish; caught on bait, small lures, flies
Crappie, white ( <i>Pomoxis annularis</i> )	North America			much like black crappie
Dace ( <i>Leuciscus leuciscus</i> )	all Europe except Ireland, northern Scotland, and Norway	1	0.5	caught on fly or float tackle
Dorado ( <i>Salminus maxillosus</i> )	northern half of South America	20	9	the outstanding freshwater game fish native to South America; takes flies, spinning lures
Eel ( <i>Anguilla anguilla</i> )	worldwide	3	1	caught by bait fishing
Gar, alligator ( <i>Lepisosteus spatula</i> )	North America, Mississippi Valley, and southern waters	50	25	heavy tackle, bait; edible, but almost never eaten
Gar, longnose ( <i>Lepisosteus osseus</i> )	St. Lawrence River, Great Lakes, southern U.S. waters	6-8	3-4	same as alligator gar
Grayling ( <i>Thymallus thymallus</i> )	all Europe except southern France, southern Italy, Portugal, Spain, Ireland	2	1	generally caught on fly or bait tackle but will take spinning lures
Grayling, arctic ( <i>Thymallus arcticus</i> )	native to Alaska, northern Canada, Montana (subspecies <i>tricolor</i> )	2-4	1-2	a splendid sporting fish, takes fly, spinner, and bait
Huchen ( <i>Salmo hucho</i> )	Danube and tributaries	20	9	a salmon peculiar to the Danube; caught generally in winter and by spinning
Mahseer ( <i>Barbus tor</i> )	India, Pakistan, Burma, Malaya	varies greatly; over 100	45	caught on bait by spinning in cold rivers
Muskellunge ( <i>Esox masquinongy</i> )	northeastern and north central United States	15-20	7-9	a very large member of the pike family; caught on fish or large lures
Perch, common ( <i>Perca fluviatilis</i> )	all Europe except Spain and southern Italy	2	1	caught by all methods
Perch, nile ( <i>Lates niloticus</i> )	tropical rivers and lakes of Africa	200	90	generally caught trolling
Perch, white ( <i>Roccus americanus</i> )	Atlantic seaboard	2	1	caught on bait and casting lures
Perch, yellow ( <i>Perca flavescens</i> )	eastern North America	1	0.5	very popular pan fish, especially the Great Lakes region; mostly caught bait fishing and on flies
Pickrel, eastern chain ( <i>Esox niger</i> )	eastern and southern United States	5	2	a small pike
Pike, northern ( <i>Esox lucius</i> )	all countries; the pike is the only freshwater fish native to Europe including the U.S.S.R., and to North America	15	7	caught mostly by spinning and trolling but will take bait and large fish imitating flies

\*Italics indicate species has been transplanted.

crushed clams, mussels, fragments of crabs, crawfish, or other shellfish is dropped into the water sparingly to sink to the bottom or drift with the current or tide, releasing oil or juices and creating a visible slick on the surface. Predacious fish crossing the stream of chum will turn and follow it to its source, or to the baits that are released into the current with the chum.

**Bottom feeders and reef fishing.** Flounders and similar bottom feeders are also responsive to chum. At times they may be lured with such odd fare as canned corn kernels and boiled rice, even canned cat and dog food. The simple process of stirring the bottom to create a mud slick will often pull fish to an anchored boat. Reef fishermen the world over are well acquainted with the efficacy of chum balls fashioned out of wet sand and minced fish. As the ball sinks and disintegrates, fish are at first visually attracted by the display of broken chum balls. Then their appetites are sparked by the fragments, and soon the aroused fish find the baited hooks.

**Live-bait chumming.** Live-bait chumming is practiced wherever the essential baitfish is plentiful and easily caught. In southern California, party boats load their bait wells with thousands of anchovies as they head offshore for the deep-water grounds plied by such favourite sport fishes as the Pacific yellowtail and the long-finned albacore. Once the quarry has been searched out, the live bait is dipped overboard. The fun begins as the predacious game fish charge into the helpless chum and seize the baited hooks lowered into it.

**Shark fishing.** Releasing chum from a drifting boat is standard procedure for shark fishing. Sometimes blood and offal are added to the slick to further entice the shark. Once the chumming has established a long, tide-borne slick in the water, baits are introduced. Live fish caught from the bottom may be used on the hook. More times than not the angler will simply fasten on pieces or whole members of the baitfish used as chum. When sharks of great size are known to be present, exotic baits

Chumming

Table 1: Fresh-Water Fish Sought by Anglers (continued)

species	where caught*	weight of good catch		comments
		lb	kg	
Roach ( <i>Rutilus rutilus</i> )	all Europe north of the Alps and Pyrenees	2	1	caught mostly on float or ledger tackle but will take flies and tiny spoons; Europe's most popular fish
Rudd ( <i>Scardinius erythrophthalmus</i> )	most European countries	2	1	caught mostly by float fishing but takes the fly well
Salmon, atlantic ( <i>Salmo salar</i> )	Iceland, Norway, Sweden, Finland, U.S.S.R., Britain, Ireland, France, Portugal, Spain; also in Greenland, eastern Canada, Maine	15-20	7-9	all methods, but spinning and/or bait fishing is banned on some waters; fly only permitted in North America
Salmon, chinook ( <i>Oncorhynchus tshawytscha</i> )	Pacific coast of North America, California to Alaska, Great Lakes; South Island, New Zealand	40-60	18-27	largest of the Pacific salmon; also known as king, tyee, spring, quinnat (N.Z.); caught by trolling (mooching), fly-fishing, and bait or plug casting
Salmon, coho ( <i>Oncorhynchus kitchin</i> )	North America as chinook; Lake Michigan very successful	9-10	4-5	very game fish; also known as silver salmon caught by trolling, bait casting, and on a fly
Salmon, landlocked ( <i>salmo salar sebago</i> and <i>s. salar ouananiche</i> )	Maine ( <i>sebago</i> ) and Lake St. John area, Quebec ( <i>ouananiche</i> ), New Brunswick, Nova Scotia	8	4	Atlantic salmon that do not migrate to sea; fine sporting fish; takes fly and spinner very well
Sturgeon, white ( <i>Acipenser transmontanus</i> )	Pacific coast of North America, California to Alaska	100	50	caught by bottom fishing with crustaceans, larva, and other bottom life
Sunfish, redear ( <i>Lepomis microlophus</i> )	southern and eastern United States	1	0.5	resembles bluegill; back of gill-cover bright orange-red; plucky pan fish; caught on bait, small lures, and flies
Tench ( <i>Tinca tinca</i> )	all European countries except Scandinavia and Scotland	4-5	2	float and ledger fishing are exclusively used
Trout, brook ( <i>Salvelinus fontinalis</i> )	originally northeastern United States, eastern Canada, all North America, northern Europe, South Africa, Sweden, South America	1-10	0.5-5	a char, it requires cold water; voracious, will take most baits and lures, sunken flies; excellent eating
Trout, brown ( <i>Salmo trutta</i> )	all European countries; brown trout have also been introduced into North America, India, South America, Africa, Australia, and New Zealand	2 (river) 4 (lake)	1 2	all methods; although many waters permit only fly fishing
Trout, cutthroat ( <i>Salmo clarki</i> )	Pacific drainage, California to Alaska	4	2	a true trout, voracious, will take fly, bait, or lure
Trout, dolly varden ( <i>Salvelinus malma</i> )	British Columbia, western United States	6-8	3-4	a voracious, bottom-feeding char; will take any bait or lure
Trout, golden ( <i>Salmo aguabonita</i> )	southern Sierra Nevada of western United States	2	1	a true trout, caught mostly on flies
Trout, lake ( <i>Salvelinus cristivomer</i> )	northern North America	10-12	5-6	largest north American char; also known as Great Lakes trout; fly and bait casting, spinning, deep trolling, bait fishing; excellent table fish
Trout, rainbow ( <i>Salmo gairdneri</i> )	Pacific drainage, other areas of North America, Europe, other countries where temperature permits	1	0.5	a true trout; wonderful sporting fish; takes fly, lure, and bait; at Lake Pend, Oreille, Idaho, called Kamloops or Kootenay
Trout, sea ( <i>Salmo trutta</i> )	all sea-board countries of Europe except Holland and Belgium; in many countries—New Zealand, North America, South America, where brown trout have been introduced some have become migratory in habit and "runs" of sea-trout occur	8	4	all methods are used, but fly fishing and spinning are considered the most sporting; sea trout are shy fish and can often be caught only at night
Trout, steelhead ( <i>Salmo gairdneri</i> )	California to Alaska, Great Lakes	10-12	5-6	migratory sea-run rainbow; caught on bait, flies, and spinners
Trout, sunapee ( <i>Salvelinus aureolus</i> )	Lake Sunapee and other lakes, New Hampshire and Maine	2-3	1-1.5	a char
Tigerfish ( <i>Hydrocyon lineatus</i> )	central Africa	10-15	5-7	a very game fish that takes fly or spinner and leaps repeatedly after being hooked; has large, sharp teeth and a high percentage of hooked fish escape
Walleye ( <i>Stizostedion vitreum vitreum</i> )	originally Canada west to Alberta and south to Great Lakes-Mississippi; now all United States and Canada	2-5	1-2	also known as walleye, pike perch, and (Canada) <i>doré</i> ; prized game fish, excellent eating
Warmouth ( <i>Chaenobryttus gulosus</i> )	southeastern to midwest United States	1	0.5	a popular pan fish of its range; sometimes known as warmouth bass, warmouth perch; caught on bait, small lures, and flies
Whitefish, mountain ( <i>Prosopium williamsoni</i> )	northern North America	1-1.5	0.5-0.75	caught on bait, flies, and spinners
Zander ( <i>Lucioperca lucioperca</i> )	northern Europe	6-8	3-4	closely related to the North American walleye; caught by spinning and bait fishing; recently introduced into Great Britain

\*Italics indicate species has been transplanted.

such as chunks of porpoise or seal meat may be used. A giant white shark will swallow a small harbour seal in a single gulp. It should be reported that the use of animal matter as chum or bait disqualifies the catch for possible record recognition under International Game Fish Association rules.

Ground fish and fish baits are quite sufficient for most shark-fishing operations, however. With such attractants, members of the Shark Angling Club of Great Britain catch as many as 5,000 sharks annually from all parts of Britain and Ireland struck by the Gulf Stream. Most of the sharks caught there are blues and porbeagles, although the spectacular, leaping makos are most eagerly sought. Individual Cornwall fishermen sometimes land several dozen sharks in a day.

In the western Atlantic, shark fishing finds new adherents each year, as more and more private boatmen become better equipped for big-game fishing. In many United States fishing ports, charter captains specialize in

catching sharks. The availability of the quarry, the simplicity of the chumming method, and the promise of energetic action (not without some danger) recruit anglers from all walks.

The shark has been recognized as a worthy angling adversary by the International Game Fish Association since the organization began its record-keeping. Six species invite competition. They are the mako, the great white shark, the blue shark, the porbeagle, the thresher, and the tiger shark.

While giant members of each species undoubtedly roam the oceans of the world, the largest specimens have been fairly caught on rod and reel only in Australian waters. Several great white sharks (also identified as white pointer sharks and man-eaters) of more than a ton in weight have been landed by anglers in the Great Australian Bight, a huge, crescent-shaped curve along the southern coast of the continent. Of the many fishermen who have pitted themselves against such monstrous fish, one man

stands unsurpassed. Alfred Dean of Mildura, Australia, has set and broken his own white shark records several times. His best specimen weighed 2,664 pounds (1,208 kilograms). But Dean also hooked and fought sharks up to 20 feet (six metres) in length, one of which he thought exceeded 4,000 pounds. This angler chums with whale oil and uses whole seal carcasses for bait.

**Party-boat fishing.** Still-fishing is perhaps carried to the ultimate on open party or "head" boats that sail on daily schedules to the fishing grounds off many ports, carrying anglers to the nearby grounds for a stipulated head fee. When the boat has reached the grounds, the anchor is set. Anglers drop lead-weighted lines to the bottom carrying down baits of clams, crabs, sea worms, cut fish, or squid. A sudden strike or pull on the line is the signal for the fisherman to tighten his grip on the rod and reel up his catch. Fishes vary according to the countries and the seasons. Fish as large as the giant sea bass, which may weigh several hundred pounds, have been caught by head-boat anglers. Such large and valiant fighters as the amberjack, bluefish, grouper, and cobia, among the many, are taken regularly. Most of the species that fill out the party-boat fisherman's bag, however, are bottom feeders of modest size—tautogs, eels, members of the weakfish family, porgies, and lesser sea basses are examples.

In larger ports, news of party-boat catches is carried in the outdoor columns of the daily newspapers. The sport has thousands of enthusiasts who descend on coastal ports, winter and summer, intent on a good catch and the camaraderie of fellow anglers. Competition is the essence of such group fishing. Not only does every man strive to prove his mettle as an angler but, as a show of confidence, he invariably invests in the boat pool with a chance of winning a substantial sum should he catch the largest fish of the day.

Significantly, the pollution that is rampant in the inner and outer harbours of almost all large cities does not deter the party-boat angler—nor the private boat fisherman, nor the commercial netter, for that matter. Often the day's fishing is done within a few minutes' run of the grounds used as sludge repositories by the city's sewage treatment plants. Industrial wastes of noxious liquids sometimes flow with the tidal currents through vast areas of the outer harbour, turning the water a sickening green or yellow, even staining the fishermen's lines. If the poisonous liquids are quickly diluted and sufficient oxygen remains in the water, fish usually adjust to the unnatural habitat and remain as long as food is available—and the fishermen with them. Neither fish nor fishermen, however, may make compromise with the sludge dumping areas. Studies have shown that the descending sludge covers the bottom in a thickening blanket until all marine life but the most elemental worms is extinguished. In some outer harbours the sludge blanket may bury a dozen square miles of sea floor.

While catch records demonstrate a gradual decline in many of the species that seasonally visit heavily fished seaport grounds, factors aside from waste disposal contribute to the reduction. Increased pressures both from commercial and sport fisheries often tax the resource. Attrition of fish spawning and nursery grounds in the bays and estuaries as the result of run-off from the land, as well as the destruction of salt marshes or wetlands through industrial and residential encroachment, play major roles in the decline of many popular species.

#### CASTING

**Surf casting.** Casting, in Great Britain called spinning, is adaptable either to shore or boat fishing. Most often associated with the surf and the fishes of the littoral, the techniques of surf and shore, or beach, casting have made great strides through innovations in tackle—the strong, supple fibre glass rod, synthetic lines, and the worldwide ascendancy of the fixed-spool, or spinning, reel over the centrepin or revolving spool reel. While longer casts are sometimes possible with the revolving spool reel, the spinning reel's freedom from troublesome snarls and backlashes as well as its ease of operation are responsible

for its popularity among surf casters, particularly neophytes. In competitive casting using standard surf spinning tackle, casts up to 480 feet (150 metres) have been made. This is about 15 or 20 feet (five or six metres) short of the best casts made with standard revolving spool reels, however.

Most surf casters are content to place their lures or baits beyond the curling breakers, distances of 100 to 200 feet (30 to 60 metres). This is readily accomplished with a rod nine to 12 feet (three to four metres). Rods vary in weight and strength in keeping with the demands made upon them. In the British Isles, where swift currents wash many shorelines and heavy bottom-grabbing sinkers are required, stout rods up to 15 feet (five metres) in length are often used. In contrast, slender eight- or ten-foot (two- or three-metre) rods may suffice on beaches where the water rolls placidly. The well-travelled surf angler may own rods for varying situations. Other special surf-casting equipment includes armpit waders, spray parka, and a webbed belt for holding a lure case, fish chain, and gaff. On rocky coasts, the experienced caster wades deep into the surge, where he hooks, fights, gaffs, and chains his catch without abandoning his strategic fishing location. A battery lamp worn on the head or chest completes the ensemble for night fishing, often the best time in the surf.

**Shore casting. Light tackle.** Shore casting, casting while wading in the shallow waters of bays and inlets, may be accomplished with the equivalent of light freshwater tackle. Even the fly rod is brought into play by an increasing number of ardent anglers. Tarpon and bonefish are frequently taken by wading light-tackle casters, more with spinning tackle than with the fly. Tarpon well over 100 pounds (45 kilograms) are frequently subdued in such narrow field of combat. Along the Gulf of Mexico, wading fishermen sometimes catch weakfish, or sea trout, tempting the tender-mouthed species with shrimp bait drifted from floats that sound noisily when drawn through the water. Fishermen long ago discovered that the popping or gurgling sounds made by an activated float are irresistible to a hungry weakfish.

**Fly casting.** The flies used in saltwater fly casting are lures imitating small fish, shrimps, etc. Generally, a strong, nine-foot (three-metre) rod is used, for long casts have to be made and many of the fish caught are relatively big and powerful. Europe and the British Isles have few places suitable for fly-fishing in the sea, but Florida and some of the other southern states of the U.S. offer splendid fly-fishing for bonefish, small tarpon, and other species including bluefish and sea trout. Farther north, the striped bass takes a fly well in places on both the Atlantic and Pacific coasts, whereas on the latter fly-fishing for coho salmon offers splendid sport.

A group of anglers who identify themselves as the Salt Water Fly Rodders of America, Inc., have caught enough prize fish to establish a category of world records for fish caught on the fly rod.

**Casting from boats.** The increased mobility made possible by casting from a boat offers a marked advantage over shore fishing. Because lengthy casts are not vital for the boat-borne caster, a shorter rod serves him well. Boat casting pays dividends when game fish actively feed on surface baitfish, a situation that is often pinpointed by hovering seabirds. Then, the boat is cautiously directed to the turmoil of slashing fish and diving birds. Anglers eagerly whip plastic plugs, artificial squids, weighted bucktails, or jigs into the melee, retrieving them rapidly to simulate crippled baitfish. Often the action is frantic and continues until the boat drifts out of range of the school, or the fish sound.

Much boat casting takes a leaf from freshwater fishing. Fishermen direct their lures at sunken boulders in a rocky surf or cast them into pot holes and pockets where fish may be expected to lurk. Of the larger species, sailfish and marlin, school tuna and tuna-like fishes are occasionally caught by boat casters who relish the advantage they give to these large fish with their frail tackle. Even the fly rod has been successfully used in such deep-sea casting, although only a handful of experts press their

Casting in shallow waters

Fish sought by party boats

luck in this direction. One fly-rod angler of supreme skill landed a 148-pound (67-kilogram) striped marlin off Ecuador on an inexpensive fly rod and reel to prove it could be done. The ensuing fight lasted four-and-a-half hours.

Many high-powered small craft have been devised for the specialized skills of the caster. Most of them are outboard powered or served with an inboard engine and stern drive (sometimes called an inboard-outboard) that permits them to operate in waters too shallow for standard inboard craft. Such versatile vehicles are used by Florida Keys guides to transport fishermen over vast distances in extremely shallow water at great speed.

#### TROLLING

Trolling, trailing a natural bait or artificial lure behind a moving boat, is greatly practiced for sea fish, for it is the best way of locating fish in great expanses of water, often of considerable depth. With the exception of trolling for what are known as big-game fish, a specialized technique that will be dealt with separately, the methods of fishing are very similar to those used for freshwater fish.

Typical of saltwater trolling is the method used on the west coast of North America to catch the large Pacific salmon. All types of craft are used, from rowboats to special power-driven ships designed for this sport. Behind such crafts are trailed spoons, plugs, and dead fish, either whole or cut up. A very popular method is known as mooching (here meaning to skulk or sneak—the bait is sneaked among a school of feeding salmon). A preferred bait is a dead herring preceded by a large spoon called a herring dodger. The dodger acts both as an attractor and as a way of causing the herring to move in a lifelike manner. Basing itself on this sport of trolling for Pacific salmon is the famed Tyee Club of Campbell River, British Columbia. This club lays down rules as to tackle that may be used, and presents buttons to anglers who catch large specimens of these salmon—bronze for 30-pound (14-kilogram) fish, silver for 40-pound (18-kilogram) fish, gold for 50-pound (23-kilogram) fish, and diamond for those of 60 pounds (27 kilograms) or more.

#### BIG-GAME FISHING

The quarry sought in big-game or deep-sea fishing are principally the members of the tuna, shark, and swordfish, or billfish, families; individual specimens may run from 100 pounds (45 kilograms) to well over 2,000 pounds (900 kilograms).

The beginning of big-game fishing inevitably is traced to the day in 1898 off Santa Catalina Island, California, when C.F. Holder tried a stout rod and reel against an up-to-that-time untouchable giant bluefin tuna and succeeded in taking a fish of 183 pounds (83 kilograms), the first of such size to fall victim to an angler. It has been said that the most formidable part of Holder's equipment was his great courage and a burn-proof thumb. In the infancy of big-game fishing, slip-clutch reels were unknown. Whatever drag that might be applied to the spool was done so with thumb pressure as the line whirled away into the water. Friction pads or thumb stalls were used to lessen the threat to the angler's fingers. But even when the fisherman mastered the scorching reel, he was additionally threatened by the revolving handles that flew around double or triple the rate of the whirling spool.

Despite the odds drawn against him, Holder proved equal to the fish that day off Santa Catalina Island. News of the conquest quickly spread and fired the imaginations of fishermen everywhere. Soon enough Holder's feat was accomplished by others and with other species of giant fish, including marlin and broadbill swordfish.

Holder's historic catch, made with a 16-ounce (450-gram) rod, not including the butt, led to the formation of the Catalina Tuna Club, which soon set the early ground rules for big-game fishing. Rod tips were limited to 16 ounces, lines to 24-thread, which, with three pounds (1½ kilograms) to the thread, meant a breaking strength of 72 pounds (33 kilograms). The catch, and the others that followed in rapid order as growing numbers of saltwater

fishermen elevated their sights to include the heretofore untouchable species, served to emphasize the inadequacy of the available tackle, particularly the reels. Not until 1913, however, when reel maker Julius vom Hofe of Brooklyn, New York, responding to the suggestions of thwarted big-game fishermen, produced a reel with an internal drag, were the problems of a scorching spool and knuckle-cracking handles solved.

Big-game fishing is considered the ultimate in sport fishing. Most serious participants are guided by the strict rules of competition set down by the International Game Fish Association, whose members act as referees and judges for record-contending fish in many countries of the world. The same rules are also applicable to saltwater fishermen of every level. Many of the records kept by the organization were made by fishermen who aspired for anything but record-breaking fish. Every angler who abides by the rules is eligible to have his name inscribed in the books if his particular catch improves on the species listed in one of several line-strength categories.

**Deep-sea trolling.** The most popular, effective, and sporting method of big-game fishing is trolling. Deep-sea trolling is a highly specialized form of fishing requiring a boat designed for the purpose and tackle designed for handling very heavy fish. The craft for big-game fishing must be capable of withstanding heavy seas and is equipped with a "fighting seat," a turntable chair from which the angler can exert the maximum pressure on a fish many times his own weight. The rod, a massive one of fibre glass or laminated wood, has a butt that fits into a socket in the chair. The reel is usually a very large multiplying reel, although some British big-game fishermen prefer a centre-pin reel; it is usually designed so that a harness that fits over the angler's shoulders or around the small of his back can be connected to it, thus allowing the fisherman to use all his strength against the fish. The reels have a throwout lever or other device to release the spool and allow it to run free, and a braking device or drag to regulate line tension. The line is made of Dacron or Terylene and the leader of wire.

Craft designed for such fishing generally have outriggers—long poles to which the lines are attached by what Americans call clothespins and the British clothes pegs, which hold the lines well clear of the boat, thus allowing more than one line to be used. The age-old problem of locating fish and determining the depth at which they are feeding has been solved in part by the use of echo sounders and other electronic aids.

All sport-fishing cruisers are not of the optimum design. This does not necessarily alter their ability to cope with huge fish. The almost primitive dory-like cruisers of the Canadian Maritime fishermen are regularly used to set new records for giant tuna. Fish of over 1,000 pounds (450 kilograms) have been caught on rod and reel from such minimal angling vessels, with the catch towed to port when it could not be lifted aboard.

Big-game fishing is not the exclusive domain of the wealthy. Its realm includes sea anglers of all ranks, and International Game Fish Association records amply attest to the truth of the statement. The majority of the listings are the product of fishing craft of modest size and structure and of fishermen whose principal asset was zest. As a matter of fact, most big-game fishermen usually go to sea to take the measure of whatever species are at hand, most of which require little muscle for landing, although hooking may be something else again.

**Techniques.** In trolling, the angler-boatman tows his lures or natural baits, as the case may be, at varying distances from the boat and at varying depths according to the habits of the species sought. Speed is the third factor the fisherman takes into consideration. Boat speed will influence the trolling depth and action of the lure. The churn of a rapidly spinning propeller will create a wake that many species, particularly the tunas, find attractive. When trolling for such species, the lures are usually brought into the white water close behind the vessel. For species that shy from a passing boat only to converge after its passing, long trolling lines may be called for. Deep-swimming species may be reached through the ad-

Table 2: Saltwater Game Fish

species	where caught	weight of good catch		comments
		lb	kg	
Albacore ( <i>Thunnus alalunga</i> )	New Zealand, Hawaii, Peru, Ecuador, California, Mediterranean, Azores, Caribbean, Gulf Stream from Bahamas to offshore New York	30	14	distinguished by long pectorals, valued commercially as the white-meat tuna; trolled and chummed with live bait
Amberjack ( <i>Seriola</i> )	Bermuda, Bahamas, Hawaii, Puerto Rico, Brazil, Mediterranean	50–60	23–27	likes live baitfish but will take cut baits, strong tackle is needed to dislodge it from reef hideouts
Barracuda ( <i>Sphyræna</i> )	Florida, Bahamas, Gulf of Mexico, West Indies, East Indies, Japan, Australia	30–35	14–16	voracious predator, sporty on light tackle, not nearly as bad as reputation, older specimens sometimes toxic
Bass, black sea ( <i>Centropristes striata</i> )	southern New England to North Carolina	5	2	often called simply sea bass, a staple fish of party boats, often associated with porgies
Bass, channel ( <i>Sciaenops ocellata</i> )	Delaware Bay to Gulf of Mexico	50	23	heaviest fish are caught off North Carolina's Outer Banks; called redfish, identified by black spot on tail
Bass, European ( <i>Morone labrax</i> )	northern European waters	8–10	4–5	caught by all means of angling including sometimes fly fishing; very sporting fish
Bass, giant sea ( <i>Stereolepis gigas</i> )	central California to Baja California, Costa Rica	300	140	also known as California black sea bass; reaches 600 lbs; not a great fighter despite its size, large baits
Bass, striped ( <i>Roccus saxatilis</i> )	Atlantic waters from Maine to South Carolina, strays to Canada and Florida, Pacific waters of California and Oregon	45–50	20–23	also called striper, rockfish, greenhead, or linesides; bait fishing and plug casting are best methods; most popular quarry among inshore surf casters
Blackfish ( <i>Tautoga onitis</i> )	New England to the Carolinas	12	5	a rough-and-tumble fighter of rough bottom, tricky to hook; also known as tautog
Bluefish ( <i>Pomatomus saltatrix</i> )	east coast of North America, North Africa, South Africa, eastern South America, Australia, Japan	12–15	5–7	takes almost any lure trolled or cast, is readily chummed; called tailor, shad, fatback, elf (South Africa); snapper when young
Bonefish ( <i>Albula vulpes</i> )	Florida Keys, Bahamas, Bermuda, Puerto Rico, Cuba, Hawaii, Japan, Australia	10	5	a wary bottom feeder that often forages in water only inches deep; known for its long, fleeting runs; caught on bait or lures, may be chummed
Bonito, oceanic ( <i>Euthynnus pelamis</i> )	western Atlantic, Cuba, Bermuda, Puerto Rico, Barbados, Madeira, Morocco, Dakar, Chile, California, Hawaii, New Zealand	15–18	7–8	often feeds on surface in splashing schools, readily trolled; commercially described as skipjack; other names, striped bonito, leaping bonito, arctic bonito, and aku
Bream, black ( <i>Spondylisoma cantharus</i> )	northern Europe	3	1	caught by float and bottom fishing in late spring and early summer in English Channel
Cobia ( <i>Rachycentron canadum</i> )	Gulf of Mexico, Bermuda, Jamaica, Brazil, Senegal, Guinea, Australia, Japan, Persian Gulf, Florida	40	18	also called cabio, crabeater, ling, lemonfish, sergeant fish; strong fighter that loiters around wrecks and sea buoys
Cod ( <i>Gadus morhua</i> )	western Atlantic from Greenland to the Virginia capes, Iceland, Scandinavia, British Isles	45–50	20–23	staple food fish of many nations; favourite of the winter sport fishery
Conger ( <i>Conger conger</i> )	British Isles, northern Europe	30	14	usually taken by bottom fishing close to rocks or wrecks; a very strong eel running 70–80 lbs and bigger
Dab ( <i>Limanda limanda</i> )	northern European waters	1.5	0.7	a small flatfish caught over mud or sand
Dolphin ( <i>Coryphaena hippurus</i> )	almost worldwide where water temperatures reach 70° F (21° C), Cape Cod to Brazil, Caribbean, Gulf of Mexico, Mediterranean, Hawaii, Southern California to the Bay of Panama, Ecuador, Japan Sea, Philippines, Australia, Kenya, West Africa	35–40	16–18	not to be confused with mammal dolphin; this brilliant fish often lurks under floating flotsam
Drum, black ( <i>Pogonias cromis</i> )	eastern North America	6	3	also called sea drum
Flounder ( <i>Platichthys flesus</i> )	northern Europe	3	1	an estuarial flatfish frequently caught on baited spoon
Halibut ( <i>Hippoglossus hippoglossus</i> )	northern British waters	100	45	a very large flatfish now being caught on rod and line in far northern British waters
Jewfish ( <i>Epinephelus itajara</i> )	Florida, Gulf of Mexico, West Indies to Brazil, eastern Pacific, Baja California to Panama	300	140	largest of the giant bass, also known as giant sea bass and warsaw grouper; sometimes caught by shore and bridge fishermen on heavy handlines
Ling ( <i>Molva molva</i> )	Greenland to Bay of Biscay	30	14	a highly predatory fish caught in deep water often in the vicinity of wrecks

dition of heavy trolling weights or through the use of a metal planer, a device that reacts to water pressure and dives deep into the wake carrying the attached lure with it. Wire lines created from extruded Monel Metal or stainless steel assist in the sinking of a moving lure. Nylon fibre braided around a lead core is the structure of another line used to troll lures below the surface. (But fish caught on metal or metal core lines are not eligible for International Game Fish Association records.) No matter what form the trolling takes, the purpose is the same—to attract a game fish to an apparently injured baitfish, which is the lure. Sometimes an angler finds it expedient to keep his baits aboard the boat until the quarry is sighted. This approach is often used in fishing

for broadbill swordfish which, normally, are not baited until they have revealed themselves finning on the surface. As soon as the boat closes on the lolling fish, the large bait of whole squid or fish is launched and manoeuvred 100 feet (30 metres) behind the boat, then sunk in front of the fish. If the swordfish follows the bait down, a strike may result. This method is also used for large sharks discovered swimming on the surface.

Live baits appeal to many game fishes. Small baitfishes are netted or taken with hook and line to be stored in live-bait wells or aerated containers aboard the fishing craft. Such bait is generally fished from a high-rising outrigger at extremely slow speed. Kite fishing is a phase of this live-baiting method. The kite replaces the outrigger fishing

fishing

Table 2: Saltwater Game Fish (continued)

species	where caught	weight of good catch		comments
		lb	kg	
Mackerel ( <i>Scomber scombrus</i> )	north Atlantic, Europe and America	2	1	if caught on light tackle is a magnificent sporting fish; caught by all means
Mackerel, king ( <i>Scomber-morus cavalla</i> )	Florida Straits to Cape Hatteras and south to the Caribbean	35-40	16-18	a spectacular leaper, it will sometimes arc a dozen feet into the air to land precisely on a trolled bait
Marlin, black ( <i>Makaira indica</i> )	throughout warm water of Pacific, also present in the Indian Ocean, East Africa, Japan to New Zealand and Australia, greatest concentrations of 1,000-lb fish in Humbolt Current off Peru and Ecuador	400-500	180-230	largest of the finfish, a giant of 2,250 lbs was once harpooned off Cabo Blanco, Peru; rigid pectoral fin distinguishes it from other marlins; trolling best method
Marlin, blue Atlantic ( <i>Makaira nigricans</i> )	western Atlantic from New England to Florida and Bahamas, Cuba, Jamaica, Puerto Rico, Venezuela, Brazil, west Africa	200-250	90-110	takes trolled baits, often runs with white marlin, a smaller and more plentiful relative; cobalt blue colour fades after capture
Marlin, blue Pacific ( <i>Makaira ampla</i> )	throughout tropical and subtropical Pacific, East African coast	200-250	90-110	prize catch of Hawaii; pectoral fin folds back to distinguish blue from black marlin; long confused with Atlantic blue marlin, it is now proclaimed a separate species
Marlin, striped ( <i>Makaira audax</i> )	coastal waters of Ecuador, Chile, Peru, Hawaii, Southern California, Mexico, Panama, Australia, Bay of Islands, New Zealand	200-225	90-100	readily identified by its vivid vertical bars, a spectacular jumper, caught on trolled, whole-fish baits or squid
Marlin, white ( <i>Makaira albida</i> )	western Atlantic from Cape Cod to the Caribbean, Bahamas, Cuba, Bermuda	80-90	35-40	smallest of the marlins; ranks second to the sailfish in popularity among anglers; trolled bait and artificial lures
Mullet, gray ( <i>Mugil cephalus</i> )	northern Europe	3	1	excellent sporting fish frequently caught on light float tackle
Permit ( <i>Trachinotus falcatus</i> )	Bahamas, Florida Keys, Gulf of California, Panama	25-30	11-14	a round, compressed member of the pompano family, it is often found in the shallowest water; a fine light-tackle fighter
Plaice ( <i>Pleuronectes platessa</i> )	northern Europe	3	1	caught over mud or sand often by drifting with baited spoon; excellent table fish
Pollock ( <i>Pollachius</i> )	northeast Atlantic waters of the United States, British Isles, Norway	25-30	11-14	a handsome hard-fighting relative of the cod; also called codfish and Boston bluefish
Sailfish, Atlantic ( <i>Istiophorus albicans</i> )	Florida (Atlantic and Gulf coasts), Bahamas, Cuba, Puerto Rico, Jamaica, Venezuela, British Honduras, Brazil	70	30	most fish are caught trolling; one of the most sought after trophy fish
Sailfish, Pacific ( <i>Istiophorus greyi</i> )	Hawaii, Japan, Guam, Philippines, Tahiti, Solomon Islands, Indian Ocean, Southern California to Salinas, Ecuador	125	55	caught with trolled baits, more than double the average size of Atlantic sailfish
Snook ( <i>Centropomus</i> )	coastal waters of Gulf of Mexico, Florida, Bahamas, Puerto Rico and south to Venezuela, Southern California to Peru, West Africa	25	11	some of the heaviest are caught by shore and bridge fishermen who use either lures or bait; also called robalo
Swordfish ( <i>Xiphias gladius</i> )	widely distributed in both hemispheres, Newfoundland to New York, Cuba, Iceland, Scandinavia to Portugal, Cape of Good Hope, Mediterranean, Bosphorus, Sea of Marmara, Black Sea, Cape Province, Durban, Madagascar, from Southern California to Chile, northern Japan to Australia and New Zealand	350	160	a highly prized game fish, difficult to hook and hard to hold because of soft mouth; except for man principal enemy is the mako shark; called broadbill, albacora, espadon
Tarpon ( <i>Megalops</i> )	waters of tropical rivers, inlets, and back bays, especially Florida, Río Pánuco, and West African coasts	100-125	45-55	best methods are bait and plug casting and fly-fishing; sharp hooks are essential; a ferocious fighter
Tuna, allison (or yellowfin) ( <i>Thunnus albacares</i> )	tropical and subtropical waters around the world, Japan, Philippines, Somalia, Australia, Hawaii, Northwest Africa, Caribbean to Brazil	80	35	most abundant in Pacific waters, older specimens develop lengthening of dorsal and anal fins; known as allison tuna and ahi in Hawaii
Tuna, big-eyed ( <i>Thunnus obesus</i> )	tropical waters of Pacific, eastern Atlantic to Azores, northwest coast of South America, Indonesia, Hawaii, Indian Ocean	150	70	second largest after bluefin tuna, deep-swimming tuna, does not often rise to surface lures
Tuna, bluefin ( <i>Thunnus tynnus</i> )	most warm and temperate waters, United States, Bahamas, waters between Sweden and Denmark, Bay of Biscay, Mediterranean, East and South African coasts, Australia	80 (school tuna); 600-700 (giants)	35 270-320	another much-sought-after trophy; fish over 1,000 lbs have been caught on rod and reel
Wahoo ( <i>Acanthocybium solanderi</i> )	Bermuda, Bahamas, northern Brazil, Ecuador, Baja California, Panama, Japan, Philippines, Australia	50	23	also called peto, queenfish, ono; the cigar-shaped wahoo is among the swifter fish of the ocean; distinguishing it from other mackerel-like fish, the wahoo has a moveable upper jaw
Weakfish ( <i>Cynoscion regalis</i> )	Cape Cod to Gulf of Mexico, Gulf of California to Peru	4-5	2	favourite of bay and shore anglers, the tender-mouthed weakfish or squeteague is also called sea trout because of its looks and dash; some Pacific members grow to 20 lbs
Yellowtail ( <i>Seriola dorsalis</i> )	Southern California to Baja, Mexico, New Zealand, Australia	35	16	an amberjack that fights as hard as the rest of the family; most are caught with live chum and bait, some are trolled

transporting the struggling baitfish well away from the boat. Fishing kites are fashioned from silk cloth mounted on an X-shaped frame. Their size is dictated by the weight of the bait used and the velocity of the wind.

When a fish has been hooked it is brought to the boat by "pumping." In pumping a large fish, the angler places both hands on the rod grip, arms straight before him, body bent forward. Legs push against the footrest, shoulder muscles against the harness. The rod is slowly forced to the perpendicular. Switching the right hand to the reel handle, the angler starts forward again, winding up the short length of line, which slackens as the rod descends. Pumping a fish has been compared to a slow rocking chair motion and is accomplished without chang-

ing the tension on the line. The backward stroke pulls the fish a little closer. The forward motion stores the line gained. When properly performed, pumping results in minimum fatigue even with the largest fish, which is evidenced by the number of women and children who land fish many times their own weight.

**Tackle.** The choice of rods and reels for a day's fishing depends on the type and size of the fish sought, or the humour of the fisherman. In the main, light or medium outfits are used in trolling for small or medium-sized pelagic species such as school tuna, bluefish, kingfish, mackerel, and dolphin. Often, however, fishermen find it sporting to take on large fish with light equipment. "Three-six tackle" was the name applied by the Catalina

Tuna Club to the rod less than six feet long, with a tip weighing less than six ounces and using a standard six-thread linen line.

With the introduction of the lightweight but strong rod made of glass fibres and resin the whole concept of the balanced rod and reel changed. Glass rod tips are several ounces lighter than rods of split bamboo or solid or laminated woods and immeasurably stronger. Fine-gauged monofilament lines or braided synthetics increase the capabilities of the extremely light outfit.

Working tools of a serious big-game angler might include a rod with six-ounce tip, fitted with a reel filled with 30-pound (14-kilogram) test line. This outfit is suitable for smaller species but capable of fish up to 50 or 60 pounds (23 or 27 kilograms). An intermediate outfit would include an eight-ounce (230-gram) tip and 50-pound (23-kilogram) test line. The heavy-duty outfit, with strength for all but the largest fish, would comprise a 14-ounce (400-gram) tip with 80-pound (36-kilogram) test line. For giant bluefin tuna, broadbill swordfish, black marlin, blue marlin, and exceptionally heavy sharks a 22-ounce (620-gram) tip may be required. Required line will test at 130 pounds (59 kilograms).

If weight records of the various game fishes continue to inch upwards—and they do—the reason must surely bear a relationship to the mounting numbers of anglers. More sports-oriented people with more leisure time discover that fishing is at once a means of relaxation while offering enough complexities to arouse their interest. Manufacturers of tackle, motors, and boats have kept pace with the surging demand for equipment, providing fishermen and boatmen with the benefit of the technical advances of modern industry.

**Contributions to science.** Big-game fishermen have been the beneficiaries of many scientific advances in tackle and boat equipment. In turn, some fishermen have made important contributions to the study of several larger pelagic species. Largely through the cooperative help of anglers, the Woods Hole Oceanographic Institution in the United States has been able to partially map the migrations of several fishes of worldwide importance. This has been done through tagging—the insertion of an imprinted plastic marker in the dorsal muscle of an angled fish, which is then released unharmed. The tags, developed by the institution, are distributed to interested fishermen. Best of the devices is in the form of a dart, which is thrust into a tiring fish as it is brought alongside the boat. The dart is driven home as with a harpoon, the leader is snipped and the weary fish is free to swim off and rejoin the school. Fish caught on rod and reel and promptly released have a much higher survival rate than those netted, hence the recruitment of big-game anglers to the study.

Migrations of large fishes, notably the bluefin tuna, have excited the curiosity of naturalists and fishermen since the time of Aristotle, but it is only since the introduction of the tag that such fishes have been tracked, often with astonishing results. Favourite tagging grounds for the giants is the eastern edge of the Gulf Stream in the Straits of Florida. Of the many fish tagged there during the several years of the study, six bluefins were recaptured in Norwegian waters, establishing beyond doubt that the bluefin is a trans-Atlantic traveller. Four of the fish were recaptured after only 50 to 119 days at large, during which time they must have travelled at least 4,200 nautical miles.

Further confirmation of the tuna's capacity for ranging over great distances resulted from extensive tagging of small fish along the east coast of the United States. From this operation, 36 school tuna of 50 pounds (23 kilograms) or less were recaptured in the Bay of Biscay on the French-Spanish coasts. While evidence is wanting to prove that the roving tuna swims a circuit of the Atlantic, many scientists believe such is the case. The French Institut Scientifique et Techniques des Pêches Maritimes hopes to give substance to the theory with tagging in the European realm of the tuna. European fishermen already have made important progress in tracing movements of bluefin tuna between various fishing grounds off the con-

tinents. Four large tuna released near Bergen, Norway, were recaptured near Cadiz, Spain. Several smaller tuna caught and released off Cadiz supplied clinching evidence that Atlantic tuna mingle with those of the Mediterranean. Two of these tagged fish were recaptured off Ceuta, Morocco, and La Línea, Spain. Another was retaken in the Gulf of Lion off southern France.

From bluefin tuna taggings undertaken by American and Japanese agencies it is now believed there is an interchange of the species from both sides of the Pacific Ocean. Taggings have also shown migrations from West Australia to New Zealand. In other taggings participated in by sportsmen, the Pacific striped marlin has been revealed as a long-distance traveller, as has the Atlantic white marlin, whose migratory circuit has been shown to extend from New England waters to the Caribbean.

#### INTERNATIONAL GAME FISH ASSOCIATION

Sitting in judgment on all big-game fishing in the role of umpire and record-keeper is the International Game Fish Association. While its headquarters is located in Fort Lauderdale, Florida, it functions through member clubs or designated representatives in over 60 regions around the globe, excluding only the Soviet Union and the nations in the Soviet orbit. Established in 1939, largely through the organizational efforts of American big-game fishermen, the IGFA attained international stature in the years of burgeoning ocean sport fishing after World War II. Serious marine fishermen everywhere subscribe to its rules and accept its decisions on record-contending fish. In seeking recognition for a catch the angler will contact either the association headquarters or a regional representative. He will be required to fill out a form provided him. This affidavit will be returned along with ten yards (nine metres) of the line used, as well as a photograph of the catch.

While records seek to spotlight the largest of each of the 49 species in contention, subdivisional records are also kept for all 49 species in several line strength categories. In addition to the all-inclusive All-Tackle class are record categories for 12-pound (five-kilogram) test, 20-pound (nine-kilogram) test, 30-pound (14-kilogram) test, 50-pound (23-kilogram) test, 80-pound (36-kilogram) test and 130-pound (59-kilogram) test lines. Only fish caught according to the rules of the International Game Fish Association are accepted by the association for record purposes.

#### SALTWATER FISH SOUGHT BY ANGLERS

A great variety of saltwater fish furnish sport to surf, shore, and deep-sea anglers. Table 2 lists the most popular saltwater game fishes, their scientific names, areas where caught, weights for a good catch, and descriptive comments. The list includes the species for which world records are kept by the International Game Fish Association. For list of world records see in **SPORTING RECORD** in the *Ready Reference and Index*.

**BIBLIOGRAPHY.** A.J. MCCLANE (ed.), *McClane's Standard Fishing Encyclopedia and International Angling Guide* (1965), covers most types of fishing in many parts of the world.

## Fitzgerald, F. Scott

Francis Scott Key Fitzgerald was the most representative novelist of the American twenties, the decade that saw the emergence of such writers as Faulkner and Hemingway, Sinclair Lewis and John Dos Passos, Ezra Pound and T.S. Eliot. It was a decade so rich in talent that it constituted a kind of American renaissance. Though the fashionable posture in the 1920s was a pose of disillusionment, it was in fact a decade of hope and enthusiasm, of what Fitzgerald was later to call "a romantic readiness" for life, one of those times when people are eager to believe they can wipe out the past and rebuild the world into something far better. In a more representative way than did any other writer of the age, Fitzgerald expressed these feelings for them.

He was born in St. Paul, Minnesota, September 24, 1896, the only son of an unsuccessful, aristocratic father and an energetic, provincial mother. Half the time he thought of himself as the heir of his father's tradition, which included the author of "The Star-Spangled Banner," Francis Scott Key, after whom he was named, and half the time as "straight 1850 potato-famine Irish." As a result he had typically ambivalent American feelings about American life, which seemed to him at once vulgar and dazzlingly promising.

He also had an intensely romantic imagination, what he once called "a heightened sensitivity to the promises of life," and he charged into experience determined to realize those promises. At both St. Paul Academy (1908-10) and Newman School (1911-13) he tried too hard and made himself unpopular, but at Princeton he came close to realizing his dream of a brilliant success. He became a prominent figure in the literary life of the university and made lifelong friendships with Edmund Wilson and John Peale Bishop; he became a leading figure in the socially important Triangle Club and was elected to one of the leading clubs of the university; he fell in love with Ginevra King, one of the beauties of

F. Scott Fitzgerald with his wife, Zelda, and daughter Scottie, c. 1927.  
Culver Pictures

her generation. Then he lost Ginevra and flunked out of Princeton.

He returned to Princeton the next fall, but he had now lost all the positions he coveted, and, in November 1917, he left to join the army. In July 1918, while he was stationed near Montgomery, Alabama, he met Zelda Sayre, the daughter of an Alabama Supreme Court judge. They fell deeply in love, and, as soon as he could, Fitzgerald headed for New York determined to achieve instant success and to marry Zelda. What he achieved was an advertising job at \$90 a month. Zelda broke their engagement, and after an epic drunk, Fitzgerald retired to St. Paul to rewrite for the second time a novel he had begun at Princeton. In the spring of 1920 it was published, he married Zelda, and

Marriage  
to Zelda

riding in a taxi one afternoon between very tall buildings under a mauve and rosy sky, I began to bawl because I had everything I wanted and knew I would never be so happy again.

Immature though it seems today, *This Side of Paradise* was, in 1920, a revelation of the new morality of the young; it made Fitzgerald famous. This fame opened to him magazines of literary prestige, such as *Scribner's*, and high paying popular ones, such as *The Saturday Evening Post*. This sudden prosperity made it possible for him and Zelda to play the roles they were so beautifully equipped for and they became what one of their friends, Ring Lardner, called them, the prince and princess of their generation. Though they loved these roles, they were frightened by them, too, as the ending of Fitzgerald's second novel, *The Beautiful and Damned* (1922), shows. *The Beautiful and Damned* describes a handsome young man and his beautiful wife, who gradually degenerate into a shopworn middle age while they wait for the young man to inherit a large fortune. Ironically, they finally get it, when there is nothing of them left worth preserving.

To escape the life that they feared might bring them to this end, the Fitzgeralds moved in 1924 to the Riviera, where they found themselves a part of a group of Amer-

ican expatriates whose style was largely set by Gerald and Sara Murphy; Fitzgerald described this society in his last completed novel, *Tender Is the Night*, and modelled its hero on Gerald Murphy. Shortly after their arrival in France, Fitzgerald completed his most brilliant novel, *The Great Gatsby* (1925). All of his divided nature is in this novel, the naïve Midwesterner afire with the possibilities of the "American Dream" in its hero, Jay Gatsby, and the compassionate Princeton gentleman in its narrator, Nick Carraway. *The Great Gatsby* is the most profoundly American novel of its time; at its conclusion, Fitzgerald connects Gatsby's dream, his "Platonic conception of himself," with the dream of the discoverers of America.

The next decade of the Fitzgeralds' lives was disorderly and unhappy. Fitzgerald began to drink too much, and Zelda suddenly, ominously, began to practice ballet dancing night and day. In 1930 she had a mental breakdown and in 1932 another, from which she never fully recovered. Through the 1930s they fought to save their life together, and, when the battle was lost, Fitzgerald said, "I left my capacity for hoping on the little roads that led to Zelda's sanitarium." He did not finish his next novel, *Tender Is the Night*, until 1934. It is the story of a psychiatrist who marries one of his patients, who, as she slowly recovers, exhausts his vitality until he is, in Fitzgerald's words, *un homme épuisé* ("a man used up"). Though technically faulty and commercially unsuccessful, this is Fitzgerald's most moving book.

With its failure and his despair over Zelda, Fitzgerald was close to becoming an incurable alcoholic. By 1937, however, he had come back far enough to become a scriptwriter in Hollywood, and there he met and fell in love with Sheila Graham, a famous Hollywood gossip columnist. For the rest of his life—except for occasional drunken spells when he became bitter and violent—Fitzgerald lived quietly with Miss Graham. In October 1939 he began a novel about Hollywood, *The Last Tycoon*. The career of its hero, Monroe Stahr, is based on that of producer Irving Thalberg. This is Fitzgerald's final attempt to create his dream of the promises of American life and of the kind of man who could realize them. In the intensity with which it is imagined and in the brilliance of its expression, it is the equal of anything Fitzgerald ever wrote, and it is typical of his luck that, on December 21, 1940, he died of a heart attack with his novel only half-finished. He was 44 years old.

#### MAJOR WORKS

NOVELS: *This Side of Paradise* (1920); *The Beautiful and Damned* (1922); *The Great Gatsby* (1925); *Tender Is the Night* (1934); *The Last Tycoon*, unfinished (1941).

SHORT STORIES: *Flappers and Philosophers* (1920); *Tales of the Jazz Age* (1922); *All the Sad Young Men* (1926), includes "The Rich Boy" and "Absolution"; *Taps at Reville* (1935).

NOTEBOOKS AND LETTERS: *The Crack-up*, ed. by Edmund Wilson (1945); *Letters*, ed. by Andrew Turnbull (1963).

BIBLIOGRAPHY. JACKSON R. BRYER, *The Critical Reputation of F. Scott Fitzgerald* (1967), contains bibliographies of Fitzgerald's work and of books and articles about him. Fitzgerald's manuscripts and papers are in the Princeton Library, and his novels are all in print. A selection of his short stories was edited by MALCOLM COWLEY in 1951, and *The Fitzgerald Reader*, ed. by ARTHUR MIZENER (1963), contains a selection of novels, short stories, and essays. Other work is collected in *Afternoon of an Author*, ed. by ARTHUR MIZENER (1957); *The Pat Hobby Stories*, ed. by ARNOLD GINGRICH (1962); and *The Apprentice Fiction of F. Scott Fitzgerald*, ed. by JOHN KUEHL (1965). Fitzgerald's letters have been edited by ANDREW TURNBULL (1963). There are two biographies: ARTHUR MIZENER, *The Far Side of Paradise* (1965); and ANDREW TURNBULL, *F. Scott Fitzgerald* (1962). Major critical studies are: H.D. PIPER, *F. Scott Fitzgerald* (1965); ROBERT SKLAR, *F. Scott Fitzgerald* (1967); AARON LATHAM, *Crazy Sundays* (1971); and *F. Scott Fitzgerald: A Collection of Critical Essays*, ed. by ARTHUR MIZENER (1963).

(A.Mi.)

## Flaubert, Gustave

A romantic by temperament, Gustave Flaubert is regarded as the great master of the Realist school of

French literature. Whether he chose a romantic subject (*La Tentation de Saint Antoine*) or one that seemed better suited to the doctrines of Realism (*Madame Bovary*), his work was always based on scrupulous research and observation. He was an indefatigable stylist who strove for complete objectivity and precise expression of the underlying emotions of his characters. His profound compassion for the characters in his novels and his relentless contempt for the bourgeoisie are particularly evident in *Madame Bovary*.

Flaubert, drawing by E.F. von Liphart, 1880. In the Bibliothèque Municipale, Rouen, France.

**Early life and works.** Flaubert was born in Rouen on December 12, 1821. His father, Achille Cléophas Flaubert, who was from Champagne, was chief surgeon and clinical professor at the Hôtel-Dieu hospital in Rouen. His mother, a doctor's daughter from Pont-l'Évêque, belonged to a family of distinguished magistrates typical of the great provincial bourgeoisie.

Gustave Flaubert began his literary career at school, his first published work appearing in a little review, *Le Colibri*, in 1837. He early formed a close friendship with the young philosopher Alfred Le Poittevin, whose pessimistic outlook had a strong influence on him. No less strong was the impression made by the company of great surgeons and the environment of hospitals, operating theatres, and anatomy classes, with which his father's profession brought him into contact. It was, for instance, with Jules Cloquet, the most learned anatomist of his time, that Flaubert, on receiving his *baccalauréat* in 1840, was sent by his father to visit the Pyrenees and Corsica. Later, on reading *Graziella*, Flaubert was to remark that Alphonse de Lamartine would have written a more powerful novel if he had had a doctor's eye.

Flaubert's intelligence, moreover, was sharpened in a general sense. He conceived a strong dislike of accepted ideas (*idées reçues*), of which he was to compile a "dictionary" for his amusement. He and Le Poittevin invented a grotesque imaginary character, called "le Gargon," to whom they attributed whatever sort of remark seemed to them most degrading. Flaubert came to detest the "bourgeois," by which he meant anyone who "has a low way of thinking."

In November 1841 Flaubert was enrolled as a student at the Faculty of Law in Paris. At the age of 22, however, he was recognized to be suffering from a nervous disease that was taken to be epilepsy, although the essential symptoms were absent. This made him give up the study of law, with the result that henceforth he could devote all his time to literature. His father died in January 1846, and his beloved sister Caroline died in the following March after giving birth to a daughter. Flaubert then retired with his mother and his infant niece to his estate at Croisset, near Rouen, on the Seine. He was to spend nearly all the rest of his life there.

On a visit to Paris in July 1846, at the sculptor James

Early influences and friendships

Last years in Hollywood

Liaison  
with  
Louise  
Colet

Pradier's studio, Flaubert met the poet Louise Colet. She became his mistress, but their relationship did not run smoothly. His self-protecting independence and her jealousy made separation inevitable, and they parted in 1855.

In 1847 Flaubert went on a walking tour along the Loire and the coast of Brittany with the writer Maxime du Camp, whose acquaintance he had made as a law student. The pages written by Flaubert in their journal of this tour "over fields and shores" were published after his death under that title, *Par les champs et par les grèves*. This book contains some of his best writing—e.g., his description of a visit to Chateaubriand's family estate, Combourg.

**Mature career.** Some of the works of Flaubert's maturity dealt with subjects on which he had tried to write earlier. At the age of 16, for instance, he completed the manuscript of *Mémoires d'un fou*, which recounted his devastating passion for Elisa Schlésinger, 11 years his senior and the wife of a music publisher, whom he had met in 1836. This passion was only revealed to her 35 years later when she was a widow. Elisa provided the model for the character Marie Arnoux in the novel *L'Éducation sentimentale*. Before receiving its definitive form, however, this work was to be rewritten in two distinct intermediate versions in manuscript: *Novembre* (1842) and a preliminary draft entitled *L'Éducation sentimentale* (1843–45). Stage by stage it was expanded into a vast panorama of France under the July Monarchy—indispensable reading, according to Georges Sorel, for any historian studying the period that preceded the coup d'état of 1851.

Composition  
of *La  
Tentation  
de Saint  
Antoine*

The composition of *La Tentation de Saint Antoine* provides another example of that tenacity in the pursuit of perfection that made Flaubert go back constantly to work on subjects without ever being satisfied with the results. In 1839 he was writing *Smarh*, the first product of his bold ambition to give French literature its *Faust*. He resumed the task in 1846–49, in 1856, and in 1870 and finally published the book as *La Tentation de Saint Antoine* in 1874. The four versions show how the author's ideas changed in the course of time. The version of 1849, influenced by Spinoza's philosophy, is nihilistic in its conclusion. In the second version the writing is less diffuse, but the substance remains the same. The third version shows a respect for religious feeling that was not present in the earlier ones, since in the interval Flaubert had read Herbert Spencer and reconciled the Spencerian notion of the Unknown with his Spinozism. He had come to believe that science and religion, instead of conflicting, are rather the two poles of thought. The published version incorporated a catalog of errors in the field of the Unknown (just as *Bouvard et Pécuchet* was to contain a list of errors in the field of science).

From November 1849 to April 1851 Flaubert was travelling in Egypt, Palestine, Syria, Turkey, Greece, and Italy with Maxime du Camp. Before leaving, however, he wanted to finish *La Tentation* and to submit it to his friend the poet Louis Bouilhet and to du Camp for their sincere opinion. For three days in September 1849 he read his manuscript to them, and they then condemned it mercilessly. "Throw it all into the fire, and let's never mention it again," Bouilhet gave further advice: "Your Muse must be kept on bread and water or lyricism will kill her. Write a down-to-earth novel like Balzac's *Parents pauvres*. The story of Delamare, for instance. . . ."

Sources of  
*Madame  
Bovary*

Eugène Delamare was a country doctor in Normandy who died of grief after being deceived and ruined by his wife, Delphine (*née* Couturier). The story, in fact that of *Madame Bovary*, is not the only source of that novel. Another was the manuscript *Mémoires de Mme Ludovica*, discovered by Gabrielle Leleu in the library of Rouen in 1946. This is an account of the adventures and misfortunes of Louise Pradier (*née* d'Arcet), the wife of the sculptor James Pradier, as dictated by herself; and, apart from the suicide, it bears a strong resemblance to the story of Emma Bovary. Flaubert, out of kindness as well as out of professional curiosity, had continued to see Louise Pradier when the "bourgeois" were ostracizing her

as a fallen woman, and she must have given him her strange document. Even so, when inquisitive people asked him who served as model for his heroine, Flaubert replied, "Madame Bovary is myself." As early as 1837 he had written *Passion et vertu*, a short and pointed story with a heroine, Mazza, resembling Emma Bovary. For *Madame Bovary* he took a commonplace story of adultery and made of it a book that will always be read because of its profound humanity. While working on his novel Flaubert wrote: "My poor Bovary suffers and cries in more than a score of villages in France at this very moment." *Madame Bovary*, with its unrelenting objectivity—by which Flaubert meant the dispassionate recording of every trait or incident that could illuminate the psychology of his characters and their role in the logical development of his story—marks the beginning of a new age in literature.

*Madame Bovary* cost the author five years of hard work. Du Camp, who had founded the periodical *Revue de Paris*, urged him to make haste, but he would not. The novel, with the subtitle *Moeurs de province* ("Provincial Customs"), eventually appeared in installments in the *Revue* from October 1 to December 15, 1856. The French government then brought the author to trial on the ground of his novel's alleged immorality, and he narrowly escaped conviction (January–February 1857). The same tribunal found the poet Charles Baudelaire guilty on the same charge six months later.

To refresh himself after his long application to the dull world of the bourgeoisie in *Madame Bovary*, Flaubert immediately began work on *Salammbô*, a novel about ancient Carthage, in which he set his sombre story of Hamilcar's daughter Salammbô, an entirely fictitious character, against the authentic historical background of the revolt of the mercenaries against Carthage in 240–237 BC. His transformation of the dry record of Polybius into richly poetic prose is comparable to Shakespeare's treatment of Plutarch's narrative in the lyrical descriptions in *Antony and Cleopatra*. A play, *Le Château des coeurs*, written in 1863, was not printed until 1880.

**Later years.** The merits of *L'Éducation sentimentale*, which appeared a few months before the outbreak of the Franco-German War of 1870, were not appreciated, and Flaubert was much disappointed. Two plays, *Le Sexe faible* and *Le Candidat*, likewise had no success, though the latter was staged for four performances in March 1874. The last years of his life, moreover, were saddened by financial troubles. In 1875 his niece Caroline's husband, Ernest Commanville, a timber importer, found himself heavily in debt. Flaubert sacrificed his own fortune to save him from bankruptcy. Flaubert sought consolation in his work and in the friendship of George Sand, Ivan Turgenev, and younger novelists—Émile Zola, Alphonse Daudet, and, especially, Guy de Maupassant, who was the son of his friend Alfred Le Poittevin's sister Laure and who regarded himself as Flaubert's disciple.

Flaubert temporarily abandoned work on a long novel, *Bouvard et Pécuchet*, in order to write *Trois Contes*, containing the three short stories "Un Coeur simple," a tale about the drab and simple life of a faithful servant; "La Légende de Saint Julien l'Hospitalier"; and "Hérodias." This book, through the diversity of the stories' themes, shows Flaubert's talent in all its aspects and has often been held to be his masterpiece.

The heroes of *Bouvard et Pécuchet* are two clerks who receive a legacy and retire to the country together. Not knowing how to use their leisure, they busy themselves with one abortive experiment after another and plunge successively into scientific farming, archaeology, chemistry, and historiography, as well as taking an abandoned child into their care. Everything goes wrong because their futile book learning cannot compensate for their lack of judgment.

The profound meaning of *Bouvard et Pécuchet*, which was left unfinished by Flaubert and which was not published till after his death, has been seriously misunderstood by those critics who have regarded it as a denial of

Theme  
and  
character-  
istics of  
*Bouvard et  
Pécuchet*

the value of science. In fact it is "scientism" (and by analogy the confusion of doctrines) that Flaubert is arraigning—i.e., the practice of taking science out of its own domain, of confusing efficient and final causes, and of convincing oneself that one understands fundamentals when one has not even grasped the superficial phenomena. Intoxicated with empty words, Bouvard and Pécuchet awake from their dream only when catastrophe overtakes all of their efforts.

Flaubert has been accused of presenting them as imbeciles, but in fact he expresses his compassion for them: "They acquire a faculty deserving of pity, they recognize stupidity and can no longer tolerate it. Through their inquisitiveness their understanding grows; having had more ideas, they suffered more." Flaubert's satire is thus to some extent the history of his own experience told with a sad humour.

Flaubert died suddenly of an apoplectic stroke on May 8, 1880. He left on his table an unfinished page and notes for the second volume of his novel. Bouvard and Pécuchet, tired of experimenting, were to go back to the work of transcribing and copying that they had done as clerks. The matter that they chose to transcribe was the subject of the notes: it was to be a selection of quotations, a *sottisier*, or anthology of foolish remarks. There has been much controversy about this bitter conclusion, as the form that it was to take was left undetermined in the notes Flaubert left, though the materials were gathered and have been published.

**Method of composition.** Flaubert's aim in art was to create beauty, and this consideration often overrode moral and social issues in his depiction of truth. He worked slowly and carefully, and, as he worked, his idea of his art became gradually more exact. His letters to Louise Colet, written while he was working on *Madame Bovary*, show how his attitude changed. His ambition was to achieve a style "as rhythmical as verse and as precise as the language of science" (letter of April 24, 1852). In his view "the faster the word sticks to the thought, the more beautiful is the effect." He often repeated that there was no such thing as a synonym and that a writer had to track down *le seul mot juste*, "the unique right word," to convey his thought precisely. But at the same time he always wanted a cadence and a harmony of sounding syllables in his prose, so that it would appeal not only to the reader's intelligence but also to his subconscious mind in the same way as music does and thus have a more penetrating effect than the mere sense of the words at their face value. Composition for him was a real anguish.

Flaubert sought objectivity above all else in his writing: "The author, in his work, must be like God in the Universe, present everywhere and visible nowhere." It is paradoxical, therefore, that his personality should be so clearly discernible in all his work and that his letters, written casually to his intimates and full of disarming sincerity, delicate sensibility, and even exquisite tenderness—side by side with jovial coarseness of expression—should be considered by some critics as his masterpiece.

(R.Dum./J.Ba.)

#### MAJOR WORKS

**NOVELS:** *Madame Bovary*, *Moeurs de province*, 2 vol. (1857), notable translations are those by Gerard Hopkins (1949) and F. Steegmüller (1957); *Salammbô* (1862; *Salambo*, trans. by E. Powys Mathers, new ed., 1950); *L'Education sentimentale: Histoire d'un jeune homme*, 2 vol. (1870; *Sentimental Education*, trans. by Robert Baldick, 1964); *La Tentation de Saint Antoine* (1874; *The First Temptation of Saint Anthony*, trans. from the version of 1856 by René Francis, new ed., 1924; *The Temptation of Saint Anthony*, trans. by Lafcadio Hearn, new ed., 1932); *Trois Contes* ("Un Coeur simple," "La Légende de Saint Julien l'Hospitalier," and "Hérodias," 1877; *Three Tales*, trans. by Robert Baldick, 1961); *Bouvard et Pécuchet: Oeuvre posthume* (1881; *Bouvard and Pécuchet*, trans. by T.W. Earp and G.W. Stonier, 1936); *Novembre* (1928; Eng. trans., 1932).

**PLAYS:** *Le Candidat* (1874); *Le Château des coeurs* (1885). **OTHER WORKS:** *Par les champs et par les grèves* (1886); *Le Dictionnaire des idées reçues* (1913; *Flaubert's Dictionary of Accepted Ideas*, trans. by Jacques Barzun, 1954); *Bibliomanie* (1926; Eng. trans., 1929).

**BIBLIOGRAPHY.** The definitive text of Flaubert's novels, short stories, and travel notes is the critical edition, 12 vol. (1938-46), by RENE DUMESNIL, which gives variant readings and an introduction and annotations. For Flaubert's juvenilia and for his plays, reference may be made to the Conard edition, 9 vol. (1926-33), and to the *Supplément à la correspondance générale*, 4 vol. (1954), ed. by RENE DUMESNIL, JEAN POMMIER, and CLAUDE DIGEON.

The standard biography is RENE DUMESNIL, *Gustave Flaubert: l'homme et l'oeuvre* (1932); for a record in English of his life, see P. SPENCER, *Flaubert: A Biography* (1952). Flaubert's passion for Elisa Schlésinger is the subject of E. GERARD-GAILLY, *L'Unique passion de Flaubert* (1932) and *Le Grand amour de Flaubert* (1944). A.A. BERTRAND, *Gustave Flaubert et ses amis* (1927), gives an account of Flaubert's significant relationships with contemporary writers and thinkers.

Of the many critical works on Flaubert, the following 19th-century studies are especially recommended: G. SAINTSBURY, "Gustave Flaubert," *Fortnightly Review*, 29:575-595 (1878); P. BOURGET, *Essais de psychologie contemporaine* (1883, also 1920); and F. BRUNETIERE, *Le Roman naturaliste* (1896). The novelist's work is put into historical perspective in L. DE-GOUMOIS, *Flaubert à l'école de Goethe* (1925); F. MAURIAC, *Trois grands hommes devant Dieu* (1930), compares Flaubert to Molière and Rousseau. A. THIBAUDET, *Gustave Flaubert* (1935), and E. MAYNIAL, *Flaubert* (1943), combine biography with critical chapters on the major works and on style and aesthetics.

There have been a great number of studies that deal with the individual works by Flaubert, but among the more modern general criticism are: V.H. BROMBERT, *The Novels of Flaubert* (1966); STRATTON BUCK, *Gustave Flaubert* (1966); and B.F. BART, *Flaubert* (1967). ENID STARKIE, *Flaubert: The Making of the Master* (1967), is a penetrating analysis. Flaubert's influence on, and links with, modern literary developments are discussed by H. KENNER, *The Stoic Comedians* (1964), a comparative study of Flaubert, Joyce, and Beckett; and by J.L. DOUCHIN, *Le Sentiment de l'absurde chez Gustave Flaubert* (1970). JEAN-PAUL SARTRE, *L'Idiot de la famille: Gustave Flaubert*, 2 vol. (1971), is a study of the novelist, whom the writer uses as a tool for his own dissection of France's bourgeoisie.

## Flight, History of

It is a curious fact, but true, that man's age-long observation of birds in flight impeded, rather than accelerated, the development of man flight. All human attempts to fly on flapping wings led only to frustration or disaster, for what comes naturally to birds is almost certainly impossible for man to duplicate with his clumsy mechanisms. The only valid bird flight/man flight analogue appears to be in gliding and soaring. Wing flappers (ornithopters) have contributed little to man-flight history, and, although some research is still in progress, they seem likely to be of little significance.

In this article, the generic term man flight is used to describe any human navigation above the surface of the earth in any form of vehicle—balloon, airship, glider, powered aircraft, rocket, etc. "Aviation" refers generally to flight in heavier-than-air craft. "Aeronautics" is the science of aviation; "aerostatics" is the science of lighter-than-air flight; and "astronautics" is the science of space flight. A fuller treatment of certain specialized areas of this subject will be found in AIRCRAFT; AIRCRAFT, MILITARY; ROCKETS AND MISSILE SYSTEMS; and TRANSPORTATION, AIR.

From a historian's point of view, exploring the development of man flight is a rewarding exercise. A substantial percentage of the significant events to be dealt with have occurred within the memory of persons still living in the 1970s, and many of the early experimenters were themselves articulate. Their notebooks and other records have been preserved, and a considerable amount of the actual hardware with which they worked still exists. Of greater importance, the invention and development of flight vehicles coincided historically with the development of photographic processes. Excellent visual records of many of the men, machines, and events that made flight history are available.

The subject has always attracted widespread coverage by the press, sometimes with dubious accuracy. Fortu-

Importance of the "right" word

nately, it also engaged the serious attention of scholars concerned with separating fact from fancy. James Means of Boston, an early collector and compiler of aeronautical literature, made a notable contribution in this area with the publication of his *Aeronautical Annals*—in 1895, '96, and '97. More recently, Charles Dollfus and Henri Bouché in France, J.E. Hodgson and Charles Gibbs-Smith in England, and Paul Garber of the Smithsonian Institution in the U.S. have established a firm and factual base for future air historians to build on. Other important contributors include V.M. Sokolsky in the Soviet Union, Ernst Klee in Germany, and Hidemasa Kimura in Japan. Their published works have provided prime sources of information for this condensed survey of flight history.

This article is divided into the following sections:

- I. Flights of fancy
- II. Developments to 1900
  - Lighter-than-air—early speculations

## I. Flights of fancy

Had the early philosophers not been obsessed with the wing-flapping flight of birds, something resembling the gliders of the late 19th century might have evolved earlier. All the necessary materials—woods, fabrics, and cordage—were readily at hand, and skilled craftsmen were plentiful. What was lacking was the concept of air as a fluid and of its behaviour as it flows around three-dimensional bodies (see AIRCRAFT).

Practically all religions clothed their celestial beings in birdlike forms. Egyptian, Minoan, and Syrian deities were equipped with magnificent wings. The Greek and Roman gods and goddesses seemed to fly without visible means of support (except for Mercury with his winged heels), but the seraphim and cherubim of the Hebrews and the heavenly hosts of later persuasions were all provided with wings.

As time went on, earthly kings often assumed the role and perquisites of deities. Accordingly, magicians and court historians were called upon to create, if not the fact, at least the legend that their masters had been airborne. Thus, during the Han dynasty in China (206 BC to AD 220), the emperor was reputed to have travelled far in his flying chariot, while the throne of the Persian king Keykāvūs was supposed to have been airborne by four eagles.

In Europe serious speculation about man flight occupied such thinkers as Roger Bacon (c. 1214–1294) and Leonardo da Vinci (1452–1519). John Wilkins (1614–1672), lord bishop of Chester and one of the founders of the Royal Society, summarized four possible ways in which man might fly: (1) with the spirits of angels, (2) with the help of fowls, (3) with wings fastened to his body, and (4) in a flying chariot. He questioned the practicability of the first three but forecast the evolution of the fixed-wing airplane thus:

If fowl can so easily move itself up and down in the air without so much as stirring the wings . . . it is not improbable that when all due proportions of [a suitable apparatus] are found out, and when men by long practice have arrived to any skill and experience, they will . . . come very near unto the imitation of Nature.

During the next 100 years, science-fiction writers popularized the idea of flight—including space flight. Francis Godwin (1562–1633), Samuel Brunt (c. 1727), Cyrano de Bergerac (1619–1655), and others described flights to the moon and elsewhere. Restif de la Bretonne (1734–1806) pictured explorers cruising over wilderness areas of Australia on a combination of batwings and umbrellalike devices.

The invention of the balloon in 1783 brought the imaginative writers back to earth. Once a means had been found for man to leave the ground, fancy became somewhat related to fact; and for a time, fantastic adventures by balloon and airship were popular subjects.

Toward the end of the 19th century, the greatest of aviation fiction writers, Jules Verne (1828–1905), emerged in France. He himself was not an inventor and made only one balloon ascension in his life (with Godard at Amiens in 1873), but in imagination he developed an extraordinarily prophetic feeling for the future of the in-

ventions of his day. He wrote of exploratory voyages around the world by airship and by helicopter and forecast a rocket trip to the moon from a launching site in Florida. He even described in detail the weightlessness that space travellers were to experience in flight.

## II. Developments to 1900

### LIGHTER-THAN-AIR—EARLY SPECULATIONS

It took many years for man to realize that the air around him was a thing, not impalpable nothingness extending to the outer limits of the sky. The invention of the mercury barometer in 1643 provided the first proof that air was, in fact, a gas that not only had weight but that also responded (as do all gases) to changes in temperature and pressure. Once that was recognized, the way was opened for speculation as to why smoke rose through air. Eventually, as advancing scientific sophistication permitted the isolation of lighter-than-air gases, it was logical to think of a bubble of such gas floating like a cork in a sea of denser air. The first hint of the application of this concept occurs in the notes of the medieval philosopher Roger Bacon, after which, for many years, nothing further was recorded on the subject.

About 1670 a Jesuit monk, Francesco de Lana, hit upon the same idea, but in reverse. He concluded that no air should be lighter than some air and, therefore, that a bubble of vacuum should rise through, and at some point of equilibrium, float about in the denser atmospheric air. He published a design for a man-carrying airship supported by four such vacuum balloons. The theory was good, but its realization was difficult. The thin copper spheres he proposed to evacuate would have collapsed under the external air pressure long before any measurable lifting force was developed. Impractical as it was, the concept was a notable philosophical achievement for the time. De Lana abandoned any effort to develop it, however, on the ground that any attempt to fly would be regarded by the Creator as impious.

Later (c. 1755), after the structure of the Earth's atmosphere was better understood, another priest, Galien, in France, reasoned that a bagful of low-density air collected from the higher altitudes should float about at lower levels and could support a considerable load. In 1766 the isolation of hydrogen by the British chemist Henry Cavendish had a profound effect on lighter-than-air activity. Although the special properties of hydrogen had been known to scientists since 1766, its application to aeronautics (or, more properly, to aerostatics) did not occur to anyone for well over a decade. The honour of the first lighter-than-air demonstration and subsequently the first man flight went to a much more common gas—hot air.

### BALLOONS AND BALLOONISTS (1783–1900)

**The work of the Montgolfiers and J.-A.-C. Charles.** The inventors of the balloon were Joseph and Étienne Montgolfier, sons of a paper manufacturer of Annonay, in southeastern France. Watching smoke rise in the chimney, they had concluded that it possessed some mysterious property, which they called "levity." They made up a small silk bag, which they held over a fire. It filled with smoke and, when released, rose to the ceiling. After several other private experiments, they issued invitations to all the citizens of Annonay (including members of the Departmental Council, who happened to be meeting at the time) to assemble in the town square on June 5, 1783, to witness an ascension of their "Globe Aérostatique." This was a spherical bag about 30 feet in diameter (about 23,000 cubic feet), made up of light fabric backed by paper. Early prints show it as fastened together by rows of buttons and buttonholes. Held over a smoky fire fuelled by chopped wool and straw (it was assumed that "levity" was a special property of smoke), it rapidly inflated to its full spherical form and, to the great astonishment of the audience, rose rapidly (allegedly over a mile in the air) and drifted more than a mile and a half from its starting point before touching down.

The excitement was great, and reports of the event spread rapidly throughout France. The Academy of Sciences asked for full information, and Étienne journeyed to Paris to report to that distinguished body.

**Use of hydrogen.** Even before Étienne arrived in Paris, the physicist J.-A.-C. Charles, with the assistance of two Robert brothers, Anne-Jean and Nicolas-Louis, sought to duplicate the Montgolfier performance. Not knowing then of the simple means used to inflate the balloon at Annonay, they adopted the newly isolated gas, hydrogen. (For some years thereafter, any hydrogen balloon in France was called a "Charlière.") They fabricated a balloon of varnished silk, some 15 feet in diameter, and produced hydrogen to fill it on a scale never before attempted. Released from the Champ de Mars, Paris, before an enthusiastic crowd, on the afternoon of August 27, 1783, it rose through a heavy rainstorm and descended some 15 miles away near the small village of Gonesse. The local peasants, alarmed by the apparition descending from the clouds, attacked the "monster" with scythes and pitchforks and tore it to pieces.

On September 12 Joseph Montgolfier appeared by invitation before the Academy (Benjamin Franklin was in the audience) to describe the work at Annonay. Montgolfier was invited to repeat his experiment before Louis XVI and his court at Versailles. A large aerostat was built but was destroyed in a storm four days before the scheduled event. A new one was hastily put together, and at about

The Montgolfiers' "Globe Aérostatique"

1:00 PM on September 19, 1783, it was released from the Great Court at Versailles carrying a sheep, a rooster, and a duck as passengers. The objective was to determine whether or not high-altitude travel had any deleterious effects on living creatures. They survived the ordeal, and the stage was set for man's first venture into the air.

A new and enlarged aerostat—some 70 feet in height—was prepared. It differed from its predecessors in having a circular gallery slung beneath it for the accommodation of the aeronauts, with arrangements for maintaining a smoky fire of straw and wool during flight. At first it was proposed that a pair of condemned criminals be used for the experiment. One Jean-François Pilâtre de Rozier, who had volunteered for the flight, however, protested that such were not worthy of the honour of being first to take to the air. In this he was joined by François Laurent, marquis d'Arlandes, who wished to share the adventure.

Louis XVI finally gave his consent, and after a number of tethered test flights (the longest of which lasted nine minutes at an altitude of 320 feet), Pilâtre and d'Arlandes took off in free flight from the Jardin de la Muette in the Bois de Boulogne. The date was November 21, 1783. Some 23 minutes later, after reaching an altitude of over 3,000 feet and an estimated distance of something short of ten miles, they landed safely near Gentilly, to complete man's first aerial voyage (see Figure 1, left).

Shortly thereafter (December 1, 1783), J.-A.-C. Charles, accompanied by Nicolas-Louis Robert, took off from the Tuileries Gardens in a large "Charlière." About two hours and 27 miles later, the balloon descended gently near the small town of Nesle, northeast of Paris. Robert climbed out of the car. The lightened balloon with Charles aboard promptly rose and continued the flight to land finally some miles away near Tour-de-Laye.

A comparison of notes by the aeronauts at once established the supremacy of the hydrogen balloon. Whereas Pilâtre de Rozier and d'Arlandes had remained airborne only by continuous labour to keep their smoky fire alive, Charles and Robert had drifted comfortably over the landscape without effort. The pattern for future development was thus set. The explosive nature of hydrogen gas was only learned later, over subsequent decades and at a cost of a number of lives. It was not until the loss of the German airship "Hindenburg" at Lakehurst, New Jersey, in 1937, that hydrogen was abandoned as a lifting gas.

**Broadening interest.** Meanwhile, the Paris flights stirred a worldwide interest in ballooning that carried into the 20th century. In the first 50 years following 1783, over 800 ascensions were made in England alone, and over 470 aeronauts (persons known to have made one or more flights) were recorded. Forty-nine of these were women.

Many names crowd the early records. Notable among them was Jean-Pierre Blanchard, who between 1784 and 1809 made flights in most European capitals. He crossed the English Channel by air on January 7, 1785, accompanied by a Boston physician, John Jeffries. He made the first balloon flight in America at Philadelphia on January 9, 1793, in the presence of George Washington and indoctrinated John Wise, the first American balloonist. Blanchard performed the earliest experiments in parachuting, using animals as subjects. He died in Paris in March 1809 after a fall from a balloon.

Among other experimenters of the period were the Sadlers, father and son, of Ireland; Lunardi and Zambecari of Italy; Gay-Lussac and Biot in France; and Green and Coxwell in England. The latter four are credited with making the first scientific observations of meteorological phenomena and of human behaviour in the upper atmosphere.

Félix Nadar of France must be mentioned on two counts: (1) he made the first aerial photographs from a captive balloon in 1858 and many successful aerial photographs (1863) from a huge balloon, "Le Gèant," fitted with a complete photographic laboratory; and (2) he was instrumental in organizing the *Ballon Poste*, which carried mail and passengers out of Paris during the siege in 1870.

**Military balloons.** The potential of the balloon in military situations had long been recognized. Francesco de Lana, who had proposed the use of vacuum globes (1670) as noted, had foreseen the advantages of balloons in war but concluded that "God would not suffer such an invention to take effect, by reason of the disturbance it would cause to the civil government of men." In spite of such forebodings, the first balloon corps in history was formed in France in 1793. Captive observation balloons were used at the siege of Mainz in 1794, and free balloons took part in the Battle of Fleurus in June 1794.

During the American Civil War, observation balloons were in use by both sides. T.S. Lowe, a Connecticut Yankee and a pupil of John Wise, provided four balloons and their portable gas generators to the Federal Army's Aeronautics Corps. These were used during the campaigns of 1862–63 for observation, and the westward movement of Lee's army from its Rappahannock camp to start the Gettysburg campaign was first detected by balloon observation. At one time, direct telegraphic communication was established between a balloon and the White House. The Confederacy made only two known attempts to launch observation balloons—one of the hot air variety and one filled with illuminating gas at Richmond—but neither was particularly successful.

**Ill-fated North Pole attempt.** The last great ballooning adventure of the 19th century began when August Andrée and two companions, Strindberg and Fraenkel, set out July 11, 1897, from the island of Spitsbergen, in a free balloon, to attempt to drift across the North Pole. They vanished into the Arctic wastes. Some 33 years later (1930), a Norwegian exploring party discovered their frozen bodies, together with Andrée's journal and even photographic plates, which were developed and printed. The balloon had drifted eastward, off course, and gone down; Andrée and his crew had been able to survive the crash but had perished in their attempt to walk back to civilization.

#### AIRSHIPS PRIOR TO 1900

From earliest ballooning days, man sought to free himself from his dependence upon the uncertain winds. Truly to navigate the skies, propulsion was needed. Sails, oars, and paddle wheels for balloons were tried repeatedly. All failed. Not until the principle of the Archimedean screw was revived and applied to propulsion was any degree of success attainable.

The transformation of the spherical free balloon into a navigable airship required two things: adoption of the cigar shape, and invention of an adequate power plant.

Gen. J.-B.-M. Meusnier of the Engineer Corps of the French Army came close to many of the right answers—on paper—as early as 1783, but he was well ahead of the state of the mechanical arts and died before anything practical could be accomplished.

A century passed before the first airship capable of steady flight under control, able to return to its starting point at will, could be demonstrated. Meanwhile, many inventors tried, and some nearly made it. Sir George Cayley, the "father of British aeronautics" (see below *Heavier-than-air—the experimenters*), like Meusnier, committed his ideas on airship design to paper (1816–34) but never reduced them to practice.

**Early power plants.** The greatest drawback of the time was lack of a lightweight, self-contained power plant. A model airship driven by clockwork was demonstrated in London in 1843. Later (1850), a Parisian clockmaker, Pierre Jullien, built a model, "Le Précurseur" (also fitted with clockwork power), that incorporated all the elements of a modern, nonrigid airship.

In 1852, making use of the sketches of Meusnier and Cayley and inspired by Jullien's model, Henri Giffard built a steam-driven airship with a cigar-shaped gasbag some 144 feet in length with a capacity of 88,000 cubic feet. He took off from the Hippodrome in Paris on September 24, 1852, and flew under control to Elancourt, near Trappes. He did not attempt to fly against the wind nor to return to his point of departure, but the date establishes the beginning of man's practical conquest of the

### The first dirigibles

air. It also marked the introduction of the term dirigible, meaning steerable, as applied to airships. The terms airship and dirigible since then have remained almost synonymous.

Several attempts at airship design were reported from America between 1866 and 1870; e.g., the Marriott steam-driven dirigible in San Francisco and a pedal-powered, elongated balloon of Solomon Andrews from Perth Amboy, New Jersey. Neither was a success.

In 1865 a German inventor, Paul Haenlein, filed a patent for a semirigid airship to be driven by an internal-combustion gas engine. The machine, 164 feet long, was actually built in 1872 but lacked sufficient power for effective propulsion and control.

An interesting but abortive attempt to apply electric power to airships occurred in 1883. Gaston and Albert Tissandier, inspired by the Exposition d'Électricité in Paris in 1881, built a small, elongated dirigible powered by an electric motor and a large bank of lead storage batteries. The ship made a trial flight on October 8, 1883, but its heavy batteries and feeble power made it helpless in even the mildest breeze, and the Tissandiers shortly abandoned their effort.

Success finally came on August 9, 1884, when two French army captains, Charles Renard and A.-C. Krebs, flew the airship "La France" from Chalais-Meudon to Villacoublay and back in 23 minutes. "La France" was also electrically powered, but its large lifting capacity, coupled with redesigned and more efficient electrical motor and batteries, made the difference. A number of other successful flights were made in the months following. Although only little further work was done with electrical power, the day of controlled mechanical flight had finally arrived.

The closing years of the 19th century were marked by the appearance in Paris of one of the most colourful figures in flight history—the Brazilian-born sportsman-scientist Alberto Santos-Dumont. He built and flew his first small airship in 1898 and continued his experiments first in lighter-than-air and subsequently in heavier-than-air craft well into the first decade of the 20th century (see below *Aviation in adolescence; Balloons and airships*).

Beginning in 1896, Germany took an active interest in airships. Even before Graf von Zeppelin launched his first large, rigid airship in 1900 (see below *Balloons and airships*), two interesting developments appeared: the Wölfert dirigible, "Deutschland" (June 1897), and the Schwarz all-metal airship (November 1897). Neither was successful; both crashed during test flights. But Wölfert was the first to install a gasoline engine in any flight vehicle, and Schwarz pioneered the use of thin sheet aluminum (a relatively rare metal at the time) as a covering material for aircraft.

### HEAVIER-THAN-AIR—THE EXPERIMENTERS

**George Cayley.** Throughout the years, the conflicting

claims of inventors to priority have plagued aviation historians. On one point, however, there is clear consensus. The title of "father of British aeronautics" and, in fact, of all aeronautics rests with Sir George Cayley.

It is true that Leonardo had sketched wing-flapping devices and even a form of helicopter (c. 1500), and kites in many forms were commonplace prior to the 17th century. Also, the records of the 18th century contain accounts of many weird and wonderful machines for mechanical man flight. But at that time, as always, men's dreams far exceeded their scientific and technical capabilities.

It was in the early 1800s that George Cayley came upon the scene. Charles Dollfus characterizes Cayley as "the outstanding technical mind [in the field of flight] of the first third of the nineteenth century . . . the true inventor of the airplane . . . one of the most powerful geniuses in the history of aviation."

Cayley's active interest in man flight spanned the years from 1792 to his death in 1857. A perceptive theorist and an active experimenter with models (see Figure 2, left) and with full-scale gliders, he eventually had at his disposal all the aerodynamic theory required for the design of a man-carrying airplane. The problem, as he saw it, was "to make a surface support a given weight by the application of sufficient power to overcome the resistance of the air." Unfortunately, no light-weight, self-contained power plant was then available. That vital component was still half a century away.

This was the problem that plagued all inventors who considered the flight of heavier-than-air craft up to the end of the 19th century. Until earthbound automobiles generated a requirement for a compact power plant that could operate on available liquid fuels, would-be aircraft designers saw no choice but to turn to the crude steam engines of the day. The best of engines, with the necessary boilers, fireboxes, condensers, fuel, and water, ran up the ratio of total weight to available power to an impossibly high figure for aeronautical use. Even now, with the advantages of light metals, high-energy fuels, and the most modern design techniques, no serious attempt is being made to apply steam power to aircraft, though in the 1800s some came remarkably close to configurations resembling successful 20th-century aircraft.

**Glider, models, and kites.** On the record, it is apparent that those who concentrated on experiments with gliding flight made the most substantial contributions toward the final man-flight solution. They did not waste effort in attempts to solve the extremely difficult and costly task of combining crude and undeveloped mechanisms with light and fragile structures. Flights by Cayley and many others in the second half of the 19th century contributed much to basic knowledge of flight in machines without power.

Model makers and kite flyers also made important contributions, notably the mid-century collaboration of Wil-

The search for a suitable power plant

Attempts  
to use  
steam  
power

liam Samuel Henson and John Stringfellow, which resulted in some far-reaching predictions on the format of a modern airplane and on future intercontinental airline operations—but only on paper. The invention of the box kite (1893) by Lawrence Hargrave in Australia had a positive influence on airplane design in the early 1900s.

**Premature attempts at powered flight.** The most conspicuous (and expensive) failures of the period were experienced by those courageous optimists who made premature attempts to take the giant leap to full-scale powered flight without intermediate steps. In 1857 Félix du Temple, a French naval officer, constructed a monoplane design fitted with a locomotive-like boiler and smokestack, but succeeded only in puffing his way down a long ramp without leaving the ground. In 1875 Thomas Moy, a British engineer, in a tethered conglomeration of wires and fabric steamed his way around a circular track, rose briefly for a few inches, but never actually took off.

A more ambitious project took shape in Russia in 1884, when Aleksandr Mozhaysky designed and built a steam-driven monoplane. Launched down the ramp of a ski jump, and airborne for a few seconds before hitting the ground, it provided the basis for a subsequent Russian claim of the world's first airplane flight.

In France, also in 1884, M.-A. Goupil, encouraged by results obtained with a kite-glider prototype, built a bird-like monoplane and a steam power plant to install in it. He never put the two together, and no attempt to fly it ever took place. The construction, however, is of interest on two counts: (1) his design was the first to incorporate opposite-acting ailerons for lateral control, and (2) many years later (1917) Glenn Curtiss, in America, built and flew a reproduction of Goupil's airplane (powered, however, with a gasoline aircraft engine) as a part of his attempt to set aside certain Wright patents covering lateral control devices.

One near miss of the period must be noted. A French self-made engineer and mechanical genius, Clément Ader, built a batlike steam-propelled monoplane that he christened "Eole." On October 9, 1890, on a friend's estate near Paris, he succeeded in leaving the ground under power. He was airborne for some 160 feet (50 metres). This was substantiated by witnesses, but despite Ader's subsequent claims of "flight" the most that can be said is that he made a short-duration hop. It was in no sense a sustained, controlled, powered flight such as was made by the Wrights in 1903, and all subsequent investigations have established that "Eole" was totally incapable of such flight.

Moy's concept of testing tethered aircraft on a circular track appealed to other experimenters. His former associate, Horatio Phillips (who, in 1884 and the years following, patented the first designs for the thick wing sections, with curved upper and lower surfaces, now used on all airplanes), so tested (1893) a curious multiplane model whose wing system resembled a Venetian blind. Except to confirm his own wing theories, no other use was made of the device.

The most spectacular and certainly the most expensive test rig of this character was put together at Baldwyn's Park in Kent by Sir Hiram Maxim, inventor of the Maxim machine gun. Over many years his experiments in aviation, which were said to have cost him some £20,000, culminated finally in the design and construction of a huge steam-driven biplane with two propellers. It was tested in rails on a circular track, fitted with a restraining rail designed to prevent lifting off more than a few inches. During one of its trials, a guard rail broke; the machine swerved off the track and was extensively damaged. Discouraged, Maxim terminated the project.

**Otto Lilienthal.** Though the steamers held centre stage for a decade, they all huffed and puffed without results, and it fell to the gliders to cross the final gap—to provide the flight experience needed to take advantage of internal-combustion power when it became available. The greatest of them, and the man whose work provided the initial impetus to the Wright brothers, was Otto Lilienthal (1848–96) of Germany.

Lilienthal's early studies of bird flight had led him to experiment (1868) with wing-flapping devices (ornithopters), but shortly he turned to gliding and in this area made his greatest contribution. He built a number of bat-like monoplane and biplane gliders (see Figure 2, right) and between 1893 and August 9, 1896 (the day of his fatal crash), made over 2,000 gliding flights from hill-tops. On one occasion he covered over 1,000 feet in gliding flight. Eventually, he was able to fly in winds up to 15 miles per hour.

Lilienthal was primarily concerned with the stability and control of his machines. Originally, he did not use any movable aerodynamic control surfaces in flight but sought for an inherently stable machine that could be controlled by shifting his body weight. This proved to be unsatisfactory, and it was in the course of an experiment to test a movable elevator that his glider spun out of control and he sustained fatal injuries. He was convinced that it was essential to get the feel of flight in gliders before attempting powered flight—a lesson that was scrupulously followed by the Wrights five years later and that unquestionably contributed to their success.

**Octave Chanute.** Lilienthal's work was widely reported and came to the attention of a French-born, American-educated engineer, Octave Chanute, who was himself deeply interested in the problem of man flight. In 1896, when he was well over sixty years old, he and a group of assistants began gliding experiments on the sand dunes of Lake Michigan near Chicago. He wanted a better system of control than the Lilienthal body-shifting technique. He sought "an apparatus with automatic stability in the wind." During 1896–97 his group built and made over 1,000 flights in five different glider types. They kept careful records and were the first to use a series of single photographs (motion-picture cameras were not then available) showing consecutive phases of a single flight.

Chanute became a close friend and frequent correspondent of the Wright brothers as they began their gliding experiments in 1900. They adopted his bridge-truss biplane configuration and drew heavily on his gliding experience. On at least one occasion (1901) Chanute visited their camp at Kill Devil Hills near Kitty Hawk and made photographs of some of their glider flights.

### III. Developments from 1900 to 1914

#### INTRODUCTION OF THE GASOLINE ENGINE

By 1899 a number of lines of experimentation were converging. Vast sources of petroleum had been discovered and tapped, and chemists had found the means of unlocking its ancient sun-generated energy. Metallurgists could produce high-strength steels and had already isolated lightweight aluminum. Toolmakers had evolved methods and machines to fabricate intricate mechanical devices, and scientists had harnessed electrical energy. All these in combination were essential to the development of the lightweight internal-combustion engine, the indispensable missing ingredient for man flight.

A requirement for such a source of power had already been established by the horseless carriage. In Europe and in America curious vehicles without harness and shafts (but usually with whip sockets still in place) were already churning up road dust to the gibes and guffaws of a skeptical public. So, by 1900, for the first time in history, the necessary power plant in a crude but usable form was waiting in the wings—for its wings.

During the first two years of the new century, while the Wrights were testing their gliders at Kitty Hawk, an Austrian piano maker turned engineer, Wilhelm Kress (1846–1913), was putting together a flying boat with three monoplane wings in tandem. The machine had two large propellers amidships, belt-driven by a Mercedes engine designed to produce 40 horsepower at a weight of 440 pounds. Actually, however, the engine delivered only 30 horsepower with a total weight of 836 pounds—a combination that militated against successful flight. Kress, himself, then 68 years of age, made the first attempted takeoff (1901) from Lake Tullnerbach. The machine showed some signs of leaving the water but was

Glider  
stability  
and control

Kress's  
flying boat

wrecked when it ran aground. It was, however, notable for two innovations: (1) it marked the first attempted use of a gasoline engine in an airplane; and (2) it employed thin-walled steel tubing for its body structure. (Steel tubing for fuselage construction became commonplace only in the early 1920s.)

#### SAMUEL PIERPONT LANGLEY (1834–1906)

The distinguished third secretary of the Smithsonian Institution, astronomer, mathematician, and inventor, spent the last twenty years of his life in active research in aeronautics. Few men before him pursued the subject more painstakingly or more scientifically, and none left as complete a record of experimental results. The *Langley Memoir on Mechanical Flight* (Smithsonian, 1911) is required reading for all serious students of man-flight history. But, in the end, Langley failed to fly. His only reward was ridicule and accusation of wasting public funds.

**Aerodynamic research.** He began his work (c. 1886) when he was professor of astronomy at the Western University of Pennsylvania (now the University of Pittsburgh). The wind tunnel as a tool for aerodynamic research had not appeared in America. Langley adopted a whirling arm device as his original test rig. This was a counterweighted 30-foot beam, pivoted at one end, and arranged to rotate horizontally, sweeping a 60-foot-diameter circle. With a steam engine driving the central shaft, top speeds up to 70 miles per hour could be attained. Models of wings and other shapes (including several stuffed birds) were mounted at the free end of the arm, and measurements made of their air resistance and other characteristics as the arm rotated. This was the first serious effort at systematic aerodynamic research in America. Appropriately, one of the principal U.S. government flying fields and its associated research laboratories bear Langley's name.

After his appointment to the Smithsonian (1887), Langley continued his aeronautical work. While still in Pittsburgh he had begun experiments with small models powered by twisted or stretched rubber bands. By 1891, in Washington, he had built and tested over 30 different configurations, keeping accurately detailed records of their characteristics and performance. Late in 1891 he realized that rubber-powered models had little practical future and began work to develop small steam power plants. At this time he coined the term aerodrome (Greek, "air runner") to describe his flying vehicles. By 1896 he had designed, redesigned, built, rebuilt, and tested Aerodromes numbers 0 to 6. This work involved literally thousands of changes and modifications to the hundreds of mechanical components involved. These are all carefully documented in his *Memoir*.

Between 1894 and early 1896 a number of launchings were attempted from a catapult device mounted on top of a small barge anchored in the Potomac River below Washington, D.C. Results were uniformly disappointing until May 6, 1896, when Aerodrome Number 5 went off successfully and flew some 3,200 feet in a series of wide circles. Recovered from the water, Number 5 made a second flight on the same day, this time covering some 2,300 feet. On November 28, in the same year, a modified machine of the same general design (Number 6) made a stable flight of some 4,200 feet in one minute, 45 seconds. These flights were observed and photographed by the inventor of the telephone, Alexander Graham Bell, himself an active student and experimenter in aeronautics (see below *Glenn Curtiss and the Aerial Experiment Association*).

Charles Manly, later to become Langley's principal assistant, introduced Part II of the *Memoir* (1897–1903) as follows:

Although in 1896 Mr. Langley had made a firm resolution not to undertake the construction of a large man-carrying machine . . . yet the longing to take the final great step of actually transporting a human being through the air, which the successful flights of the models had now for the first time in the history of the world actually proved to be possible, soon became irresistible.

At this point history took a hand. The United States was then involved in a war with Spain over Cuba. With unusual prescience, Pres. William McKinley and the War Department, intrigued by the possibilities of a flying machine as an instrument of warfare, granted Langley an allotment of \$50,000 with which to build a man-carrying Aerodrome (December 1898).

**Power-plant problems.** Langley had no doubts of his ability to build the airframe, but he was gravely concerned, as were all experimenters before him, over the power plant. Steam was out of the question. Some form of internal-combustion engine was clearly indicated, but none of the automobile manufacturers of the time would undertake to build an engine to meet his specifications; i.e., to develop 12 horsepower continuously at a total weight not to exceed 100 pounds.

Finally, after communicating with all known sources in America and in Europe, he signed a contract (December 12, 1898) with one S.M. Balzer, an engine builder in New York City, to deliver an engine to the Langley specification by February 28, 1899. The engine proved to be a disappointment, and Langley went to Europe to search for a suitable power plant. Before his departure he turned the design problem over to his young engineering assistant, Charles M. Manly, recently graduated from Cornell. Langley returned empty-handed, but Manly's reworking of the Balzer engine was beginning to bear fruit. Actually, Manly abandoned most of the original design and built his own engine.

Manly's engine

It was a remarkable accomplishment. By the spring of 1903 the engine, with a weight of 187 pounds, was developing over 50 horsepower. On a later occasion (August 1904, after the ill-fated flight tests), the Manly engine ran for ten consecutive hours at a rating of 52.4 horsepower. No other engine was to equal that record for many years.

**Final attempts.** While work was progressing on the large engine, a one-quarter scale Aerodrome was built, powered by a small, air-cooled, five-cylinder gasoline engine that developed just over three horsepower at 1800 rpm. Although work on the model was completed by October 1901, because of work priority given to the large machine it was not test-flown until August 8, 1903. Only one flight was made—1,000 feet in 27 seconds—but it demonstrated to Langley's satisfaction that the design of the large Aerodrome was fundamentally correct. This, incidentally, was the first flight of a heavier-than-air vehicle powered by a gasoline engine.

Shortly after the model flight, the full-scale machine was ready for test. By early October the necessary modifications had been made on the launching mechanism to accommodate the Aerodrome. On October 7, Charles Manly took his place at the controls, the engine roared, and the machine was released. Result: total failure. The Aerodrome plunged nose down into the river only a few yards from the boat. As a skeptical and disgruntled reporter described the incident in the next morning's *Washington Post*, "It simply slid into the water like a handful of mortar." Manly was unhurt and the wreckage salvaged. Two months later, December 8, the test was repeated. Immediately after launching, the rear wing structure collapsed and the machine went into the river, tail first. To the end of his life, Langley ascribed the accident to a failure of the launching mechanism. Again, Manly survived unhurt.

This was the end for Langley. He was subjected to a flood of ridicule and abuse in the press. Government funds were cut off, and a congressional investigation was threatened over wastage of public money "because, some man, perchance a professor wandering in his dreams, was able to impress [the War Department] that his aerial scheme had some utility." Langley never recovered, and he died two years later.

Only nine days after the Aerodrome's final crash, Orville Wright rose from the sands of Kitty Hawk on man's first successful airplane flight.

**Curtiss and the Langley machine.** There is a historical footnote to the Langley machine: in connection with a long and bitter legal controversy over claims of Glenn

Langley's aerodromes

Flights  
with  
Curtiss  
engine

Curtiss and the Wright patents, the original Langley Aerodrome was lent to Curtiss by the Smithsonian Institution in 1914 and sent to his factory at Hammondsport, New York. There it was reconditioned, allegedly in accordance with the original plans, though significant structural modifications were made to enable the craft to operate off the water as a seaplane. It made one or two brief off-the-water hops (five seconds) with the original Manly engine, and later, after further structural changes, and with the substitution of a Curtiss aircraft engine and a propeller, it made several straightaway flights at low altitude over Lake Keuka, in New York. Returned to the Smithsonian, it was then labelled as "the first airplane capable of sustained free flight with a man," to the great annoyance of Orville Wright (Wilbur Wright had died in 1912).

The entrance of the United States into World War I, and the subsequent pooling of all aeronautical patents, ended the legal controversy, but the personal bitterness between Wright and the Smithsonian persisted for many years. In view of the institution's claims, Orville refused to deposit the original "Flyer" in the Smithsonian. In 1928 he sent the historic aircraft to the Science Museum in London, where it remained on display (except for the war years 1939–45, when it was placed underground for safety) until 1948. At that time, after due apologies by the then Smithsonian secretary, C.G. Abbot, the machine was returned to the United States aboard a U.S. aircraft carrier and, on December 17, 1948, formally installed in the Arts and Industries Building in Washington, D.C., where it is now displayed.

#### WILBUR AND ORVILLE WRIGHT

That the Wright brothers of Dayton, Ohio, were the actual inventors of the world's first practical powered airplane is unequivocally accepted by all serious aeronautical historians.

The notion that the Wrights were semi-literate bicycle mechanics who happened to stumble upon the secret of flight is fanciful. The fact is that, with limited formal education, they became research scientists in the most literal sense. Says Dollfus, "Brought up in austere simplicity, they shared the same character, combining the soul of the apostle with the spirit of practicality. . . . These qualities permitted them to triumph where all their forerunners had been halted." The Wrights first tried printing and publishing a newspaper, then built up a bicycle manufacturing and repair business in Dayton. This provided them with the tools, the mechanical knowledge, and the income on which their subsequent experiments in aviation were based. In 1899, after becoming interested in bird flight and reading of Lilienthal's experiments, they determined to make a serious study of aviation. A request to the Smithsonian in Washington, D.C., for a list of books and articles on flying was the starting point. Chanute's *Progress in Flying Machines*, published in 1894, became their basic text, but they absorbed everything else that was available. In a relatively short time their intensive studies transformed them into scientists. Their own contributions to the literature of flight are contained in over a thousand pages of the two-volume edition of *The Papers of Wilbur and Orville Wright*, edited by M.W. McFarland of the U.S. Library of Congress.

The Wrights did not make the mistake common to many of their predecessors; i.e., to attempt powered flight without first learning to fly. They made their first tests on kites (1899–1900). From this they progressed first to tethered gliders (1900) and finally to gliders in free flight (1901–02). Only after becoming airmen in the true sense of the word were they ready in 1903 to attempt powered, man-carrying, controlled flight.

Between 1900 and 1903, they embarked on a remarkable program of research and development. The prior art had produced little but speculation and a record of unsuccessful experiments. Wilbur summarized the difficulties that then obstructed success as "(1) those which relate to the construction of sustaining wings; (2) those which relate to the generation and application of the

power required to drive the machine through the air; (3) those relating to the balancing and steering of the machine after it is actually in flight." He conceded that some progress on items (1) and (2) had already been made, but considered that until item (3) could be resolved, "all other difficulties are of minor importance."

Methodically and persistently they set about finding solutions to all three, but in the end it was their work on the interrelated problems of flight stability and control that brought success.

Considering today's vast accumulation of aerodynamic, structural, and power-plant data in thousands of textbooks and hundreds of millions of informational bits stored in computers, the Wright's technical resources were thin indeed. Step by step they had to test every wing and propeller shape, first by mounting crude measuring devices on the handlebars of a moving bicycle, later in a small wind tunnel of their own construction. Painstakingly, they recorded, tabulated, and applied these data. But it was on stability and control research that they concentrated their greatest effort.

**Kites and gliders.** They began with kites. They built the first in August 1899, a biplane of five-foot span of the Chanute type, fitted with control wires by which the wing cellule could be twisted—or warped—in flight. Wing-warping to achieve lateral control became the core of the subsequent Wright patents. The success of the kite led them to undertake a larger (17-foot span) man-carrying glider. It was completed in September 1900, and they moved their experiments to a site near Kitty Hawk, North Carolina, where the U.S. Weather Bureau had reported the existence of steady and reasonably constant winds and where the sand dunes offered cushioning for hard landings. (Secrecy was never a factor in the selection of Kitty Hawk, as has sometimes been asserted.)

The new machine was first flown as an unmanned kite, and after some skill had been acquired, it was flown with a man aboard but with ground control. The few attempts at free flight were disappointing (based on Lilienthal's data, the wing area appeared to be too small), and the brothers returned to Dayton to reconsider.

During that winter they built a larger (22-foot span) glider with an innovation—a front horizontal rudder (i.e., elevator). Returning to Kitty Hawk in July 1901, the Wrights found that their revised calculations were still uncertain. At one point they almost duplicated Lilienthal's fatal crash. They did succeed, however, in overcoming some of the machine's erratic behaviour, and they eventually made a successful glide of some 300 feet. Octave Chanute spent some time at the Kitty Hawk camp and made a number of photographs of the Number 2 machine in flight.

At this point, discouraged by the scarcity of reliable aerodynamic information ("Truth and error were everywhere so intimately mixed as to be indistinguishable," Wilbur wrote in the *Century* magazine in September 1908), they almost gave up. But building their own wind tunnel, they began systematic compilation of their own data. (The original wind tunnel and some of the experimental wing and propeller sections tested are now in the Franklin Institute in Philadelphia.) Here they became scientists. When they interpreted and applied their results to the construction of a practical flying machine, they became engineers.

In 1902 they turned the corner. In August and September 1902, they built Glider Number 3 (see Figure 3, top) which incorporated all their experimental findings. It retained the forward elevator but added a double fixed fin, which later was to become the rudder. Returning to North Carolina in September, they made over 1,000 glides on this machine. The early flights were unsatisfactory, but when the fixed tail fins were made steerable, so that banking and yawing (turning) could be coordinated (a characteristic common to all successful airplanes), the stability and control problem was solved. Gibbs-Smith writes, "After this vital step, the Wrights had a fully practical glider—the first in history—and with it made some hundreds of perfectly controlled glides." They applied for a patent in March 1903.

**Powered flight.** Back in Dayton, with this achievement behind them, they finally turned their attention to powered flight but like Langley, they could find no manufacturer to make an engine of the power and weight they could use. Like Langley, they designed and built their own in their bicycle shop, with the expert help of their assistant, Charles Taylor.

Wright "Flyer I" (later known as the "Kitty Hawk") was not a reconstruction of Glider Number 3, with engine attached. It was an entirely new machine. A biplane with a wing span of 40 feet four inches and a wing area of 510 square feet, it retained the front elevator and rear rudder configuration of 1902. The Taylor engine was a horizontal four-cylinder type mounted in the centre of the lower wing, turning two chain-driven, counter-rotating, pusher propellers. The pilot, as in the gliders, lay prone on the lower wing beside the engine. It was designed to land on a pair of sledlike skids, and takeoff was accomplished from a simple droppable dolly running along a 60-foot monorail track.

The inevitable constructional and mechanical delays put off the trials until late in 1903. With winter almost upon them, the machine was finally ready for test by mid-December. On December 14, 1903, they tossed a coin for the first-flight honour. Wilbur won and made the attempt. Due to overcontrol of the elevator, the "Flyer" plowed into the sand at the end of the launching rail. Three days later, after repairs and a weather delay, Orville had his turn. At 10:35 AM, on December 17, into a 20–22-mph wind, he made a successful takeoff, flew for 12 seconds, and landed without damage—the first controlled man-carrying mechanical flight in history (see Figure 3, bottom).

That morning, three more flights were accomplished, with alternating pilots. On the fourth, Wilbur flying, the machine was airborne for 59 seconds, covering 852 feet on the ground, the equivalent of a flight of one-half mile in still air. After the fourth flight, while the aircraft was being returned to the starting rail, a strong gust of wind overturned and damaged it beyond immediate repair.

Before breaking camp and starting back to Dayton, Orville sent a wire to his father: "Success four flights

Thursday morning all against twenty-one mile wind started from level with engine power alone average speed through air thirty-one miles longest 57 seconds inform press home Christmas." The "57 seconds" was a telegrapher's error—59 seconds was correct.

**Aftermath.** Ten years later, Orville Wright, looking back on that day, said,

With all the knowledge and skill acquired in thousands of flights in the last ten years, I would hardly think today of making my first flight on a strange machine in a twenty-seven mile wind, even if I knew that the machine had already been flown and was safe . . . Yet faith in our calculations and the design of the first machine, based upon our tables of air pressures, secured by months of careful laboratory work, and confidence in our system of control developed by three years of actual experiences in balancing gliders in the air, had convinced us that the machine was capable of lifting and maintaining itself in the air, and that, with a little practice, it could be safely flown.

Few editors paid any attention to the story, and those who used it embroidered it with facetious embellishments à la Jules Verne. Incredibly, almost five years went by before the citizens of the United States really accepted the fact that the Wrights had flown in 1903. Even their friends and neighbours in Dayton took the news very calmly. Wilbur and Orville were a pair of nice fellows, but who were they to make such claims when the most learned professors of the day had already proved mathematically that mechanical man flight was impossible!

**Later flights.** Wilbur and Orville also took the situation very calmly; in fact, it was exactly to their liking. They called no press conferences; they could not spare the time. During the winter of 1903–04 they built a new and larger "Flyer," with a much improved engine. In the spring of 1904 they rented a 90-acre cow pasture, "Huffman Prairie," near Dayton. There they set up shop, assembled the new machine, and began to fly.

The Wrights were not secretive about their work. It was there in the open for anyone to see. When first ready to test the Number 2 "Flyer," they sent invitations to the press, but after one or two postponements of the promised flight due to weather, and unforeseen mechanical difficulties, the already skeptical reporters went off on more promising leads.

The summer of 1904 was employed in perfecting their flight techniques and eventually in learning to make turns in the air. On September 20, Wilbur made the first full circle in flight and returned to land at his starting point. This feat generated the first published eyewitness account in history of the flight of any airplane. It appeared, strangely enough, in the January 1905 issue of a small magazine called *Gleanings in Bee Culture*, published in Medina, Ohio. The editor, A.I. Root, had travelled to Dayton to see the Wrights fly and had observed the first circular flight. On November 9, Wilbur stayed in the air for over five minutes, making almost four complete circles of the pasture.

"Flyer" Number 3, incorporating all the improvements gained from the experience with Number 2, was first flown at Huffman Prairie on June 23, 1905. By October 16 some 49 flights had been completed, including several ranging in length from 11 to 24½ miles, at average speeds of 38 mph. Most flights were terminated only because of exhaustion of fuel. It could be said, and with confidence, that for all practical purposes the conquest of the air had been accomplished.

The Wrights' attitude toward publicity had also changed. The word had got around, and others, particularly abroad, were beginning to show interest in their work as possible competitors. Their basic patent had not yet been granted (it was not to be issued until 1906), and the Wrights were concerned about legal protection of, and financial reward for, their work. To avoid possibilities of military or commercial surveillance, they stopped all flights and prohibited any public inspection of their airplanes from October 16, 1905 until May 6, 1908. They then went back to Kitty Hawk with the greatly improved Number 3 machine to refresh their skill as pilots.

The changes in detail were many, but the most obvious

First full-circle flight

History-making flight at Kitty Hawk

were the upright positions of both pilot and engine. The prone pilot position was abandoned in favour of a seated configuration on the lower wing, facing forward. The flat engines of the No. 1 and No. 2 Flyers were replaced by a more powerful and more efficient vertical, in-line type.

**Signal Corps project and European activities.** Between 1907 and 1908 the Wrights entered into negotiations with the U.S. War Department for an experimental airplane for military use. Their original proposal was received with a notable lack of enthusiasm. The Signal Corps could see little value in a flying machine but finally drafted a specification that was designed to discourage, if not to eliminate, all bidders. Required was a machine capable of flying for one hour carrying a pilot and a passenger (combined weights not less than 350 pounds); top speed at least 40 mph, and enough fuel on board for 125 miles of flight. In addition, the aircraft had to be readily demountable to be transferred from place to place in a standard horse-drawn army wagon. All this for a price of \$25,000.

Although understandably discouraged by their own government's attitude, the Wrights went to work on the project. At the same time, however, they began to look for markets overseas.

A few experimental short-duration, straightaway hops had already been made in France by Santos-Dumont, Ferber, Blériot, and others, but nothing had been seen in Europe comparable to the by now routine performances at Dayton. When reports finally did filter through, the reaction abroad was total skepticism. A technical paper on the Wrights' work, read before the French Aéro-Club early in 1906, was covered by the *New York Herald* (Paris edition) under the headline "Flyers or Liars?"

In 1907 the brothers divided the field: Orville remained at home to develop the machine to meet the Signal Corps specification; Wilbur packed up a new and much improved "Flyer" and shipped it to France for demonstration.

Orville was the first to get his machine into the air. (Wilbur's "Flyer" was unaccountably impounded by French Customs and was not released for many months after its arrival.) The army demonstrator was shipped to Ft. Myer, Virginia, and, beginning September 3, was put through public trials on the parade ground. With Orville Wright at the controls, it passed or exceeded all specifications. Suddenly the American press awoke to the realization of its mistake, and press reports became ecstatic and numerous.

But the triumph was short-lived. On September 17, with Lieut. Thomas E. Selfridge as passenger, a guy wire snapped, fouled a propeller, and the machine dove into the ground out of control. Selfridge was killed instantly, to become the first fatality in a powered airplane. Orville was seriously injured.

In France, after many delays, Wilbur made his first flight at Le Mans on August 8, 1908. In the following months he proved to the world that both his piloting and his "Flyer" were far superior to anything that Europe could offer. On December 31 he established a world endurance record of two hours 20 minutes, covering a distance of 77½ miles to win the Michelin Prize. The European press and the technical community went wild. The Wrights were indeed flyers—not liars.

Orville, still suffering the effects of the Ft. Myer accident, joined Wilbur in France in mid-January 1909. After making demonstration flights in several European countries, they returned to the United States in May to prepare for renewed Signal Corps trials with a new machine. Orville again began test flights at Ft. Myer on June 28. By July 30 the army was satisfied that the specifications had been met (or exceeded), and the Signal Corps acquired its first airplane. This machine is now on display in the National Air and Space Museum in Washington, D.C. That fall, Wilbur set up the army's first flying school at College Park, Maryland.

**Later years.** Wilbur Wright contracted typhoid fever and died on May 30, 1912. For a few years Orville Wright carried on alone, manufacturing and testing his own aircraft and becoming involved in a bitter controversy with Glenn Curtiss over basic patents.

#### GLENN CURTISS AND THE AERIAL EXPERIMENT ASSOCIATION

Between 1908 and 1914 Curtiss had become the Wrights' greatest competitor. It was no friendly rivalry. Not only fame but potential fortunes were at stake, and the bitterness ran deep on both sides.

Curtiss was a natural competitor. Basically a mechanic and a showman, he was never a scientist nor even an engineer. He emerged first as a racer of motorcycles. His growing reputation as a designer and manufacturer of light-weight, high-speed gasoline engines brought him to the attention of Thomas Baldwin, then (1904-09) building and flying nonrigid airships (see below *Balloons and airships*). In 1907 his work with Baldwin attracted the notice of Alexander Graham Bell, experimenter with large tetrahedral kites and aspirant to the solution of the man-flight problem.

**Aerial Experiment Association.** Bell was the key figure and financial backer of the Aerial Experiment Association (AEA) with headquarters at Hammondsport, New York, and a test site at Bell's estate in Nova Scotia. He gathered around him a group of young, enthusiastic, and capable men, including Lieut. Thomas E. Selfridge (later killed in the crash of the Wright "Flyer" at Ft. Myer), F.W. Baldwin, J.A.D. McCurdy, and Glenn Curtiss. The association's objective was to conduct scientific research in heavier-than-air flight.

The AEA adopted the pusher-biplane configuration of Chanute and the Wrights, with the added advantage of more powerful and lighter engines, and a decided improvement in takeoff and landing gear, a three-wheeled undercarriage. The latter permitted operation from reasonably smooth fields without the somewhat clumsy launching rail and landing skid required by the Wright machines. (Gibbs-Smith considers the use by the Wrights of skids, after everyone else had shifted to wheeled landing gear, to have been one of their few serious mistakes.)

In turn, each of the association's members tried airplane design. Baldwin was first off, with Selfridge's "Red Wing." On March 12, 1908, he flew 319 feet from ice-covered Lake Keuka. A few months later (May 22, 1908), Baldwin's "White Wing," piloted by Curtiss, flew more than 1,000 feet in 19 seconds. Curtiss' own design, "June Bug," covered some 2,000 yards in one minute 43 seconds on July 4, 1908, to win a prize posted by *Scientific American* magazine. Later (November 1908), he mounted the aircraft on a pair of canoe-like floats, renamed it the "Loon," and attempted unsuccessfully to take off from the surface of the lake.

McCurdy's contribution, "Silver Dart," was tested at Bell's Nova Scotia estate. On February 23, 1909, he took off from the frozen surface of a nearby lake to record the first heavier-than-air flight in Canada.

During the next few years Glenn Curtiss became one of the leading figures in aviation both in the United States and abroad. In an improved machine, the "Gold Bug" (four-cylinder, 30-horsepower engine), he made the first public flights in New York City and won the second *Scientific American* prize at Mineola, Long Island, New York, on July 17, 1909, with a flight of 24.7 miles at 35 mph. This also won for him official representation for the Aero Club of America at the Gordon Bennett Cup race at Reims, France, in August of that year. With a more powerful engine (eight-cylinder, 50-horsepower) and some structural modification, his "Golden Flyer" won the race at 47 mph.

Back in the United States, Curtiss in 1910 won a \$10,000 prize posted by the *New York World* for a flight from Albany to New York City. These successes established him as the principal competitor of the Wrights and led to the battle over patents that dragged through the courts for several years. Principal issue was the method of lateral control: wing warping (Wright), or opposite-acting ailerons (Curtiss). Finally, on January 13, 1914, the courts ruled in favour of the Wrights, by which time wing warping was a dead issue. Practicality and aerodynamic superiority had long since decided in favour of the aileron.

**Seaplanes.** While the Wright litigation was in full swing, Glenn Curtiss established a reputation in another

Wheeled  
landing  
gear

Wilbur  
Wright  
at Le Mans

vital area—he gave wings to the United States Navy by the development of successful hydro-airplanes and flying boats. Although the “Loon” of 1908 had not got off the water, the concept had been pursued.

Curtiss’  
work with  
U.S. Navy

Curtiss first cooperated with the navy in proving that an airplane could be launched from and landed upon a ship. The initial demonstration was a takeoff by Eugene Ely, a U.S. civilian pilot, from a platform erected on the bow of the cruiser USS “Birmingham” at Hampton Roads, Virginia, November 14, 1910. A little over two months later (January 18, 1911) Ely, in a similar machine, landed aboard the battleship USS “Pennsylvania” in San Francisco harbour, was turned around, and took off safely for a return flight ashore.

Shortly after Ely’s flights Curtiss’ research on properly shaped floats for seaplanes paid off. In the A-1 (a modification of the standard land plane) he made successful water takeoffs and landings. On February 17, 1911, he flew from the naval base at San Diego out to the USS “Pennsylvania” at anchor in the harbour, landed alongside, and was hoisted aboard by one of the ship’s cranes. After paying his respects to the commanding officer, he and his plane were lowered into the water for a successful flight back to the base. For this, Curtiss was awarded the Collier Trophy for 1912 “for the greatest achievement in aviation in America . . . during the preceding year,” and the navy became airborne.

With the navy’s interest assured, Curtiss turned his attention to developing a truly integrated water aircraft. So far, his hydro-airplanes had been simply standard land types mounted on floats instead of wheels. In 1912 he built the “Flying Fish,” the prototype for all true flying boats—a boatlike hull to accommodate pilot and passengers, to which wings, engines, and propellers were attached.

#### AVIATION IN ADOLESCENCE

**Activities in Europe.** While the Wrights were successfully flying circles and figure eights in America, aviation in Europe was only slowly coming to life. The hopes raised by Lilienthal and Pilcher in 1890 had faded. The dream of man flight had once more seemed out of reach. Gibbs-Smith summed up the situation between 1902 and 1905 as follows:

No systematic, persistent and progressive study of the problems of glider control was made, hence no one came near to any kind of proficiency in gliding, let alone mastery . . . Europeans had available all the necessary facts and clues in Chanute’s articles, and . . . in the two excellent Wright papers of 1901 and 1902, which were easily accessible. Yet, during the three years (1902–04) the total product of European endeavors amounted to only some four ineffectual gliders.

Ferber, Archdeacon, and Esnault-Pelterie tried so-called exact copies of Wright gliders with little success. Léon Levavasseur learned little from a full-sized bird-form machine (1903). They all failed to solve the basic stability and control problems.

Only little progress was made through 1905. A few tentative trials of float-mounted gliders towed behind motor boats were made in France by Archdeacon, Blériot, and Voisin. All followed Wright designs, or showed strong relationship to Hargrave’s box kites, and the results were not promising.

The turning point in Europe came late in 1906. After two unrelated failures (one in France and one in Denmark), Alberto Santos-Dumont coaxed his awkward canard (tail first) 14-bis biplane off the ground at Bagatelle for six flights, the longest covering some 720 feet in 21½ seconds, at a maximum altitude of six feet. It was a modest achievement compared with the Wrights’ performances, but it earned him an Aéro-Club de France prize of 1,500 francs and the honour of having made the first powered airplane flight in Europe. His reputation as an airplane designer, however, rests more solidly on a subsequent machine, the fly-weight single-place “Demoiselle” of 1909.

During 1907 things began to move, but slowly. Of some 14 aircraft tested, only six showed any ability to get off the ground. Of these, only one, built by Gabriel and

Santos-  
Dumont’s  
biplane  
flights

Charles Voisin for the French sportsman Henri Farman, remained airborne over a minute. Its nearest competitors were up only 55 and 45 seconds. Farman, in the course of his one minute-plus record, achieved the first full circular flight in Europe. Less spectacular, but possibly of greater importance, was the appearance (late in 1907) of Léon Levavasseur’s eight-cylinder, 50-horsepower Antoinette engine, which was to power many of Europe’s successful aircraft.

Finally, in 1908, European aviation got off the ground. Greatest impetus came from the performance of the imported Wright “Flyer” at Le Mans in August 1908. Wilbur Wright’s mastery of the air astonished the European experimenters after their years of disbelief.

Even before the Wright demonstration, however, some progress had been made. Henri Farman and Léon Delagrangé were rated the best of the European pilots. The former flew 12 miles in 20 minutes in July after having made a short hop with a passenger in May. By year’s end Farman had doubled his July performance. Louis Blériot, in a monoplane of his own design, came close to Farman’s records. Each made true cross-country flights of 11 and 20 minutes, respectively, in October. Elsewhere in Europe, England, Denmark, Germany, and Italy, dozens of curiously designed aircraft were making tentative hops.

Two major events marked the year 1909: (1) the crossing of the English Channel on July 25; and (2) the first

### English Channel crossing

great aviation meet at Reims in August. The Channel crossing ended the concept of political isolation by oceans, and the second established beyond all doubt that aviation was here to stay.

The English Channel posed a challenge to aviation that could not be resisted. At midsummer three of Europe's best pilots, Hubert Latham, Louis Blériot, and the Count de Lambert, were encamped along the Pas-de-Calais preparing for the attempt. De Lambert was delayed by aircraft damage. Latham, in an Antoinette monoplane, got away first in early morning July 19. Halfway across his engine quit, and he landed in the water, to be rescued shortly by a French torpedo boat. Six days later, Blériot, in his Blériot XI monoplane, took off from Les Boraques near Calais and after a flight of 37 minutes landed on a hillside near Dover (see Figure 4, top).

The Blériot flight touched off a flurry of excitement all over Europe and focussed attention on the first of the great aerial circuses that marked the years 1910–12. The Grande Semaine d'Aviation, at Reims, sponsored by the local champagne industry, attracted not only the best airplanes and pilots of the world but also tens of thousands of people from all walks of life anxious to see for themselves the miracle of man flight. Prizes totalled over 200,000 francs.

**Meets and prizes.** For the next few years prize money for record flights became plentiful, many of the donors being newspapers eager to profit from the attendant publicity. Race meets and aerial circuses brought keen competition among itinerant pilots.

From 1910 to the advent of war in 1914, the aviation carnival in America as in Europe became a "movable feast." The first important meet was held in Los Angeles in January 1910 with Curtiss and Louis Paulhan setting world speed and altitude records. In September, the Harvard-Boston Meet at Squantum, Massachusetts, attracted United States and European competitors, with thousands of spectators, including Pres. William Howard Taft. The biggest show was staged in Belmont Park, Long Island, New York, October 22–31. Some 40 aircraft, mostly of American or French design, participated. Thousands of New Yorkers turned out to witness speed runs (up to 61 mph), altitude records (over 9,700 feet), and a race around the Statue of Liberty. The newspapers of the country posted substantial prizes (\$15,000–\$30,000) for record flights to or from their respective cities. A manufacturer of a popular soft drink subsidized the first trans-continental flight. C.P. Rodgers, in a well-marked ("Vin Fizz") Wright biplane, accompanied all the way by a special train carrying first-aid equipment, a mechanic, spare parts, and his wife, flew from New York to Los Angeles in a series of 68 hops (and almost as many crashes) between September 7 and November 5, 1911. His plane is now in the Smithsonian Institution. In Europe the London *Daily Mail* put up £10,000 for a flight to be completed in less than 24 hours covering 183 miles

between London and Manchester. Two pilots, Claude Grahame-White and Louis Paulhan, both in Farman biplanes, made a race for it on April 23–28, 1910, with Paulhan the winner in four hours two minutes.

The Italian Aviation Society offered 70,000 francs for the first pilot to cross the Alps. Jorge (or George) Chávez flew from Switzerland to Italy via the Simplon Pass on September 23, 1910, in a Blériot monoplane, but on landing his machine crashed, and he was killed.

By 1911–12, racing from town to town, called "circuit racing," became popular in Europe, over courses up to 1,000 miles. The temptation to fly in all kinds of weather in such contests left a long trail of wrecked machines and dead pilots. But stimulated by such competition, airplane and engine performance improved tremendously. Altitudes leaped to thousands of feet, speeds approached 100 mph, and endurance flights were measured in hours rather than minutes.

France was still the aviation leader of Europe, but other countries were joining the sport: in January 1911 France had 353 certified pilots, England 57, Germany 46, Italy 32, Belgium 27. Rather amazingly, the United States, where heavier-than-air flight had begun, had only 26.

### HELICOPTERS

During the decade when the first airplanes were attracting wide public attention, the concept of vertical flight by direct action of Archimedean-screw propellers (envisioned by Leonardo and postulated by Cayley) was not entirely forgotten. A number of helicopter models had appeared at the London Aeronautical Exhibit of 1868, and flying models with steam and electric drives were demonstrated during the late 1870s. Also, Jules Verne's fictional hero, Robur le Conquérant (1886), cruised around the world in a remarkable craft airborne by 37 pairs of vertical propellers mounted atop 37 masts.

In 1904 Col. Charles Renard (who had piloted the first controlled airship) used an unmanned, twin-rotor, gasoline-powered helicopter as a part of his continuing researches in aerodynamics. About the same time, Paul Cornu tried a model of somewhat similar configuration. Encouraged by its performance, he tried a full-scale machine powered by a 24-horsepower Antoinette engine. On November 13, 1907, Cornu made several lift-offs of a few seconds' duration, the first by any helicopter. Once airborne, however, the machine proved uncontrollable and was shortly abandoned.

In America in 1908, Thomas Edison, after experimenting with vertical air screws driven by electric motors mounted on platform scales to measure lift, commented, "Whatever progress the airplane might make, the helicopter will come to be taken up by the advanced students of aeronautics." But over 30 years were to pass before his prediction came true. A young Russian, Igor Sikorsky, at that time was making his first serious studies of the helicopter. During 1909 and 1910 he built two machines

### Circuit racing

powered by a 25-horsepower Anzani engine (see Figure 5, right). The most that either helicopter could do was to lift its own weight off the ground without a pilot. Many years later (November 1964) in a lecture before the New York Wings Club, Sikorsky said of his experiences in 1910,

... by that time I had learned enough to recognize that with the existing general state of the art, engines, materials and ... lack of experience, ... I would not be able to produce a successful helicopter at that time.

Nevertheless, several others tried. After Cornu gave up, a large and ungainly combination of airplane and helicopter (the Broquet-Richet No. II) managed to rise a few feet, only to crash on landing. Also, a persistent Danish experimenter, J.C.H. Ellehammer, in his twin-rotor helicopter attained a maximum altitude of about two feet (1912) but did not achieve flight. The real difficulty, then and for many years thereafter, was control. Until Juan de la Cierva (see below *Rotary wing aircraft*) designed independently articulated roto blades for his first autogiro, that problem remained unsolved.

#### BALLOONS AND AIRSHIPS

With the advent of the steerable airship (dirigible), little interest remained in free ballooning until it became an important tool for upper-atmospheric research in the 1930s. Actually, scientific research of this sort had its beginnings very early. Blanchard and Jeffries made scientific observations on their cross-Channel flight in January 1785, and the French Academy of Sciences sponsored several upper-air research flights by Gay-Lussac and Biot in 1804. Coxwell and Glaisher in England (September 1862) recorded atmospheric data up to an altitude of approximately five miles. On July 31, 1901, two German physics professors, A. Berson and A.J. Süring, made an atmospheric survey flight to an altitude of some 35,000 feet, a record that stood for 30 years, when it was exceeded by Auguste Piccard.

**Ballooning.** During the first decade of the 20th century ballooning was looked upon largely as a form of sport. The Aéro-Club de France encouraged competition by establishing rules for racing and by promulgation of records for distance, altitude, etc. Its Balloon Park at Saint-Cloud near Paris became a centre for amateur and professional aeronauts. During 1913 some 479 ascensions were recorded from this site alone.

Balloon racing became an international sport. Every year new records were made and broken, both in Europe and in America. But apart from such popular activities, limited use was made of free balloons as preliminary training for airship crews.

**Airships.** With the increasing availability of suitable engines (c. 1900), airship experimentation proliferated. New and improved designs emerged, and it became necessary to differentiate among three distinct categories: nonrigid, semirigid, and rigid airships.

Nonrigid airships consist simply of an elongated fabric gasbag (envelope), below which a car for the accommodation of crew and power plant is suspended by ropes or cables. The bag holds its shape solely because of the gas pressure inside. If the gas escapes, the whole apparatus collapses into a shapeless mass of fabric. All airships prior to 1900 were of this class.

Semirigid airships have a structural keel (or truss) fore and aft to which the envelope is directly attached. The keel provides housing for crew and power plant. If the gas escapes, only the envelope collapses. This type became popular in the 1900–20 period.

Rigid airships are characterized by an external structural skeleton covered by light fabric to preserve the overall shape surrounding a series of internal lifting-gas cells. Power plants, control surfaces, and passenger and crew accommodations are integrated into the main structure of the airship. The external appearance of the ship remains the same whether or not the gas cells are inflated. These make up the Zeppelin class of airship, which reached its developmental peak during World War I and persisted in both military and commercial form into the 1930s.

**Nonrigid airships.** Prior to 1904 when he turned his attention to heavier-than-air flight, Alberto Santos-Dumont was the world's greatest builder of nonrigid airships. A wealthy sportsman, Santos-Dumont flew largely for fun but created great public interest in aviation and contributed much to the technology of airship flight. Success came largely from his adoption for aeronautical purposes of the light gasoline engine then in popular use in small tricycle automobiles. His ships numbers 1–3 (1898–99) were not successful. None was able to return to the point of departure under its own limited power. Number 4, with a nine-horsepower engine (1900), did little better, but it established the configuration for Number 5, which, with installation of a 16-horsepower engine weighing only 215.6 pounds, began to show positive results. The car was an elongated, open, triangular wooden framework with a single propeller at the rear and with engine and pilot located near the centre (see Figure 1, right). The engine was in the open, but the aeronaut rode in a small wicker balloon basket mounted some 20 feet forward of the engine. The whole apparatus was suspended beneath an elongated fabric envelope by means of steel piano wire, the first use of metal instead of rope in nonrigid airship construction.

In this machine Santos-Dumont made his first attempts at the Deutsch de la Meurthe Prize established in 1900 for the first flight from the Aero Park at Saint-Cloud, around the Eiffel Tower, and return. His first several tries were unsuccessful and included one crash in the courtyard of the Trocadéro. That same evening he started construction of a new airship, Number 6, in which, after several more abortive efforts, he completed the flight to win the prize. During the following five years a series of 11 more of his airships appeared at Saint-Cloud, including one, Number 9, a small ship of only three horsepower, in which he landed and took off on the Champs-Élysées and in the Bois de Boulogne.

After Santos-Dumont turned to airplanes, interest in nonrigids tapered off in Europe. The French Société Zodiac built a series of small ships that were sold in limited numbers to the military services of France, The Netherlands, Russia, and Belgium, prior to World War I.

In America, exhibition flights in nonrigid airships (along with parachute jumps from hot-air balloons) became stock features at county fairs and expositions. A dozen or more pilots and their ships toured the racing circuits around the country from 1900 to 1910. Thomas Scott Baldwin, one of the prominent figures in this activity, in search of a suitable light-weight engine for his airship, discovered Glenn Curtiss, then building motorcycle engines, and started him on his career as an airplane designer and pilot. The Baldwin-Curtiss team produced the first U.S. military aircraft, the SC-1 airship, test flown at Ft. Myer, Virginia, in 1905 and subsequently purchased by the U.S. Army. Little further interest was shown in nonrigid ships by the military services of any country until the latter part of World War I, when both France and Britain built large numbers for offshore antisubmarine patrol work.

**Semirigid airships.** The success of a series of large semirigid airships built for the French government by Paul and Pierre Lebaudy (1903–07) focussed attention on this class of airship. "La Jaune" was the first (1902), followed in sequence by "La Patrie," "La République," and "La Liberté" (1908), each larger and more powerful than its predecessor. The latter two were 200 feet long, 33 feet in diameter, and powered by 70-horsepower engines. Each carried a crew of four. Ships numbers 2 and 3 were destroyed in accidents, but the performance of the fleet was so impressive that foreign governments became interested. Russia purchased two French airships, and England followed suit, taking delivery of one in September 1910 and another later in the year. The latter covered the 230 miles from the factory at Moisson, France, to Farnborough, England, in 5½ hours.

By 1902 Germany was committed to the development of rigid airships under Graf von Zeppelin but was also keeping a watchful eye on the French semirigids. Under the supervision of Maj. August von Parseval, several

Santos-Dumont's airships

Upper-air research

Lebaudy airships

semirigid ships were built between 1906 and 1911. The largest and most successful was 224 feet long, 47 feet in diameter, and was driven by two 120-horsepower engines. It was demonstrated as a passenger carrier at the Frankfurt Aeronautical Exhibition in 1909 and later participated in military and naval exercises. But the performance of the Zeppelins was so far superior that by 1911 all other lighter-than-air programs were abandoned.

Only two American attempts at semirigids are recorded. In 1906 Walter Wellman, a journalist living in Paris, began construction of the "America"—185 feet long and powered by an 80-horsepower engine. His objective was to fly to the North Pole. Two attempts were made, in September 1907 and October 1909. Both failed. He then enlarged "America" (228 feet long, with two engines) for a transatlantic attempt. Wellman and his crew took off from Atlantic City, New Jersey, on October 15, 1910. Motor trouble developed almost immediately, and after drifting as a free balloon for two days to a point some 400 miles east of Hampton Roads, the ship descended. The crew was rescued by a passing steamer, and the ship was abandoned.

One of Wellman's crew, Melville Vaniman, decided to try again in the "Akron," a semirigid of his own design. While on a test flight off Atlantic City on July 2, 1912, it caught fire and crashed, killing Vaniman and his four companions. This was the end of semirigid development in the United States until a brief but abortive program was undertaken in 1923.

**Rigid airships.** Among all classes of lighter-than-air craft, the large rigid dirigible had the longest and most spectacular history. It began when Ferdinand, Graf von Zeppelin, launched his first ship from Lake Constance in 1900. It terminated when the "Hindenburg" exploded and burned on the naval air station at Lakehurst, New Jersey, in early May 1937.

Zeppelin, as a military observer, had witnessed U.S. Army balloons in service during the American Civil War, and he made his own first ascent at St. Paul, Minnesota, in 1863. Around 1873 he became convinced that the future of lighter-than-air development lay in very large rigid ships. This concept was not wholly original. David Schwarz, a German, had built a ship with an external aluminum framework in Russia in 1897. It proved unsuccessful and was abandoned. Zeppelin was the first, however, to reduce the idea to practice. He patented his first design in 1898 and built LZ-1 (Luftschiff Zeppelin Nummer 1) during the next two years.

Assembled in a floating hangar on Lake Constance and launched from the water on July 2, 1900, the ship was 420 feet long with 38-foot maximum diameter. Its structure consisted of 24 longitudinal girders and 16 transverse rings, all of aluminum, tied together with a forest of diagonal bracing wires. The outside covering was smooth cotton cloth. Its 16 internal cells of rubberized fabric held a total of 338,410 cubic feet of lifting gas. Two 16-horsepower gasoline engines were mounted in separate cars rigidly attached to the keel girder. Although all subsequent Zeppelins (up to and including LZ-129, the "Hindenburg") varied widely in size, shape, and mechanical detail, the basic pattern was established with LZ-1.

The first trials of LZ-1 were reasonably encouraging, but the following years (1900–10), in which LZ-1 to LZ-6 appeared, were marked by disasters and discouragement. The ships were continuously improved and enlarged, but natural forces, mechanical failures, and financial difficulties almost brought the program to a standstill. But Zeppelin, foreseeing a commercial potential for his airships, organized Delag (Deutsche Luftschiffahrts-Aktien-Gesellschaft) in 1910 and began to carry passengers for hire. In the years remaining before the outbreak of World War I, Delag's five airships ("Deutschland," "Schwaben," "Viktoria Luise," "Hansa," and "Sachsen") spent over 3,000 hours in the air and carried 34,228 passengers a distance equivalent to four times around the Earth, without injury to passengers or crew. In late 1913, this remarkable record was marred when LZ-14 and LZ-18, both on military missions, were destroyed with a loss of 50 lives.

The onset of war changed the character of Zeppelin development. By 1918 some 100 airships had been built, primarily for the bombardment of London.

Britain was the only other country that, before the war, took any interest in rigid airships. One ship, at the time the largest in the world (510 feet long, 40 feet diameter, with two 200-horsepower engines), was constructed by Vickers Ltd., under Admiralty orders.

Christened "Mayfly," the aircraft was destined never to leave the ground. While being towed out of her hangar, she was caught in a severe crosswind and broken in two.

#### PARACHUTES (LEONARDO TO WORLD WAR I)

Though parachutes are not flight vehicles within the meaning of this article, their operation depends upon aerodynamic principles, and their association with man flight is intimate and of long standing. Even before any human being left the ground, Leonardo had sketched a fall-breaker in the form of a cloth pyramid and had discussed the aerodynamic factors involved (1514). Fausto Veranzio (1595) published a book containing a drawing of a man ("Homo Volans") descending from the top of a tower supported by a fabric panel stretched over a rectangular wooden framework. In 1632 Desmarests de Saint-Sorlin published a novel in Paris (*Ariane*) in which the hero escapes from a prison tower by jumping with a parachute made from a bed sheet.

Blanchard, the early balloonist, claimed to have experimented with parachutes as early as 1777. Prior to the invention of the hot-air balloon, Joseph Montgolfier is reported to have dropped a sheep, without damage, in a basket tied below a seven-foot parasol from a tower in Avignon. Several similar attempts were reported between 1785 and 1797, when the first manned parachute drop was accomplished.

On October 22, 1797, André-Jacques Garnerin took off from the Parc Monceau in Paris in a basket attached to an umbrella-like parachute suspended beneath a balloon. At an altitude of about 3,000 feet, he cut the suspension cord and descended without injury. Wilbur Wright later characterized this as one of the most courageous acts in aviation history.

Garnerin's original canopy-type set the pattern for virtually all subsequent parachutes. A conical parachute studied by Cayley and tested (July 1837), with fatal results, by Robert Cocking, attracted early attention but was shortly abandoned.

During the greatest period of free ballooning, hundreds of parachute drops were made, mostly to provide thrills for the public at county fairs. It was not until the latter part of World War I that the device began to be important as a means of saving the lives of pilots in disabled planes.

#### IV. Developments of the World War I era

The circus-and-carnival era of man flight ended abruptly with the outbreak of World War I in 1914. The millions that belligerent governments were willing to pay aircraft designers suddenly made aviation big business on a scale no one had yet contemplated. Aircraft had found work to do, and the frantic competition of wartime brought, in a few years, performance improvements that might otherwise have required decades.

In the first weeks of the war, aircraft played a considerable role in reconnaissance; French aircraft spotting the movements of the German 1st Army led to the Battle of the Marne. But few thought that airplanes could be effectively armed.

In 1914 France mobilized some 150 military planes and several airships, Germany about 260 planes plus a fleet of 14 Zeppelins, and Britain fewer than 100 aircraft. The planes of course were flimsy kitelike structures powered by engines of uncertain power and longevity. At best, they could climb 2,000–3,000 feet and fly at 60–70 mph, sometimes for as much as 200 miles. At worst, they could barely get off the ground. But four years later, 150–200-horsepower single-seat fighters, armed with two synchronized machine guns, were fighting each other at 15,000

Zeppelin's  
dirigibles

Garnerin's  
parachut-  
ing

feet or higher. Two-place reconnaissance machines were supplying hundreds of photographs of the ground action daily, and heavy bombers were penetrating deep into enemy territory both by day and by night. Airplanes had not only found jobs to do but had evolved into highly diversified forms to meet specialized requirements.

The production of aircraft, engines, and related material expanded tremendously to keep pace with combat needs. For the first time the need to manufacture large numbers of aircraft of identical types put builders on a production line rather than a jobbing basis. Also, mass training of pilots became a prime necessity. Flying had, indeed, ceased to be a game.

The following sections emphasize the status of aviation in the various belligerent nations. A more detailed description of the leading military aircraft and their armament appears in AIRCRAFT, MILITARY.

#### GERMANY

In the immediate prewar period, German planes and pilots held world endurance (24 hours 12 minutes) and distance (1,178 miles) records. German aircraft appeared over Paris within weeks of the declaration of war. Germany produced military planes of standardized design for ease of maintenance and replacement, fitted with excellent engines by Benz and Mercedes. In a rapidly changing technology, however, too much standardization can be a liability. The air war rapidly became a seesaw affair with the better aircraft on one side soon outperformed by newer machines of the enemy.

Probably the greatest contributor to German aircraft development was a Dutch designer, Anthony H.G. Fokker, whose synchronized forward-firing machine guns restored combat superiority to the Germans in 1915 and whose excellent triplane fighter D-VII, used by Baron von Richthofen, could compete with anything put up by the Allies in 1917-18.

By 1918 the imperial government's inventory included many well-known single-seat fighters—Albatros, Roland, Halberstadt, Pfalz—and a series of efficient two-place observation types—Aviatik, A.E.G., Rumpler, Albatros, etc. A number of seaplanes, largely twin-float, single-engined biplanes, were produced for fleet cooperation.

**Airships.** Germany's initial long-range heavy bombardment effort centred about its fleet of rigid Zeppelin-type airships. During the war over 100 were built by Zeppelin and some 20 more by the Schütte-Lanz Company. Many raids were launched against London and other cities, but by 1916 the Allied defenses had improved to the extent that airship missions became too costly in men and machines. During the latter phases of the war the big airships were used only for naval patrols at sea and for general over-land observation.

Performance, however, had improved tremendously. In the summer of 1917, LZ-120 made a 100-hour observation flight over the Baltic Sea. In November 1917, LZ-59 attempted a relief mission deep into German East Africa. Although the mission failed to reach its destination, the airship stayed in the air for more than 95 hours and covered over 4,000 miles.

**Large bombardment aircraft.** With the blunting of the Zeppelin attacks against London and a need to provide an operational capability for night attack against other distant cities, German interest toward the end of the war centred on bombardment airplanes of very large size. Some 60 such aircraft were built in 1916-18. Most familiar were the Gotha biplanes of 1916, with a wingspan of nearly 90 feet, powered by two Mercedes engines of 260 horsepower each. With a 2,000-pound bomb load they had an operating range of some 300 miles. The largest of these giants, however, was the Siemens-Schuckert R-VIII, with a wingspread of over 150 feet and powered by six 300-horsepower engines.

#### FRANCE

France entered World War I with the largest inventory of military aircraft and probably the largest cadre of aviators. Most of the machines were the immediate descendants of the 1910-12 racers (Blériot, Deperdussin,

Nieuport, Morane, etc.), but production was under way on improved and specialized military types, including the R.E.P. monoplanes and the Farman, Voisin, and Caudron biplanes. Bréguet and Durand designs with fabric-covered fuselages were already in evidence.

French military aircraft improved tremendously under the pressures of war. The early birdcage Voisin and Caudron bombers and observation planes gave way to the more efficient long-range Bréguet and Letord day bombers. In the single-seat fighter category, France made great progress. In the end, French, British, and American fighter pilots flying single-seat Nieuports and Spads proved a match for the German Fokker, Pfalz, and Albatros squadrons. Of great importance was the mass production of reliable engines, particularly the eight-cylinder Hispano-Suiza, which was used in the Spads and in the British S.E. 5 fighters.

Apart from combat operations, the French developed ground-support aviation to a high degree. Photographic missions over the lines provided ground commanders with needed battlefield information. Radio telegraphy and visual signals were also widely employed. For naval support, for scouting, and for bombing attack against submarines, a number of float-type seaplanes were in service.

In the early stages of the war the small fleet of non-rigid airships was used by the Army for reconnaissance and for bombardment, but these slow, low-flying machines were so vulnerable to ground and air attack that surviving specimens were turned over to the navy in 1917 for antisubmarine patrol use. Captive balloons were used in large numbers on all fronts for observation purposes.

The growth of the French aviation effort in the course of the war was enormous. As of November 1918, some 180,000 people were employed in the aircraft-manufacturing industry.

#### GREAT BRITAIN

Of the three major western European powers, Britain went into World War I in the weakest position in the air. The Royal Flying Corps (RFC), organized in 1912, mustered only 1,800 officers and men and fewer than 150 flyable aircraft when war was declared in 1914. By November 1918, however, the corps consisted of some 300,000 officers and men, with 22,000 aircraft organized in over 200 squadrons.

Coincident with the formation of the RFC, a Royal Aircraft Factory had been established at Farnborough. Between 1912 and 1914 several experimental military machines were turned out from designs by De Havilland (first of the D.H. series); the British Experimental 2c; and the Sopwith Tabloid. The Tabloid was the ancestor of later high-performance fighters used by both American and British pilots—the Camels, Snipes, Kittens, Bullets, and Hawks—but the 70-horsepower, 75-mph B.E. 2c was the backbone of the RFC in 1912. By 1918, however, the Hispano-Suiza-powered British S.E. 5 performed with the best that Germany could put up.

The earlier British airplanes made use of French engines, Gnome and Clerget radial, and Renault in-line types. Later, the Hispano-Suizas were widely used. As the war progressed, however, excellent British-built engines—Rolls-Royce, Sunbeam, and Beardmore—became available in quantities. Such engines powered the D.H. 4 day bombers and the long-range Handley Page night bombardment types. Night operations began in 1916. By 1918 Handley Page bombers were being turned out in quantity in England and in America.

Naval aviation developed rapidly in Britain. Squadrons of seaplanes and flying boats were used for the protection of principal naval bases and for antisubmarine patrol offshore. Eventually, some 350 airplanes were assigned to the British Grand Fleet. During the last two years of the war, over 100 bombing attacks were made against German submarines at sea.

The modern aircraft carrier had its genesis during this period. Experiments were conducted in launching small fighter planes from platforms built over battleship gun

Ground-  
support  
aviation

Fokker's  
fighter  
planes

Naval  
aviation

turrets, or from barges towed behind high-speed destroyers. At least one former passenger liner was fitted experimentally with a large landing platform above its superstructure.

Interest in nonrigid airships revived early in the war for antisubmarine convoy and coastal patrol work. Hundreds of blimps (from "British Class B airship" plus "limp"—i.e., nonrigid) were built during the four-year period. In the last year of the war over 9,000 sorties against floating mines and submarines are recorded. Also, in spite of the disastrous experience with the rigid airship "Mayfly" in 1911, and based on designs of several Zeppelins shot down in England, construction was begun on several rigid ships. These had little significance during the war but did touch off a brief (and disastrous) postwar airship program (see below, *Developments from 1918 to 1930: Significant technical developments*).

#### OTHER COUNTRIES

Only three other countries—Italy, Russia, and the U.S.—made significant contributions to aviation during World War I.

**Italy.** Italy was among the first to recognize the importance of aircraft in warfare. Beginning in 1911, its bombardment squadrons were active in Libya. Out of this experience emerged the multi-engined Caproni bombers. Italian manufacturers in 1914–18 produced a considerable number of trainers, observation planes, and single-seat fighters, but the most spectacular were the large two-, three-, and four-engined Capronis. Day bombing started in 1916. Night operations with larger types were begun early in 1917. Built originally as two-engined biplanes, the later Capronis (some of which were produced under contract in the United States, with Liberty engines) were three- and four-engined triplanes.

**Russia.** Russia's contribution to aviation development of the period was a giant four-engined bomber (1915) by Sikorsky. It was derived from the "Ilya Mourometz" of 1912. After Sikorsky had abandoned (temporarily) his work with helicopters, he designed and built the first successful multi-engined plane—a large biplane carrying 16 passengers in a closed cabin, powered by four 100-horsepower Mercedes engines. A bomber version of this machine with four 120-horsepower engines was used on the Russian front in 1915.

**United States.** When the U.S. entered the European war in April 1917, army aviation was still a section of the Signal Corps. It mustered 65 officers and 1,087 men and possessed not a single aircraft capable of combat. The naval air arm consisted of 38 naval aviators, some 160 enlisted men, and possibly a dozen hydro-airplanes and embryonic flying boats, all based at a single air station at Pensacola, Florida. None of the flyable airplanes carried any armament.

An Aircraft Production Board was appointed by Pres. Woodrow Wilson, and the decision was made to manufacture British, French, and Italian planes and engines in quantity. The only fighting plane that came out of the program in time to see action was the American-built British D.H. 4. Some 1,370 were in Europe at the Armistice, but only 740 ever saw service at the front.

A major United States accomplishment, however, was the rapid design and production of the famous Liberty engines. By October 21, 1917, the first 12-cylinder Liberty was test-flown. At the Armistice, orders on the books totalled 52,000. Some 13,000 had already been delivered, and production was 150 engines a day.

#### V. Developments from 1918 to 1930

From 1914 to 1918 all aviation activities focussed on a single objective, the winning of a war. When that task ended, most of the machines and the thousands of people involved suddenly found themselves unemployed. Thousands of aircraft were simply piled up and burned. Manufacture of aviation equipment of all kinds halted. Former military pilots, trying to make a living by their war-acquired flying skill, revived the circus-and-carnival atmosphere of the prewar period. With a surplus "Jenny" or "Avro" or "Cannuck," the barnstormers provided

thrills wherever they could get a crowd; they sustained popular interest in aviation, and, even more important, they sold rides to the public—the thin wedge that, a decade later, cracked open the air-transport market.

A few found employment in flying the mail. In the spring of 1918 the U.S. Post Office Department had sought bids for special mail-carrying airplanes to operate between Washington and New York. With nonmilitary aircraft in short supply, the U.S. Army was requested to undertake the assignment. Flights were inaugurated in May, but by midsummer the army had found that with the heavy demands of the war in Europe it could not spare either planes or pilots for the mail service. On August 12, 1918, the Post Office took over the New York–Washington airmail run as a civil operation. On September 8, 1920, transcontinental airmail was inaugurated. At first, operations were restricted to daylight hours, but on February 22, 1921, day and night flights were started, marking the real beginning of commercial air transport in America and creating a new demand for more pilots and better airplanes.

One of the factors that limited technical development well into the mid-1920s was the great surplus of wartime engines that were in production at the time of the Armistice. The result was that for the first five or six years, in spite of far superior power plants on drawing boards, or actually running on test stands, economic necessity dictated that new airplane designs be laid out around wartime engines.

Toward the latter half of the 1920s substantial advances in design and construction of aircraft came into being. Concurrently, organized research laboratories, both governmental and private, were established to meet the needs of the scientifically oriented designers and engineers entering the industry.

**Guggenheim Fund.** In January 1926 an event occurred in America that had a profound effect on all subsequent development everywhere—announcement of the establishment of the Daniel Guggenheim Fund for the Promotion of Aeronautics. Daniel Guggenheim (1856–1930), who never in his life owned an airplane, nor derived any profit from participation in aviation, made grants totaling \$3,000,000 (beginning January 16, 1926) for the following purposes: (1) To promote aeronautical education both in institutions of learning and among the general public. (2) To assist in the extension of fundamental aeronautical science. (3) To assist in the development of commercial aircraft and aircraft equipment. (4) To further the application of aircraft in business, industry, and other economic and social activities of the nation. By February 1, 1930, when the fund was completely liquidated, each of its objectives had been fulfilled many times over. Its greatest importance was in the fields of education and research. Beginning in 1926, several Guggenheim schools of aeronautics and Guggenheim aeronautical laboratories were established. These centres attracted such outstanding scholars and teachers as Alexander Klemin, Theodore von Kármán, Robert and Clark Millikan, and William F. Durand. Many of the most significant advances in aviation—and in space exploration since the 1940s—were the result of work by graduates of Guggenheim schools or by recipients of Guggenheim research grants.

#### GOVERNMENT-SPONSORED RESEARCH

Government-sponsored aeronautical research in the United States lagged far behind that of other major powers in 1914. Since 1866 the Aeronautical Society of Great Britain had been stimulating research and experimentation and fostering the exchange of information in the aeronautical sciences. The Royal Aircraft Factory was actively engaged in development projects by 1912. France had several major experiment stations: Eiffel's two wind tunnels, one at the tower and one at Auteuil; an army laboratory at Chalais-Meudon; and the Institut Aérotechnique at Saint-Cyr. Germany supported research laboratories in universities and technical schools at Göttingen, Aachen, and Berlin and operated a national installation at Adlershof. Italy and Russia had

Table 1: Principal Record Flights (1919–30)

<b>1919</b>		<b>1927</b>	
February 21	U.S. Army, using Thomas Morse "Scout" with 300-hp Hispano-Suiza engine, sets American speed record of 164 mph.	May 20–21	Charles A. Lindbergh, after a one-stop flight from San Diego to New York, in the Ryan-built monoplane "Spirit of St. Louis," makes first nonstop flight from New York to Paris (33 hours, 30 minutes) to win the Orteig Prize (see Figure 4, bottom).
May 6–31	A squadron of U.S. Navy Curtiss flying boats attempts first Atlantic crossing. NC-1 and NC-3 lost at sea off Azores, crews rescued. NC-4 completes crossing, (see Figure 4, center) via Azores, arriving at Plymouth, England.	June 4–5	Clarence Chamberlin and Charles Levine in a single-engine Bellanca monoplane, fly from New York City to Eisleben, Germany.
June 14–15	Capt. John Alcock and Lt. Arthur Brown (ex-RFC) fly from Newfoundland to Ireland in Vickers "Vimy" 2-engined biplane.	June 28	Lieuts. Maitland and Hegenberger (U.S. Army) in 3-engined Fokker fly from Oakland, Calif. to Honolulu, 2400 miles over open ocean.
July 2–13	British dirigible R-34 makes round-trip flight from England to New York with 6 officers and 21 men.	June 29–30	Cmdr. Richard Byrd and crew of three fly from New York to France in 3-engined Fokker "America."
September 18	Roland Rohlf in Curtiss "Wasp" sets 34,910-ft altitude record.	July 4	Lieut. C.C. Champion, USN, pushes world's altitude record to 37,995 ft over Washington, D.C., in a Wright "Apache."
<b>1922</b>		July 14–15	Bronte and Smith fly 2340 miles from Oakland, Calif. to Molokai, Hawaii in 25 hours, 36 minutes.
March 30–June 5	Two Portuguese officers, Capt. S. Cabral and Vice Admiral G. Coutinho, fly by stages from Lisbon to Rio de Janeiro in British-built Fairey seaplane to record first crossing of South Atlantic.	October 14–15	Costes and Le Brix in Breguet biplane cross from Senegal, Africa, to Rio de Janeiro in 21 hours, 18 minutes.
October 18	World speed record set by General William Mitchell in Curtiss racer at 222.96 mph.	November 6	Lieut. A.J. Williams in Schneider Cup Racer establishes an unofficial speed record of 322.6 mph.
<b>1923</b>		<b>1928</b>	
May 2–3	U.S. Army pilots Kelly and Macready make first nonstop transcontinental flight (New York to San Diego) in Liberty-powered T-2 monoplane.	February	Bert Hinkler makes solo flight London to Australia.
August–December	Former German Zeppelin L-72 acquired by France after war, renamed "Dixmude," makes series of five flights across Mediterranean into North Africa.	April 12–13	Lady Mary Heath flies solo from Cape Town to London. German Junkers monoplane "Bremen" makes first east-west Atlantic crossing.
November 4	Lieut. A.J. Williams raises world speed record to 266.6 mph in Navy-Curtiss Racer.	May–June	Charles Kingsford-Smith and crew of three in Fokker "Southern Cross" fly from Oakland, Calif. to Sydney, Australia via Honolulu and the Fiji Islands.
<b>1924</b>		June 17–18	Amelia Earhart with pilots Stultz and Gordon fly Atlantic in monoplane "Friendship."
April–September	Four U.S. Army Douglas "World Cruisers" attempt round-the-world flight. Two lost en route; two, "New Orleans" and "Chicago," complete 26,345-mi. trip.	October 11–15	Airship "Graf Zeppelin" flies from Friedrichshafen, Germany to Lakehurst, N.J. with 23 passengers.
May 21	Lieut. J.A. Macready, USAS, sets altitude record at 35,239 ft.	<b>1929</b>	
October 12–15	Zeppelin LZ1-1126 (ZR1-13) renamed "Los Angeles," crossed from Friedrichshafen (Ger.) to Lakehurst for delivery to U.S. Navy.	January 1–7	U.S. Army Fokker C-2 "Question Mark" flies for 150 hours, 40 minutes over Los Angeles in first major air-to-air refueling test.
<b>1925</b>		August 15–20	Mamer and Walker in single-engined Buhl monoplane "Spokane Sun God" make nonstop transcontinental round-trip from Spokane, Washington, in 115 hours, 45 minutes with 11 air-to-air refuelings en route.
April–November	Italian Commander de Pinedo and mechanic in single-engined Savoia flying boat, fly from Italy to Australia, returning via Japan—30,000 miles.	August	"Graf Zeppelin" makes first round-the-world airship flight including nonstop distance record from Friedrichshafen to Tokyo of 6,980 miles.
November	Alan Cobham flies from London to Cape Town via Cairo—8,500 miles in 94 hours.	November 28–29	Commander Byrd and crew of three fly over South Pole in Ford 3-engined monoplane "Floyd Bennett."
<b>1926</b>		<b>1930</b>	
May 9	Commander Byrd and copilot Floyd Bennett fly from Spitsbergen over North Pole and return in 3-engined monoplane "Josephine Ford."	May–July	Kingsford-Smith in "Southern Cross" makes round-the-world flight.
May 11–14	Amundsen and crew fly over North Pole from Spitsbergen to Pt. Barrow, Alaska, in Italian-built semirigid dirigible "Norge."	July 4	Lieut. Apollo Soucek, USN, raises world altitude mark to 43,166 ft.
		July 29–August 1	British airship R-100 flies from England to Canada in 78 hours, 51 minutes.
		September 1–2	Costes and Bellonte make first Paris-New York City flight—4100 miles in 37 hours, 18 minutes.

well-organized laboratories before the United States took its first official steps in that direction.

Following a study of the United States position with respect to wartime aviation in Europe, the Smithsonian Institution in 1915 recommended to Congress the establishment of a National Advisory Committee for Aeronautics (NACA). In addition to other activities the committee was authorized to own laboratories and to conduct research. The enabling legislation was approved on March 3, 1915, and the first full committee meeting was held on April 23.

During the next decade the record of aeronautical research progress at Langley Field, Virginia, the site of the committee's first research laboratory, was phenomenal. From a standing start in 1917, with a handful of technical personnel and three or four test airplanes, it was recognized by 1930 as the greatest research centre in the world, with a large and growing scientific staff and a capability of testing virtually all forms of aircraft in all regimes of flight under controlled conditions in the laboratory.

#### GOVERNMENT COORDINATION OF AVIATION ACTIVITIES

Slowly but surely a market for new aircraft began to grow. Aircraft manufacture revived to meet the demand for new military types and to serve the needs of a growing airmail service. Intercompany competition for new customers benefited airplane and engine performance. Airplanes became more reliable, more comfortable, easier to fly. There was some preliminary activity in

building larger planes to carry passengers and cargo for profit on regular schedules.

By 1925, however, it was apparent everywhere that the expanding manufacture and use of aircraft must be subject to some overall coordination and regulation if chaos was to be avoided. In the United States, a board was appointed by Pres. Calvin Coolidge to establish a national policy for the development of all aspects of aviation. The board's recommendations resulted in passage of the Air Commerce Act of 1926, the Navy Five Year Aircraft Program (1926), and the Army Five Year Aircraft Program (1926). These acts provided a relatively stable base for American aviation development for the next decade.

The same problems were attacked by governments everywhere. Britain, France, Italy, and other countries established air ministries at Cabinet level to coordinate their civil and military aviation requirements. When international commercial flights became possible, international commissions were established to control traffic and to promulgate rules and regulations covering flight operations and passenger safety.

#### RECORD FLIGHTS

With the growing improvement in performance and reliability, public interest focussed on long-range flights, both cross-country and intercontinental. Just as the English Channel had posed a challenge to Latham and Blériot in 1909, so ocean crossings and transpolar flights became the targets of many ambitions in the middle

Prizes for  
record  
flights

1920s. Again, for their publicity value, newspapers and wealthy private citizens posted substantial prizes for such flights. The London *Daily Mail* offered £10,000 for a nonstop Atlantic crossing, and in 1919 Raymond Orteig established a \$25,000 prize for a nonstop flight between New York and Paris. Later (1927) first and second prizes of \$25,000 and \$10,000 were posted by James Dole for a race from California to Hawaii.

Although the military services of most countries were ineligible to compete for monetary prizes, many special long-range flights were organized for their value as military exercises. To illustrate the expanding capabilities of aircraft during the 1920s, a selection of successful trans-continent and transocean flights (both by airplane and by airship) is given in Table 1. Between 1927 and 1930, of 31 transatlantic attempts, only 10 succeeded, and 16 men and three women died in the failures. The Dole Race across the Pacific (August 1927) cost six planes and ten lives. A few milestones in speed and altitude performance have been included in the table.

#### SIGNIFICANT TECHNICAL DEVELOPMENTS

While the public imagination was captured by the headline flights, sound technical progress behind the scenes was contributing powerfully to the great forward steps of the 1930s and 1940s. A number of postwar ideas tested and found wanting eventually disappeared, notably airships and autogiros.

**Airships.** Development of nonrigid airships (blimps) in Europe halted at the end of the war. In the U.S., however, both the army and the navy carried on limited programs during the 1920s. Most interesting design innovation was the navy's all-metal ZMC-2, first tested in 1929. Only one was built.

The U.S. Army purchased the 400-foot semirigid airship "Roma" from Italy in 1921. It crashed and burned at Langley Field in 1922 with a loss of 34 lives. This not only ended the use of hydrogen as a lifting gas in the U.S. airships but terminated U.S. interest in this class of airship.

As noted above, Britain had become actively involved in a rigid-airship construction program toward the end of the war. The successful transatlantic round trip of the R-34 induced the U.S. Navy to order a British-built ship (R-38), which was completed in mid-1921. During a test flight on August 21, however, she broke up in the air and crashed with a loss of 45 men. This terminated U.S. interest in British airships.

Britain's construction program continued, however, and culminated in 1930 with the launching of two super-airships of the Zeppelin type, the R-100 and R-101, designed for the transatlantic and the Far East trade. The R-100 made one round trip to Canada in July, but the R-101 crashed and burned on a French hillside on her maiden voyage to India, killing a number of high-ranking RAF and civil officials and terminating British interest in airships.

Meanwhile, the United States had some disastrous home-grown experiences. Parallel with the construction of the ill-fated British R-38, the U.S. Navy built an airship at the Philadelphia Naval Aircraft Factory and assembled it at the Naval Air Station, Lakehurst, New Jersey. The 680-foot "Shenandoah" was the first rigid dirigible to be filled with helium rather than with hydrogen. She was commissioned in October 1923 and for two years participated in naval exercises over land and with the fleet at sea. In September 1925 she ran into a storm over southern Ohio and broke up in the air with a loss of 14 officers and men. Twenty-seven of her complement were saved by riding sections of the ship to the ground as free balloons.

A month later the German-built LZ-126 (ZR1-13), acquired by the United States under reparations agreements, arrived at Lakehurst. Commissioned as the "Los Angeles," she was operated for nine years on missions of many kinds, in all weather conditions, without accident or serious incident, an all-time record for airships. Decommissioned in June 1932, she was kept intact for test purposes and finally broken up in 1939.

On the strength of the experience with the "Los Angeles," the navy ordered construction of two much larger ships, the "Akron" and the "Macon," from the U.S. Goodyear-Zeppelin Corporation. The "Akron" went into service on October 27, 1931. After a year and a half of active service, including successful experimentation as a carrier for fighter aircraft, she went down in a storm at sea, losing 73 officers and men.

The "Macon" was well along when the "Akron" was lost. She went into service on June 23, 1933, and operated successfully until February 12, 1935, when, after what appeared to be a minor structural failure, she collapsed and was lost off Point Sur, California. Most of her crew were rescued, but this terminated U.S. interest in airships.

Graf von Zeppelin had died in March 1917, and Germany's defeat had stopped all airship construction except for those due for delivery to the Allies under the reparations program. Restrictions on commercial airship construction were relaxed in 1926, and work was started on LZ-127, best known as the "Graf Zeppelin." She was launched in September 1928. Under the command of Hugo Eckener, Zeppelin's successor, she explored many areas of the world as a passenger carrier. Her successful performance encouraged the construction of a much larger ship, the "Hindenburg," in the early 1930s.

During the summer of 1936 the "Hindenburg" made 10 routine round trips between Friedrichshafen and Lakehurst, New Jersey. On her first trip the following year (May 5-6) as she was approaching the mooring mast at Lakehurst, for reasons that have never been fully explained, the ship exploded and burned. She, like all her European predecessors, was hydrogen-filled. This terminated interest in rigid airships everywhere in the world.

**Rotary-wing aircraft.** Interest in vertical mechanical flight lapsed during World War I except for an abortive effort by a young Hungarian scientist, Theodore von Kármán, to substitute a tethered helicopter for the conventional gas-filled military observation balloon. During the 1920s, however, an amazing variety of experimental vertical risers appeared in Europe and in America, all conspicuously awkward and complicated in configuration, all conspicuously unsuccessful as flying machines. Most of these machines, with a great deal of thrashing about, managed to rise a few feet off the ground but once airborne proved to be virtually uncontrollable.

It remained for a Spanish engineer, Juan de la Cierva, in a search for an airplane that could be slowed down in flight and landed vertically, to provide the key to practical rotary-wing flight. Between 1920 and 1923 he built a series of machines with conventional airplane fuselages (including engine and propeller) above which was mounted in a horizontal position a large multibladed windmill. The unpowered windmill was free to rotate under aerodynamic forces as the machine was driven forward by the action of its normal propeller. This autorotation of the wing system produced the required lift and gave the device its name—the autogiro.

Cierva's work was uniformly unsuccessful until in 1923 he hit upon the idea of articulating (or hinging) the rotor blades at the hub and allowing them to respond individually to the aerodynamic and centrifugal forces involved (see Figure 5, left). This arrangement not only solved the immediate problems of the autogiro but provided the experience that paved the way for helicopter development of 1930 and later.

During the early 1930s the autogiro created a great wave of popular interest everywhere, particularly in Britain and in America. Ninety autogiros were in service by 1932 in the United States alone, some in the hands of private owners, some for advertising and publicity purposes, a few under experimentation by the military services and the Post Office Department, which considered them for transferring mail from post office rooftops to airfields.

Although design improvements were continuous during the 1930s, and many new applications for autogiros were found, the type had virtually disappeared by 1940 and is unlikely to be revived in any appreciable numbers, sim-

The  
autogiro

The "Shen-  
andoah"  
disaster

ply because there is nothing that autogiros could do that helicopters cannot do better and more economically.

**Aircraft-carrier operations.** Carrier operations were forecast as early as 1911 when Eugene Ely made the first landings and takeoffs from a U.S. Navy ship in a Curtiss biplane. During World War I the Royal Navy of Great Britain developed the first true aircraft carrier, the HMS "Argus," converted from a commercial vessel. In the early 1920s both the United States and Japan took active interest. The USS "Langley" (converted from the collier "Jupiter") and the Japanese "Hosho" both went into operation in 1922. The Washington Arms Limitation Treaty of 1922 put a size limitation on conversions and new construction. During the late 1920s a number of such vessels were under construction, including the USS "Saratoga" and USS "Lexington." These were the experimental ships on which were tested the carrier-based aircraft and operating techniques that were to play such dramatic and determining roles in World War II, a dozen years later.

**Blind-landing research.** By the mid-1920s it became obvious that all aircraft operations, both military and commercial, had to be made independent of weather. By that time, long-range flights over land areas were feasible, using rudimentary radio direction finders and lighted beacons at night, but the problem of landing and takeoff when the pilot could not see where he was or where he was heading was still unsolved. Instrument displays in cockpits had vastly improved over the improvised arrangements of wartime, but the pilots of rapidly moving airplanes required a reliable fix in three-dimensional space for landing and takeoff in conditions of limited visibility.

To deal with this problem, the Daniel Guggenheim Fund established a Full Flight Laboratory at Mitchel Field, Long Island, in cooperation with the Army Air Corps and the several manufacturers of aircraft instruments. Lieut. (later Lieut. Gen.) James H. Doolittle was selected to head the operation. On September 24, 1929, in a fully hooded cockpit, he made the first completely blind flight in history, taking off, flying over a predetermined course, and landing at the point of departure, all by instruments alone.

**Rocket research.** The idea of flying by rocket power goes far back into history. By 1920 it had captured the imagination of Robert H. Goddard, a young professor of physics at Clark University in Worcester, Massachusetts, who had made his first theoretical studies of a liquid-fuel rocket in February 1909. His basic patent for a rocket apparatus was granted in July 1914, and in 1918 he developed and patented a rocket missile, the forerunner of the shoulder-type rocket launcher of World War II known as the bazooka.

In September 1916 he applied to the Smithsonian Institution for a research grant to continue his work on rockets. He received \$5,000, and in September 1919 the Smithsonian published his classic paper, "A Method of Reaching Extreme Altitudes." The first experimental liquid-rocket flight was made on March 16, 1926, from a farm near Auburn, Massachusetts. Three years later and after a number of spectacular and noisy rocket firings, the local fire and police authorities suggested that he move to some more remote place. By 1930, supported by a grant of \$50,000 from the Guggenheim Foundation, Goddard's entire operation was moved to a desert site near Roswell, New Mexico.

Meanwhile, rocket research was going forward independently elsewhere in the world. Unknown in the '20s (but amply documented in later years), active rocket research was under way in the Soviet Union under the direction of Konstantin Tsiolkovsky. Germany's official interest in rockets as weapons stemmed from the limitations imposed by the Treaty of Versailles on development of conventional artillery. As a by-product of the military-research program, an active society for space travel by rocket was formed in 1927. The first flight of a rocket-powered aircraft was made on September 30, 1929, by Fritz von Opel in a glider with a gunpowder rocket attached to the rear.

**Gliders and sailplanes.** Between 1910 and 1920 interest in gliders almost disappeared. The airplane had taken over. Beginning in 1919, however, and again as a direct result of the limitations in the building and use of powered aircraft imposed on Germany by the Treaty of Versailles, a renaissance of gliding and soaring occurred. It is still actively going on.

At first ostensibly a sport, gliding in Germany became a means of training fighter and bomber pilots to man future Luftwaffe squadrons. Furthermore, the design and construction of light and efficient sailplanes gave German scientists and engineers an opportunity for sophisticated research in aerodynamics and in the efficient use of light materials, which proved useful in the early 1930s when Hitler abrogated treaty limitations and began to rearm Germany in the air.

The first motorless aircraft competition was held in the Rhön Mountains in 1920. Some two dozen machines participated. Best performance was a flight of 6,000 feet in about 2½ minutes. Two years later, a permanent soaring centre had been established at the Wasserkuppe in Germany, and competitions were being staged frequently in France, Switzerland, and England. Thousands of young glider pilots were in training. By that time, as a result of improvements in design and in piloting techniques, the soaring record had been raised to over three hours.

By 1930 development was well under way in America. A number of soaring and gliding sites had been established, notably at Elmira, New York, and on the West Coast near San Diego, where wind and terrain conditions were favourable.

Periodic competitions at such centres attracted machines and pilots from all over the world. Using highly efficient sailplanes and taking advantage of mechanical updrafts (along mountain ridges) and thermal updrafts (in the vicinity of thunderstorms), by 1930 altitudes of over 17,000 feet had been reached, and flight ranges extended to nearly 300 miles.

**Amphibians.** In the early 1920s interest developed in amphibious airplanes that could operate equally well from land or from water. Chief proponent of the idea was an American engineer, Grover Loening. As a successor to an experimental air yacht, his first amphibian was test-flown in June 1924. In appearance it was unique—a biplane powered with an inverted Liberty engine on a deep fuselage-hull combination with a long, slipper-like forebody to protect the propeller. A number of these machines were built for the military services and Coast Guard and were eventually sold to a number of airlines and to a few private owners.

A number of smaller amphibious types appeared in Europe in the late 1920s (Schrek, Savoia, etc.). By 1929 Pan American Airways Corporation had begun service to South America using Sikorsky S-38 and S-40 amphibians, but these were shortly replaced by large flying boats.

In the next ten years, however, interest in amphibious aircraft declined. High first cost and maintenance expense limited their acceptance by both military and civilian users. In addition, the greatly increased availability of suitable landing fields all over the world reduced the advantage of their dual operational capability.

#### THE RISE OF COMMERCIAL AIR TRANSPORT

Commercial air transport, the carrying of paying passengers from point to point on preannounced schedules, began with the inauguration of Graf von Zeppelin's airship service, Delag, in 1912, and revived briefly in 1919. Since that time, however, the only commercial lighter-than-air operation (apart from sight-seeing flights by blimps at such places as Miami and Los Angeles) was that offered by the "Hindenburg" in 1936. All other commercial development has been based on the use of airplanes and (more recently) on helicopters.

Shortly after the close of World War I, international air transport services in Europe began to proliferate. By 1920 passenger flights on regular schedules were offered between many major cities. The equipment was war surplus, ranging from converted small craft with one or two

regular  
passenger  
flights

seats up to modified Handley Page and Farman bombers. Seating accommodations were Spartan at best, usually a row of wicker chairs replacing the former military gear in the uninsulated, unheated fuselages. Such ships were noisy and uncomfortable, and, passengers, for the most part, once embarked, got along without any attention from the crews. Operating procedures were sketchy. Air-to-ground communications were uncertain or lacking. There was little available in the way of ground equipment, either for servicing the aircraft or for flight information for pilots. Originally all such services were far from reliable, and accidents were not uncommon.

Major European governments early recognized the economic and political advantages of airline development under their own flags and gave official encouragement in the form of substantial subsidies to their nationals to extend their air services on the Continent and out to their colonial possessions. In the course of 10 years, Europe was crisscrossed with a regular air transport network. During this period the great airlines of Europe had their origins—Imperial Airways Ltd. (later BOAC and BEA), Air France, KLM (Royal Dutch Airlines), Lufthansa, Swissair, Alla Littoria. Also, with increasing competition for passengers, the earlier converted bombers disappeared, and especially designed passenger aircraft with more comfortable accommodations and better services for the customers (both on the ground and in the air) became standard equipment.

While the European countries were underwriting their passenger-carrying systems, the United States was expanding its airways and airway communications for the benefit of its rapidly growing airmail system, operated by the Post Office Department. It was not until 1925 that private companies were encouraged to handle U.S. airmail under contract, actually as a form of subsidy to encourage the development of passenger traffic. The present U.S. airline system can trace its origins to legislation passed in 1925 and designed to connect a large number of American cities and towns to the transcontinental mail routes operated by the Post Office. Passenger service supported by the system began on April 4, 1927, with a flight from Boston to New York City. Passenger demand was light until Lindbergh's flight in May of 1927. From 1927 to 1930, business began to boom, encouraged by Lindbergh's survey flights around the United States and his pioneering of new routes to South and Central America. Pan American Airways was already reaching out into the international market. Internally, new transcontinental and interurban lines were being formed by merger. New equipment, including the famous Ford and Fokker trimotors and the Sikorsky Clippers, was becoming available.

## VI. Developments from 1930 to 1945

To pinpoint the exact time when aviation turned a corner and won recognition as an important contributing factor to the world's economy would be difficult, but a definite breakthrough in this realm did occur in the early 1930s. Aeronautical research programs that had been developing in university- and government-supported laboratories both in Europe and in America in the late 1920s began to produce results. A rapidly accumulating body of experimental data became available to aircraft and engine designers. It became possible to make accurate mathematical forecasts of performance and flight behaviour and to check out calculations in wind tunnels (up to full-scale) before subjecting machines to the hazards of free flight. Much of this information was circulated in the form of scientific reports or technical publications.

Simultaneously a growing cadre of young, optimistic, and enthusiastic aeronautical engineers and scientists was coming out of the schools and universities in Europe and the United States, all eager to apply these data to new designs that would fly higher, farther, faster. Apart from purely military objectives, there now emerged a new and eventually more important idea: that aircraft could be designed to produce profit for their owners in commercial operations.

As a result, the external configurations and the inboard

arrangements of virtually all categories of airplane underwent radical changes in the 1929–32 period. There were occasional exceptions, but the average pre-1930 airplane was only slightly distinguishable from its World War I prototype—a wood, fabric-covered, “stick and wire” braced biplane with fixed-pitch propellers and an open or only partially enclosed, pilot's cockpit. Passenger accommodations (if any) were primitive.

By 1932 the impact of research was clearly in evidence. Streamlining had become the order of the day. Again, there were exceptions, but the average airplane in all categories became an externally smooth, internally braced, low-wing, all-metal monoplane with air-cooled engine (or engines) and with controllable-pitch propellers (*i.e.*, the blade angle could be adjusted); landing gear retracted completely in flight, and pilots and passengers were housed in insulated and sound-proofed compartments. Except that jet engines have replaced the 1930–40 air-cooled engine-and-propeller combination, the same general description applies to most military and commercial configurations of the 1970s.

### COMMERCIAL AVIATION

**Europe.** In Europe, commercial air transportation was well developed by the early 1930s. By then the converted bombers from World War I had largely been replaced by aircraft designed primarily for the handling of passengers and cargo. For the western European services, because city-to-city distances were short, comfort and convenience for the passengers were more important than high speed. On long colonial routes, however, conditions were reversed. Passenger comfort was compromised in favour of higher speeds and longer range.

Most of the aircraft in use were multi-engined (usually three-engined) monoplanes, such as the German Junkers G 24 (prototype of the Ju 52), the French Wibaut 210, the Italian Savoia Marchetti SM.73, etc. Britain, however, for many years retained the huge, four-engined Handley Page biplanes that lumbered between London and Paris at about 100 mph. In the late 1930s Imperial Airways introduced the fast and efficient four-engined “Ensign”-class monoplanes on many of its services. This machine was useful as a troop carrier in World War II.

**United States.** In the United States commercial air transport got off to a slow start. Until 1927 developmental emphasis was focussed on the airmail service rather than on passenger carrying. This in the end proved advantageous, for when the commercial demand developed, the country was already laced together by a network of established airways, beacon-lighted for night operations and equipped with relatively reliable radio navigation and communication facilities.

The United States airways system was operated by the Post Office Department until September 1, 1927, when the mail routes were turned over to a group of private corporations under contract. Under the impetus of U.S. government subsidy for carrying the mail, many small companies combined into larger units, extended their range of operations to more distant cities, and began to think in terms of improving and standardizing both ground and airborne equipment. About this time (1928) Henry Ford's interest in aviation led to the production of the Ford trimotor all-aluminum plane as a competitor to the all-wood Fokker trimotor, which was a civil version of the U.S. Army's Fokker bombers.

During the first few years of the 1930s, airline passengers in Europe and the U.S. totalled only a few thousand annually. Accidents were common, the fatality rate being about one for every 8,000,000 passenger-miles. But a decade later several million passengers a year were riding the world's airlines, and the average fatal accident rate had dropped to less than three for every 100,000,000 passenger-miles.

The most apparent change (from the standpoint of the travelling public) was in the aircraft themselves. Almost overnight (1933–34) old planes vanished, and in their places came the streamlined, all-metal, efficient, and comfortable Boeing 247D's, the Douglas DC-2's and 3's, and the Lockheed 10's. These were to become the nucleus

Stream-  
lining

U.S.  
emphasis  
on airmail  
service

of most air-transport fleets in America and in Europe for many years. They and their direct descendants established performance standards that served the travelling public well for more than a decade; *i.e.*, until the introduction of jet aircraft in the 1950s.

**Intercontinental service.** For intercontinental commercial transport it first appeared that the flying boat was the logical vehicle. During the 1930s these reached the peak of their development, both in Europe and in America. A German-built Dornier WAL flying boat successfully explored the North Atlantic routes in 1930, and in the same year the world's largest flying boat, the 12-motored Dornier Do X, built for Lufthansa, left Friedrichshafen in November and, after a series of accidents and mechanical delays, finally reached New York nine months later (August 1931). It was shortly abandoned to end its days in a German museum. Meanwhile, France had established a service across the South Atlantic using Latécoeur-300 flying boats.

By the summer of 1939 French, German, and Italian air services were operating regularly between Africa and South America. Germany, in particular, was penetrating deep into South America with passenger and cargo operations. It had also piled up three years' experience with mail-carrying seaplanes catapulted from ocean liners in both the North and South Atlantic. All such activity terminated with the outbreak of World War II.

Britain's Imperial Airways and Pan American Airways of the U.S. cooperated in opening up passenger services between North America and Europe. Both were operating experimental services between New York and Bermuda in 1937. Shortly thereafter, flights were extended across the North Atlantic via Newfoundland and Ireland or the Azores.

**Pan American World Airways.** The history of America's intercontinental airlines was, for many years, largely the history of Pan American World Airways. Founded in 1928, the company originally operated between Florida and Cuba; by 1938 routes circled South America and reached across the Pacific to Manila and across the Atlantic to England. Large amphibians, then two- and four-engined flying boats were used.

In opening its Pacific routes in 1935, the company put into service the Martin M-130 four-engined flying boat (see Figure 6). It was replaced in 1938 by the still larger

Boeing 314 Clipper, which performed service in both the Atlantic and Pacific through World War II.

But the flying boat had outlived its usefulness as a commercial vehicle, and by 1950 virtually all overseas schedules by major airlines were being flown by the more economical and more flexible land-type aircraft.

**U.S. government regulation.** The development of air transportation in the United States was not without problems. Assignment of routes and regulation of rates, certification and licensing of airplanes and pilots, and the establishment of safety standards came under the general purview of the Aeronautics Branch of the Department of Commerce. In 1934 a scandal over allegedly illegal contract awards led to the sudden cancellation of all existing domestic mail contracts. Concurrently, the President ordered the Army Air Corps to take over the airmail services. Many problems ensued, and a temporary airmail law was rushed through Congress to enable the mail services to be returned to private contractors. The bill carried with it provision for the appointment of a Federal Aviation Commission to make a study of the overall aviation situation and to make recommendations for its future reorganization. This resulted in the Civil Aeronautics Act of 1938 and the creation of a Civil Aeronautics Authority. Later, in July 1940, the Civil Aeronautics Authority became a licensing and regulatory agency within the Department of Commerce, and a Civil Aeronautics Board (directly under the secretary of commerce) was established to control airline economic and safety functions. In 1968 these agencies were transferred to the newly created Department of Transportation.

Authority

#### GENERAL AVIATION

All nonmilitary and non-airline airplanes and helicopters are considered to be engaged in general aviation activities.

**Long-distance flights.** Popular interest in spectacular long-distance flights was strong up until the outbreak of World War II. Whereas successful ocean crossings had been the prime objectives of pilots in the late 1920s, around-the-world attempts provided headlines for the 1930s. Since no nonstop, around-the-world capability then existed, such flights of necessity required numerous refuellings en route. Refuelling in the air had previously been tested by Sir Alan Cobham in England and by the Air Corps in America, but the logistics of an around-the-world refuelling system were beyond then-current capabilities.

**Notable around-the-world attempts.** Wiley Post and Harold Gatty left Roosevelt Field, New York, on June 23, 1931, in the single-engined Lockheed monoplane "Winnie Mae" and returned to their starting point on July 1 after covering 15,474 miles around the Northern Hemisphere in eight days 16 hours flying time. Wiley Post took off alone in the "Winnie Mae" from Floyd Bennett Field, New York, on July 15, 1933, and returned on July 22, after covering 15,596 miles on the same course.

Amelia Earhart (after her successful solo transatlantic and transpacific flights) made two attempts at a world flight in a twin-engined Lockheed Electra with Fred Noonan as navigator. In March 1937 they took off on a westbound course from San Francisco, but sustained takeoff damage in leaving Honolulu, which necessitated shipping the airplane back to the United States for repair. On a second attempt they departed from Florida, eastbound, on May 21, crossed the South Atlantic, traversed Europe and southern Asia, and started across the Pacific from Australia. Somewhere in the vicinity of Howland Island they disappeared. In spite of an extensive sea and air search no traces were found.

Howard Hughes, a motion-picture producer and sportsman pilot, took off from Floyd Bennett Field on July 10, 1938, in a twin-engined Lockheed 14 with a crew of four. Three days and 19 hours later they returned, having flown some 15,500 miles.

**Other notable long-range flights.** In 1933 and again in 1939 Commander Richard E. Byrd and the Arctic explorer Lincoln Ellsworth led separate expeditions into Antarctica, exploring huge unknown areas by air.

In the summer of 1931 Col. and Mrs. Charles A. Lindbergh flew a single-engined Lockheed Sirius monoplane on floats to Shanghai, China, via Canada, Alaska, and Japan. In 1933, in the same aircraft, they made a survey flight on behalf of Pan American Airways over

the North Atlantic to England, across Europe, down the West Coast of Africa, over the South Atlantic to Brazil, thence to New York City, a cruise of over 30,000 miles.

In July 1933 the Italian air minister, Italo Balbo, led a flight of 24 twin-engined Savoia Marchetti flying boats from Italy to Chicago via Iceland, Labrador, and Canada. The squadron returned to Italy via New York.

In 1937 the Soviet Union established an air-supplied navigation and communications base on the ice less than 15 miles from the North Pole. In June, two Soviet single-engined monoplanes (using this facility for navigation purposes) made nonstop flights from Moscow to the United States, the first landing in Oregon and the second in central California.

**Races.** A notable sporting event of the period was the MacRobertson International Race from England to Australia staged in 1934. The winners were the British pilots C.W.A. Scott and T. Campbell Black flying a specially built twin-engined de Havilland Comet racer. Second and third places were won by standard American transport planes: a Douglas DC-3 flown by a KLM (Royal Dutch Airlines) crew, and a Boeing 247D flown by an American pilot, Roscoe Turner. The result had some influence on the subsequent decisions by a number of European airlines to adopt American flying equipment.

Closed-course racing, popular in the 1910–14 period, was revived both in Europe and in America. In theory, at least, the point of the competition was to improve the equipment. The most spectacular and probably the most costly show of this sort was the international competition for the Schneider Cup. Established in 1916, it was awarded for top speed in a free-for-all class. In the early 1930s, annual races were run in highly specialized, high-powered seaplanes developed and flown under government sponsorship. In 1931 Britain won the cup with a Supermarine S.6B at 340 mph. Several years later an Italian Macchi raised the record to 440 mph. Many of the competing machines were direct ancestors of single-seat fighters of World War II. By 1939 a stripped-down, super-powered German Messerschmitt fighter (not in a race) was officially clocked at 469 mph.

In Europe during the prewar period a number of less spectacular race meets were established under civilian auspices, designed for amateur participation. Every year, British pilots raced for the King's Cup over a course around the British Isles. Germany not only encouraged competition among glider pilots but fostered interest in amateur powered flying in annual round-Germany races. In the United States the National Air Races at Cleveland became annual September events. The practical value of such events is open to question. Though they were originally thought to be good publicity for aviation, the fact is that participation by amateur pilots in home-built racers sometimes left a trail of wreckage and fatalities that had the opposite effect.

**Private flying.** Far more important for the development of aviation was the great upsurge in private ownership of aircraft for business and personal use that followed the Depression years. This trend was visible both in Europe and in the United States. Flying clubs and both private and municipal flying fields became centres of popular interest. By 1939 there were over 33,000 certified civilian pilots in the United States, and the records show that private owners were logging over 50,000,000 miles of flying annually for business and pleasure.

In spite of these impressive totals, however, private flying was not yet firmly established. Wartime demands of the early 1940s channelled development in other directions.

#### MILITARY AVIATION

During the 1920s economic conditions and arms-limitation agreements reduced most military budgets to a minimum and left relatively little for new aircraft. Behind the scenes, some aeronautical research and development went on in government and university circles, but until Italy, Japan, and Germany began rebuilding their military establishments in the early 1930s, little that was radically new came into aviation inventories.

Two new strategic concepts put into practice during the period had far-reaching effects on developments throughout the 1930s and well beyond World War II. The first was typified in U.S. Gen. William ("Billy") Mitchell's publicly expressed conviction, which cost him his job and his rank by court-martial, in favour of an air force completely independent of ground and naval forces. The other was the Italian Gen. Giulio Douhet's doctrine that wars of the future would be won in the air by huge formations of bombers striking deep into enemy territory against industrial targets and centres of civilian population to disrupt production and to destroy national morale.

Two innovative tactical concepts were fully developed and widely employed in World War II. The first was the massive assault by paratroops with air-dropped supplies, developed first by the Soviet Union as early as 1932. The second was the intensive development of carrier-based aviation by the navies of the major powers. This greatly increased range and striking power of waterborne fleets and eventually all but eliminated the heavy battleship as a major element of naval power.

Active aerial warfare was resumed with Japan's invasion of Manchuria (1931) and Italy's war against Ethiopia (1935). Most of the aircraft used were derived from World War I types, but by the mid-'30s the effects of research and development programs began to be in evidence. The Spanish Civil War (1936) and the Russian attack against Finland (1939) offered testing opportunities for German, Italian, and Soviet planes and pilots that subsequently participated in World War II.

Germany's rearmament program began in 1933 when Adolf Hitler came to power. Consistent with the beliefs of General Mitchell, Hitler established an independent Luftwaffe (air arm). Between 1934 and 1939 German factories produced 15,927 combat aircraft and 13,889 trainers and other types.

After 1936 Hitler took few pains to conceal his program. A number of qualified observers from the United States were permitted to visit certain factories and research centres and reported what they saw. But Britain, France, and the United States were slow to react. It was only after the Munich crisis of 1938 that Britain inaugurated an emergency air-force expansion, and it was not until after more than a year of active warfare that British factories began to approach the German output of aircraft. The French situation was even worse, and the defeat of 1940 prevented its being remedied.

In the U.S., though the fiasco of the army's attempt to carry the mails in 1934 attracted public and congressional attention, air corps appropriations, only \$25,000,000 in 1933, rose only to \$74,000,000 in 1938. Under the impetus of the outbreak of war in Europe they jumped to \$320,000,000 in 1939. Finally, the German blitzkrieg of May 1940 led Pres. Franklin D. Roosevelt to propose a combined active strength for the air corps and the navy of 50,000 airplanes, backed by a production capacity of 50,000 new planes per year. The cost of such a program was estimated at over \$7,000,000,000. Though the proposal seemed fantastic at the time, the actual accomplishments of the next five years went far beyond it. The magnitude of the efforts of the United States, Germany, and Japan are shown in Table 2.

#### RESEARCH

In periods of international tension and of actual warfare, research is seldom pure; *i.e.*, it is seldom a search for new knowledge with which to augment the general welfare. It inevitably becomes developmental research; *i.e.*, research for the improvement of weaponry. This was the principal characteristic of aeronautical research of the period. In Germany, the theoretical work of scientists at Aachen and Göttingen was put to practical application at the laboratories of the Deutsche Versuchsanstalt für Luftfahrt (DVL) at Adlershof, and at the rocket research station at Peenemünde. Although it was not realized at the time, extensive research in supersonic aerodynamics, essential for the development of the V-2s and other rockets, was assigned to Gudonia, Italy's great research centre near Rome.

\*Aviation Facts and Figures, Aircraft Industries Association of America (1953). †Overall Report—European War, U.S. Strategic Bombing Survey (1945) (rounded numbers). ‡Effects of Strategic Bombing on Japan's War Economy, USSBS (1946).

In the U.S. during the early 1930s, the research programs of the National Advisory Committee for Aeronautics Laboratories at Langley Field were directed toward the general improvement of commercial aviation, but beginning in 1937 the emphasis shifted to research directly connected with improving military aircraft.

The paragraphs following outline only a few of the more important areas of research covered by this period, particularly those that have had a major influence on present-day aircraft.

**Jet propulsion.** The most radical developments of the period occurred in jet propulsion. In 1928 an Englishman, Frank Whittle, published his fundamental thesis on the use of gas turbines for aircraft, and by 1930 he took out his first patents on a jet engine. Hans von Ohain, in Germany, doing research in the same area, applied for a patent in 1935. The first flight of a jet-powered aircraft was made by a Heinkel He 178 at Rostock, Germany, on August 27, 1939. The first Whittle engine (W-1) was flown in a Gloster E.28/39 at Cranwell, England, on May 15, 1941 (see Figure 7). In June 1941 a prototype W-1X

The first jet flight

By courtesy of the Royal Aeronautical Society

Figure 7: A Gloster E.28/39, a pioneer jet-propelled plane.

Whittle engine was flown to the United States, where copies were quickly made by General Electric, and an experimental aircraft was designed by Bell Aircraft of Buffalo. On October 1, 1942, the Bell XP-59A, powered by two GE I-16 engines, made the first U.S. jet flight at Muroc Lake, California.

The idea spread quickly. By the end of the war the Junkers Jumo 004 engine was in full production for the Messerschmitt Me 262 fighters, of which some 1,400 were produced. The Gloster Meteor twin-jet fighter was in limited production by the end of the war, but only a few reached service status, and no combat is on record. The U.S. Lockheed XP-80 fighter prototype was test-flown on Jan. 9, 1944, with a British-built engine.

These events marked a major breakthrough in aviation. From this point there was almost no limitation to the power that could be applied for man flight. Horizons, in fact, became unlimited.

**Rocket research.** The flight of the first rocket-powered Opel glider in Germany (1929) has been noted (see above *Developments from 1918 to 1930: Rocket research*). That

same year (though it was not known abroad until some time later) the Soviet Union published the first section of a nine-volume encyclopaedia on interplanetary flight. The first demonstration of a rocket-assisted takeoff took place in Germany. In 1930 the Deutsche Verein für Raumschiffahrt set up a test site near Berlin, and the German Army Ordnance Corps established a rocket weapon experimental station at Kummersdorf. Later (1937) the Rocket Test Center at Peenemünde was opened. The Soviet Union had already established rocket research centres at Moscow, Leningrad, and Kazan.

During 1942 initial test flights were conducted at Peenemünde on the A-4 rocket, later widely known as the V-2. After several disastrous failures, the first successful launching occurred in October of that year. Two years later, after the usefulness of the V-1 pulse-jet-powered flying bomb had been neutralized by the British defenses, the first V-2 rockets began to fall on London. Between November 1944 and March 1945 over 1,200 of these weapons landed in the London area. Another 800 were used against Antwerp.

The V-2 rockets

Meanwhile, in the U.S., Robert Goddard continued his rocket research. Early in 1930 he had moved his operations to a desert site near Roswell, New Mexico. There, for the next ten years (with occasional interruptions when funds ran out) he continued to work on liquid-fuelled rockets. The results of his work were carefully studied by the German rocket experts at the time, and similarities between Goddard's designs and the later V-2s are unmistakable.

**Helicopters.** For almost a decade interest in the helicopter seemed to have disappeared. In Germany, however, designers had been quietly at work. In 1937, without prior notice, the Focke-Achgelis Company announced that it had built a helicopter that had all the desired qualifications; *i.e.*, vertical ascent and descent, the ability to hover, and a capability of flying forward, backward, or sidewise at the will of the pilot. Skepticism, particularly in the United States, was dispelled by repeated cross-country flights (including one from Bremen to Berlin at an average speed of 68 mph) and by spectacular public demonstrations by Hanna Rasche inside the great Deutschlandhalle in Berlin (1938). In the following year Ewald Rohlf set an altitude record of 11,700 feet, but there was little evidence of further helicopter development. No available records indicate the use of helicopters by Germany during the war.

About that same time a spark of interest came alive in the United States. Igor Sikorsky, who had tried and failed to fly helicopters in Russia in 1910–11 (see above *Developments from 1900 to 1914: Helicopters*) and had then focussed his interest on airplanes, designed and built an experimental machine under the aegis of United Aircraft Corporation. The first flight of the VS-300, with Sikorsky at the controls, occurred on September 14, 1939. During 1940 he was able to stay in the air for 15 minutes at a time and in 1941 set an official world's endurance record of one hour 32½ minutes. Although the machine was demonstrated successfully for the NACA, the Air Corps, and the U.S. Navy, the increasingly heavy pressures of wartime put off further development of the helicopter until after 1945.

**Balloons.** Despite the use of barrage balloons to protect cities against aerial bombardment, and an abortive attempt by Japan to bomb the United States mainland by drifting explosives in free balloons across the Pacific (1944–45), the most significant employment of balloons during the period was in the area of upper-atmosphere research.

Until 1931 the highest human penetration of the Earth's atmosphere had been at about 35,000 feet by A. Berson and A.J. Süring (1901). The limiting factor had been the inability of the aeronauts to survive low temperatures and pressures in an open balloon basket.

Early in 1930 Auguste Piccard, a Swiss physicist, conceived the idea of enclosing crew and scientific instruments in an airtight, pressurized, and air-conditioned spherical gondola suspended from a balloon. With such equipment he reached an altitude of 51,775 feet in May

Auguste Piccard's ascensions

1931, and 53,152 feet in August 1932. In 1933 three Soviet scientists (G. Profkoviev, F.N. Birnbaum, and K.D. Godunov) were reported to have reached 60,680 feet in a similar balloon.

In the United States, under the auspices of the air corps, the navy, and the National Geographic Society, a number of upper-atmosphere research flights were made between 1933 and 1935, the most successful of which took place on November 11, 1935, when Capt. A.W. Stevens and Capt. O.A. Anderson of the air corps set an altitude record at 72,395 feet.

## VII. Developments since 1945

Early in 1944, when jet propulsion was familiar chiefly to readers of science fiction, the following prescient comment appeared (*Wings After War*, page 11, Duell, Sloan & Pearce Inc., N.Y. 1944):

There is little reason to expect that the jet principle will have any appreciable effect on post-war commercial aviation of the next five years. Ten years from now the picture may be different.

By 1955 the picture had indeed changed. All major powers had adopted jet propulsion for combat aircraft. All major airlines were deeply involved in the design and procurement of jet-powered passenger and cargo planes and were watching with intense interest the performance of a four-jet De Havilland Comet (1952), a turbine propeller-driven Vickers Viscount (1953), first placed in service on Britain's airlines in 1953-54, and the French Caravelle with twin jets mounted at the rear of the fuselage.

Fifteen years later the revolution was complete. Research and development had solved the problem of speed with economy, and the conventional engine-plus-propeller combination that dominated the scene until the end of World War II virtually disappeared from both military and commercial aircraft. By 1970 this configuration was limited almost entirely to general aviation types (see also JET ENGINE).

### COMMERCIAL AVIATION

Postwar  
expansion

Commercial air transport revived and expanded rapidly after the war. In 1939 U.S. air carriers had carried fewer than 2,000,000 passengers with a combined fleet of some 340 aircraft. A decade later, they handled over 16,700,000 passengers with an inventory of some 1,080 aircraft. In 1949, however, all these machines were direct descendants of prewar configurations, including DC-3s, DC-4s, DC-6s, Convair 240s, Martin 202s, and Lockheed Constellations. All were powered by two or four radial air-cooled engines with conventional propellers.

Between 1949 and 1959 the revolution came. The first jet airplane to appear on commercial routes was the British De Havilland Comet, which began service in 1952. Two serious accidents, later shown to have been caused by metal fatigue, led to the grounding of the aircraft. It was reintroduced into commercial service in 1958. In spite of this discouraging experience, the swing toward all-jet operation began.

America's first jet transport, the prototype four-engined Boeing 707, was first test-flown on July 15, 1954. It went into airline service in 1958. Other jet types soon began to appear, Boeing 720, Convair 880, McDonnell Douglas DC-8, Vickers VC10, the three-jet Boeing 727, the British Aircraft Trident, and the Sud-Aviation Caravelle, the twin-jet Boeing 737, BAC One-Eleven, McDonnell Douglas DC-9, and Dassault SE-20. By 1969 U.S. airlines were flying some 2,200 turbine-powered aircraft with fewer than 300 piston-powered machines remaining in their inventories. By 1971 most of these had also disappeared.

During the 1950s and 1960s the Soviets, also starting from scratch, made great strides in their development of jet-powered and turboprop commercial air-transport equipment. Beginning with the post-World War II development of twin-engined propeller-driven machines (similar in size and performance to the U.S. DC-3s), they produced in a little over a decade a large fleet of pure jet and turboprop transports of a size and capability equal to any in the world. Typical are the Tu-104 pure

jet and the large multiple turboprop transport the Tu-114.

Originally, jet-powered transports were accepted reluctantly by operators, who were dubious as to their technical and economic feasibility. Experience soon indicated, however, that maintenance and operating problems were not as formidable as had been anticipated, and the availability of fast, safe, comfortable transportation to virtually any point on the globe created a new travel demand that very quickly made airlines the dominant form of transportation. There was a comparable growth in cargo transportation (see TRANSPORTATION, AIR).

In 1970 the second phase of the civil jet age began. Beyond the stretched versions of DC-8s and 727s (stretched to increase their passenger capacity), a number of wide-bodied jets came into service. An example of these is the Boeing 747, a 720,000-pound, four-jet aircraft 185 feet long, carrying, depending upon seating arrangement, between 365 and 490 passengers at 625 mph. Several European designs for "Airbus" configurations were in prospect. All of these aircraft were subsonic.

The third phase of the civil jet age opened in the spring of 1970, when the British-French Concorde (see Figure 8) and the Soviet Tu-144 first flew at supersonic speeds. Both are Mach 2 aircraft, with approximately 1,200 mph maximum speed. Commercial transatlantic services were forecast for 1975, but the future of the Concorde was clouded by economic problems and that of the Tu-144 by a fatal crash at an exhibition in Paris in 1973.

The possibility of adverse environmental effects was cited by opponents of supersonic aircraft in the United States. A government contract was awarded to the Boeing Company for a Mach 3 supersonic transport (SST), expected to fly in 1972, but in the spring of 1971 the U.S. Congress cut off all government funding for this purpose.

Supersonic  
flying

### GENERAL AVIATION

Favourable economic conditions in the United States fostered an enormous postwar growth in non-airline flying. This category includes more than 50 times as many machines as are in the combined U.S. airline fleets, and they carry more passengers annually. Great interest in non-airline flying exists in many countries, but on a much smaller scale. Detailed statistics are generally not available.

The use of single- and twin-engined types carrying four to ten passengers for business purposes is rapidly increasing. The decentralization of many large corporations has increased the need for rapid transportation of personnel and critical materials between widely separated points. Commercial airlines, however, serve less than 10 percent of American cities, and it is this situation that has encouraged the growth of third-level air carriers (other than trunk or feeder airlines) to provide air taxi services on a charter or nonscheduled basis. At the same time many business concerns have found increasing use for their own planes, to connect with airline stops, to fly directly from point to point, utilizing the thousands of available smaller airports, or to land at flight strips at their own plants.

Although their numbers are still relatively small, helicopters and STOL (short takeoff and landing) machines are increasingly popular. In the latter category, more interest has been evidenced in Europe, where distances are generally shorter and local airports smaller. An increasing number of STOL transports for 10 to 20 passengers are now available, including Canada's De Havilland, Britain's Britten-Norman, and the Short Brothers Skyvan, Germany's Dornier, and Switzerland's Pilatus Porter. In the U.S., Fairchild Hiller, Robertson, Helio, and Wren are developing similar machines designed to operate from runways less than 500 feet long.

Substantial numbers of general-use aircraft are employed in agriculture, mainly for the spreading of insecticides over large farm areas. Crop dusting began in the late 1920s with surplus World War I airplanes fitted with powder-storage bins and crude distribution devices. These proved effective but hazardous because of the low-

Crop  
dusting

Figure 8: The Concorde, a British-French supersonic jetliner, taking off from Heathrow Airport, London, September 14, 1970.  
The Press Association Ltd.

altitude flight requirement, including the need for frequent tight turns near the ground. Machines specially designed for low-level, highly controllable slow flight have become available that are effective in spreading large loads of powder or liquids, or both, accurately and evenly over large areas.

On the strictly private, flying-for-fun side, less than 20 percent of the more than 500,000 licensed private pilots in the U.S. own aircraft. The majority rent planes on an hourly basis, or participate in flying clubs that own and service the planes to be rented to members at relatively low rates.

With increased interest in personal and private flying there has come a revival of sporting aspects of all kinds, including high-speed, closed-circuit racing, gliding and soaring competitions, parachute jumping, sky diving, model flying contests, and even hot-air balloon racing.

#### MILITARY AVIATION (1945-70)

By early 1960 most military and naval combat aircraft had shifted to jet power. In the U.S. the rocket-powered Bell X-1 had demonstrated (October 1947) that the so-called sonic barrier was not impregnable. Soon the new fighter aircraft of all major powers were supersonic.

As flying speeds increased, the performance capabilities of the aircraft began to exceed the physical limitations of human pilots. More and more automatic electronic equipment was necessary for the detection, pursuit, and destruction of enemy aircraft. Some single-seat fighters began to approach the size and weight of some bombers of World War II.

External configurations also changed. Swept-back wings and delta plan forms replaced the straight or tapered wings of World War II types. The U.S. McDonnell Douglas F-4 Phantom series, the Anglo-French Jaguar swept-wing interceptor, and the Swedish Saab AJ 37 delta-wing tailless canard are good examples. Soviet fighters exhibited similar characteristics.

In the late 1960s several variable-geometry arrangements (with sweep or wing camber variable at will to achieve maximum efficiencies in slow-speed or high-speed flight regimes) were tested in the U.K. and U.S. The most novel fighter of the period was the Hawker Siddeley Harrier with both direct-lift capability at zero forward speed and Mach 2 capability in normal flight.

Bomber types have also undergone radical changes. Jet engines and aerodynamic improvements (*e.g.*, swept wings) have made higher speeds possible. In-flight refueling from aircraft tankers has extended flight ranges.

In the early 1950s the prototypes of Britain's V series bombers were flying (Avro Vulcan, H.P. Victor, and Vickers Valiant) and the six-jet swept-wing Boeing B-47 was replacing the B-29s in the U.S. Strategic Air Command (SAC). In 1957 the B-47s were replaced by eight-jet Boeing B-52s. Also in 1957 SAC acquired the first Mach 2 bomber, a four-jet delta-winged B-58 Hustler. More than 100 were built. Some were still in service in 1970, though production had been terminated in the early 1960s. In 1957 a contract was let for three experimental Mach 3 bombers. A prototype was built and flown in the fall of 1964, but the project was eventually abandoned (1968) in view of increasing intercontinental missile capability.

The military requirement for intelligence, both strategic and tactical, has forced the development of reconnaissance aircraft carrying extensive electronic and photographic gear. In the early 1950s surplus bombers and transport types were modified for the purpose, but as the Cold War progressed the need for sophisticated equipment for the collection of data over large areas of the world was recognized. Highly specialized aircraft were developed for such purposes; *e.g.*, naval, land, and carrier-based antisubmarine tracking and patrol machines; the much-publicized U-2 high-altitude reconnaissance and meteorological research plane of the late 1950s; and the long-range Mach 3 Lockheed SR-71 strategic reconnaissance aircraft in use by the USAF. In the 1960s much of this activity shifted to reconnaissance satellites.

Worldwide military and diplomatic operations require a capability to move officials, troops, and supplies rapidly over long distances on short notice. All major powers maintain transport fleets, ranging from luxurious high-speed jets and helicopters for official use to huge personnel and cargo carriers capable of delivering men, heavy equipment, and supplies to remote areas, sometimes by parachute. In 1969 the largest machine for such purposes, the Lockheed C-5 Galaxy, went into service with the USAF. This aircraft, with a gross weight of 728,000 pounds, cruises above 400 mph over ranges up to 5,500 nautical miles.

The most unusual items in the transport category are the large helicopter "Skycranes" designed to lift large and bulky loads over relatively short distances. Such machines have been under development in the Soviet Union and in the United States and are in active military service in a number of areas.

With the end of World War II, the aircraft-carrier fleets of the combatants were largely decommissioned or destroyed. The surviving naval powers, however, continued

Modern  
bomber  
types

The  
Skycrane

operational development with a limited number of aircraft carriers. Aircraft in service include carrier-based strike fighters, antisubmarine search and destroy aircraft, carrier- and land-based transports, helicopters, and a few amphibians. The strike and attack types are high-performance, catapult-launched jets with supersonic capability. The others, except for the helicopters, are generally propeller-turbine- or propeller-engine-powered.

For landing on carriers, naval aircraft (except helicopters) are provided with reinforced fuselage structures and retractable tail hooks to engage arresting gear on landing decks. The most unusual feature of ASW (antisubmarine warfare) types for tracking and early warning is a housing for a radar antenna resembling a large pie plate mounted over the midsection of the fuselage.

An outstanding development of the military actions in Korea and in Indochina was the use of helicopters in large numbers for transport of troops and supplies, for evacuation of wounded, and as gun ships firing both rockets and normal ordnance.

#### RESEARCH

During the course of World War II the emphasis in all countries was on aeronautical development; i.e., accepting the best scientific data available and applying them to the improvement of existing aircraft to outperform those of the enemy. In the first postwar decade, as immediate pressures were removed and as general economic conditions improved, funds again became available for long-range scientific research in aeronautics. Although such work made considerable progress in the U.K. and Canada and revived in other countries, the most extensive and most widely reported research was performed by the then National Advisory Committee for Aeronautics (now the National Aeronautics and Space Administration, or NASA) at its laboratories at Langley Field, Virginia; Moffett Field, California; and at Cleveland, Ohio; and its Test Flight Centers at Edwards Air Force Base, California, and at Wallops Island, Virginia.

Some of the aircraft-oriented projects undertaken since World War II, indicating the scope and extent of the work, are trans-sonic wind-tunnel research that resulted in the so-called Coke-bottle shape for fuselages and swept- or delta-wing configurations for supersonic aircraft; flight tests on supersonic aircraft to determine stability and control characteristics; studies on variable-geometry wing configurations; analysis of structural flutter and vibration problems at high speeds; studies of helicopter stability and control; research in wind tunnels and in towing basins on high-speed submarines and on jet-powered flying boats; studies of arrested landing problems on carrier decks and on short runways; analyses of flexible-wing aircraft; studies of aerodynamic heating and the behaviour of aircraft materials at high temperatures; vertical takeoff and landing research; and research, development, and flight-testing the X-15 high-altitude Mach 6 airplane.

Of these, the last is of particular significance, for the X-15 may represent the ultimate in airplane performance and bridge the gap between man flight in the Earth's atmosphere and man flight in space. Three of these special-purpose research machines were built under joint auspices of the U.S. Air Force, Navy, and NASA and flown by their pilots. First flight occurred on June 8, 1959, and in the following ten years (to September 28, 1968) a total of 197 flights were made. Speeds over 4,500 mph and altitudes of over 350,000 feet were attained.

#### THE FORESEEABLE FUTURE

Early man-flight prophets gazed into crystal balls and forecast wonderful things to come for centuries ahead. Accomplishment has almost always exceeded their anticipation. The temptation, therefore, is to follow their example and take off into the wild blue future, but caution, plus a considerable respect for physical facts and economic uncertainties, suggests but a limited look ahead—approximately a decade.

**Commercial aviation.** The pattern for the 1970s seems reasonably well established. Short of political or eco-

nomie catastrophe, the passenger demand on world airlines should about double, with a possible fourfold increase in cargo tonnage carried. By 1980 most of the present large jet transports will still be in service, supplemented by possibly 150 new subsonic wide-bodied and 50 to 60 supersonic machines in intercontinental services. Hypersonic transports and space shuttle craft will still be in the future.

**Airport operations.** Not much improvement over the current high level of passenger comfort in the air can be anticipated, although much must be done to improve the handling of passengers and their luggage at airports, particularly at international terminals. The problems involved in getting passengers to and from airports might be eliminated if vertical landing and takeoff by high-speed aircraft can be effected economically, but this seems unlikely by 1980.

**Environmental problems.** In the early 1970s, the sonic boom was still a major concern for prospective SST operators. A short-term solution is to prohibit supersonic flight over populated areas. It now seems possible, however, that research may uncover means of controlling the propagation of shock waves to dissipate their energy before they reach the ground. Landings and takeoffs over cities are no problem, as none of these aircraft achieve supersonic speeds until they reach high altitudes. In addition, long-range environmental effects of the SST on the Earth's atmosphere call for continuing study.

**Flight safety.** Flight safety is of continuing concern, for the prospect of a mid-air collision between two fully loaded large jets, or of an SST crashing in a populated area, cannot be tolerated. By 1980, however, fully automated flight patterns, including takeoffs and landings, and in-flight collision avoidance will be possible. Each flight will be pre-programmed from takeoff to touchdown to follow automatically the safest, fastest, and most comfortable flight profile with only minimum attention by flight crews. In the spring of 1971 a system of fully automated landings was successfully demonstrated using a Boeing 747 aircraft.

**General aviation.** The future use of small aircraft and helicopters for business or pleasure will depend on the general economic conditions of the 1970s. It is certain that the costs of such flying will continue to rise, particularly since all aircraft flying beyond the vicinity of home airports in any but clear weather will be required to carry enough radio and navigational equipment to enable them to use established air routes subject to air-traffic control.

**Military aviation.** The immediate prospects for military aviation depend both on the economic and the political situation. If economic conditions are favourable, and no immediate hostilities are in prospect, long-range research and development will continue, and year by year bigger and better fighters, bombers, and missiles will be added to the inventories of all countries that can afford to stay in the competition. If active warfare threatens, research funds will dry up, and maximum effort will be focussed on producing what is then available in the greatest possible number.

## Floor Coverings

Included in this article is a treatment of both handmade and machine-made rugs and carpets and of smooth-surfaced floor coverings. The history of floor coverings is sketched from early primitive types through the development of the modern carpet and rug industry and the smooth-surfaced flooring industry. Modern manufacturing techniques, including both processing steps and the various end products, are examined and economic aspects of the industry set forth. Aesthetic and decorative aspects are treated in the article RUGS AND CARPETS.

Although the words carpet and rug are frequently used interchangeably in referring to textile floor coverings, in modern usage carpets are fastened to the floor and usually cover an entire floor area, and rugs are not fastened and rarely cover the entire floor. Carpets and rugs may be classified as handmade or machine-made.

Handmade carpets and rugs are usually made by knotting a number of pile tufts to a backing structure so that the loose knot ends form the pile. Mainly produced in Asia and the East, knotted types are often given the general name of Oriental carpets and may be classified according to the country of manufacture, such as Persian (originating in Iran) or Chinese. Well-known districts or towns may give their names to the carpets they produce; the Persian Kirman is an example. Other hand-knotted rugs include the Savonnerie rugs of France and the modern rya rugs of the Scandinavian countries. Handmade rugs woven by the tapestry method, often described as the Aubusson type, for the French town in which the method was perfected, have a flat or slightly ribbed surface instead of pile. Hooked rugs are made by drawing yarn or fabric strands through a basic material so as to form a pile of loops that may be clipped or remain uncut.

Machine-made carpets include such woven types as Axminster and Wilton, and also tufted, knitted, and flocked types. Axminsters resemble hand-knotted carpets, but their pile yarn is mechanically inserted and bound and not knotted. Wilton types may have looped (uncut) or cut pile, with designs formed by bringing yarns of the desired colour to the surface and burying the others beneath the surface. Velvet carpeting is made by looping strands that form the pile over wire strips that are removed as each row of loops is completed. Chenille rugs have soft, deep pile formed by long, furry strips. The pile of tufted carpets is formed by tufts inserted into a backing with needles. In knitted carpets, the backing, locking, and pile yarns are all looped together. Flocked types are produced by systems in which adhesives are used to bind fibres or yarns to the backing fabric.

Smooth-surfaced floor coverings include linoleum, rubber floor coverings, cork tile, asphalt tile, printed felt base, and the vinyl types. Most are available in varying degrees of thickness, usually from  $\frac{1}{16}$  to  $\frac{3}{16}$  inch, and may have some form of backing. Although flexible types are available in rolls at least six feet wide, square tiles are increasingly popular in all types. The various materials differ in their ability to take colour or pattern, and mottled or spatter effects are often achieved by blending in one or more mixes of the same general composition as the basic material.

### HISTORY OF FLOOR COVERINGS

**Early floor coverings.** Prehistoric man may have happened upon a method of forming thread from twisted grass or hair. Evidence obtained from recent excavations near the Caspian Sea indicates that the shearing of sheep and goats, and the spinning and weaving of the fibres obtained, was practiced as early as 6000 bc. Before the development of weaving, fibres were probably interlaced to produce a simple form of plaited basket-work matting, replacing still earlier crude mats made of strands of dry stalks and tendrils.

Findings in burial mounds at Pazyryk in southern Siberia, 2,400 years old, indicate that furs, leather, woven

textiles, and felts were used, not as floor coverings, but as wall hangings. The first true carpets, characterized by pile surfaces, were probably rough cured skins that early hunters laid on the floors of their crude dwellings. Most carpets still retain the same tough flexible backings and upright pile, affording protection from cold and hard floors, agreeable to the touch, and serving a decorative function.

Smooth floorings also have ancient origins. In the Late Bronze Age (1600–1000 bc) water-worn pebbles were laid as flooring in Crete and also on the Greek mainland. The Greeks refined the technique between the 6th and the 4th centuries bc, and ancient decorative pebble mosaics have been found in Greece, Asia Minor, and Sicily. Such mosaics were also made of marble, serpentine alabaster, some forms of granite, and other stones suitable for polishing. Timber flooring, originally used in rough form for a strictly functional purpose, was eventually made into smooth boards, and was later used decoratively in parquet designs.

**Carpet and rug weaving.** Although the exact origins of carpet weaving have not been determined, it is known that the Egyptians of the 3rd millennium bc wove carpets for the most part of linen ornamented by sewn on brightly coloured pieces of woollen cloth. Egyptian influence apparently spread throughout the Middle East and then to Mongolia and China. Some investigators credit Central Asia, Turkestan, and China with the origination of carpets, and in the early 1950s a rug dating back 2,400 years, made with Turkish knots, was found in Siberia.

Early Chinese carpets were made of knotted silk pile with backings of wool or cotton, but the pile of later carpets was made of wool. Wool pile was also used in Central Asia by early nomadic tribes who acquired it easily in their wanderings. Nomadic rugs were woven on simple horizontal frames that could be rolled up for travelling.

Early looms consisted of two forked branches joined by a crosspiece holding the suspended warp, or lengthwise threads, through which the weft, or crosswise threads, were woven. A wooden bar was used to flatten the binding weft threads, allowing the loose warp ends to stand out to form the luxurious pile. The early weavers used wools in their natural gray, white, cream, fawn, brown, or black colours, but eventually learned to produce fast colours with dyes made from vegetable, flower, and insect materials.

During the Middle Ages, Italian merchants imported Oriental rugs to Europe, where they were usually hung on the walls; Europeans continued to cover their floors with rushes and straw. Moorish weavers were probably taken from Spain in the 13th century to set up the looms at Aubusson in France. Eleanor of Castile introduced Spanish rugs to England in 1255, and carpets imported from Turkey in the 15th century encouraged the development of an English rug-weaving industry.

By 1600 French carpet weavers had formed a strong guild, and in 1608 Henry IV set up looms in the Louvre. During the reign of Louis XIV, carpet manufacture was revived at Aubusson, where it had suffered from the religious wars of the 16th century, and was established at Beauvais, in Normandy. The revocation of the Edict of Nantes, that had guaranteed religious and civil freedom to French Protestants, drove French and Walloon Protestant artisans into England and Germany, where they contributed to the development of spinning and weaving techniques.

English carpet weavers were chartered at Wilton and Axminster in 1701, and in 1740 the Earl of Pembroke brought weavers from France to perform Brussels and Wilton weaving. At about the same time, carpet weaving was also established at Kidderminster, and the trade extended to northern England and Scotland. In 1830 a Parliamentary paper noted that carpet wool comprised one-twenty-eighth of the wool produced in the United Kingdom.

In the 18th century Richard Arkwright and others invented machinery that radically improved textile manufacture and together with the steam engine led to the development of the power loom, first applied to carpet

Early  
matting

Early  
looms

making in 1839. The so-called Jacquard mechanism, which employed punched cards to control the warp yarns, gradually began to replace the complicated harness of the hand loom for the production of designs. The tapestry process of printing patterned carpets was evolved in Edinburgh in the 1830s, and in 1839 a chenille Axminster process, which was patented by James Templeton of Glasgow, gave increased colour range to carpet designs.

The U.S. carpet industry began by adapting the British system on a modest scale. Largely a cottage industry, it was organized by agents who marketed the small amount produced, until the first half of the 19th century. By 1830, the use of carpets had become popular throughout the eastern U.S., and factories were being established in New England, New York, and Pennsylvania. The continued dominance of the U.S. market by British carpets led U.S. manufacturers to encourage the development of power equipment, and a power loom first appeared in 1841. In 1876 an Axminster loom was invented. This development stimulated the carpet industry by permitting an unlimited range of colour and design with an economy of pile.

**Broadloom** Loom widths increased from the formerly conventional 18, 27, or 36 inches (46, 69, or 91 centimetres), to the broadloom, usually 12, 15, or 18 feet (4, 5, or 6 metres) wide, resulting in large economies in weaving costs and producing larger and more convenient unseamed areas for laying. After World War II, needle tufting developed, employing a prewoven backing for the basic construction, and the major portion of carpeting manufactured in the U.S. was produced by this system. Some tufted carpet manufacturers even began to produce outdoor carpets and imitation lawns.

**Smooth-surfaced floor coverings.** In 1860 Frederick Walton of Great Britain patented a process for making linoleum, the first widely used smooth-surfaced floor covering. Plain linoleum, without design, was popular until the mid-1930s, when decorative linoleum was developed. In the 1920s, dark-coloured asphalt sheet and tile materials were developed in the U.S., made from mixtures of asbestos fibre, mineral fillers, and asphalt, and although light-coloured resins, not containing asphalt, became available within the next ten years, the name asphalt tile persists in the U.S. for this type of flooring. In the U.K. the term asphalt tile was used for a different product, and the somewhat misleading term thermo-plastic tile was applied to a similar British product. Vinyl asbestos tiles, containing asbestos fibres, were developed next and introduced at the Chicago World's Fair in 1933, but resin shortages prevented quantity production until 1948. Vinyl, a newer composition material with a high content of polyvinyl chloride resins, was eventually perfected. The number and variety of smooth-surfaced floor coverings multiplied after World War II, and plastics had considerable impact. Although traditional linoleum was still in use, such materials as asphalt, cork, rubber, vinyl asbestos, and the various types of vinyl were achieving greater popularity. A new development in the 1960s was a type of flooring applied directly to the area to be covered and allowed to harden; epoxy resins have generally been used.

#### HANDMADE CARPETS AND RUGS

**Orientals.** Major classifications of Orientals, based on place of origin, include Persians, the largest and most important group; Turkomans, popular red carpets including Turkoman, Afghan, and Baluchistan rugs made in Central Asia; Caucasian carpets, from Caucasia and Transcaucasia; the Turkish Anatolian group, less intricately designed than other Orientals; and the Indian, Pakistani, and Chinese group, frequently less durable than the other types.

**Materials.** The availability of excellent materials is probably the factor most responsible for the origin of carpets in the East. The nomads had access to fibres from their camels, goats, and sheep; cotton was cultivated in Persia and China, and silk in China. Nomadic carpet makers often used wool for the warp and weft of a rug

foundation fabric, as well as for the pile. Although a variety of materials may be used in making Oriental rugs, wool is the most important pile fibre, and cotton is most often used as the base and binder material.

**Knots.** The pile surface of knotted rugs is formed entirely by the ends of knotted tufts. The Ghiordes, or Turkish, knot brings both tuft ends to the surface together between two warp yarns. It is common in the Near East, especially in Turkey and the Caucasus. The Sehna, or Persian, knot brings each end of the tuft to the surface separately. It predominates in Central Asia and the Far East, mainly in Afghanistan, India, Pakistan, Turkestan, and China. In Iran either knot is used, depending upon the origin or site of the tribe or town producing the rug.

Ghiordes  
and Sehna  
knots

From I. Wingate, *Textile Fibers and Their Selection*  
5th ed. Prentice-Hall Inc. © 1964

Figure 1: (Left) Ghiordes knot. (Right) Sehna knot.

**Looms.** The loom employed is upright, consisting of two strong beams connected by two vertical posts to make a steady frame. It is often adjustable for the weaving of different sized carpets and rugs. The weaver is positioned conveniently in relation to the row of knots being worked either by means of a seat that can be raised, moving him upwards, or by winding each completed row of knots onto a separate cloth beam. The warp, or lengthwise, threads stretched between the two beams are evenly spaced and regularly spun, assuring that the pile forming beneath the surface will also be even.

**Weaving.** The weaver ties his rows of knots forming the pattern, and when an entire row of pile is knotted, the two, three, or four weft, or crosswise, threads are forced down by a comb or knife, causing the pile to stand out. Density of pile is about 300 knots to the square inch and a weaver completes about 8,000 per day; several weeks' work is needed to produce an ordinary carpet, and possibly months for a more complex one. The weaving instructions required to produce the desired pattern may be chanted by a Salim or may be provided on a coloured chart of squared paper.

**Dyestuffs.** In olden days, craftsmen used natural dyestuffs, obtaining reds from the roots of the madder plant; carmine red from cochineal, the bodies of the female *Coccus cacti*; reddish-browns from ox blood; yellow from the reseda plant or from saffron crocus, vine leaves, and pomegranate skins; and blue from the indigo plant. Mixtures of certain blues and yellows produced greens; and natural wool shades produced greys and brown, although nutshells and bark were also used. Oak apples were often used to produce black, but if their iron oxide content was high the wool was likely to be damaged; some old carpets today show the most wear in the black portions. Modern synthetic dyestuffs allow greater flexibility than these traditional dyes.

**Characteristics.** Persian rugs have intricate all-over patterns, mainly floral, but sometimes including animal or human figures, often with a central medallion. Colours include soft pastels and muted reds, browns, and blues. The rugs are fringed at both ends.

Turkoman rugs are woven in geometric designs, employing vivid reds, browns, and greens, and usually have webbed fringes at the ends. Caucasian rugs have sharply outlined, bold, geometric patterns. Brilliant and strongly contrasting colours are employed, frequently including

reds, yellows, and blues. Turkish rug patterns have precise, stylized geometric or floral designs, with bright, sharp, contrasting colours. Indian rugs are made with botanical designs in a naturalistic style and are brilliant in colour. Chinese rug designs include religious symbols. Designs are usually in blue, and background colours include dulled yellows, browns, and roses.

**Other handmade carpets and rugs.** *Tapestry weave.* Another kind of hand weaving is the tapestry method, wherein the coloured weft threads, wound upon wooden needles, are threaded around and between the warp ends, leaving a flat or slightly ribbed surface. Since a tapestry carpet lacks a tufted pile, it does not have a luxurious texture, even though a fine pitch, the number of warps per inch, can be employed, and the richest and most delicate effects of design and colour obtained. Carpets of this type have long been made at Les Gobelins, Paris, Aubusson, and Beauvais in France, and Tournai in Belgium. The work involved in producing tapestry carpet is slow and requires great skill; the product therefore is expensive (see TAPESTRY).

*Hooked rugs.* The origin of the hooked rug is obscure. A rug of this type is made by pulling narrow strips of wool or cotton cloth or wool yarn, with a tool roughly resembling a buttonhook, up through a basic material of coarse linen or burlap. The loops, approximately ½ inch high and the width of from two to four of the mesh openings in the basic material, are often clipped. Frames of various designs hold the basic material taut. Frequently the rug is made by pushing, instead of pulling, the loop through the basic material, usually employing a large threaded needle.

*Modern handweaving.* It is possible to weave rugs, with or without a pile surface, on hand looms. Almost any material can be used for hand-weaving, including plastic strips and some forms of rope. Weaving speed can be increased by the use of a chain-and-pedal drive similar to that used on bicycles. In modern times, handweaving is mainly limited to design development and study in educational institutions and to the most costly floor coverings, frequently made to order and considered fine works of art.

#### MACHINE-MADE CARPETS AND RUGS

Early machine processes employed hand or water power to duplicate processes originally performed completely by hand. The invention of the power loom greatly reduced the amount of time and labour, and therefore the cost, of carpet manufacture.

**Nomenclature and types.** Machine-made rugs and carpets take their names from the looms employed, such as Wilton or Axminster, or the construction method, such as ingrain or Brussels.

*Ingrain.* After 200 years of use, the ingrain became almost obsolete during the 1930s because of its relatively poor wearing qualities. Also called Kidderminster or Scotch, it is flat ribbed, reversible, and completely without pile, and usually could be made with two- or three-ply warp and weft yarns, dyed before weaving.

Design on the surface of the carpet was easily produced by bringing to the surface, at the chosen area, the desired colour of the weft; the latter almost completely formed the surface colouring. Although the warp intruded into the design, its colour was carefully chosen to blend satisfactorily. The term Venetian has been applied to lesser grades of ingrain carpet.

*Wire-formed piles.* Brussels carpet, with uncut looped pile formed by round wires, was first introduced about the mid-18th century. Shortly after, Wilton followed with the development of bladed wires producing a cut pile. Both were capable of producing elaborate pile designs, and the Jacquard device was used with them from about the 1820s, when it replaced hand selection of coloured pile threads. Bigelow's power principles were applied to the loom from about 1849. Pile not used for surface design is woven longitudinally into the body of the backing fabric. Brussels carpets, woven on the Wilton loom, but with their pile remaining uncut, are no longer sold in large quantities.

Velvet carpet is basically a Wilton type with the design printed on the yarn before weaving. Normally, up to five or six different coloured pile threads per dent, the space between two wires, are used for Jacquard Wilton (i.e., five or six frames of pile yarn). Velvet carpet with only one frame is sometimes termed plain (coloured) Wilton.

Tapestry carpet, although constructed as velvet, remained uncut. A full set of threads produced the desired design in the outer loop pile carpet. Basically a two-process carpet, it was more economical than Wilton or Brussels because of its single-frame design, and was woven more quickly because no jacquard was required. Invented about 1830 in Scotland, tapestry carpets are now virtually obsolete, with few of them produced in the main carpet centres (Kidderminster, West Riding of Yorkshire, and Scotland) after World War II.

Typical high quality Wilton and Brussels carpets contain about 120 tufts per square inch with up to 13 rows per inch. Tapestry, generally up to about 80 tufts per square inch, but as low as 50, is possible. Velvet may be similar in density to tapestry, but not necessarily so; it can be made with pile as dense as Wilton if desired.

Wilton carpet can be produced on the "face-to-face" principle. Two carpets are simultaneously woven sandwiched one above the other, and the two are then cut apart by a reciprocating blade traversing the loom width. The linear rate of production is thus almost doubled; Jacquard designs can be produced by this method.

*Loom-formed pile.* Axminster carpets, in which all of the pile yarn is effectively used for design (unlike Wilton and Brussels that waste some "dead" pile yarn by hiding it in the body of the carpet) include spool, gripper, and chenille.

Spool looms were invented in the U.S. in 1876, and the gripper Axminster loom was developed about 1890. The chenille two-stage process was invented in Glasgow about 1830.

**Axminster  
carpets**

By courtesy of David Crabtree & Son Ltd.

Figure 2: Gripper-Jacquard carpet loom, producing patterned and coloured Axminster pile carpet. The carpet is woven entirely in the loom, which is supplied with weft, warp, selvage threads, and pile yarn. The pile yarn is contained in creels at the rear of the machine.

With the first loom, each row of pile is drawn from an individual spool, and two blades cut away the tufts when woven. On the gripper loom, each tuft is held by its beak-like gripper and taken from its yarn carrier to the fell of the carpet, the point at which the warp and weft intersect, after being precisely cut away by a traversing knife blade. One type of spool-gripper Axminster loom employs spools instead of a jacquard; the tufts are taken from them and woven on the gripper principle. Chenille pile (from the French word for caterpillar) is formed on the carpet loom by weaving the "fur," or pile yarn, as a weft. The tufts are usually bound by cotton threads forming a long strand. The fur is woven in the first weav-

Kidder-  
minster

ing process on normal cloth looms and cut longitudinally into the requisite patterned strips; pile yarn is woven as weft, and the warp is the cotton binding threads. A simple gauze or the lacelike leno weave is used to bind the weft pile yarn so that the pile does not fall away when the strips are cut, before they can be woven into the carpet.

Jute weft and cotton warp are common materials for Axminster carpets. All-wool pile is popular, although nylon-wool mixtures and various combinations of natural and man-made fibres are becoming common. Carpets made of 100 percent man-made fibres are increasing in popularity. Spool and gripper qualities average about 40 to 50 tufts per square inch, the two extremes being about 30 and 60.

*Unconventional carpets: tufted, knitted, and bonded.* In tufted carpets, the tufts are inserted by means of vertically reciprocating needles pushing through prewoven backing and are held below the carpet backing by loopers. The loop pile slips off the loopers, or is severed when cut pile is desired, as the formed carpet moves away from the looping elements. The rate of pile yarn feed from the creel, the bar holding the bobbins, governs pile height. The variation of this rate for groups of pile threads is the basis for certain patterned effects resulting from the inclusion of both high and low pile areas or achieved by alternating two different coloured threads across the full width, emphasizing the pattern in one colour by hiding the other low-pile colour with higher adjacent loops. Different rates of feed can be obtained by electrical or mechanical means. In the former, the pattern, in small scale, is placed on a pattern drum, and feelers touching the pattern areas change the delivery rate of the pile feed roller. Photoelectric means of influencing the delivery rate have also been devised. The mechanical device pushes down the required pile lengths by means of a castellated metal plate cut to the required pattern. Other effects can be obtained from fancy or printed yarns, and some tufting machines reciprocate the carpet widthwise to obtain a longitudinal zigzag effect. Designs including up to eight colours are possible, with quality almost as satisfactory as in traditional carpets having an equal number of colours.

Polypropylene  
backing

Quality ranges now vary as much as for traditional carpets, since needle spacings may be as high as 12 to the inch, giving the same number of tufts per square inch as in Wilton. Traditional pile materials are employed, but polypropylene, a synthetic fibre, is commonly used on prewoven backing. There has also been some development of nonwoven backings.

Production rates can be many times greater than that of Axminster looms; one machinery manufacturer has developed a yarn looping technique whereby the backing is pierced by a needle and the pile is then blown through the resulting opening. This method increases the rate of production up to about 1,200 rows of pile per minute. Patterned carpets have been produced mainly in the United States with either cut or loop pile, or a combination of both. In warp knitting, beams are used to feed in the yarn supply; in weft knitting, the yarns are fed from smaller packages.

A Czechoslovakian Arachne stitch-bonding machine achieves high production rates with low pile costs, employing a fibrous web stitched on the knitting principle with yarns drawn from beams. An East German Malipol machine uses knitting principles to bind pile to a backing fabric, although a later model uses unknitted weft threads instead of backing. Production rates for knitting are higher than for traditional looms, but do not reach the high speeds of modern tufting. The quality of the materials used and the finished carpet are much like that of the middle range of traditional carpets. No spectacular growth, however, in the sales of such carpets has occurred, since there are currently limitations in design, although development work is progressing. Several methods use the principle of bonding fibres, fibrous webs, or yarns with various adhesives. The technique imposes design limitations, but the less complicated pile forming method results in high production rates. The needle loom

principle involves a fibrous lap attached to a base fabric and another method forms a lap into a loop pile sheet and sticks it to a base fabric. A special finishing operation can convert the loops into cut pile.

A German device projects positively charged fibres toward a negative pole; the fibres are then stuck to an adhesive-coated backing fabric. A Czechoslovakian technique makes double, or face-to-face, carpet by looping and bonding a fibrous web to two backing fabrics; the full layer is then cut into two separate carpets. A French machine cuts fibres from a sheet and then binds them to a fabric backing, with electrostatic means used to keep the fibres vertical.

**Manufacturing methods. Raw material preparation.** The warp and weft backing structures of carpets, and the pile yarn superimposed upon it, made originally from natural fibres, are now mostly synthetic. Backing yarns are frequently made from the lower priced cut-staple normal or high-tenacity viscose rayons. Selvages of synthetic filaments and pile yarns are produced from mixtures of cut-staple man-made and natural fibres, the latter primarily wool. Pile yarns composed of the more expensive synthetic materials are increasingly used, and viscose rayon has been used extensively for less costly carpets. As the use of man-made filament pile yarns has increased, traditional processing of natural and staple man-made fibres has decreased in importance.

The preparation of natural fibres for backing and pile yarns involved many labour-consuming operations. Fibres had to be cleansed, often by mechanical means and a wet treatment. Pile-yarn wools had to be thoroughly scoured, and cotton fibres also needed special cleaning treatment. Straightening of fibres prior to spinning was a long-drawn-out process, with spinning often followed by additional single twisting operations to form ply or cable yarns. In contrast, man-made filament yarns are extruded in clean, continuous, and parallel form, and the twisting operation is uncomplicated. Backing fabrics are currently made from fibrillated yarns, consisting of small fibres twisted together, and sliced narrow tapes are made from sheets of synthetic film.

**Selection and preparation of design.** Design creation or selection involves consideration of the range or limitations of the various methods of carpet manufacture. The number of colours that can be used for Jacquard Wilton and gripper Axminster are limited; spool and chenille Axminster allow unlimited colour range. Density tends to be greatest for Wilton carpet, sometimes reaching as high as 130 per square inch.

Spool Axminster designs are made from a chain of spools, with one spool to each row of pile. There are usually seven threads to the inch across the width, with a pile yarn length per thread of about 35 feet (11 metres). Spool width varies according to the loom, the smallest is usually 18 inches (46 centimetres) wide. The person operating the machine creels all necessary colours for the tufts in a row and winds the full spool, repeating the process until the full set for the design is made.

Gripper Axminster and Wilton Jacquard looms utilize a perforated card system to select the required combination of different coloured threads per row of pile. There is one card per row, punched according to the predetermined design, and the possible colour choice for each tuft is usually one in five for Wilton and one in eight for gripper Axminster. "Planting" of several additional colours in the pile-yarn creel may increase the number of different colours possible in a design. High- and low-cut and uncut effects are also possible in Wilton carpets. Normally employed on tufted carpets, the process can be applied to all types. Different pile height effects are produced in tufted carpets by using different rates of yarn feed, and are sometimes emphasized by alternating the colours and hiding the colour of low pile under adjacent high pile. Mechanical and photoelectric devices are used to regulate the rate of yarn feed to the tufting needles.

**Construction.** The basic structure of traditionally manufactured carpets consists of the backing fabric and the pile, which is bound under and between the weft. Pile

Preparation  
of  
natural  
fibres

is formed on Axminster looms by inserting weft, with reciprocating needles, across the warp chain yarns. A central stuffer warp usually separates top from bottom weft. In Jacquard Wilton and Brussels carpet, the pile not used for surface design effect is concealed between top and bottom weft; Axminster carpet uses all pile yarn for surface effect. Wilton pile is formed by looping the yarn over wires that project it mechanically across the width of the loom and beneath the decorative pile yarns. When the wires are withdrawn, they either cut the pile, forming Wilton, or leave it uncut to form Brussels carpet.

In spool Axminster carpets each row of tufts is inserted and cut away from the spools. On gripper Axminster looms each tuft is inserted by its individual beaklike gripper, after being cut away from the carrier. Backing fabrics have warps held on flanged beams; in Wilton weaving, weft threads wound on cones are shuttled across the loom. Axminster weft is drawn from large stationary cones at the side of the loom.

Tufted carpets differ basically from traditional types because they have a prewoven backing into which the tufts are inserted. One unconventional method of making carpet involves the forming of pile on knitted structures. Another method involves the application of pile yarns or even undulating webs of fibres to backing fabric by means of adhesives. These methods often lack the means for controlling design.

*Finishing.* After weaving, carpeting may require machine brushing to remove loose fibre or yarn, before any correction of processing faults. Traditional carpets have a separate repairation process, but on tufted carpets, missing pile, the most common fault, is stitched in by a portable "gun" operating a reciprocating needle. The carpet pile is then sheared to uniform level with cutting blades similar to those of a wide lawn mower. Steaming of the pile causes it to expand or "burst" into an aesthetically enhanced state. Natural back-sizings were formerly applied to Axminster carpets, and Wilton and Brussels weft threads on their cones were soaked in sizing. Increasing use of such synthetic backing compounds as polyvinylacetate, and different kinds of lattice backings now produce excellent tuft bind and stiffness.

Other modern finishing processes include mothproofing of wool, often performed in the dyeing sequence, and application of soil-resistant finishes to man-made pile, rot-proofing, and antistatic treatment.

Reinforcement or screening, particularly used for tufted backing, may employ adhesives on open structure woven materials, and the use of such cushioning materials as synthetic rubber foam is increasing.

#### SMOOTH-SURFACED FLOOR COVERINGS

*Linoleum.* Linoleum is produced by pressing a sheet containing oxidized linseed oil, gums and resins, ground cork or wood flour, and pigments on to a backing, and it is hung in huge "curing" stoves to toughen.

Two general types, plain and printed, or inlaid, linoleum, are produced; the latter has a constant pattern throughout its thickness. Different methods are employed to create various design effects. Thickness ranges from about 1.6 to 4.5 millimetres, depending upon the traffic expected; a standard width is six feet (two metres), and the weight in 3.2 millimetres gauge is about 7.6 pounds per square yard (3.5 kilograms per square metre).

Recently developed products are specially hardened to resist indentation. Certain alkalies and organic solvents, however, will attack linoleum if left in prolonged contact; staining and discoloration can arise from certain anti-oxidants in tires, rubber castors, or rubber heels. Linoleum is resilient, warm, unaffected by reasonable floor temperatures, and does not readily support combustion.

*Printed felt base.* Printed felt base is formed by applying a heavy film of paint to felt saturated with asphalt; the felt is sealed at both the top and bottom with one or more layers of coating before application of paint, preventing discoloration from the paint and leveling the surface. The paint used has low volatility and little flow, dries quickly in thick layers, and gives high gloss with

good wearing properties. Wooden blocks are used to apply the paint on the base, with several colours being printed separately. The material is next dried in an oven, with the product hanging from racks or festooned, and this maturing process requires several days. Rugs or rolls are available in several thicknesses and sizes.

*Asphalt tile.* The tiles are made from asphalts (25 percent) or synthetic resins, asbestos fibres (25 percent), pigments, and mineral fillers (50 percent). If asphaltic binder is used, colour is restricted to black, brown, and dark reds. The plasticised resin-based tiles are much lighter in colour, including blues, reds, yellows, and greens, and some recently developed tiles have a small amount of vinyl binder, giving brighter, clearer colours and improved grease resistance. The ingredients are mixed at relatively high controlled temperatures to form a dough, that is then forced through successive calenders until the required thickness and finish is obtained. The sheet is die cut when cool, ensuring dimensional stability. Common sizes are nine inches (22 centimetres) by nine inches by 1/8 inch or 1/10 inch (three or two millimetres). The tiles are resistant to fungal attack, mild acids and alkalies, and oils and grease; and they are suitable for use where floor heat is less than 80° F (27° C). Sweeping and washing with warm water and soap or detergent keeps them clean; wax or resin emulsion polishes improve their appearance and prolong life.

*Vinyl floor coverings.* Vinyl asbestos tiles were developed from asphalt tiles. Asbestos fibres, mineral fillers, and pigments are all bonded together with copolymers of vinyl chloride, or with vinyl acetate. Vinyl resin binders have greater flexibility without requiring heat treatment prior to installation.

Vinyl sheet coverings are made by calendering from various combinations of vinyl chloride resins, pigments, stabilizers, and fillers. Tiles 9 inches, 12 inches, or 18 inches (23, 30, or 46 centimetres) square can be cut from these sheets; widths vary from 3 to 6 feet (1 to 2 metres). Sheets can be unbacked or backed with felt, hessian, plastic foam, cork, or fabric. One method adds a coat of vinyl to a backing, and the surface appearance is influenced by the nature of the backing. Jointless seam welding can usually be applied to vinyl sheeting. A blowing agent can be added to vinyl paste, producing a foamed back and fully bonded vinyl floor covering. A thin layer of the paste and agent is spread on the back of a premanufactured vinyl sheet; these are passed through a heated tunnel causing the release of a gas from the agent, forming the foam.

An "all through" flushing in the mix can be used for secondary colour effects. Some laminated sheets have rotogravure pattern printed with vinyl inks and covered by a protective layer of transparent vinyl. Backed vinyl sheets can have added coloured chips, with a final clear coating producing a three-dimensional effect. Embossing allows the addition of a second colour into the resultant depressions, producing an inlaid effect.

*Rubber floorings.* Production figures for this material are comparatively small. Previously made with natural rubber, it is now produced with synthetic rubber mixed with pigments, fillers, resins and curing materials, and when sheeted is heat cured. Mottled effects are available, and thicknesses around two- and three-sixteenths of an inch (three to four millimetres) are available in tiles up to one foot square or in rolls. It is a comparatively expensive, excellent wearing flooring, although somewhat susceptible to grease damage, and is appropriate for use in public buildings where traffic is heavy.

*Cork tiles and carpet.* When ground cork is heated, either for long periods or by rapid high-frequency heating, the granules adhere, creating a resilient mixture that can be formed into tiles, usually two- to five-sixteenths of an inch thick, and six or nine inches square. This tile has a comfortable resilient feel and absorbs sound, but appearance and wear properties are only fair.

Cork carpet, although limited in use, can be produced from graded cork granules and polymerized linseed oil, homogeneously pigmented and calendered on a jute canvas backing.

Tufted  
carpets

Asbestos  
tiles

**Epoxy resins.** Flooring compositions based on epoxy resins have developed steadily, giving a hard, chemical-resistant, seamless, and firmly adherent floor covering. The resin and curing agent must be blended immediately before use; colours and fillers can be added. The comparatively high cost of epoxy-resin systems restricts them principally to repairing or surfacing existing flooring substrates; e.g., concrete. They frequently employ composition based on a cement aggregate and natural rubber latex. Polyvinyl acetate may be substituted for rubber latex, and such resins as acrylic, polystyrene, and styrene-butadiene have also been employed.

#### ECONOMIC ASPECTS

Modern research and development have resulted in improved equipment, processes, and materials contributing both to increased production and greater product durability. Although per capita use has increased, greater competition exists. Larger companies usually have larger facilities for development and expansion than smaller companies and are more likely to survive any large decrease in profit margins. The heavy capital expenditure required for increasingly sophisticated processes, and the equipment they require, may accelerate the trend in the developed countries toward larger groups of floor-covering manufacturers and their suppliers.

(P.E.)

## Floral Decoration

Since the earliest days of civilization, man has used floral decorations, composed of living or dried cut-plant materials or artificial facsimiles, to embellish his environment and his person. They have played an important part in folk festivals, religious ceremonials, public celebrations of all kinds, and, of course, courtships. Sophisticated cultures have generally expressed a love for decorating with flowers by carefully arranging them in especially chosen containers, while less sophisticated societies have used them more informally: strewn, made into garlands and wreaths, or casually placed in water-holding vessels without thought of arrangement.

This article will cover the elements and principles, the materials, the techniques and forms, and, finally, the historical and stylistic developments of floral design.

#### ELEMENTS AND PRINCIPLES OF DESIGN

The term flower arrangement presupposes the word design. When flowers are placed in containers without thought of design, they remain a bunch of flowers, beautiful in themselves but not making up an arrangement. Line, form, colour, and texture are the basic design elements that are selected, then composed into a harmonious unit based on the principles of design—balance, contrast, rhythm, scale, proportion, harmony, and dominance. Line is provided by branches or slender, steeple-like flowers such as snapdragon, delphinium, and stock. Form and colour are as varied as the plant world itself. Moreover, forms not natural to the plant world can be created for contemporary abstract compositions by bending and manipulating branches, vines, or reeds to enclose space and create new shapes. Texture describes surface quality and can be coarse, as in many-petaled surfaces such as chrysanthemums, or smooth, as in anthuriums, calla lilies, and gladioli. There are many variations between these extremes. Leaves and woody stems also have varied textural qualities.

A flower arrangement includes not only the flowers themselves but the container that holds them and the base on which the container may rest. If an accessory, such as a figurine, is included, that too becomes a part of the total design. The whole composition should relate in textural quality to its frame of reference, which might be a wood or glass table top or a linen cloth, and should be in close harmony with the style of the room for which it was planned, be it Louis XV or Danish modern.

As the components of a design are selected and combined, a silhouette, or arrangement outline, is created. This outline is generally considered most interesting when the spaces in the composition vary in size and shape. Third dimension, or sculptural quality, is accomplished by allowing some of the plant materials in a grouping to extend forward and others to recede. Flower heads turned sideways, or toward the back, for example, break up contour uniformity and draw the eye into and around the composition. When a formal, static quality is sought, the contour is restricted or evenly shaped, often into such graduated forms as a pyramid or mound.

Balance is psychologically important, for an arrangement that appears to be leaning, top-heavy, or lopsided creates tension in the viewer. (Occasionally, however, as in some modern arrangements, this is the very effect desired.) Colour as well as the actual size of the plant material influences design stability. Dark colour values look heavier than light values; a deep red rose, for example, appears heavier in an arrangement than a pale pink carnation, even though they are the same size. An arrangement in which dark colours are massed at the top and light colours at the bottom can therefore appear top-heavy. Similar flowers placed in identical positions on either side of an imaginary vertical axis create symmetrical balance. If there is an unequal distribution of varying flowers and leaves on either side of the axis but their apparent visual weight is counterbalanced, asymmetrical balance is achieved. This compositional device is more subtle and often more pleasing aesthetically than symmetrical balance, for its effect is less apparently contrived and more varied. Contrasts of light and dark, rough and smooth, large and small, also give variety to the composition. An arrangement generally has a dominant area or centre of visual interest to which the eye returns after examining all aspects of the arrangement. An area of strong colour intensity or very light values, or a rather solid grouping of plant material along the imaginary axis and just above the container's rim, are devices commonly used as compositional centres. The rhythm of a dynamic, flowing line can be achieved by the graduated repetition of a particular shape, or by the combination of related colour values. Scale indicates relationships: the sizes of plant materials must be suitably related to the size of the container and to each other. Proportion has to do with the organization of amounts and areas; the traditional Japanese rule that an arrangement should be at least one and a half times the height of the container is a generally accepted use of this principle.

Line and mass

Rhythm, scale, proportion, and harmony

Proportion also relates to the placement of the arrangement in a setting. A composition is either overpowering or dwarfed if placed on too small or too large a surface or in too small or too large a spatial setting. Harmony is a sense of unity and belonging, one thing with another, that comes with the proper selection of all the components of an arrangement—colour, shape, size, and texture of both plant materials and container.

#### MATERIALS

Many different kinds of plant materials are used in floral decorations, among them flowers, foliage, grasses, grains, branches, berries, seeds, nuts, cones, fruits, and vegetables. The materials may be living, dried, or artificial. Initially, man was restricted to using native wildings, or uncultivated plants, but as civilization developed over a period of thousands of years, man became less dependent on the seasons and on the resources of the particular region in which he lived. As means of transportation improved and trading grew, plants were introduced from foreign countries and many have since been hybridized to improve or vary shape, size, and colour. In the 20th century the floral decorator has an enormously varied medium in which to create because plant materials can be flown from one part of the world to another. Since the 19th century, when extensive greenhouse cultivation first made it possible to purchase fresh flowers at any time of the year, there have been commercial growers of plant materials who supply the world's floral wholesale markets. The Netherlands, for example, is famous for the ten-mile stretch of greenhouses at Aalsmeer near Amsterdam. In the United States, California and Florida, particularly, have vast areas under cultivation for commercial flowers.

Dried plant materials are generally used for what is traditionally called a winter bouquet. The cultivated flowers that are often dried are those with a naturally dry, stiff surface quality—such as strawflowers (*Helichrysum bracteatum*), globe amaranth (*Gomphrena*), and statice. North temperate zone wildings picked and preserved for dried arrangements include pearly everlasting, heather, and the sea lavender of salt marshes, as well as goldenrod, orange bittersweet berries, cattails, dock, teasel, and sumac. Many kinds of grasses—pampas, sea oats, millet, and sorghum, for example—are also dried, as are seed-bearing capsules such as the flat paper disks of honesty (*Lunaria*), orange Chinese lanterns (*Physalis*), and the wood roses from the Hawaiian morning glory (*Ipomoea tuberosa*). Other dried materials sometimes used in floral decorations are cones and nuts, long used for making wreaths and festoons for such winter festivals as Christmas; straw, used for Christmas decorations in Sweden and Lithuania; and grains, especially wheat and oats, often arranged in bunches for harvest decorations in Europe and America. Because of their fleshy substance, most fruits and vegetables do not dry well; the main exceptions are gourds, pomegranates, and artichokes.

There are various ways of drying plant materials. Certain garden flowers (among them celosia, blue salvia, globe thistle, alliums, and hydrangeas) can be gathered at their peak of bloom and dried by hanging them upside down in a dark, dry place for several weeks. Flowers may also be individually dried using one of several techniques. A 17th-century Italian writer on horticulture, P. Giovanni Battista Ferrari, described a process of gently burying the flower heads in clean, sun-dried sand and allowing them to remain in a sun-heated place for several months. The same method was used in the 19th century. Later, borax was used, and in the 20th century silica gel, because of its ability to absorb moisture. This solution is gently brushed between and over every petal. Since this method of drying does not preserve the stems, the flower heads must be wired before they are arranged.

Leaves and ferns are dried by pressing. The most delicate pressed flowers and foliage have been composed, mounted, and framed as pictures—a practice especially popular with 19th-century Romantics, who preserved floral souvenirs as sentimental personal memorabilia.

Throughout history and in almost every conceivable

medium man has created artificial plant materials. The Chinese fashioned peony blossoms and fruits from semiprecious stones and carved jade leaves, which they assembled into small trees. Gold lotus blossoms were highly treasured in eastern Asia. For European royalty in the late 19th century, the Russian-born jeweller Peter Carl Fabergé (1846–1920) designed exquisite single-stemmed flowers of gold, enamel, gems, and semiprecious stones set in small rock-crystal pots. During the 18th and 19th centuries, the Sèvres porcelain factory in France produced porcelain flowers with stems and leaves of ormolu (a metallic alloy resembling gold). At the same time, the Royal Worcester, Crown Staffordshire, and Royal Doulton factories in England became world-famous for their highly realistic porcelain floral arrangements, which are still made. The Victorians developed a home craft of making and arranging flowers and fruits. Wax, cloth, yarn, feathers, shells, and seeds were used

to make the flowers and fruits, which were then either framed or placed under glass domes. Perhaps the most curious of these 19th-century decorations were the wreaths and floral displays made by twisting, knotting, and weaving the hair of one's family and friends around wire supports. Beaded flowers for cemetery and funerary bouquets have been popular in France since the 19th century; and paper flowers for festivals and home decoration have become a major folk art medium in Mexico and Japan. Because of their relatively low cost, durability, and easy maintenance (an occasional washing or dusting), plastic flowers and plants are in such great demand that their production has become an important 20th-century industry. Though still primarily used in public places, plastic plant materials are increasingly found in private homes, especially in the United States.

plant  
materials

### TECHNIQUES

Cut plant materials, especially flowers, need special care and treatment before they are placed in vases. Ideally, flowers are picked some hours before they are arranged and never in the heat of the day. Generally, the bottoms of the stems are cut on a slant, placed in deep tepid water, and kept in a cool place, preferably overnight. Different materials have different conditioning needs. Woody stems are split several inches with pruning shears, then soaked in hot water. Stem ends may be crushed with a mallet instead, but clean cuts make it easier to impale branches on a needle holder. Milky stems, such as those of poppies, poinsettias, and large dahlias, are sealed by placing the tips in boiling water or over a flame for a few seconds. Foliage and flowers are protected from steam and flame by inserting the stems through a hole punched in newspaper, which is then drawn up over them. When arranging flowers, all foliage below the water line must be removed in order to prevent bacterial decay and the resulting unpleasant odour. Since the stems of flowers often seal over while being held in a florist shop or market, they must be recut by the purchaser. Packaged formulas do not aid in revival but are meant to be used during the preliminary soaking period. Roses and woody-stemmed flowers such as chrysanthemums can frequently be revived by recutting and placing them in hot water.

### Arranging techniques

Many tall containers can easily display flowers without holding mechanics, but if necessary they can be stuffed with upright pieces of privet or fine evergreens, such as juniper, which are sheared flat across the vase opening. The Japanese *kenzan*, or metal pin holder, usually called a needlepoint holder, is the most generally used mechanical aid. It is held in place with floral clay. In silver vases, melted paraffin is used as a fastener, for, unlike clay, it will not tarnish the container and can be removed easily with hot water. Crumpled chicken wire, or wire netting, is frequently stuffed into vases as an aid to support, and a water-absorbing plastic foam, sold in bricklike blocks, has also become very popular.

The selection of a suitable container is an individual problem in every arrangement. It is considered a part of the overall design of the arrangement and is related to it in scale, colour, and texture. Its colour must enhance, not compete with, the arrangement. For the same reason many floral decorators prefer to use simply shaped, unadorned vases. The texture of the container is also chosen for compatibility with the floral arrangement. Coarse, heavy plant materials are usually arranged in a substantial container of pottery, pewter, copper, or wood. Delicate flowers and foliage are usually displayed in porcelain, glass, or silver. Fruits and vegetables are often arrayed in wooden or pottery bowls and baskets. The size of the container is also important. If it is too small, the plant materials will overpower it and the arrangement will appear top-heavy. If it is too large, it will not only dwarf the arrangement but will frequently destroy the unity of the composition, dividing the viewer's attention between the floral arrangement and the container. Containers are not used for all arrangements of plant materials. Compositions of driftwood, flowers, fruits, and vegetables are often arranged on a flat base of wood or bamboo, a tray, or slab of wood. To keep them fresh, flowers or foliage used in such an arrangement often are placed in solid-walled pin holders that hold water.

A wooden base frequently completes a composition, since it can add visual weight at the bottom, which assists in balance. The Japanese traditionally use wood or lacquer bases and stands with all arrangements, and a porcelain vase in China was not considered complete without a carved teakwood stand. The stand has both aesthetic and practical advantages: it adds height to a display and prevents moisture stains on furniture or textiles.

### FORMS OF FLORAL DECORATION

Plant materials are customarily arranged in containers, woven into garlands, and worn or carried for personal adornment. Flower bouquets that are carried include the nosegay and corsage. In the mid-19th century, the nosegay, or posy (a small bunch of mixed flowers), was much

in fashion. No well-dressed Victorian lady appeared at a social gathering without carrying one, edged with a paper frill or delicate greens and sometimes inserted into a silver filigree holder. Messages of love were often spelled out in the flowers of the nosegay, for the "language of flowers" was carefully studied at the time, and courtships progressed through the sending of such floral symbols.

### Nosegays and corsages

Marc Garanger

Elegant 19th-century use of flowers for personal adornment: "Empress Eugénie," oil on canvas by Édouard Dubufe, 1854. In the Musée National de Versailles et des Trianons, Versailles, France.

Worn since the 18th century, the corsage has become especially popular in the 20th century. Instead of a nosegay, an admirer frequently sends a lady an orchid, a gardenia, or a small bunch of wired flowers to be worn at the waist, shoulder, or on the wrist, or attached to a handbag and carried. Only the flower heads are used in a corsage. Wires are inserted through the calyx (the usually green or leafy external portion of a flower) and bent to thrust the flowers forward or to the side; then the ends are bound together with tape or ribbon. Leaves or foliage threaded crosswise with wire are usually added. A ribbon bow often completes the corsage.

Sprays are large, flat bouquets of long-stem plant material. They are either carried or placed on caskets or at tombs as commemorative offerings. If the plant material used is short-stemmed, wire is used to add length. The ends of the stems or wire extensions are frequently thrust into a block of moss or stiff plastic foam to secure the arrangement. A blanket of flowers is often laid over a casket at a funeral or over a racehorse in the winner's circle. Blankets are made by stretching burlap over a frame, covering it with a layer of flat fern, and then adding delicate asparagus fern (*Sprengerii*). The fern surface is then covered with flower heads, which are threaded with wire and fastened on the underside of the blanket.

Garlands are bands of plant materials that have been woven or in some other way attached together; they are not arranged in a container. A circular garland is called a wreath, or if it is worn around the head, a chaplet. Garlands draped in loops are called festoons or swags. The origin of these forms is unknown, but evidence of

### Garlands and wreaths

their use dates from ancient times and is not restricted to any particular culture.

Garlands have been used for many purposes. Ancient Egyptians placed them on mummies. The Greeks used them to decorate their homes, civic places, and temples. For festive occasions the ancient Romans wore garlands of strung rose petals. When these garlands of roses were suspended from ceilings, the conversation that took place beneath them was *sub rosa*. On European festival days such as Corpus Christi, cattle are bedecked with neck garlands. On Indian holy days, the Hindus take garlands to the temple to be blessed before wearing them; they also hang garlands on the statues of their deities.

In the ancient world it was probably the Romans who most fully developed the ornamental form and use of the festoon. Fine examples are carved in marble on the Ara Pacis or Altar of Peace (13–9 BC) near the Mausoleum of Augustus in Rome. Roman festoons were usually made of fruit, grain, leaves, and flowers. In the late 17th and early 18th centuries it was fashionable, particularly in England, to create artificial festoons over fireplace mantels. Called swags, they were usually carved of wood. Among the most famous are those executed by the English sculptor Grinling Gibbons.

Wreaths have been both worn and displayed. In antiquity the wreath was bestowed upon public officials, athletes, poets, and returning warriors. The ancient Greco-Roman custom of bestowing a laurel crown, or wreath, upon a poet was revived during the Renaissance, especially in Italy. Napoleon chose a laurel wreath of gold for his crown, emulating the emperors of the Roman Empire. At Christmas time since the 19th century, wreaths of evergreens, holly, or pinecones and nuts have been traditionally hung as decorations in northern Europe, the United States, and Canada. In medieval and Tudor England the boar served for Christmas dinner had a wreath of rosemary and bay. During Advent, a period including the four Sundays before Christmas, a wreath with four candles (each symbolizing one of the Advent Sundays) is traditionally hung in Christian homes and churches.

Plant materials have been used for personal adornment in forms other than corsages, nosegays, garlands, and wreaths. Ancient Egyptian wall paintings show women

with lotus blossoms in their hair, and today the hibiscus adorns the hair of women of the South Seas. Necklaces of flowers are commonly worn in South and Southeast Asia. In Hawaii, Vanda orchids or velvety frangipani blossoms are strung into long necklaces called leis, the customary gifts of both welcome and farewell.

Many types of dress accessories are decorated with flowers. Staffs ornamented with plant material are seen in ancient art and mentioned in ancient literature. Egyptian servants or standard bearers were often depicted holding staffs of papyrus and lotus blossoms. An attribute of Dionysus and his satyrs was the thyrsus, a staff topped by a pinecone and sometimes further decorated with vine or ivy leaves and grapes. Well-known flowering staffs or rods include those of Aaron, the brother of Moses, and St. Joseph, the earthly father of Jesus.

Pictorial effects have been achieved by using cut flower heads or petals to create masses of colour that are then worked into patterns. The traditional carpet of flowers laid down on the Via Livia in Genzano, Italy, for the feast of Corpus Christi is incredibly intricate and colourful. Figures of angels, madonnas, and saints, geometric designs, and coats of arms are worked out with flower petals to form a carpet over which the religious procession passes. Mexicans frequently carpet their churches with mosaics of wild flowers, and in The Netherlands during tulip time flower pictures are made for competition. About 12 feet square, made for the most part of tulip and hyacinth blossoms, they are designed on inclined backgrounds for better visibility. Some of these pictures are three-dimensional.

For centuries flower-covered floats have been used in parades. The Italian painter and architect Giorgio Vasari (1511–74), for example, described 21 garland-decorated floats he designed for a pageant in Florence. The most famous of modern floral parades is the Tournament of Roses parade held on New Year's Day at Pasadena, California. Floats up to 50 feet (15 metres) in length are constructed over the chassis of motor vehicles. Rough framework is covered with chicken wire shaped and sprayed with a polyvinyl coating. Flower heads are attached with either glue or wire.

#### HISTORICAL AND STYLISTIC DEVELOPMENTS

**Western.** *Ancient world.* There is evidence through painting and sculpture that during the Old Kingdom (c. 2686–c. 2160 BC) the Egyptians placed flowers in vases. In the tomb of Perneb bas-relief carvings show lotus blossoms and buds alternately arranged in flared bowls that were set upon banquet tables or carried in processions. Paintings of functional vases with spouts designed to support the heavy-headed lotus flower are found in the tombs of Beni Hasan (c. 2500 BC). Formal bouquets of lotus and berries offered to the dead are represented in the paintings from the tomb of Apuy at Thebes. Garlands and wreaths, floral headdresses, and collars were woven. Because of the formalized rules of Egyptian art, the lotus (*Nymphaea*), sacred to the goddess Isis, and papyrus, both of which were easily conventionalized, were the plant materials depicted almost exclusively for 2,000 years. During the Ptolemaic era (305–30 BC) perfume recipes, flower garlands found on mummies, and Greek and Roman writings reveal a more varied native plant life and show that foreign plants had been introduced, most notably the rose.

The ancient Greeks' love of flowers was expressed mainly in the making and wearing of wreaths and garlands. Vase paintings, temple friezes, and architectural ornamentation all illustrate their widespread use. They were also frequently mentioned in Greek literature. The techniques of making garlands and wreaths, the most appropriate plant materials, and the proper time and way to wear or display them, were the subjects of several treatises. Fruits and vegetables mounded in baskets or spilling in profusion out of a cornucopia were types of arrangements used for religious offerings.

The earliest depiction of mixed cut flowers, artfully arranged in a container, is a mosaic dating from the early 2nd century AD of a basket of flowers from the emperor

Figures wearing wreaths of leaves and flowers, "Heracles and Telephos Before the Personification of Arcadia," Roman wall painting from Herculaneum (c. 1st century AD), after a Hellenistic original, early 2nd century BC. In the Museo Archeologico Nazionale, Naples.

Hadrian's villa at Tivoli near Rome. Garlands and wreaths continued to be popular among the Romans, as did displays of fruits and vegetables in cornucopias and baskets.

**Middle Ages.** Little evidence remains of floral decoration in early medieval Europe. In the mosaics of Ravenna, the Byzantines depicted highly contrived formal compositions. Symmetrical, with an emphasis on height, these arrangements were usually spires of foliage with regularly placed clusters of flowers or fruit.

Illuminated manuscripts of the Gothic period (from the 13th century to the 15th) occasionally include simple floral bouquets holding symbolic flowers. This was a time of intense religious fervour, and plant symbolism assumed great importance. There was both a liturgical and a secular language of flowers. In the church, for example, the rose symbolized the Virgin; in the chivalric courts, passionate love. Usually plant materials were casually placed in utilitarian containers such as earthenware jugs, bottles, glass tumblers, and in majolica, or glazed and enamelled pottery, drug jars called albarelli. The still life in the foreground of the open centre panel of the "Portinari Altarpiece" by the Flemish painter Hugo van der Goes is an illustration of this type of arrangement. Metal ewers often held Madonna lilies (*Lilium candidum*), as in the 15th-century painting "The Annunciation" by Rogier van der Weyden (Metropolitan Museum of Art, New York).

**15th and 16th centuries.** Floral decorations became more studied and elaborate during the Renaissance period of the 15th and 16th centuries. The revival of interest in antiquity influenced the widespread use of garlands and wreaths in Renaissance Europe, especially in Italy.

They were popular for pageants and feasts as well as for decorating houses and churches, and were commonly depicted in the art of the time. Among the most notable examples are the terra-cotta wreaths that framed the decorative ceramic plaques and reliefs made by the della Robbia family in the late 15th century, and the garlands of flowers, fruits, and vegetables in the paintings of such northern Italian masters as Andrea Mantegna and Carlo Crivelli. Cut-plant materials were generally arranged in either high sparse bouquets or tight low bunches. There were also pyramidal compositions in pedestal vases, such as those in the background of the painting "Virgin and Child and St. John" (Borghese Gallery, Rome) by the Florentine artist Sandro Botticelli. Arrangements of fruits and vegetables on salvers or in baskets also were popular.

**17th century.** The arrangement of plant materials truly became an art and an important decorative device in the 17th century. During this period of worldwide exploration, colonization, and commerce, new plants were introduced into Europe, where an avid interest in horticulture developed. Still-life paintings of the late 16th, 17th, and early 18th centuries reveal what a great variety of plants there was in the gardens of Europe. Beginning with Jan Brueghel (called "Velvet Brueghel"; 1568–1625), a tradition of flower painting developed in Flanders and Holland, which culminated with the works of Jan van Huysum (1682–1749). The canvases of the many hundreds of still-life painters of the period are valuable source material for the student of the history of floral decorations and gardens. They must, however, be considered as idealized compositions and not as literal translations onto canvas of actual bouquets. Early 17th-century pictures, particularly those of Jan Brueghel, who painted one-of-a-kind arrangements, seemed most interested in displaying the content of the garden itself. Depictions of later 17th-century bouquets show profuse arrangements that reflect the sensuality and exuberance of the Baroque style. Curvilinear elements such as sinuous S curves are other Baroque devices of design used to cre-

ate grandiloquent, dramatic compositions. The massed bouquets of the Baroque period are studies in dominance, contrast, rhythm, and sculptural effect. The eye is drawn around and into the bouquets by the turning of flower heads, the reversing of leaves, and the curving of graceful flower stems.

National  
styles of ar-  
rangement

The French style of the Louis XIV period (1643–1715) is best exemplified in the flower engravings of Jean-Baptiste Monnoyer. The plates for his famous portfolio *Le Livre de toutes sortes de fleurs d'après nature* (*Book of All Kinds of Flowers from Nature*) accurately portray flowers from a horticultural standpoint and at the same time show prototypes of display. These floral arrangements are freer and more airy than those of the Low Countries and yet suggest Baroque opulence. *Flora ouero cultura di fiori* ("Flora: The Cultivation of Flowers"), a renowned garden book published in Rome in 1633 by the horticulturist P. Giovanni Battista Ferrari, illustrates the styles of floral displays preferred by the Italians and also describes arranging techniques and devices. Among the ingenious devices illustrated is a vase with holes in its removable top that made it easy to arrange flowers and change water.

**18th century.** The floral arrangements of the early 18th century were dominated by French and English taste. In France, cultural and social life centred in the intimate rooms of Parisian town houses rather than in the vast rooms and halls of Louis XIV's Versailles palace. Bouquets, therefore, were comparatively small, to be in scale with their setting. The more delicate colouring and lighter visual weight of these arrangements can be attributed in part to feminine taste, which decidedly influenced the Rococo style. Personal and charming, the Ro-

coco bouquet and its variations remained popular into the 20th century. English bouquets of the corresponding Georgian period were often more profuse than the Rococo. Many books written to catalog the wide variety of plant materials available in 18th-century England gave incidental information on how to care for and display them. One of the best known of these works is the two-volume *Gardeners Dictionary* by the horticulturist Philip Miller. In it he mentions dried bouquets and chimney flowers. It was customary in English homes to arrange flowers and branches in the hearth during the summer months when the fireplace was not in use. These arrangements were referred to as "bough pots." The best known English illustrations of Georgian flower arrangements are those designed by the Flemish artist Peter Casteels for a nursery catalog called *The Twelve Months of Flowers* (1730). Since the flowers in each bouquet are numbered and keyed to a list at the bottom of the plate, and are one-of-a-kind collections, they are not truly representative of live arrangements. Jacob van Huysum's monthly paintings display flowers more naturally. Both series are invaluable as source material for garden flowers.

The Neoclassical period of the late 18th and early 19th centuries brought about a revival of wreaths and garlands in the style of Greco-Roman antiquity. Floral bouquets were arranged in vases of classical severity.

**19th century.** The interest of the 19th-century Romantics in nature made floral arrangements an important part of a decorative scheme. With the advent of the clipper ship more exotic plant materials were introduced into Europe and the United States. From China came new varieties of chrysanthemums, bleeding heart, rhododendrons, and azaleas; from South Africa, the gladiolus, freesia, and pelargoniums; and from Mexico, the dahlia, gloxinia, and fuchsia. Many old garden favourites were greatly improved as a result of widespread scientific interest in horticulture and botany. The Industrial Revolution made it possible to manufacture a great variety of economically priced ceramic and glass containers. Artificial flowers were extremely popular and were made in many different materials in both home and factory.

The books and magazines of the Victorian age agreed that the art of arranging flowers was an accomplishment all young ladies should acquire. Except for the single flower in the small bud vase, the most popular style of Victorian arrangement was a tightly compact mass of flowers, greens, grasses, and ferns. The two-level epergne, with a flared top for flowers and lower tier for fruit, frequently was used for the centre of the dining table. Since the flowers selected were usually of a brilliant hue, strong colour contrast was a characteristic of Victorian arrangements. These gay floral groupings, however, were usually softened by ferns and other kinds of foliage.

Victorian  
arrange-  
ments

**20th century.** The book *Flower Decoration in the House* (1907) greatly influenced the development of 20th-century floral decoration as an art. The author was Gertrude Jekyll, already notable in the gardening world. For a long time, floral decoration in big houses had been the charge of the head gardeners or the local florists; in smaller houses, the charge of the mistress of the house. In any case, arrangement was done with varying degrees of skill and little guidance. With Gertrude Jekyll's book, the idea that flower decorations actually could be planned and designed in such a way as to heighten the quality of a room came to be widely accepted. Interior decorators added their specialized knowledge to the practical expression of this view.

The rise of the women's Garden Club movement in the 1930s and the growth of flower shows led to establishing definite rules for arrangement, especially in the United States. The classic Japanese rules of design (see below) were adopted, and others were formulated. Three main types of arrangement were recognized—the mass, the line, and the combination line-mass. Emphasis was placed on design shapes such as the crescent, or Hogarth curve, and colour studies in related or contrasting harmonies. In exhibitions thematic compositions were popular, and often arrangements interpreted abstract ideas, emotions, places, and natural phenomena. Naturalistic

compositions with just a few flowers made use of stones, moss, and branches or driftwood with striking line interest. In the mid-20th century flower arranging tended to follow contemporary art trends. A Japanese revolt against traditional aesthetic canons also had great influence on Western development of free-style arrangements that reject naturalism and are often unconventional in their placement and use of treated material. Traditional principles of visual design are often rejected in such modern arrangements.

#### Assemblages and abstract arrangements

Assemblages of diverse elements outside the plant world, such as scrap metal, rope, and plastic, are composed with a minimum of plant material. Transition and rhythm yield to heightened contrast. Space is important, and new forms are created by bending plant material to create new shapes. Psychological tension is created by upsetting balance and symmetry.

Constance Spry Ltd.

Naturalistic 20th-century composition of spring flowers: daffodils, daisies, primroses, and pasqueflowers arranged with moss and heath in a frame of bracket fungus.

**Eastern. China and Korea.** The ancient Chinese could enjoy and feel themselves at one with the growth, maturity, and decline of a few flowers or a branch. The floral expressions of the Chinese have traditionally been based on the Confucian art of contemplation, the Buddhist principle of preservation, and Taoist symbolism. For the Confucian, a floral arrangement was philosophically contemplated both as a symbol of organic existence and for its aesthetic aspects. Buddhists used flowers sparingly because of their religious doctrine prohibiting the taking of life. At least since the T'ang dynasty (AD 618-907), flowers have been placed on temple altars in a *ku*, an ancient bronze ceremonial wine beaker dating from the Shang dynasty (c. 1766-c. 1122 BC) whose shape was translated into porcelain in later dynasties. Hua Hsien, the flower goddesses of the Taoists, have traditionally been represented carrying flower-filled baskets. In Taoist symbolism, the four seasons were denoted by the white plum blossom of winter, the peony of spring, the lotus of summer, and the chrysanthemum of autumn. Each month also had its own flower. Longevity in plant arrangements was symbolized by pine, bamboo, and the long-lasting *ling chih* fungus. New Year floral displays featured the paper-white narcissus, and the tree peony (*Paeonia moutan*), designated the "king of flowers," was used to symbolize good fortune.

Usually the floral arrangements of the Chinese, like those of the Koreans, appear to be more casual, less obviously contrived than those of the Japanese. A composition frequently will be made of two or more floral arrangements placed in containers of different heights and shapes and often grouped with rocks or decorative objects. Chinese bouquets in baskets have a bouquet-like quality reminiscent of Western floral arrangements.

**Japan.** The arrangement of flowers in Japan is an elaborate and unique art form, with highly developed conventions and complex symbolism. The oldest studied form of this art, developed from the custom of offering flowers to the Buddha, was introduced into Japan early in the 7th century by Ono Imoko, Japanese ambassador to China and, in Japan, founder of the first and oldest school of floral art, called the Ikenobō. All the

"Western Queen Mother" (detail of flower border), silk and metal thread embroidered on silk, Chinese, 19th century. The plant material includes (left to right) plum, pine, citron, lotus, orchid, magnolia, peony, peach, chrysanthemum, *Osmanthus*, and *Narcissus tazetta*. In the Metropolitan Museum of Art, New York.

By courtesy of the Metropolitan Museum of Art, New York, bequest of William Crawford, 1929

later masters of the Ikenobō school are descendants of the founder. Most important among the earliest styles was the *mitsu-gusoku*, an arrangement of three or five articles often consisting of an incense burner, a candlestick in the form of a stork, and a vase of flowers. These were usually displayed before pictures of the Buddha or of founders of Buddhist sects.

Early styles were known as *tatebana*, standing flowers; from these developed a more massive and elaborate style, *rikka* (which also means standing flowers), introduced by the Ikenobō master Senkei around 1460. The early *rikka* style symbolized the mythical Mt. Meru of Buddhist cosmology. *Rikka* represented seven elements: peak, waterfall, hill, foot of the mountain, and the town, and the division of the whole into *in* (shade) and *yō* (sun). (In Chinese the characters for *in* and *yō* are read *yin* and *yang*, the passive or female and the active or male principles of oriental philosophy.) Formal *rikka* is arranged out of nine main branches and some accessory ones. Three branches are placed so that their tips form a triangle with unequal sides. From this pattern all later styles of Japanese floral art developed.

Early  
Japanese  
styles

Traditional *rikka* flower arrangement of nine different plant materials. In the Tokyo National Museum.

In the early 18th century a three-branch, asymmetrical style, *shōka*, evolved from the *rikka* and was cultivated by the Ikenobō school. *Shōka* is written with Japanese characters meaning living flowers. These characters can also be read *seika* and *ikebana*; *seika* is the preferred reading by some schools, while *ikebana* today is the general term applied to any style of Japanese floral art. Up to the advent of *shōka* all styles of arrangements other

than *rikka* had been known as *nageire*, meaning to throw, or fling into. This term was confined to arrangements in tall vases, and *heika*, vase flowers, is preferred to *nageire* by some schools. *Shōka* utilized three main branches, and emulated the natural growth of plant life. This illusion of growth was achieved by using buds, foliage, and blossoms; by superimposing stems as they emerged from the container; by turning up the tip ends of branches unless of a naturally drooping kind; and by placing tree branches above flowers and mountain material above that of the lowland. All combinations were seasonally correct. Uneven numbers of materials were always used, and rules of proportion dictated that plant material be at least one and one half times the height of the container. By the late 18th and early 19th centuries the *shōka* style had supplanted the *rikka* in popularity and many new schools flourished, including Enshūryū, Koryū, Kōdōryū, and Mishōryū. All these new schools utilized the three-branch form but adopted different nomenclatures for them.

Western flowers were introduced into Japan following the Meiji restoration (1868). The flower master Unshin Ohara, who established the Ohara school (early 20th century), devised for them a new container, based on the low bowls used for dwarfed plants. This new style, known as *moribana* (heaped-up flowers), permitted greater freedom in the choice and placement of materials. A variation was the creation of small realistic landscapes called *shakei*, sometimes referred to as memory sketches. In these, exposed water surface was a part of the design. In 1930 a group of art critics and flower masters proclaimed a new style of floral art called *zenei-bana* (avant-garde flowers), free of all ties with the past. Foremost in this group was the Ikenobō master Sofu Teshigahara (b. 1907), who had founded the Sōgetsu school in 1926. The new style emphasized free expression. *Zenei-bana* utilized all forms of plant life, living and dead, and elements that had been previously avoided, such as bits of iron, brass, vinyl, stone, scrap metal, plastic, and feathers. Vines and branches were bleached and painted and even used upside down. Stems were crossed, even numbers of materials were used, and containers were often crude and exotic in shape.

Japanese  
styles

Until 1868 Japanese flower arrangement was generally a man's avocation, engaged in primarily by Buddhist priests, warriors, and the nobility. Following the Meiji restoration and particularly after the beginning of the 20th century, it was taken up by large numbers of women. Men, however, still head most of the principal schools.

The total number of schools throughout Japan in the 20th century is believed to number from 2,000 to 3,000, varying in size from several thousand to millions of adherents. Each school has its own rules of arrangement, though styles may differ only slightly from one another. All arrangements are asymmetrical and achieve a three-dimensional effect. The traditional styles are still taught, many with modern variations, but the bolder, less restrained, and unconventional free-style forms of arrange-

ment now seem to be the most popular. The material used in Japanese floral arrangements is held in position by various artifices, the most popular of which are the *kubari*, forked twig, and the *kenzan*, needlepoint holder.

Japanese flower arranging has influenced that of the West considerably, particularly in the mid-20th century. Many popularizations of the art have flourished in the United States.

**Other cultures.** Outside the West and the Far East, the arranging of plant materials was more a casual part of everyday life than a formally recognized medium of artistic expression. The elaborate stylistic traditions evolved and formulated in the West and Far East through centuries of sophisticated creative activity are rarely found, therefore, in other cultures. In the Islāmic world, for example, simple, modestly scaled arrangements predominated: sparse, symmetrically arranged bouquets; casually grouped bunches of flowers; or blossoms floating on liquid surfaces. The garlands made in India for adorning home, temple, statuary, and man himself were simpler than the bouquet or arranged floral materials found in the more aesthetically complex traditions of the West and Far East. Also in contrast to these artistically self-conscious arrangements are the stiff, mounded groupings of plant materials made for festivals in South-east Asia.

## Florence

A former republic, a former seat of the duchy of Tuscany, and a former capital of Italy, Florence (Italian, Firenze; Latin, Florentia) lies almost at the centre of the Italian peninsula, some 145 miles northwest of Rome. The rolling Tuscan hills that rise around the city are stitched with villas and farms, vineyards and orchards,

very much the varied domestic tapestry of the early Florentine artists. The city was founded to control the only practicable north-south crossing of the Fiume Arno (Arno River) to and from the three passes through the Apennines, one to Faenza, two to Bologna. Two thin streams, the Mugnone and the Affrico, come down through town to meet the Arno. The latter, not long out of its source in the Apennines, is most of the time a grudging gurgle amid wide gravel beds far below the quays, but sometimes it rises and ravages the city, as it did with appalling consequences to Florence in 1966.

The present glory of Florence is its past. Its buildings are works of art abounding in yet more works of art. The splendours of the city are stamped with the personalities of the men who made them. The geniuses of Florence were backed by men of towering talent, and the city is made of the bones of their personal passions for religion, for art, for power, or for money. Among the most famous of the city's giants are Leonardo da Vinci, Michelangelo, Dante, Machiavelli, Galileo, and its most renowned rulers, the generations of the Medici family.

It is still a matter of fascination for scholars that this small city of money lenders and cloth-makers without much political or military power produced what Bernard Berenson called a "diluvial influence upon the entire white man's world, and beyond it." The Florentine vernacular became the Italian language; and the local coin, the florin, became a world monetary standard. Florentine artists formulated the laws of perspective; Florentine men of letters, painters, architects, and craftsmen began the Renaissance; and a Florentine navigator, Amerigo Vespucci, gave his name to two continents.

For information on related topics, see the articles ITALY; ITALY AND SICILY, HISTORY OF; and RENAISSANCE. See also biographies of the major Florentines mentioned in the article.

### THE HISTORY OF FLORENCE

**Founding and growth.** Founded around the 1st century BC as a colony for soldiers of the armies of Rome, Florentia (the flourishing town) was laid out as a rectangular garrison town (*castrum*) below the hilltop Etruscan town of Faesulae. Its streets formed a pattern of rectangular blocks, with a central forum and temple. By the 3rd century AD it was a provincial capital of the Roman Empire, a major crossroads of the Italian peninsula, and a prosperous commercial centre.

Monasteries preserved the older culture during centuries of domination by Goths, Byzantines, and Lombards, but during the Carolingian period, from the late 8th century, the town began to revive and rebuild. Ruling margraves of Tuscany and the growing authority of bishops gave the town increasing autonomy from the Holy Roman Empire in the late 11th century, the beginning of the period that witnessed, in Romanesque church architecture, the first flowerings of the Florentine arts. By 1197 the Tuscan League solidified the strength that the commune of Florence had achieved through many decades of expansion at the expense of feudal lords and the empire itself; and a new and large system of walls symbolized the physical growth of the city.

**Turmoil and artistic fertility.** The 13th and 14th centuries saw Florence awash with the battles of the Guelphs and the Ghibellines, factions that alternately ruled the city in uncomfortable union or engaged in open warfare with one another. Alliances with popes or foreign powers, warfare with other Italian cities (notably Ghibelline Pisa), and the temporary ascendancy of one or the other party (with or without intrigue, popular support, or bloodshed) made of the centuries a confusion of rulers and transfers of power, of changing forms of civic and regional rule, of shifting allegiances and balances of power among groups of nobles and the several major and minor merchant and craft guilds.

During this period, however, Florence continued its climb to eminence among the Italian cities. Its florin was first minted in the 13th century, and Florentine bankers became the most powerful in Europe. Churches rose in the new Gothic style; Florentine historians and poets,

Character  
of the city

The  
Guelphs and  
the Ghibellines

chief among them Dante, Petrarch, and Boccaccio, raised the Tuscan dialect to a place of dignity above others of Italy; and such painters as Cimabue and Giotto brought the visual arts to the aesthetic boundaries of the Renaissance, which were shortly to be crossed by the architects Brunelleschi and Alberti, the sculptors Donatello and Ghiberti and the Della Robbias, and the painters Masaccio and Uccello—among a host of others.

**Rule of the Medici.** The Medici family came from a background of banking prestige and solidity. After Giovanni di Bicci de' Medici had been elected chief arbiter in 1421 and his son Cosimo 13 years later returned from exile to popular acclaim, the history of this family and that of Florence and Tuscany were intertwined for three centuries.

For over a century the Medici ruled Florence without benefit of public title, combining their financial resources with diplomacy, frequent magnanimity, personal flourish, and artistic taste to fashion the Florence of the Renaissance, the city that by and large has impressed itself upon the present. The dynasty perhaps reached its height under Cosimo's grandson Lorenzo (1449–92). A brief intermission occurred during the theocratic republic of the fanatical friar Girolamo Savonarola, from 1494 to his execution in 1498, after which the Medicis returned and, in 1527, proclaimed the republic.

The reign of Cosimo I (1519–74), created grand duke in 1569, brought a long period of peace and Medici alliances across Europe by marriage and diplomacy. With the extinction of the line in 1737, title to Florence passed to the duke of Lorraine, husband of Maria Theresa of Austria.

**Evolution of the modern city.** The 18th century, under the dukes of Lorraine, saw great changes toward more modern theories of government, economics, and church–state relations, but in the 19th, Florence suffered politically and economically from the chaos engendered by the Napoleonic Wars. While it was beginning to feel the coming of modern industry and technology, it was becoming a centre of international fame for its past and a haunt of exiles, writers, and artists. It united with the new kingdom of Italy in 1861 and from 1865 to 1871 was the provisional capital.

Yet during these and succeeding years much of Florence's past was seriously jeopardized: many of its finest structures were altered or defaced, its medieval walls pulled down, its ancient centre laid waste. City boundaries and population continued to grow chaotically into the 20th century, when order and sense were slowly restored to the renovations.

Even graver problems, however, were impending. In addition to the human despoliation, nature had been an occasional adversary of Florentine life, mainly in the form of floods of the Arno. The bridges were destroyed in the 12th century, again in 1333. In 1557 the Ponte Vecchio (Old Bridge) held fast, but the others were destroyed. In 1944 their replacements were blown up by the retreating German Army, which spared the Ponte Vecchio but destroyed antique quarters at either end of it. Of the latter, the oldest were rebuilt with the fragments according to the original 16th-century plans.

The most devastating occurrence was the flood of November 1966: the city's cultural heritage was grievously damaged by waters coursing through the streets and swirling into buildings, depositing debris, mud, and oil. In some places the water rose as high as 20 feet, submerging sculpture, paintings, mosaics, and manuscripts in the city's libraries. An armada of international experts, financed by contributions from around the world, arrived to try to save the water-and-muck-damaged treasures. To an astonishingly large degree they succeeded, although the work of restoration was still underway in the early 1970s.

The salvage operations revealed to the world what officials of Florence had known for a century: the city had never recovered from the costly honour of being Italy's provisional capital. The municipal treasury was depleted. The museums, palaces, and convents had been turned into offices, schools, barracks, and hospitals; and money

for their reconversion was not forthcoming. There was not enough money for the simplest safeguards or maintenance. In the libraries and archives, uncataloged volumes piled up in cupboards and on floors for lack of shelf space and personnel. The few scientific and cultural experts who gnawed at the mountain of work—preservation, restoration, classification, examination—accepted their posts at financial sacrifice and laboured without proper space or equipment. As for protection against future floods, the city has had plans as far back as the 15th century, but it has done little more than replace the riverbanks with high walls. Administrators hoped that the city's position in the 1970s as a seat of one of Italy's provinces would allow Florence the autonomy to carry out its plans for self-preservation.

#### THE CONTEMPORARY CITY

Present-day Florence, the capital of Firenze province, covers an area of 39.54 square miles (102.41 square kilometres) and holds a population of some 480,000. Nearly 1,700,000 tourists visited the city annually in the early 1970s, deluging the 20,000 beds of the 350 hotels and pensions and the facilities of youth hostels and religious hospices.

Viewed from the hills, the riverbank city has not changed beyond recognition since the time of its temporal greatness. The highest tower is still the one built for the people's government at the end of the 13th century, and it shares the skyline with the early-15th-century cathedral dome. The inner city is still structured somewhat on the lines of the Roman *municipium*. The forum of Roman times, a centre of commerce and socializing, is now the Piazza della Repubblica, still the city centre. The main avenues of the city trace the pathways of antiquity through and out of the city.

Thousands of Florentines work in industrial suburbs, but the city lives primarily from tourism and from the traditional handicrafts—glassware and ceramics, wrought iron, leatherwork, wares of precious metals, art reproductions, and the like—with some high-fashion clothing and shoe production. Festivals of music, opera, and the visual arts continue through much of the year, many of them resplendent with the trappings of medieval pageantry and procession.

Craft work is sold throughout the city, but several traditional marketplaces still exist. The vendors of straw objects—from tiny figurines to full-sized dresses—raise the awnings of their stalls almost to the lofty roof beams of the Loggia di Mercato Nuovo (New Market. 1547–51). Goldsmiths, silversmiths, and jewellers are concentrated on the Ponte Vecchio, one of the world's most famous bridges. They opened for business there in the 16th century, when Grand Duke Ferdinand I deemed it inelegant for butcher shops to line the bridge as they had for the previous 200 years. He ordered practitioners of the “vile arts” to give way to workers in precious metals. The new occupants eventually enlarged their shops by building outward over the water, propping their three-story additions on brackets from the bridge. The back elevations of these extensions give the bridge its picturesque higgledy-piggledy air. Above the shops a covered passage was constructed in 1564–65 to connect Cosimo's palace (the Pitti Palace) on the left bank with the newly erected government offices (the Uffizi) on the right bank.

Artisans who fashion the gold, silver, jewelry, straw, intarsia (Florentine mosaic), leather goods, glass, pottery, and embroidery complain that they are being squeezed out of existence by the pressures of modern economic life. They can be seen today through the open doors of their workrooms engaged in the tasks and poised in the attitudes shown in the carvings on the 15th-century facade of the guildsmen's church, Or San Michele.

The passersby in these same narrow streets—they display the agility of fish in passing one another and the cars and delivery vans—have the strong-boned Tuscan faces of the Renaissance sculptures and paintings. Although the days of Florentine power long ago evaporated, the men of this city retain much of the swagger of swordsmen of the bygone age, and their dandyism psychi-

cally clothes them in hose and doublet. Their vanity, patently masculine, is made visible at the early evening hour, when they troop to the caf  s while performing the rites of hair smoothing, lapel patting, and trouser adjusting.

#### FLORENTINE TREASURES OF THE PAST

This rich, materialist, worldly capital expelled its prince in an hour of peril in 1528 and formally elected Jesus Christ to be king of Florence, his mother Mary to be queen. At the same time, it asked the genius of the age, Michelangelo, to redesign the defenses of the city. Part of his work can be explored today along the south bank of the Arno. The rest of the city wall was razed at the end of the 19th century; and outer avenues, the Viali di Circonvallazione, were laid along their course. Eight of the city gates remain, most of them dating from the 13th century.

**Centres of government and commerce.** Much of Florence's political history was made in the Piazza della Signoria. Named for the 13th-century fortified castle that occupies one side of the square, the piazza was created when the Guelphs razed the townhouse of a Ghibelline family. Ironically, the head of that family earlier had prevented the Ghibellines from razing all Florence.

Work on the castle, built as the seat of government (which it still is), was begun in 1299. At first the building was called the Palazzo del Popolo e del Commune, then dei Priori (Dante Alighieri was one of the first *priori* "superiors" installed there), and finally della Signoria. After the first grand duke of Tuscany, Cosimo I, installed himself in the recently completed Pitti Palace, the old palace was called the Palazzo Vecchio. It is a stern stone square, five stories high, topped by a crenellated, machicolated gallery. The 308-foot-high tower, square and slender, rises first to a battlemented gallery of the same design; from the latter rises an open belfry roofed by a miniature reproduction of the same martial gallery.

In 1537, Cosimo de' Medici installed himself in this traditional seat of the commune's political power. He had most of the interior redecorated in the sumptuous style it displays today. The lower house of the Italian legislature sat here in 1865–71, where the City Council holds forth today. The mayor's chambers are also in the palazzo.

An equestrian statue of Cosimo I (by Giambologna, 1594), stands to the left below the palazzo, part of the open-air sculpture gallery that the piazza has become. The central Neptune Fountain, with bronze and marble figures, dates from c. 1565. Before it is a marble disk to mark the spot where, as it says, "the iniquitous sentence" of hanging and burning was carried out on Savonarola and his two companions in 1498.

A copy of Michelangelo's "David"—the original was moved to the Accademia in 1873—stands naked at the top of the steps, and behind him the doorway is flanked by fig-leaved Philemon and Baucis. Down below are a copy of Donatello's Florentine lion, the "Marzocco" (original in the Bargello, also known as the Museo Nazionale), supporting the city's lily-emblazoned shield, and his "Judith and Holofernes."

To the right of the palace is the Loggia dei Lanzi (1376–82), so called because Cosimo I stationed his lancers there. Among the dozen statues in the loggia is the "Perseus" (1553) of Benvenuto Cellini, another Florentine master. The loggia, a sort of carved stone canopy, or an arched, unwall building, is one of 12 that survive of the 26 that decorated Florence in the 16th century. Many palaces had *loggie* serving as grandstands for their martial tilts and holiday dances, as well as for the family's outdoor drawing room at weddings, betrothals, and obsequies—during which the townspeople gathered in the street received gifts and refreshment.

From behind the loggia and from the flank of the palazzo, the tall, colonnaded, twin wings of the Uffizi stretch down to the Arno. An elegant exercise in Mannerist architecture by Giorgio Vasari, it was begun in 1560 to house the grand ducal offices. In 1574, Grand Duke Francesco I ordered the top story converted to display the Medici art treasures. The Uffizi's collection, one of the most precious in the world, offers examples of painting from the 13th century through the 18th and includes most of the significant names in Florentine art.

A little further inland is another high-towered civic palace-fortress, the Bargello. Completed in 1255, some 43 years before the Palazzo della Signoria, it was the seat of the Capitano del Popolo, then became the seat of the mayor (*podest  *), and finally that of the chief of police (*bargello*), whose prison cells were removed along with other impedimenta in the restoration of 1857. A state museum since 1865, it has whole vaulted rooms devoted to the sculptures of Michelangelo, Donatello, Cellini, and Della Robbia.

Between the civic centre and the religious centre lies the old mercantile centre, currently the Piazza della Repubblica and the core of animation of the inner city. From medieval times, it was the Old Market, from which the Loggia del Pesce (Fish Market) was taken down and re-erected among the open-air food vendors on the Via Pi  trapi  na. Scores of antique buildings were ripped out of the district in clearing the square in 1880, in order to "revive it from its ancient squalor," as the inscription says on the 19th-century arch. The square is now bordered by caf  s; and one side is arcaded, giving shelter to book-sellers, newspaper dealers, expensive shops, a cinema, and the central post office. From under the arcades issues

Centre of the old and modern city

The ubiquity of sculpture

The skyline of Florence from the Piazza Michelangelo. At far left is the Ponte Vecchio over the Fiume Arno. Rising above the city are the slender tower of the Palazzo Vecchio (left), the Duomo (centre) and the church of Sta. Croce (right).

a happy uproar, a continually excited, echoing hubbub pierced by shrill cries.

**Religious structures and their holdings.** Further inland is the historic religious centre of the city, site of the Battistero S. Giovanni (baptismal church of St. Giovanni) and the Duomo (the cathedral "house"—i.e., House of God). The baptistery is probably the oldest surviving building in Florence, although its date of construction is uncertain. Florentines generally accept the year 1000, some other scholars opting for a century or more later. It is an octagonal, three-storied structure with a tentlike roof. The exterior, like that of the cathedral and many local churches, is polychromatic. Cunningly worked bands of green marble accent the structural lines and lend movement and perspective to the exterior of the white marble-clad building. Like its near contemporary, S. Miniato al Monte (1062), this Tuscan Romanesque church includes classical elements, the graceful use of which contributed to the Florentine development of Renaissance architecture in the 15th century.

Since Baptism was administered only twice a year, the baptistery is large, with three huge sculptured bronze doors, two sets of which are the masterpieces of Lorenzo Ghiberti, who spent from 1403 to c. 1453 carving the 20 gilded panels. The east door, containing Old Testament scenes, was the last to be done; it was said by Michelangelo to be "worthy of paradise."

The cathedral of Sta. Maria del Fiore was begun in 1294 and consecrated in 1436. It is Gothic, but a Tuscan Gothic that mutes or transmutes the international conventions. Rather than soaring paeans in stone, it offers broad harmonies in marble, an airy flow rather than a fevered thrust. The first architect was Arnolfo di Cambio (often called the greatest architect of the Middle Ages, to whom the Palazzo della Signoria is attributed), succeeded (1334–37) by the painter Giotto, who designed the Campanile, then (1337–48) by Andrea Pisano, then (1349–59) Francesco Talenti, and (1360–69) Giovanni di Lapo Ghini. Talenti continued Arnolfo's unfinished facade but never completed it, and it was removed in 1588. In 1875 a facade was finally erected in correct but cold imitation Gothic. The marvellous dome was designed by Filippo Brunelleschi c. 1420.

While Brunelleschi was constructing the Gothic dome, he was also designing the facade of the Ospedale degli Innocenti (Foundling Hospital), which has been called the first Renaissance building. It stands on the Piazza Santissima Annunziata, a lovely Renaissance square decorated with 17th-century bronze fountains.

The hospital has a ground floor colonnade of delicate Corinthian columns supporting wide, airy arches, the spandrels of which are decorated with Della Robbia's blue-and-white terra-cotta medallions of a swaddled babe—reproductions of which are the stock in trade of souvenir-vending Florence. The Roman motifs in the building seem to refer more to Florentine Romanesque than to empire originals. Later, Brunelleschi went to Rome (c. 1433) to study and sketch the antique ruins, after which his work became more purely Roman revival, as in his centrally planned Sta. Maria degli Angeli, begun in 1434 but left unfinished (restored and roofed in 1937).

The facade of the church of SS. Annunziata adjoining the hospital echoes the Foundling facade. A medieval church, rebuilt from 1444 to 1477, its round east end is a direct copy by Michelozzo of the Temple of Minerva Medica in Rome. The miraculous portrait of the Virgin, whose face was said to have been painted by angels while the 13th-century artist slept, became the centre of veneration by the whole city. The Florentine calendar was adjusted to begin the year on March 25, Annunciation Day, and remained righteously unchanged until 1750.

Among the medieval religious practices still in force is the Exploding of the Cart on Easter Sunday. The "cart," a wheeled pagoda four stories high and gilded, panelled, tassled, and topped with a crown, stops before the Duomo. From the High Altar a dove (aided by a wire) swoops through the open door and strikes the cart, which thereupon bursts into flames before the appreciative crowd and the alert fire brigade.

Behind the cathedral is the museum (Opera del Duomo) of works that once decorated the baptistery and the cathedral. Most notable are the sculptured marble choir lofts: the Donatello (1435–38) decorated with chubby, cavorting children; and the Luca della Robbia (1431–38) vibrant with youthful choristers, musicians, and dancers. Among the works in the cathedral itself is Michelangelo's "Deposition," carved in his last year.

On a corner of the cathedral square (Piazza del Duomo) and the Via Calzaioli stands another Florentine-Gothic structure, the Loggia del Bigallo (1352–58), in which orphans were shown to prospective foster parents. The L'Arciconfraternita della Misericordia, formed in the 16th century and one of the city's most esteemed institutions, is across the street. Its members are prepared to answer emergency calls clad in their black hoods and robes. On the far side of the baptistery is the 16th-century archiepiscopal palace.

From the Piazza del Duomo the Via Borgo S. Lorenzo leads to the Medici parish church of S. Lorenzo, for which Brunelleschi began the Old Sacristy in 1423 before rebuilding the 11th-century church entirely. Michelangelo was later commissioned to add a facade, a project cancelled because transport of the marble from the quarry was too cumbersome and costly, and as of the early 1970s the church remained faced with bare brick. Michelangelo was asked instead to construct the New Sacristy, a family chapel (1521–34) of which the architecture is obscured by the power of the sculptures he made for the tombs of Julius II and Lorenzo II. He also designed the Laurentian Library (starting 1524) to the left of the church. In the severely disciplined, artificial architecture that Michelangelo devised, some experts profess to see the beginnings of the Baroque, and others, with more justice, the seeds of Mannerism. The library's treasures include da Vinci notebooks, a Horace annotated by Petrarch, a 1384 *Decameron*, a 5th-century Virgil, and the Pandects of Justinian of 533.

Further north toward the edge of the city is the Convento di S. Marco (Monastery of St. Mark), rebuilt for Cosimo de' Medici by Michelozzo in 1437. Each of the cells in the top story is painted with a mystery of the Christian faith by Fra Angelico. The cell of Savonarola is preserved with furnishings from the period of his passionate evangelism, when S. Marco was the centre of Florentine religious fervour.

Across the river the church of S. Spirito, built—not entirely faithfully—to the designs of Brunelleschi, marks another advance toward the Renaissance. The feeling of order and harmony sought by the architect in his search for the mastery of space is revealed in the proportions he imposed: the height of the nave is the double of its width; the ground floor and the clerestory are of exactly equal height; the height-to-width proportions of the nave are repeated in the aisle bays. Nearby, the church of Sta. Maria del Carmine contains frescoes by one of the painter-founders of the Renaissance, Masaccio.

The churches of the two rival orders, Dominican and Franciscan, are on opposite sides of the central section of the city. To the west is the Dominican Sta. Maria Novella (1278–1350), behind a 15th-century polychrome facade by Leon Battista Alberti, a brilliant Florentine noble, architect, writer, and aesthetic theorist, most of whose major buildings were constructed outside his native city. It has frescoes by Masaccio and Orcagna, its Green Cloister decorated by Uccello and, off the cloister, the Spanish Chapel.

The chapel, built c. 1350 as the chapter house, is covered from floor to ceiling in vivid Gothic frescoes from the ardent hand of Andrea da Firenze. In it, the Dominicans are shown as the Hounds of God—Domini Canes—rending the wolves of heresy.

Santa Croce, built by the Franciscans on the east end of town, is larger, its facade an afterthought (c. 1860), its interior regrettably modernized by Vasari in 1560. Among its jewels are Giotto frescoes, a Cimabue crucifix almost destroyed by the 1966 flood, Donatello carvings, a splendid classical chapel (1430–45) by Brunelleschi for the Pazzi family, whose forebears tried to assassinate

The first Renaissance building

S. Spirito of Brunelleschi

Lorenzo the Magnificent in this church, and a Medici chapel by Michelozzo (1434). Michelangelo, Galileo, Machiavelli, and the composer Gioacchino Rossini are buried there.

The Countess of Albany, wife of Bonnie Prince Charlie of Scotland, also is entombed in the church; and there is a memorial plaque to Florence Nightingale, born in the city in 1823. From the late 18th to the mid-20th century a large Anglo-American colony was an integral part of the Florentine scene. The poet Elizabeth Barrett Browning, who is buried in the small English cemetery, noted that the city was "cheap, tranquil, cheerful and beautiful." The Horne Museum, near Sta. Croce, and the Stibbert Museum in the north are examples of houses and collections left by foreigners to their adopted city.

**Palaces and parks.** Of the 57 palaces built as private residences, the biggest and historically the most imposing is the Palazzo Pitti. It is another of the world's great museums, stuffed with the works of Raphael (11), Titian (14), Tintoretto (eight), Veronese (five), and Rubens (12), among the principal works. The central block of the palace was started in 1440 for Luca Pitti, a merchant banker who wanted to outshine the rest of Florence but lost his fortune trying to break the rival Medicis and left the building unfinished. In 1549, Elenora of Toledo, wealthy daughter of the viceroy of Naples and wife of Grand Duke Cosimo I, bought the property. Cosimo's enlargements were continued by successors until 1852. The palace was the official residence of King Victor Emmanuel II while Florence was Italy's capital. The facade, huge blocks of partly smoothed stone virtually bare of decoration, is 627 feet long, spanning 23 grand windows. The interior of this enormous and forbidding hulk is light and, depending on the periods and purposes of the rooms, gay or stately and always implacably rich.

The hill behind the house, from which much of the building stone had been quarried, was transformed into the Boboli, among the most admired gardens of the Renaissance world. Grotto-dotted, statue-strewn, planted with orchards, pools, fountains, knolls, glades, arbors, and alleys, it is still a place of surprises and pleasures. The amphitheatre, hewn from the hill, is still used for summer entertainments. Above the gardens is the restored Palazetto di Belvedere, built in the late 16th century, which served for several centuries as the Forte di San Giorgio.

The Boboli is only one of the splendid public parks with which Florence is graced. Although the city centre is all pavements, towers, and pressing people, the area immediately surrounding it is handsomely endowed with green spaces, including 22 sports grounds and four large outdoor swimming pools. The largest park is the Cascine (cowshed), along the right bank of the Arno, which Cosimo I bought as a cow pasture and which eventually became a park with promenade for aristocrats' carriages. Today, among other attractions, it offers tracks for various kinds of horse racing, riding paths, tennis courts, and a modern outdoor velodrome. At the Campo di Marte sports centre, architect Luigi Nervi built a stadium (1930-32) of curved concrete slabs in tension. It became a landmark of modern architecture, with curved cantilevered roof arcing out some 50 feet and a meshed pair of cantilevered spiral staircases in back.

Although the other Renaissance palaces of Florence are not so immense and glowering as the Pitti, they are all massive, with heavy cornices and heavily rusticated blocks of stone. Renaissance feelings of delicacy and movement are apparent only in their courtyards. The first was the Medici Palace, begun by Michelozzo in 1444. Once the seat of Lorenzo the Magnificent's court of philosophers, artists, and poets, it is now the seat of the provincial prefecture.

The Palazzo Rucellai was designed by Alberti in 1458 and exemplified his theories of achieving harmony and "all-pervading order" through mathematical rules of proportion. With this building, Alberti was the first to replace medieval eaves with Renaissance cornices and to employ the three superimposed architectural orders in the pilasters. The Palazzo Strozzi was begun in 1489, but

because of the political vicissitudes of the Strozzi family, the palace was not completed even after it had been restored to their ownership in 1568. In 1937 an insurance association bought the long-neglected, money-gobbling palace from Prince Rodolfo Strozzi and restored it. The low stone bench across the front has become the traditional display stand for flower sellers. The iron rings for tethering horses, the torch holders, flag and bunting brackets, and the spike-crowned lanterns, all designed by the original architects and wrought by Niccolò Grosso, a 16th-century ironmaster, are Florentine masterpieces.

**Cultural institutions.** Florence has a total of 40 museums, mostly devoted to painting and sculpture. The Biblioteca Nazionale Centrale (National Central Library) has been the Italian library of deposit since 1870, receiving a copy of every book published in the nation. It houses more than 3,000,000 autographs, manuscripts, letters, incunabula, and books, including many rare editions. The Ricardiana and Moreniana libraries adjoining the Palazzo Medici-Riccardi have the most complete collection, including valuable manuscripts, of works on Tuscan history. The Biblioteca del Gabinetto Scientifico Letterario G.P. Viessesux is a library founded in 1821 by Jean-Baptiste Viessesux, who was the central figure of a group that included the leading literary figures of Italy at that time.

After Lorenzo de' Medici transferred the "Studio Fiorentino" (founded 1349) to Pisa in 1472, the medical school remained behind, leading the scientific movement in Italy and forming the nucleus for the university that was legally constituted only in 1923. The Academy of the Crusca was established in 1582 to prepare an Italian dictionary; its name means "bran," its symbol is a sieve, and its object remains to winnow impurities from the language. The new edition of the dictionary is due in the year 2000. Other specialized learned institutions include an observatory; academies of fine arts, science, letters, and agrarian economics; institutes of Etruscan and Italian studies, of the history of art, and of the history of optics. The Italian Dante Society, the Italian Botanical Society, and the Society for Geographical Studies are in Florence.

An increasing number of foreign nations and universities conduct study institutes in Florence. The Harvard University Center for Italian Renaissance Studies is located at the exquisite Villa I Tatti, in the hills at Settignano, bequeathed by art historian Bernard Berenson. The universities of Grenoble, Paris, Syracuse, and Stanford, the universities of The Netherlands, and the state colleges of California are represented.

#### BIBLIOGRAPHY

**General works:** MARY MCCARTHY, *The Stones of Florence* (1959), an analytic examination of the city past and present with an emphasis on works of art, rich in historical background; EDWARD HUTTON, *Florence*, new ed. (1966), a comprehensive presentation of the city's districts and places of interest; EVE BOROOK, *The Companion Guide to Florence* (1966), a historical introduction followed by an area-by-area survey, with summaries of the chief monuments in each; EDMOND RENE LABANDE, *Florence* (1949; Eng. trans., 1951), an examination of the monuments in the centre of the city and the principal museums, with descriptive tours of both sides of the Arno and a few excursions into the countryside.

**History:** FERDINAND SCHEVILL, *Medieval and Renaissance Florence*, 2 vol. (1963; a reduced reprint of the 1936 edition entitled *History of Florence*), a scholarly summation of the city's past; GIUSEPPE MARTINELLI (ed.), *Tutto su Firenze Rinascimentale* (1968; Eng. trans., *The World of Renaissance Florence*, 1968), exceptionally well illustrated with 300 colour pictures accompanied by text by various scholars on many aspects of public and private life; VINCENT CRONIN, *The Florentine Renaissance* (1967), a description of Florentine civilization as a whole during the 15th century based on primary sources, including a list of the whereabouts of works of art mentioned in the text or reproduced as illustrations.

**Art:** MARCO ROSCI, *The Uffizi and Pitti Galleries* (Eng. trans. 1964), a well-documented survey with illustrations in black and white and colour; FILIPPO ROSSI, *Art Treasures of the Uffizi and Pitti* (1957), many reproductions, with explanatory text; ROBERT SALVINI, *The Uffizi Gallery: Visitors' Guide and Catalogue of Paintings* (1965), a serviceable, popular

guide with brief comments on the works; EVELYN SANDBERG VAVALA, *Uffizi Studies: The Development of the Florentine School of Painting* (1948), for the intelligent visitor who wishes to become better informed about the history and character of Florentine painting.

**Chiefly photographic:** MARTIN HURLIMANN and HAROLD ACTON, *Florence* (1961), historical notes accompanying 138 pictures in photogravure and 12 colour plates; LAZZARO DONATI, *Florence* (1959), views of landmarks, daily life, churches, art, and other aspects of the environment; BENNO PREMSEL, *This Is Florence* (1954), smaller paperback, but with excellent photographs and informative text.

**Special topics:** JOSEPH MACLEOD, *People of Florence* (1969), the character and way of life of the inhabitants as they are shaped by their locality, told in a personal, essayist style; FRANCO NENCINI, *Firenze, i giorni del diluvio*, 5th ed. (1966; Eng. trans., *Florence: The Days of the Flood*, 1967), a journalistic account of the November 1966 flood, with 107 photographs of its ravages.

(B.E.)

## Florida

The geographical situation of Florida has been the key factor in a long and colourful development that is without parallel in the United States and goes a long way to explaining the striking contemporary character of the state. The greater part of Florida lies on a peninsula protruding southeastward from the North American continent, separating the waters of the Atlantic Ocean from those of the Gulf of Mexico and leading toward the island of Cuba and the Caribbean Sea beyond. The nearest foreign territory is the Bahamian island of Bimini, some 50 miles to the east of the state's tip. With the exception of Hawaii, Florida is the most southern state of the United States, with its northernmost point lying 100 miles farther south than California's southern border. The Florida Keys, an island crescent forming the state's southernmost portion, lie within 1,700 miles of the Equator. Florida lies in the same latitude as Egypt. Its size, 58,560 square miles (151,670 square kilometres), is comparable to that of England and Wales.

The state lies close to the geographical centre and the median population point of the New World land mass and its position commands not only the entrance to the Gulf of Mexico but also the strategic crossroads between North and South America and historic routes to the European and Mediterranean worlds. Florida played a prominent role in the struggles of the European powers to control the New World, and it is fitting that St. Augustine, on its northeastern coast, founded in 1565, should be the oldest European settlement within the boundaries of what became the continental U.S.

After a long and turbulent early history, Florida became a U.S. possession in 1821, entering the Union in 1845. Even then, the full development of the state by peoples of European descent had to await the final elimination of the indigenous population, and the opening of the territory by an injection of northern capital into the transportation system. Only in the late 19th century did the rich potential of Florida's beautiful tropical and sub-tropical environment—another endowment of its geographical position—undergo full development. The population soared: the total shown by the 1850 census, the first taken after the state entered the Union, was 87,445, ranking last among the states; by 1900 it had expanded to 528,542 (33rd among 45 states), and a spectacular 20th-century expansion carried its total over the 7,000,000 mark by 1971, when it ranked among the top 10 states, as well as being among the top three fastest growing states. Although agriculture and the manufacturing industry of Florida continue to be important, the climate and scenery of the "Sunshine State" have attracted enormous numbers of visitors, and tourism is now the mainstay of a well-diversified local economy. Some 3,400 persons a week were taking up permanent residence in the state by the early 1970s, and a good proportion of these were making their retirement homes in Florida, making a distinctive contribution to the character of the state. During the same period, Florida has become a global centre for the most modern of explorations, that of space, with the

vast launching complex at Cape Kennedy. (For related information see UNITED STATES, HISTORY OF THE; UNITED STATES; NORTH AMERICA; and EVERGLADES.)

## HISTORY

**Exploration and settlement.** The early history of Florida reflected the conflicts of the Spanish, French, and English crowns for empire and wealth. Juan Ponce de León's quest for the Fountain of Youth brought him to the mainland in 1513, and 1521. An abortive settlement in 1528 led to eight years of Indian captivity and wandering through the South and Southwest by Alvar Núñez Cabeza de Vaca and three companions. A colony of Protestant Huguenots established on the St. Johns River was wiped out in 1565 by Spaniards, who boasted of slaughtering the Frenchmen not for their nationality but for their religion. This Spanish expedition, under Pedro Menéndez de Avilés, proceeded to found St. Augustine near the decimated settlement.

**Shifting alliances and allegiances.** The following centuries saw frequent raids by English seafarers, including Sir Francis Drake in 1586, and clashes with French colonizers along the northern coasts of the Gulf of Mexico and English settlers in the Carolina and Georgia colonies. Shifting alliances among the three powers reflected the vicissitudes of European politics, and St. Augustine and the English ports of Savannah and Charleston were besieged at various times through the first half of the 18th century.

England received Florida in return for Havana in 1763 and instituted civil for military government. Expenditures for economic development brought prosperity as well as loyalty from most Floridians during the Revolution, when the colony was used as a base for attacks on American coastal cities. Three decades of political and social instability followed Florida's return to Spain after the Revolution, with American expansionist interests in constant conflict with the Spanish presence. Pensacola was a base for the British during the War of 1812, when Indians and runaway Negroes were employed to harass American settlements. General Andrew Jackson's capture of Pensacola led finally to cession of Florida to the United States in a treaty signed in 1819 and ratified in 1821.

**Statehood.** The Seminole War of 1835–42, the result of attempts to remove the indigenous people to Oklahoma after their centuries of relative peace with the Spanish, became the darkest chapter in Florida's history. By 1845, when Florida was admitted to the Union as the 27th state, all but a few hundred Seminoles had been transported from their ancestral home.

Florida was a part of the Confederacy during the Civil War, but action in the state was limited to the capture of coastal cities by Union troops. In the 1880s an era of railroad building began that opened the state to permanent settlers and a new tourist trade and brought it into the heart of the nation's economic life as the winter vegetable and citrus centre of the East.

**The 20th century.** The growth of Florida in the 20th century was frantic to the point of chaos. Land booms and the building of high-rise resort and convention cities paralleled economic diversification and military installations such as the missile site at Cape Kennedy.

## THE LANDSCAPE

**Natural landscape.** *Physiography.* Florida is a geologically young, low-lying plain, mostly under 100 feet, with its highest point, in Walton County, a mere 345 feet. Sedimentary deposits of sand and limestone cover most of the state, with areas of peat and muck marking where freshwater bodies once stood. The contemporary topography has been largely molded by running water, waves, ocean currents, winds, changes in sea level, and the wearing away of limestone rocks by solution. These forces have produced enough variation in the state's surface to permit classification into seven basic physiographic regions: the coastal lowlands, the Lake Okeechobee–Everglades Basin, the Kissimmee lowlands, the Marianna low-

Spanish  
dominionEvolution  
of the con-  
temporary  
state

lands, the central highlands, the Tallahassee hills, and the western highlands, although these scientific divisions are scarcely apparent to the naked eye.

**Soils and vegetation.** Soils and vegetation are closely related to the basic physiographic provinces. In general, Florida's soils consist of sands, sandy loams, clayey marls, peat, and mucks, and over 300 soil types have been mapped. The variety of trees is great, with more than 300 species being described: more than 60 percent of the state is covered by trees. Dominant trees include pines, oaks, cypresses, palms, and mangroves. Most tropical plants will thrive in south Florida, while beech, red maple, sweet gum, tulip, magnolia, and hickory are common in the north. Almost half of the tree species of the United States grow in the state, and more than 3,500 non-tree plants have been identified. Included in this number are many imports.

Six broad soil-vegetation regions may be described. The Flatwood lowland soils form the largest soil region in Florida, which corresponds roughly to the coastal lowlands. The terrain here is level and underlain by a hardpan that impedes drainage and encourages flooding; slash and longleaf pine, oaks, sabal palm, and grass typify the region. Organic soils are found in many parts of Florida, but the type locality is the Lake Okeechobee-Everglades Basin—probably the largest area of neutral organic soils in the tropics—where saw grasses, cypress, sabal palm, myrtle, willow, elderberry, and gum are important. In this soggy environment, submergence often prevents the oxidation, decay, and shrinkage of peat and muck, but, when the soils are drained, they deteriorate rapidly. Southern limestone soils occur in the Kissimmee Valley, the Big Cypress Swamp, and the Miami-Homestead area. Pines and oaks grow in some areas, but grasses, along with saw palmetto and sabal palms, predominate in the Kissimmee Valley. Cypress, bays, and gumbo-limbo, a tall tree with a brown, bright lacquered trunk, are typical of the extreme southern areas of this type. Northern upland soils occur in the region stretching across the north of the state and support hardwoods, loblolly pine, and longleaf pine, while northern slope soils lie immediately to the south, producing slash and longleaf pine, oak, and saw palmetto. Central upland soils—with a vegetation similar to that found in northern slope soils—are located in the higher ridge area of central Florida and westward to the Apalachicola River. A number of other distinctive zones of soils and vegetation exist: dune types fringe the magnificent beaches of the state, while the lush, dank mangrove swamps, along with tropical hardwoods and sand pine and oak, are found in the Ocala National Forest.

**Water.** The flat Florida landscape is covered by a latticework of 1,711 named streams (mostly in the north and northwest) and no fewer than 30,000 named lakes (mostly in the central region). The state also contains 17 of the 75 first-magnitude artesian springs in the nation, most of them located in the central region. Some 39 drainage basins are recognized, with the Lake Okeechobee-Everglades Basin (17,000 square miles) being the largest. Lake Okeechobee (700 square miles) is the third largest freshwater lake entirely in the United States (after Lake Michigan and Lake Iliamna, Alaska). This vast water network is fed by the state's porous limestone substructure, which stores large quantities of water.

**Wildlife.** Florida's rich and distinctive tropical and subtropical environment is inhabited by a huge and varied wildlife population, the rarer forms of which are fully protected. Approximately 100 species of mammals are represented, and the range includes deer, puma, bobcat, boar, black bear, armadillo, otter, mink, and gray fox, while bats and other smaller animals are numerous. Manatees (sea cows) still inhabit streams and canals in the south, and several species of porpoises and dolphins lend their own distinctive charm to the clear coastal waters.

Over 400 species and subspecies of birds have been cataloged: land birds include the turkey, quail, dove, eagle, hawk, owl, and most smaller birds common to the southeastern states, while coastal birds—gulls, brown pelican, sandpiper, osprey, and cormorant—are also numerous.

Freshwater and marsh birds include the gallinule (marsh hen), duck, goose, coot, egret, heron, ibis (stork), and flamingo. Vast natural rookeries exist in the Everglades, and numerous wildlife refuges are maintained for the protection of migratory birds.

The less attractive alligator is the king of Florida reptiles, his role as a builder of water holes being vital to south Florida's ecology, while the crocodile still inhabits part of the Everglades National Park. The 40 species of snakes in the state include the nation's four poisonous types: coral, rattlesnake, moccasin, and copperhead (the latter restricted to limited areas of north Florida); turtles, tortoises, lizards, and frogs are also abundant.

Florida's 4,000,000 acres of water (of which 2,750,000 acres are inland) contain more than 700 species of fish and shellfish. Common saltwater varieties are bluefish, pompano, flounder, mackerel, mullet, trout, redfish, snapper, grouper, snook, sailfish, tarpon, shad, weakfish, bonefish, marlin, and shark, and others. Crawfish, oysters, stone and blue crabs, clams, and shrimp may be added to the list. The largemouth black bass is the state's foremost freshwater species, while others include bream (bluegill), sunfish, speckled perch, and catfish.

**Climate.** Climatically, Florida is divided into two regions. The tropical zone lies generally south of a west-east line drawn from Bradenton, via the south shore of Lake Okeechobee, to Vero Beach, while to the north of this line the state is subtropical. Summers are uniform throughout Florida, and, while freezing weather, of short duration (but often crippling to agriculture), can occur as far south as Miami, the Keys—a crescent of islands strung out at the southern tip of the state—have never experienced frost.

Rainfall is heaviest in summer, with drier weather prevailing in the winter months. The average annual rainfall ranges from 39.8 inches (1,011 millimetres) in Key West to 61.7 inches (1,567 millimetres) in West Palm Beach. Snow falls occasionally in the northern areas and has been reported as far south as Fort Myers. Hurricanes, occurring about once a year on the average, bring much needed rain to the state near the end of the rainy season. These storms may cause great damage, although Florida is no more vulnerable than the other Gulf states or, indeed, the Atlantic coast up to Boston. The hurricane season is from June to November, although September is the month they are most likely to occur.

Average annual temperatures show little variation, ranging from 68° F (20° C) in Tallahassee in the north to 77° F at Key West in the south. Corresponding monthly averages range from the middle 40's F (in the north) to the middle 50's F (in the south) in January, and are in the lower 80's F in August.

**Regions.** North and south Florida are often distinguished as separate regions. North Florida is often thought of as colder, historically older, oriented toward field agriculture and timber, rural, and hilly; and south Florida is regarded as warmer, more recently settled, citrus-livestock-vegetable oriented, tourist centred, urban, and flat. A refinement would add central Florida, with its lake region and citrus belt. A more scientific regionalization might identify the east coast, the west coast, central Florida, the Keys, the Everglades, and the panhandle. More popular regional names are: the Gold Coast (the Miami-West Palm Beach metropolitan sprawl), the Sun Coast (the Tampa Bay area), and the Big Bend (centring on Tallahassee). Lesser known designations include the Silver or Platinum Coast (a term applied to the lower southwest), the Island or Mangrove Coast (the extreme southwest), Suwanneeland (the Suwannee River basin), Miracle Strip (the upper northwestern coast), Florida's Crown (the northernmost part of the peninsula), the Surf Coast (mid-east coast), and the Tropi-Coast (Miami-West Palm Beach).

**Cultural landscape.** *Rural life.* To a stranger entering the state from the north, the Florida landscape may appear quite empty and devoid of human imprint. It is, in fact, in use, but the use is of a type unfamiliar to many eastern Americans. About 55 percent of Florida is covered by commercial, national, and state forests, state and

The  
organic-  
soil  
complex

Hurricanes

Huge and  
varied  
wildlife  
population

federal parks, lakes, cities, highways, military reservations, and beaches. Of the remaining 45 percent, only one-fifth is in farmland, and half of this is in either pasture or timber: the net result is that only about 5 percent of Florida's total land is in harvested crops, with field crops accounting for half the harvested total, citrus fruit for one-quarter, and vegetables for one-quarter.

The effect on the landscape is striking: farmsteads are generally common in north Florida, where field crops are important, but even here timber covers thousands of acres. Citrus groves occupy much of central Florida and the east coast, while along the west coast and north and south of the citrus belt spread vast expanses of cattle land. Around Lake Okeechobee, the cultivation of sugarcane and vegetables has produced the modern equivalent of plantation agriculture. The small, private farm has little place in these systems, the settled farmer having been superceded as a result of mechanization and the use of migratory labor. The social conditions of the latter, which have, on occasion, given rise to national concern, remain one of the less happy aspects of a generally affluent state. The rise of what has been termed corporate agriculture has thus led to an inevitable increase in farm size and a corresponding reduction in farm numbers. Since 1940, the number of Florida farms has almost halved, while, by the early 1970s, one-half the total farm acreage was owned by fewer than 1,000 farmers.

**Urban settlement.** Even the small town seems to be disappearing, as more and more people find it relatively easy to commute from urban and suburban centres: at the 1970 census, 80.5 percent of the people were urban, and, of the remainder, only 2 percent lived on farms. Seventy percent of the total state population lived, in fact, in 10 of the 67 counties, with 30 percent occupying the extensive Miami–West Palm Beach urban complex in the southeast of the state. This area appeared to many observers to be duplicating the less desirable aspects of the great urban belts burgeoning in other areas of the nation. On the west coast, the Tampa Bay metropolitan area contained another 15 percent of the population. Further north, the Orlando–Cape Kennedy–Daytona Beach triangle is central Florida's dominant urban area; Jacksonville is the major centre of the upper east coast and southeast Georgia; and Pensacola dominates the western panhandle and part of Alabama. Lesser metropolitan areas—notably, Tallahassee, Gainesville, and Fort Myers—are hubs of local influence.

#### THE PEOPLE OF FLORIDA

**Cultural and racial groups.** *The legacy of the Indians.* Ancient Indian groups drifted into Florida from the north as early as 10,000 years ago, but farming did not appear much before 500 BC, and some southern indigenous groups remained hunters, fishers, and gatherers until their extinction. Indians continued to arrive in small numbers after 500 BC, and contacts with Cuba, the Bahamas, and, possibly, Yucatán reflected Florida's unique situation. By 1750 virtually all of these peoples had been destroyed by disease, slavers, and wars, responsibility largely resting with English and Creek raiders from Georgia. The latter, accompanied by a few runaway Negro slaves and renegade whites, were collectively called *Cimarrónes* (Spanish: "wild, unruly, runaway"). The name Seminole evolved from *cimarrón*, and there were approximately 5,000 Seminoles in Florida when it came under formal United States jurisdiction in 1821. Within 25 years, this population declined to about 150, at which juncture most Seminoles were removed to Oklahoma; by the 1970s some 2,000 of the descendants of those who remained lived in three south Florida reservations.

*Early European contributions.* The first Spanish settlement, of 1559, was abandoned in 1561, but San Agustín (St. Augustine), founded in 1565 after the destruction of the French settlement there, became the first permanent European settlement in the United States. For the next 250 years, Florida was little more than a wilderness in terms of any permanent European settlement, although its importance as a historical pawn was considerable. A population of European origin was not to grow until the

United States established effective civil control in 1822, and the great increases of the late 19th and 20th centuries owed much to economic factors (see below *The state's economy*).

*The Black contribution.* It is not known when the first Negroes arrived in Florida, but it is known that some accompanied the first Spanish expeditions. A few runaway slaves came in with the Seminoles, but it was only with American rule that the Negro population began to increase. By 1830 there were as many Negroes as whites (about 11,000 each). The subsequent increase of Negro population coincided with the development and spread of the Southern plantation system, based on slavery. The U.S. Civil War overthrew the slave system, but the agricultural patterns remained, and not until the end of the 19th century did an influx of whites cause their component of the population to increase faster than that of the Negroes. The Negro percentage of the total population continued to decline in the 20th century, and by the 1970s the proportion of black Americans amounted to about 17 percent, although larger percentages were still found in the old plantation belt (north central Florida) and in the Everglades truck-farming region.

*Other distinctive groups.* Cubans came to Key West after 1868, when, as a result of revolutionary turmoil in Cuba, Vicente Martínez Ybor moved his cigar factories there from Havana. Labour troubles and disastrous fire encouraged Ybor to move again in 1886, this time to Tampa, and again many Cubans followed the factories. A similar Cuban influx occurred after the revolution of the early 1960s, with over 350,000 Cubans fleeing their homeland. A third of these settled in Florida (mostly in the Miami area) during the decade.

Immigrants from northern Spain came to Tampa about the time of World War I, drawn largely by the expanding cigar industry and the prospect of living in a Spanish-speaking community. Italians also came in large numbers. By the 1970s, approximately 20 percent of Tampa's population remained Spanish speaking.

Tarpon Springs was settled around 1880, and by 1905 Greek immigrants, drawing on the traditions of their homeland, had established the nation's major sponge industry. Greek is still widely spoken, and the city is a centre for the Greek Orthodox religion. Other ethnic contributions lending character to the overall population of the state range in size from the distinctive Jewish community at Miami–Miami Beach (over 100,000) to the Slovak settlement at Masaryktown (about 1,000).

**Demography.** Florida's 1970 resident population of 6,789,443 marked a 37.1 percent increase over that in 1960. The population passed the 7,000,000 mark in 1971 and was confidently projected to exceed 8,000,000 by the close of the decade. While the birthrate (17.0) was close to the national rate of 17.7 per 1,000 in 1969, the death rate was 11.6 per 1,000, as compared with a national rate of 9.6 per 1,000 in 1968. Florida's death rate has climbed steadily since 1960, when it was 9.7 per 1,000, while the birthrate has dropped from 23.3 per 1,000; in part, this trend undoubtedly reflects the immigration of older people. During the late 1960s, excess of births over deaths added approximately 30,000 persons a year to the state total, while immigration, on the other hand, brought in some 180,000 persons annually. By the early 1970s, Florida was the third fastest growing state, with a 2.7-percent annual increase, exceeded only by Arizona (2.8 percent) and Nevada (5.0 percent). This still represented a slowing of Florida's hectic growth in the 1950s, when the total population registered a remarkable 79-percent increase.

In terms of intrastate trends, it appears that the state's northwestern counties will continue to lose population to the large urban areas, while those areas heavily dependent on military and space programs may well be affected by the budgetary vicissitudes affecting those activities. Key West, for example, a Navy-oriented city, suffered a 19-percent population loss over 1960, while Brevard County (in which Cape Kennedy is located) registered a gain of no less than 106 percent. On the other hand, cutbacks in the space program created Florida's

Corporate  
agriculture

Contacts  
with  
Central  
America

highest unemployment rate in the latter area during the first years of the 1970s, and further rapid growth appeared unlikely. Instead, developing southwest Florida seemed destined to be the next boom region of the state, for Charlotte and Collier counties each gained more than 100 percent in population over the 1960s, while Lee County increased by 93 percent. Overall, the accelerating urbanism of the early 1970s led to predictions that, within a decade or so, Florida's population would be less than 10 percent rural, while some 11 counties, containing approximately 90 percent of the population, would be totally urban.

#### THE STATE'S ECONOMY

**Overall factors.** Florida experienced virtually no economic development before 1821, when the United States took formal possession, and the 60 years to follow were dominated by small-farm and plantation agriculture; the supplying of naval stores and the production of beef and hides, pork, salt, tobacco, and cotton were the main activities. The 1880s, by contrast, marked the beginning of a new era in Florida, for, in 1881, phosphate—the state's most important mineral—was discovered in the Peace River Valley, while in that same year Hamilton Disston, a Philadelphia industrialist, bought 4,000,000 acres in the Everglades for 25 cents an acre. This key action freed the state from its post-Civil War debt and opened the way for the development of much of the peninsula. In the west, a railroad reached Pensacola in 1883, and in the following year another thrust as far as Tampa; this, too, was financed by a northern capitalist—in this case, Henry B. Plant—while on the east coast his counterpart, Henry M. Flagler, was building a rail and hotel empire that would soon extend past Miami to Key West. Agricultural development, settlement, industry, and tourism all followed the rails: the 1890 population of the state was double that of 1870, while the total passed the half-million mark by the turn of the century and continued its spectacular growth thereafter.

**Distribution of resources.** Directly or indirectly, Florida's tropical and subtropical climate affects almost every aspect of the local economy, and it can be quite justifiably considered as the state's chief resource. Together with land and water—both of which have possessed a rich potential for economic development—it forms the basis of the state's wealth. The water resources, important to fisherman and tourist alike, include not only 4,424 square miles of fresh inland water but also an even larger area of adjacent saltwater. In the United States, only Alaska has a tidal shoreline whose length exceeds that of Florida, which totals no less than 8,426 miles (Gulf coast, 5,095 miles; Atlantic coast, 3,331 miles). On land, forestry activities and livestock rearing are supported by the fact that about 60 percent of the state (mostly in the north) is wooded, while grasslands spread over another 20 percent (mostly in the central and southern areas). Florida also yields several important minerals, with phosphate—used in fertilizer and livestock feed and by chemical industries—being the principal one. It is found in the west central portion of the state, whose production accounts for 75 percent of the national total. Titanium (used in paint and jet engines), zircon (used in foundries, gas engines, and atomic reactors), and such other important heavy minerals as thorium and cerium are mined near Jacksonville, Starke, Vero Beach, and in west central Florida. Petroleum is produced at Jay, (north of Pensacola), and averages 180,000 barrels a month. A small field in Collier County produces 25,000–40,000 barrels monthly. Kaolin is mined in Putnam County; Fuller's earth comes from the Tallahassee region; while clay, sand, and gravel are mined in numerous locations, with pure silica sand being extracted mostly in areas around the 100-foot contour line. Limestone, from the northern portion of the peninsula, is used as cut building stone and road-surfacing material and in cement, concrete, and fertilizer; peat, used as a soil conditioner, is dug in many areas. The versatility of the marine resources of Florida is indicated by a plant at Port St. Joe on the Gulf coast for the recovery of magnesium from seawater.

**Sources of income.** *Tourism.* Approximately 23,000,000 tourists visited Florida annually in the early 1970s, spending a total, each year, in excess of \$6,000,000,000. Tourism is by far the predominant industry and has developed into a year-round activity, with July and August being the leading months.

*Manufacturing.* Manufacturing contributes, on a value-added basis, in excess of \$4,000,000,000 annually, second only to tourism. Production is well diversified, with food processing leading in value.

*Agriculture.* Cash farm income amounted to some \$1,500,000,000 annually by the 1970s. Florida produces about 75 percent of the nation's total citrus fruit, and the state is second only to California in vegetable production. Although Florida has almost 2,000,000 head of cattle, it is perhaps better known as one of the leading North American regions for the rearing of thoroughbred horses.

Completing the major sources of income for the local economy, the state's annual manufactured value of forest products exceeds \$600,000,000, and of minerals, \$320,000,000; and commercial fishing brings in almost \$40,000,000. This overall diversification of a developing economy, utilizing the richly varied natural endowment, has been a key factor in the remarkable population growth of the state in the 20th century.

**Management of the economy.** Labour-management relationships in Florida tend to follow the national pattern. Manufacturing, mining, communication, and transportation tend to be unionized; services, less so; while the professions and agriculture are generally nonunion. The cooperative movement is especially strong in citrus and commercial fishing. The Florida Citrus Mutual works closely with growers and the state in research, production, processing, marketing, and regulation, while about eight fishing cooperatives exist, primarily to help market the catch.

The state government cooperates closely with the private sector of the economy; it is instrumental in inspection, licensing, regulation, and research and education, but the state rarely competes with private business.

**Transportation.** *Overall patterns.* Florida's transportation system is a comprehensive one, covering the entire state except for certain isolated areas in the Everglades. In general, highway arteries run across the north of the state, from Jacksonville to Pensacola; down the east coast, from Jacksonville to Miami; diagonally across the state, from Jacksonville to Tampa–St. Petersburg on the west coast, bisecting the state from Tampa–St. Petersburg to Daytona Beach; and through the southwestern portion, linking Tampa–St. Petersburg to Miami. Rail and air traffic follow these patterns, with one exception: although there is no direct Miami–Tampa railroad, air traffic on this route is extremely heavy.

*Component systems.* Florida has approximately 87,000 miles (47,000 paved miles) of state, county, and municipal roads. The most heavily travelled through routes are the interstate and state turnpike systems that connect all major cities. There are 20 airports with regularly scheduled flights, augmented by numerous private airfields, and the international terminals at Tampa and Miami are among the most modern in the world. An extensive rail network, some 4,348 miles long, provides an adequate passenger and freight service to most areas. An integrated system for domestic and foreign shipping is provided by 13 deepwater ports and several lesser ports and harbours, while more than 1,000 miles of navigable channel are maintained by the federal government. Construction of the Cross-Florida Barge Canal was halted by President Richard Nixon in 1971, pending further ecological studies.

Florida has the world's only moonport, the John F. Kennedy Space Center at Cape Kennedy, which occupies 88,000 acres. Not only is this a major Florida industry (employing as many as 35,000) but it has also become a prime tourist attraction.

#### ADMINISTRATION AND SOCIAL CONDITIONS

**Governmental structure.** *The constitution.* The government of Florida operates under the revised constitu-

Agricultural specialties

Role of Northern capital

Cape Kennedy

tion of 1968, with the executive department—headed by the governor and six Cabinet officers (secretaries of agriculture, state, and education; comptroller; attorney general; and treasurer)—the law-administering and law-enforcing branch. Essentially, the Cabinet officers control their departments, divisions, and assorted boards directly, while the governor controls nine departments of quasi-Cabinet status that report to him. The legislature is composed of a Senate of 48 members and a House of Representatives of 119 members. Senators serve four-year terms, and half that body is elected every two years, while House members are elected for two-year terms.

**The legal system.** The judicial department is the law-interpreting branch, and its powers are exercised primarily through courts established by the constitution: the Supreme Court, 4 district courts of appeal, 20 circuit courts, and a variety of county and municipal courts are found, with most judges elected for four-year terms. Florida is also part of the 5th judicial circuit of the federal court system and has three lower level district courts.

Though the Florida of the early 1970s was becoming a two-party state in many respects, Democrats typically outnumbered Republicans in both houses by about two to one, a preponderance traditionally reflected in national representation. The growing population of the state has occasioned constant reapportionment of representation at both the federal and national levels and was partially responsible for the adoption of the new constitution of 1968.

**Taxation.** Florida has no state income tax on individuals or corporations, and approximately 50 percent of the state's tax revenue comes from sales and use taxes and the gasoline tax. The remainder is derived from a wide range of other taxes, including those on pari-mutuel betting, principally at horse- and dog-racing tracks.

**The social framework.** Socially, Florida regards itself as a progressive state, and a major proportion of the state's financial resources certainly go into those areas that serve the public, with education, welfare, health, and hospitals receiving 64 percent of the total appropriations. The state supports the public school system to the extent that no child is deprived of a minimum standard of education, while the counties are expected to supplement this minimum. Virtually the entire population of the state is within commuting distance of a state-supported college or university, part of an extensive system of higher education.

Florida has about 200 hospitals, with approximately 30,000 beds; in general, there has been a steady improvement in health and health-care facilities during the recent decade, not unconnected with the growing proportion of elderly residents.

At the start of the 1970s, Florida's per capita income was close to \$3,600 per year, the highest in the southeast of the nation and 54 percent higher than a decade earlier, while, in total personal income, Florida ranks tenth in the nation. There are no serious labour shortages in Florida except in a few highly skilled and professional occupations and, at certain times, in service occupations. Unemployment in Florida usually runs below the national average, and the diversified economy of the state has not been as subject to labour fluctuations as in many other areas where one industry dominates the economy. Cost of living is generally below the national urban average, and in some areas, such as clothing, it is considerably below the average—another small but significant benefit accruing from the favourable climate.

#### CULTURAL LIFE AND INSTITUTIONS

Florida is well endowed with a variety of cultural activities and supporting institutions, a situation stemming partly from the importance of tourism and partly from the increasing leisure time available to the growing number of retired residents. The state itself maintains over 800 parks and recreation areas, many of historic or natural-historic interest; counties and municipalities support another 1,300 parks, as well as almost 600 indoor centres; and the Everglades National Park contains 1,400-

500 acres in the heart of a unique natural region. Florida's rich history is preserved in such places as St. Augustine, the nation's oldest town, portions of which have been restored, while its famous fort, Castillo de San Marcos, has been made a national monument.

Sarasota is a centre for both art and theatre. The John and Mable Ringling Museum of Art possesses an internationally famous collection, and the city—once the winter quarters of the famous Ringling Circus—also contains a circus, museum, and hall of fame. The Florida State Museum, located in Gainesville, is but one among the numerous noncommercial cultural attractions in Florida, while the Florida State Fair is held every February in Tampa, in combination with Gasparilla, a festival whose proportions are comparable to those of the great Mardi Gras celebrations of New Orleans.

Sports are well represented in the state, with the Orange Bowl in Miami, the Gator Bowl in Jacksonville, and Tampa Stadium attracting major university and professional events. The climate of Florida enables it to host a number of outdoor events, including five major golf tournaments and three internationally known auto races. Horse racing is also important.

Commercial attractions seem almost countless; many are educational and contribute not only to the cultural well-being of the state but also their share of taxes. Walt Disney World (near Orlando), which opened in late 1971, appeared to have a good chance of becoming the largest tourist attraction in the country, affecting the entire economy of central Florida. Before the opening of this project, Busch Gardens, in Tampa, was Florida's leading attraction, with over 30,000 visitors a day during the winter months.

In addition to other cultural offerings, Florida's universities and educational-television stations offer broad programs in continuing and adult education and similar ventures, on a scale larger than that of most other American states.

#### PROSPECTS

Florida is one of the fastest growing states in the nation and seems to have a good chance of meeting the projected annual increase of approximately 140,000 people a year during the 1970s. Employment is increasing in certain categories of professional and skilled occupations, but prospective residents have found it to their advantage to investigate the job market very carefully before moving into the state. Whereas a few years ago a newcomer could, for example, enter business by purchasing or building a small motel, the motel industry of the early 1970s was fast becoming a chain or franchise operation, with costs averaging \$10,000 per rental unit. The same pattern was to be noted in agriculture, where farm and grove units are larger than in the past, and mechanization requires a heavy investment. Even migratory agricultural labour—hitherto an important, if decidedly unattractive, source of employment for the unskilled—is on its way out, while heavy industry, with its large labour demands, seems highly unlikely to become a part of the Florida scene, primarily because of the lack of power resources. Manufacturing, already the number two income producer in the state, appears likely to continue to expand, especially in the more sophisticated areas of modern technology. As the state's urban character continues to intensify, it appears that many of the new housing units will be condominium, cooperative, or modular form: sprawling suburban developments have already begun to be less evident, and this trend will continue as the cost of land continues to mount. Tourism shows no signs of losing its pre-eminent position, but new areas—particularly central, west central, and southwestern Florida—are beginning to feel its impact and are already showing indications of becoming future growth regions. Air- and water-pollution controls are well established in Florida and play an important role in any activity that affects the quality of the environment. The dredge-and-fill era of Florida bays has come to an end, and some communities have ordinances prohibiting the cutting of trees. Wanton and irresponsible exploitation of

Political trends

Employment and living costs

Conservation measures

the state's resources is being halted, and the earlier concept of short-term gain is being replaced with one of beneficial, long-range development. As a result, it is to be hoped that Florida, one of the last states of the United States to be developed, will be able to preserve its beautiful environment and avoid a repetition of some of the more obvious defects that have afflicted the longer established regions of the country lying further to the north.

Fluid and Electrolyte Disorders

The chemical events by which the bodily tissues are built and maintained and by which energy is provided for bodily activity can take place only in a watery solution in which the hydrogen ions and electrolytes (discussed below) are kept within relatively narrow limits (see HOMEOSTASIS). Disturbances of water, electrolyte, and acid-base balance occur as a consequence of a large number of pathological conditions; these impair the functioning of many organs, especially those concerned with contractility and nerve conduction.

THE NORMAL FUNCTION OF WATER AND ELECTROLYTES IN THE BODY

The fluids and electrolytes of the body are the water that pervades it and the ions formed from the acids, alkalis, and salts that are dissolved in it. Ions are atoms or groups of atoms bearing positive or negative electrical charges. Those bearing positive charges are called cations; those bearing negative charges are anions. The ions are called electrolytes because the solution that contains them is able to transmit an electrical current.

The fluids in the body may be classified into two main divisions: the fluid in the cells and that outside (the extracellular fluid). The extracellular fluid can be further divided into the fluid within blood vessels (the intravascular fluid), and the fluid around the tissues.

**Electrolytes.** The electrolytes and their concentrations are shown in the Table. They are not dispersed evenly throughout the fluids of the body. Sodium and chloride are confined mainly to the extracellular fluids; potassium, magnesium, phosphate, and organic acids are present in highest concentration inside the cells. Bicarbonate is found in the extracellular fluid at a little more than twice its concentration in the tissue cells, while the concentration of free hydrogen ions is twice as great within the cells as outside them. This difference with respect to hy-

Normal Distribution of Ions in Intracellular (Muscle) and Extracellular Fluids in Man

drogen means that most tissue cells are slightly more acid than the fluid that bathes them.

Because of the permeability of the walls of the capillaries, the smallest of the blood vessels, the concentrations of electrolytes in the plasma (the blood apart from its cells) and in the extracellular fluid outside the blood vessels is similar. Interchange between these two extracellular compartments is limited, however, in respect to protein molecules, the concentrations of which, except in the fluid bathing the cells in the liver, is much greater in the plasma.

Thus, the plasma volume is largely the result of two opposing forces—the hydrostatic pressure, which tends to force water outward, and the osmotic pressure of the plasma proteins, which attracts water into the network of vessels. In spite of the differences in the pattern of ions in the cells and in the extracellular fluid, their osmotic pressure under normal conditions is identical. By hydrostatic pressure, in this context, is meant the pressures in the bodily fluids as a result of the mechanical forces exerted upon them. These forces include that resulting from the contractions of the heart. Osmotic pressure comes into play when two solutions of differing concentrations are separated by a semipermeable membrane. The solvent—e.g., water—tends to move through the membrane into the more concentrated solution.

**Hydrogen-ion concentration.** Life is possible only if the blood is kept within a narrow range of alkalinity. The normal range, in terms of hydrogen-ion concentration (pH), is from 7.35 to 7.45. This range is close to neutrality, represented by a pH of 7; a pH of less than 7 represents acidity.

The blood contains the bases bicarbonate, proteins, and phosphate, and the weak acid, carbonic acid. The degree of alkalinity of the blood depends principally upon the ratio of the concentration of carbonic acid (H<sub>2</sub>CO<sub>3</sub>) and the base bicarbonate (HCO<sub>3</sub><sup>-</sup>).

In the pulmonary alveoli, the small air-filled spaces in the lungs from which oxygen is removed and into which carbon dioxide from the blood is added, the partial pressure of carbon dioxide is about 40 millimetres of mercury; in a mixture of gases the partial pressure of each gas is the proportion of the total gaseous pressure contributed by that particular gas. This alveolar carbon dioxide pressure gives rise to a concentration of carbonic acid in the blood plasma of about one milliequivalent per litre. (A milliequivalent [mEq] is the number of grams of a substance dissolved in one millilitre of normal solution.) The alveolar pressure of carbon dioxide is kept steady by the equal rate at which carbon dioxide is produced by the tissues and eliminated by the respiratory system.

Bicarbonate concentration, on the other hand, is regulated in the kidneys by the tubules. These are the long, fine tubes of the kidney's functional units, the nephrons. In health the bicarbonate concentration is kept at about 22–24 milliequivalents per litre of plasma. When the plasma bicarbonate falls below 24 milliequivalents, the amount filtered out of the blood in the kidneys is entirely reabsorbed by the tubules until the concentration is raised

Hydrostatic and osmotic pressures

to this level; when the concentration rises above 24 mEq per litre, all the bicarbonate filtered out is excreted in the urine.

**Water.** The body of a normal man weighing 65 kilograms (about 145 pounds) contains approximately 40 litres (about 42 quarts) of water; of this about 28 litres are inside the cells of the body and 12 litres are outside. Of the 12 extracellular litres, about 2–3 litres are in the blood plasma—and the rest are around the tissues outside the blood vessels.

Water passes rapidly through almost all cell membranes and readily enters and leaves almost all the bodily spaces normally containing fluid. Its final distribution is determined by osmotic and hydrostatic pressures.

The volume of bodily water normally remains constant because the amounts ingested and eliminated are equal. Physiologically, thirst and satiety are influenced by a group of nerve cells in the hypothalamus, at the base of the brain.

At rest, and in temperate climates, there is an imperceptible loss of water from the surface of the body and in the air breathed out. This loss amounts to about 800 millilitres (about 0.85 quart) in 24 hours. It is increased when the surrounding temperature is elevated or when atmospheric humidity is low. Losses in this range become perceptible in other circumstances and form the cloud of moisture in one's breath on a winter day or the moisture that condenses on the inner side of a waterproof garment. Greater losses of water occur, of course, during vigorous exercise in the heat, and the losses from the bodily surfaces are then perceptible as sweat. The amount of water lost in the urine amounts to from one to two litres in 24 hours.

#### THE DEPLETION OF WATER AND SALTS IN THE BODY

**Sodium depletion.** In health the equality between the amount of sodium excreted and the amount ingested depends largely on normal kidney function. In temperate climates negligible amounts of sodium are lost in the stools and from the skin, and the power of the normal kidneys to conserve sodium in the face of reduced intake is virtually absolute. Salt depletion is usually the result of excessive loss of salt through faulty kidney function, rather than of inadequate intake.

Loss of sodium is usually accompanied by a reduction in body water. Pure sodium depletion unaccompanied by water loss, although uncommon, may arise when the response to abnormal losses of salt and water is unrestricted water intake, as, for example, when excessive sweating occurs in unfavourable environments and when the fluid loss is replenished by salt-free liquids. In these circumstances, the change in total body water may be negligible, in spite of considerable salt deficiency.

**Causes.** Failure of the kidney to conserve salt may occur because of kidney disease or because of inadequate hormonal control. Thus, a chronic infection of the urinary tract, acute ischemic renal failure (failure of the kidney to function normally because of inadequate blood supply), or insufficient adrenocortical hormones—hormones from the outer substance of the adrenal gland—may be responsible. Excessive loss of salt and water in the urine also occurs during the excessive secretion of urine that is induced by high levels of blood sugar in the disease diabetes mellitus. If the diabetes causes acidosis, which is a decreased alkalinity of the blood and tissue fluids, the process by which sodium is returned to the blood from the tubular filtrate in return for hydrogen ions is upset. Salt depletion may also be induced by the excessive or prolonged use of diuretics, substances that induce increased excretion of urine. Salt depletion also results from diarrhea, vomiting, and other situations involving external loss of salt-containing fluids.

**Consequences.** Because sodium is predominantly extracellular, salt depletion leads quickly to a fall in the volume of extracellular fluid. Water tends to be excreted to balance intracellular and extracellular osmotic pressures. This volume decrease is responsible for such effects as loss of elasticity of the skin, diminution of the pressure within the eyeballs, and dryness of the tongue.

Thirst may be prominent, but tends to be less severe when the sodium levels in the blood are low. The fall in blood volume causes fainting, low blood pressure, a reduced rate of glomerular filtration in the kidney, and a reduced volume of urine. (The glomeruli are clusters of minute blood vessels, capillaries, through the walls of which fluid is filtered from the blood into the nephrons, in the first stage of the production of urine.) The capacity of the body to rid itself of wastes decreases, and kidney failure develops. The pulse rate rises. Constriction of blood vessels diminishes the circulation through the skin so that the skin and the hands and feet become cold.

**Treatment.** Persons with mild cases of sodium depletion, whose blood pressure is normal, usually need merely to drink salted water to recover a normal sodium level. In more severe cases, or when there is vomiting, the physician injects isotonic salt solution into a vein. (An isotonic salt solution is of the same osmotic pressure as the plasma; it contains about 0.9 percent sodium chloride.) When there is severe sodium depletion there often are losses of other electrolytes, which must also be restored.

**Water depletion.** The reduced water intake that is most often responsible for water depletion may result either from difficulties in drinking, as when there are sores in the mouth and throat, or from circumstances that cut off access to fresh water—for example, shipwreck, or becoming lost in the desert.

Excessive loss of water in the urine because of disease that interferes with the kidney's ability to concentrate the urine is a less common cause of water depletion.

As water is lost from the blood, the plasma concentration of sodium rises. Water is drawn from the cells, and intracellular dehydration occurs. The body loss of water is thus shared both by the extracellular and the intracellular fluids. For this reason, the clinical features of dehydration are not as obvious as those of salt depletion. Thirst, the result of stimulation of a thirst centre in the hypothalamus, is usual unless the person is senile, confused, or unconscious. The migration of water from the intracellular fluid to the extracellular helps to maintain the volume of the latter for a time, so that the blood pressure remains unaltered until considerable water depletion has occurred. The affected person then often shows mental confusion or complains of dizziness and difficulty in swallowing. Ultimately, flow of blood to the kidneys is reduced, and blood levels of urea and other wastes become abnormally high. The water depletion is treated by giving liquids; these should be salt-free unless salt loss is also present.

**Potassium depletion.** Potassium depletion occurs in a wide variety of disorders. The healthy person eliminates about one-quarter of his daily intake of potassium in the stools and three-quarters in the urine. The bulk of urinary potassium is delivered into the channel of the nephron tubule by the cells lining the far end of the tubule (the distal tubule); these cells excrete potassium or sodium ions and, in exchange, take sodium ions from the liquid filtered out of the blood and into the tubule from the glomerulus.

**Causes.** Potassium depletion results from excessive loss of potassium from the intestinal tract or in the urine. Gastrointestinal losses are caused by severe acute or chronic diarrhea and by loss of intestinal fluid from vomiting, drainage through a gap in the intestinal wall (a fistula), or by aspiration—withdrawal of intestinal contents by suction in the course of medical treatment.

Loss of potassium in the urine is more subtle in its development. It occurs when the excretion of potassium ions in exchange for sodium ions is increased in the renal tubules. This increased excretion may result from administration of large amounts of sodium-containing fluids or from the use of diuretics, or it may occur as one feature of disorders such as Cushing's syndrome (a symptom complex resulting from overproduction of adrenocorticotrophic hormone by the pituitary) or aldosteronism (the overproduction of the hormone aldosterone by the adrenals).

Excessive loss of potassium also results from diseases or drugs that suppress tubular secretion of hydrogen ions;

Imperceptible loss of water

Sodium loss during diabetes

Two types of potassium loss

with fewer hydrogen ions to exchange for sodium, more potassium will be lost in the exchange process.

Conditions that interfere with the activity of the cells in the maintenance of their concentration of potassium and in excluding or eliminating sodium (the process called the sodium pump) also lead to potassium depletion and increased loss in the urine. These conditions include a deficiency of oxygen; impaired carbohydrate metabolism, as in starvation or diabetes; dehydration; and acidosis.

**Consequences and treatment.** Because most of the body's potassium is inside the cells, severe depletion of potassium may occur without alteration in the potassium level of the plasma, and identification of the disorder is made difficult by the inaccessibility of the intracellular fluid to analysis.

Symptoms of potassium depletion

A person whose potassium is depleted tends to be apathetic and physically weak; he is mentally confused, and his abdomen is distended. Potassium deficiency, sufficiently severe to cause a fall in plasma-potassium levels, is characterized by generalized muscular weakness with some degree of paralysis. Sensations of pins and needles in the skin are common. The electrocardiogram—tracings reflecting heart activity—shows characteristic changes. Severe potassium depletion may lead to death if uncorrected.

The condition is treated by administration of potassium salts orally or by injection into a vein. Oral administration is more commonly used and is less dangerous.

#### THE ABNORMAL ACCUMULATION OF WATER AND SALTS IN THE BODY

**Potassium intoxication.** A rise in plasma-potassium levels above normal usually occurs only when the kidney fails to function normally and there is a resultant reduction in the amount of urine excreted.

Persons with this disorder are dull, lethargic, and confused. The condition of weakness and paralysis of muscles is indistinguishable from that seen in persons with low blood levels of potassium. The pulse becomes irregular, and some degree of heart block develops. (In heart block, the upper and lower chambers of the heart tend to beat independently, which interferes with the heart's efficiency as a pump.) If the plasma-potassium level rises above eight milliequivalents per litre, there is danger that the heart will stop beating.

Measures taken to correct the high plasma levels of potassium include avoidance of fruits and fruit juices that are rich in potassium, avoidance of protein, and taking of substances such as sodium- or calcium-ion-exchange resins, which tend to absorb potassium from the blood and from the intestinal secretions.

**Magnesium deficiency and intoxication.** The adult body contains about 25 grams (0.9 ounce) of magnesium, 60 percent of which is in the bones. The most frequent cause of deficiency of magnesium is replacement of fluids lost during prolonged diarrhea or vomiting with fluids containing electrolytes, but without magnesium supplements. Depletion also may result from prolonged use of diuretics, chronic diarrhea, severe malnutrition, and alcoholism. In addition, excessive secretion of the hormone aldosterone or of parathyroid hormone may lead to magnesium deficiency. Magnesium chloride and magnesium hydroxide are given to correct the condition.

Magnesium intoxication occurs in kidney failure and causes symptoms related to the central nervous system. When the kidney recovers normal function, the abnormal levels of magnesium disappear without special treatment.

**Water intoxication.** When healthy persons drink large volumes of water, they can respond to this with corresponding increases in the amounts of urine excreted. The capacity of the body to excrete water depends upon many factors, which include the rate of glomerular filtration and the power of the distal tubules of the kidneys to produce a dilute urine; this condition in turn depends upon the presence of sodium in the distal renal tubules and the ability of the nephron to reabsorb the sodium without reabsorbing water. (Each distal tubule is that portion of the nephron tubule that is furthest from the portion of the nephron that encloses the glomerulus.)

Many persons who are ill have a restricted ability to dilute the urine when given large amounts of water, including persons suffering from acute and chronic kidney disease, severe heart failure, disease of the adrenal glands, and cirrhosis of the liver (a disease involving destruction of liver cells and formation of scar tissue). Occasionally, tumours of the ovaries or bronchus secrete a substance with antidiuretic properties that lead to water intoxication. After surgery some people may be incapable of diluting the urine because of the liberation of vasopressin by the stress of the operation. Vasopressin is a hormone released by the hypothalamus; its many functions include contraction of small blood vessels and suppression of urine excretion.

Effects of vasopressin

In all the circumstances mentioned, even a modest water intake reduces the level of sodium ions in the plasma and may produce disordered cerebral function, dizziness, headache, nausea, mental confusion, convulsions, coma, and death.

Treatment consists of restricting water intake. In severe cases salt solution is injected into a vein.

**Water and salt retention (edema).** Abnormal accumulation of water and salt in the body has fascinated physiologists and clinicians for several centuries, and before the discovery of modern diuretic drugs gross edema was a common complication of a variety of diseases, the victim being drowned, as it were, in the high tide of his own body fluids. Death from edema was well known to the ancients, who often made a series of superficial cuts in the limbs in an attempt to release the fluid from the distended tissues as a remedy of the last resort.

**Causes.** The fundamental cause of edema is a fault in the physiological mechanisms that control the volume of the extracellular fluids. Figure 1 illustrates how a healthy individual undergoes slight fluctuations in the water and salt content even when consuming a diet fixed in calories, nitrogen, water, and salt. These natural ripples on the

Figure 1: Cumulative sodium ( $\text{Na}^+$ ), potassium ( $\text{K}^+$ ), and water ( $\text{H}_2\text{O}$ ) balance in subject on a constant diet at rest.

surface of the body fluids, which ebb and flow over periods of several days, are due to the operation of a hunting, or servo-feedback, mechanism for the control of body fluid volume. Such a mechanism must involve (1) a detector that identifies lack of stability in the system, (2) an integrator that analyzes the information, and (3) an effector organ that adjusts the rate of excretion of water and salt according to need. Whatever its clinical cause, edema represents a vast tidal wave upon the extracellular sea and arises from a breakdown in the system responsible for volume control. Little is known about the first two components of the volume-control system, but the kidney is certainly the effector organ, and edema arises when the kidney fails to meet its biological commitment.

The common primary event responsible for all types of generalized edema is an inadequate blood volume induced either by loss of plasma proteins or by inadequate cardiac output. The first condition may arise because of excessive loss in the urine or from the gastrointestinal tract, failure of protein synthesis by the liver, or as a result of gastrointestinal malabsorption or of malnutrition; inadequate filling of the arterial circulation also occurs in heart failure.

Pressure-sensitive areas

A fall in the concentration of plasma proteins disturbs the balance of factors that influences the exchange of fluid between the vascular and extravascular compartments. As a result, fluid moves from the blood into the tissues, where it accumulates. The resulting fall in blood volume activates the volume-control system and stimulates the kidney to conserve water and salt in an attempt to repair the deficit; as a result, the accumulation of edema fluid is merely aggravated. The physiological link between low blood volume and reduced arterial-filling pressure, on the one hand, and renal water and salt retention by the kidney, on the other, is far from clear, but probably includes the operation of pressure-sensitive areas in the thyrocarotid and renal arteries, the atria (upper chambers) of the heart, the juxtaglomerular apparatus in the kidney, and the adrenal cortex (Figure 2). The thyrocarotid pressure-

(From R. Passmore and J.S. Robson (eds.), *Companion to Medical Studies*)

Figure 2: *Volume-control system.* Low blood volume leads to increased secretion of vasopressin (also called antidiuretic hormone, ADH), adrenocorticotrophic hormone (ACTH), and aldosterone, leading to conservation of salt and water and consequent increase in the volume of the blood.

sensitive area is also called the carotid sinus; it is located at the point where the common carotid arteries, the principal arteries to the head, divide to form the internal and external carotids. The renal arteries, the arteries to the kidneys, are branches of the abdominal portion of the aorta. The juxtaglomerular apparatus is made up of specialized cells in the middle coat of the arterioles (small arteries) that bring blood to the glomeruli. As a consequence, both the rate of secretion of aldosterone and vasopressin (ADH) is increased, and water and salt conservation is promoted. In addition, hemodynamic effects on the renal circulation and the influence of other hormonal agents (as yet inadequately defined), which may act principally on the reabsorption of sodium in the proximal convoluted tubule of the kidney, may contribute.

**Consequences.** The effects of generalized edema vary with its severity and with the part of the body predominantly affected. All tissues are involved to some extent, but swelling of the legs is almost universal and is partly the result of the hydrostatic effect of the upright posture. In the nephrotic syndrome, in which the urinary loss of protein is caused by glomerular disease, the edema is generalized; in heart failure it tends to accumulate either in the pulmonary circulation (pulmonary edema) or in the systemic circulation—i.e., in the legs and the abdominal cavity; in liver disease caused by local factors within the liver and disturbance in the portal circulation, the peritoneal cavity (the space that in disease develops between the membrane lining the abdomen and the membrane covering the abdominal organs) is the most com-

monly involved. Edema in this region is called ascites. Localized edema may arise in a limb or other single part from venous or lymphatic obstruction; even localized edema activates the volume-control system, since the edema fluid is derived from the body fluids as a whole. The detector mechanism is stimulated, and water and salt retention encouraged. When the water and salt content of the rest of the body then remains within normal limits, the swelling of the affected part continues.

**Treatment.** The treatment of edema is the correction of the underlying cause of the disturbance; this correction involves appropriate therapy for kidney, heart, and liver disease, and measures aimed at ameliorating absolute and conditional undernutrition. If, as is often the case, this is not possible, the kidneys may be induced to excrete water and salt by the administration of diuretics that specifically inhibit sodium transport somewhere in the nephron; a large number of these agents are available and are remarkably successful.

#### DISTURBANCES IN ACID-BASE BALANCE AND MINERAL METABOLISM

**Disturbances in acid-base balance.** Fluctuations in hydrogen-ion concentration arise in many circumstances in health and disease. Four primary types of disorder are recognized: metabolic acidosis and alkalosis, and respiratory acidosis and alkalosis. The first two of these involve increased or decreased alkalinity of the blood plasma because of some change in the metabolic process; the second two arise from disorders in the carbon dioxide exchange in the lungs.

**Metabolic acidosis.** Metabolic acidosis arises from three main causes: (1) there may be an increased formation of acids during the metabolic process, as occurs, for example, in diabetes or starvation, during exercise, or as a result of reduced levels of oxygen in the tissues (acetoacetic and lactic acids are especially important in these contexts); (2) there may be diminished excretion of hydrogen ions, as occurs in several situations, including kidney failure; (3) there may be increased loss of base such as bicarbonate ions, as occurs in diarrhea and as a result of fistulas (openings) in the walls of the intestines.

The increased concentration of hydrogen ions in the plasma interferes with the reversible process by which carbon dioxide combines with water to form carbonic acid, and by which carbonic acid in turn becomes ionized into hydrogen ions and bicarbonate ions. Because of the high hydrogen-ion concentration, the production of bicarbonate falls and carbonic-acid levels rise.

The increase in hydrogen ions also stimulates the respiratory centres in the brain to increase the rate and depth of breathing. Increased amounts of carbon dioxide are, thus, eliminated by the lungs, and the carbon dioxide pressure in the blood plasma falls below normal levels. This decrease reduces the formation of carbonic acid and lessens the tendency of the blood to become less alkaline.

Recovery of the normal alkalinity depends on the regeneration of bicarbonate by the cells of the kidney tubules during the process of hydrogen-ion excretion in exchange for sodium ions. In severe cases, this process is assisted by administration of sodium bicarbonate.

**Respiratory acidosis.** If the ability of the lungs to expel carbon dioxide is impaired—for example, by depression of the respiratory centre, as occurs in barbiturate or morphine poisoning, or because of paralysis of respiratory muscles, as in poliomyelitis—carbon dioxide is retained in the body and the plasma-carbon dioxide pressure rises above its normal value of 40 millimetres of mercury. As a result, levels of carbonic acid and of hydrogen ions rise in the tissues and blood. This situation is mitigated by the acceptance of hydrogen ions by substances such as proteins, with the resultant generation of bicarbonate ions. The kidneys also respond to the elevated carbon dioxide pressure by reabsorbing bicarbonate ions and forming new bicarbonate ions.

Respiratory acidosis is dealt with by treatment of the underlying disease. Occasionally assisted or artificial respiration is needed.

Causes of respiratory acidosis

**Metabolic alkalosis.** During digestion of a large meal the secretion of hydrochloric acid (HCl) by the stomach involves the withdrawal of hydrogen ions from the blood. If vomiting occurs, the hydrogen ions are lost from the body along with chloride ions, and the blood-hydrogen-ion concentration falls, increasing the alkalinity of the blood plasma. At the same time, the plasma levels of bicarbonate ions rise.

The fall in hydrogen-ion concentration reduces the stimulus to respiration. Carbon dioxide elimination by the lungs is reduced, and the pressure of carbon dioxide in the plasma rises, causing increased formation of carbonic acid and reducing the excess alkalinity.

Chronic metabolic alkalosis, induced by the taking of large amounts of sodium bicarbonate over long periods, especially when there is a high intake of calcium in the diet, may lead to deposition of calcium in the kidneys.

Severe potassium depletion also causes metabolic alkalosis, and depletion of chloride ions sometimes contributes to the condition. In the maintenance of sodium balance, sodium cations filtered into the nephron tubules from the glomeruli are reabsorbed in conjunction with chloride anions and also by the exchange process involving hydrogen or potassium cations. When the body is deficient in chloride, as may occur as a result of prolonged vomiting, the conservation of sodium by the nephron tubules is achieved by employment of hydrogen and potassium exchange for sodium ions to a greater extent than normal. This conservation leads to excessive loss of hydrogen and potassium ions and, thus, to metabolic alkalosis.

The electrolyte disorders may be corrected by intravenous administration of an isotonic solution containing sodium, ammonium, and potassium chloride.

**Respiratory alkalosis.** When one climbs a mountain of about 12,000 feet (about 3,650 metres), oxygen lack becomes a significant stimulus to respiration, and carbon dioxide is eliminated in larger amounts than occurs at sea level. As the carbon dioxide pressure falls, the plasma-hydrogen-ion concentration is reduced; but the extent of the reduction is lessened by the release of hydrogen ions by nonbicarbonate buffers such as proteins and by a compensatory kidney excretion of bicarbonate ions. A similar response occurs in hysterical overbreathing, in salicylate poisoning, after head injury, and in severe liver failure.

When respiratory alkalosis is the result of hysterical overbreathing, breathing into and out of a paper bag is often helpful.

**Disturbance in calcium metabolism.** Calcium is an essential component of bone, being present in the hydroxyapatite crystals of the intercellular substance (hydroxyapatite is a calcium phosphate). The adult human skeleton contains about 1.2 kilograms (about 2.6 pounds) of calcium. Because the skeleton takes about 20 years to be formed, the growing child must retain from his diet an average of 160 milligrams of calcium a day. There is a continuing turnover of skeletal calcium, about 500 milligrams being reabsorbed from the bone and replaced daily. The surfaces of the hydroxyapatite crystals have a layer of ions and water, and it is around this layer that exchange of calcium and other ions takes place.

Among the many factors that affect calcium-plasma levels are the two hormones thyrocalcitonin and parathyroid hormone, vitamin D levels, and the hydrogen-ion concentration of the plasma.

High levels of parathyroid hormone tend to raise plasma levels of calcium, and vitamin D causes absorption of calcium from the intestine. Thyrocalcitonin depresses the plasma-calcium levels.

Disorders of calcium metabolism are most commonly the result of endocrine abnormalities or of nutritional deficiency. Thus oversecretion and undersecretion of parathyroid hormone cause elevated and depressed levels of calcium in the plasma, respectively. Increased secretion of thyrocalcitonin is extremely rare, but may result from a tumour of the thyroid cells that secrete the hormone.

In kidney failure, high levels of urea in the blood appear to increase resistance to the action of parathyroid

hormone and of vitamin D; this increased resistance causes a depressed level of calcium in the plasma, which, in turn, leads to secondary enlargement of the parathyroid glands.

Low levels of plasma calcium are also found in rickets and osteomalacia. These two related diseases, occurring in children and adults, respectively, involve inadequate deposition of calcium and phosphorus in the bones; a principal cause is insufficient intake of vitamin D. In another disease, osteoporosis, characterized by light, brittle bones, the plasma levels of calcium are normal or only slightly reduced, and no benefit is derived from taking increased amounts of vitamin D.

**Disturbances in phosphorus metabolism.** The human body contains about 700 grams (about one and one-half pounds) of phosphorus; of this about 80 percent is in the bones. Phosphorus deficiency is known to occur in cattle that graze on poor land and has been held responsible for stunting of growth and weakness. The existence of a primary phosphate deficiency in man is not yet established. It may occur in persons who take large doses of nonabsorbable antacids such as aluminum and magnesium hydroxide, which interfere with the intestinal absorption of phosphate.

## Fluidics

Fluidics is the technology of using the flow characteristics of liquid or gas to operate a control system. The name is a combination of two words, fluid and logic. The newest of the control technologies, fluidics has in recent years come to compete with mechanical and electrical systems. (For a description of control systems in general, see CONTROL SYSTEMS.)

Although fluidic principles are fairly old, it was not until about 1960 that researchers attempted to use fluidics commercially. The demand for reliable controls in space research stimulated progress. In the 1930s Henri Coanda, a Romanian scientist, described what is now known as the Coanda effect, a major contribution to fluidic technology. He observed that as a free jet emerges from a jet nozzle the steam will tend to follow a nearby curved or inclined surface. It also "attaches" itself to and flows along this surface if the curvature or angle of inclination is not too sharp. Coanda explained this tendency as being caused by the jet stream's entraining (picking up) nearby fluid molecules. When the supply of these molecules is limited by an adjacent surface, a partial vacuum develops between the jet and the surface. If the pressure on the

calcium  
disorders

Figure 1: (A) OR circuit, (B) AND circuit, and (C) proportional circuit (see text).

other side of the jet remains constant, the partial vacuum, which is a lower pressure region, will force the jet to bend and attach itself to the wall.

Because fluidics is not as rapid as electronics, it is unlikely to compete in fields with ultrahigh-speed requirements. On the other hand, in many applications, fluidics is advantageous. It is now possible to detect, interlock, and power complex operations by using air throughout a system. Controls can be installed by a competent fitter who might not be capable of dealing with electronic or electrical systems. The elimination of electrical contacts eliminates a possible fire hazard.

Pneumatic circuits require controls with simple interlocking, performed by air-piloted and mechanically operated control valves. Because it employs the same medium, fluidics is useful for sensitive detection and complex control as part of a pneumatic system.

Combining hydraulics and fluidics is more complicated, however, because the same medium is not used. Yet since both systems require plumbing expertise, labour problems can be reduced. Power-output devices handling hydraulic pressures that respond to fluidic signals are available commercially.

The basically simple and robust character of fluidics, its resistance to contamination and damage, and its high degree of reliability give it an important place in the rapidly expanding field of control.

Fluidic devices operate on either the digital principle (they are either "on" or "off") or the analogue principle (the output of the device is continuously proportional to the input). Figure 1 illustrates the distinction.

In Figure 1A input *a* or *b* can produce an output signal, because each has a path through which the signal can flow to the output. This system is called logical (and digital) because no output is possible without an input. Either condition will satisfy the required output (the OR function, as an output is produced whenever one OR the other input is energized).

In Figure 1B both inputs are required for an output because the flow from *a* or *b* alone, without a counterbalancing force, will go out one of the vents. If both are applied, they will collide, producing flow out of the centre port marked *a* and *b*. This again is logical (and digital) because no output is possible unless both signals are applied. All conditions must be satisfied before an output is obtained (the AND function) as an output signal will be produced only if an input is applied to both inputs *a* and *b* simultaneously.

In Figure 1C fluid flowing from the supply will go out of the vent unless input *a* is applied. This is an analogue effect because the output can be altered proportionally

from minimum to maximum by varying the power of input *a*.

Fluidic devices can thus produce both logic (digital) and analogue (proportional) effects or functions. The OR and the AND are the most common logic functions.

In most fluidic devices, low-value input pressures or flows can control higher output pressures or flows. This is what is meant by the term fluid amplifier. A supply of fluid entering a device becomes a stream forced to follow a chosen path through carefully designed internal shapes before giving an output. Input jets of far lower power are positioned to give the greatest possible effect on the stream, thereby controlling the output. Fluid amplifiers respond to very small fluid signals provided by such devices as temperature or velocity detectors, generally by input sensors attached to existing mechanical movements. The number of devices controlled by one similar device is called the fan-out ratio. For example, if the output of one device is so strong that it can switch four others at the same time, the fan-out ratio is four. The following terms are important to an understanding of fluidics.

**Logic function or "gate."** This is an element or combination of elements that can satisfy a logic function. That is, if the correct inputs are applied, the correct output is obtained, as shown by the illustrative OR and AND devices (Figure 1A, B). A gate is a circuit that has one output and several inputs. The output is not energized until certain predetermined conditions are met.

**An element.** This is an indivisible part of a logic function or circuit, like a component.

**Active element.** An element requiring a constant supply of power to remain operative is called an active element. Figure 1C illustrates such a device.

**Passive element.** An element not requiring a constant supply of power and operated solely by input signals is a passive element. Figure 1A, B illustrate passive devices.

**Pure fluid amplifier.** This is an amplifier in which fluid flows give required outputs solely by changing the characteristics or direction of flow.

**Moving-part amplifier.** This is an amplifier that changes the direction of flow or even shuts off the flow entirely by means of moving parts such as spool valves or balls inside the device. Control inputs move the mechanical parts into the position that produces the desired output.

**Digital amplifier.** For all practical purposes, this amplifier works on the all or nothing principle. The output and input signals are either on or off (see Figure 1A, B).

**Analogue amplifier.** An analogue amplifier produces variable output values corresponding to progressively increasing or decreasing input signals as shown by the device in Figure 1C.

**Wall attachment.** Fluid flow attaches to a surface and continues to flow over it unless an opposing or interrupting fluid signal is applied.

**Momentum exchange.** Fluid flows interact with each other and change direction in accordance with the relative forces used.

**Laminar turbulence.** A smooth (laminar) fluid jet flows across a gap to give an output, unless prevented from doing so by a signal that makes it turbulent.

**Vortex effect.** Fluid is made to move in a circular path by a signal or shape. The constant change in direction reduces velocity to give control over flow.

#### PRINCIPLES OF COMMERCIAL DEVICES

Since most fluidic devices use air as their operating medium, air is assumed to be the fluid in all of the devices described.

**Wall attachment.** When fluid flow touches a surface, friction slows it down. The fluid nearest the surface is overtaken by the remainder and space is created at the surface (Figure 2A). This attracts faster fluid flowing above which "bends down" to fill the space. A low-pressure vortex bubble is formed, maintaining attraction.

The flow can be attracted to preferred surfaces. The fluid jet (Figure 2B) causes surrounding fluid (air) to move with it, drawing air into the device (entrainment)

Fluid  
amplifiers

Comparison with  
other  
control  
methods

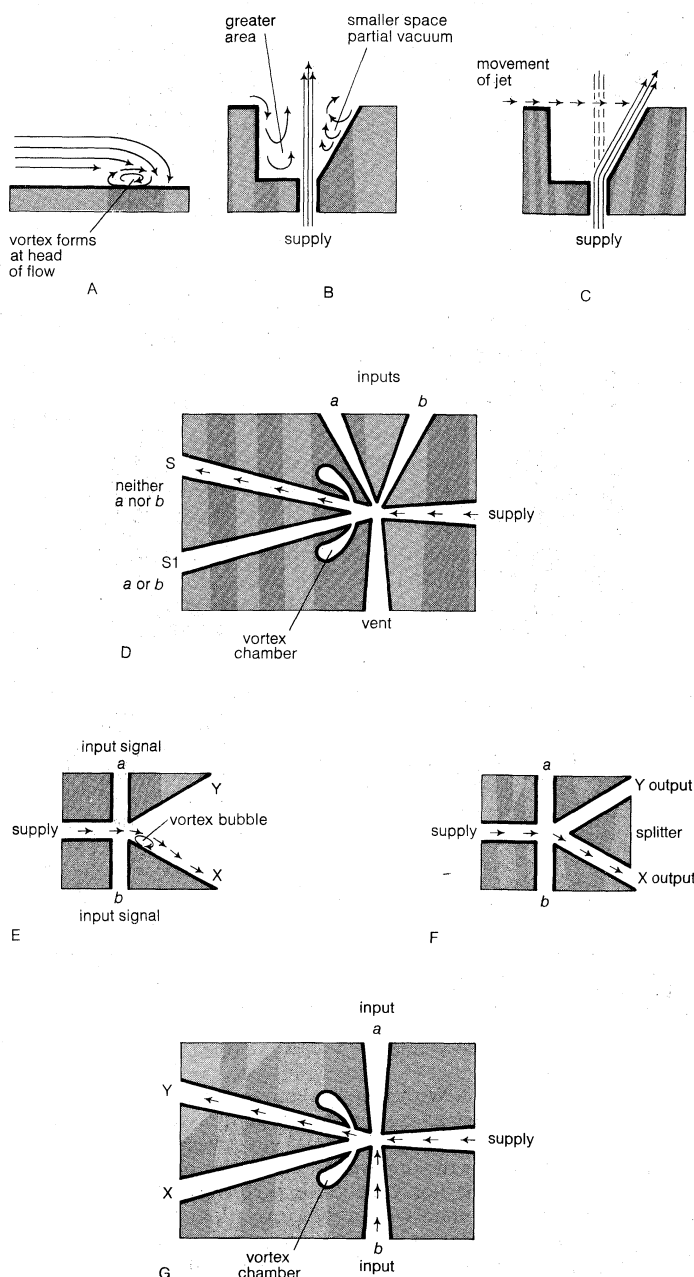

Figure 2: Operating principles of several types of commercial fluidic devices (see text).

By courtesy of I-T-E Imperial Corporation

to replace that "pulled out" by the jet (shown by arrows). Because there is less space for replacement air to enter, a greater shortage of air exists at the wall nearest the jet, which moves toward this wall to make up the loss. The closer it gets to the wall, the less air can enter and the greater the attraction will be. Finally, the jet will stay against the wall because of the low-pressure region previously explained (Figure 2C). All of this will have happened very quickly, with a total switch-over time of about one millisecond.

In one device (Figure 2D), the supply is attracted to the upper wall and flows out of port S. An input at *a* or *b* will detach the flow from the upper to the lower wall, giving output S1. This device is said to be monostable because a constant input at *a* or *b* is required to obtain output S1. It is called an OR/NOR because either input *a* or *b* gives output S1, and neither *a* nor *b* can be present if output S is required.

In Figure 2E fluid is attracted to either wall equally spaced around a jet. The supply will flow to either X or Y depending entirely on chance. This device has two

Mono-stable devices

stable states (bistable), with the fluid maintaining flow over one wall or the other until switched. A brief pulse at *a* will give a maintained output at X, and a brief pulse at *b* will give a maintained output at Y. In Figure 2F, the wedge shape, called a splitter, separates the two flow paths so that X or Y can provide pressure outputs. In Figure 2G, a commercial flip-flop outline is shown. The flow indicated by arrows in the upper channel is the stable condition obtained by input *b*.

The above devices are digital: there is present either a full signal or no signal at all. They are active devices requiring a constant power supply. Vents ensure stable operation when the outputs are fully loaded.

Commercial wall-attachment devices are made of injection-molded plastic; connections are made by mounting them flat on manifolds that contain suitable ports for supplies, etc. Most wall-attachment devices require supply pressures of approximately two to 15 pounds per square inch (psi).

**Momentum exchange.** If two passages are in line and sufficient power is applied, fluid will flow from one to the other across a gap, producing an output at the other side.

In Figure 3A the supply will normally flow across the gap to output S, but, as shown in Figure 3B, with an input signal at *a*, the jet stream will deflect and go out

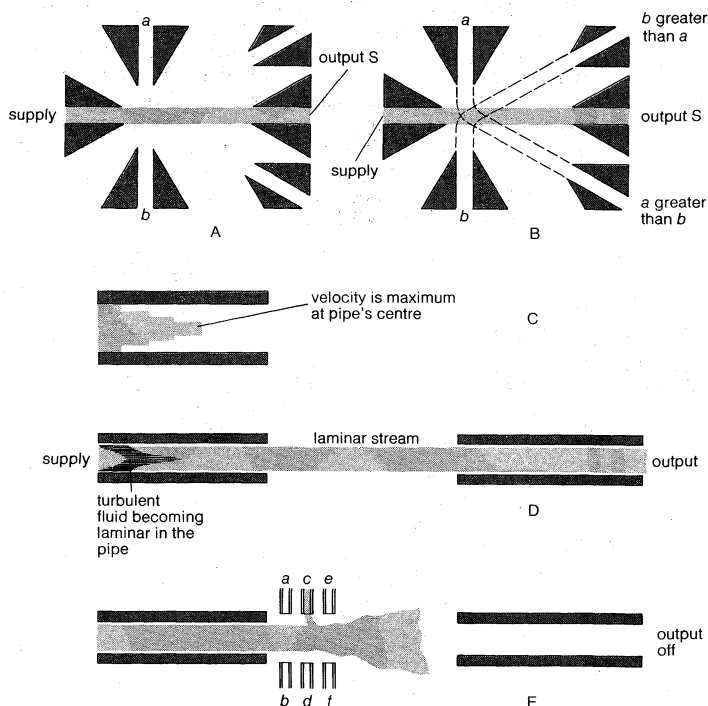

Figure 3: Momentum-exchange and laminar-turbulence effects. A momentum-exchange device is shown (A) with no input and (B) with inputs at *a* and *b*. Application of laminar flow and turbulence to an amplifier is indicated in C, D, and E (see text).

from the lower output. An input at *b* can deflect the jet stream out from the upper output. With both inputs applied it is possible to get an output from the upper port if *b* is greater than *a*. The opposite also applies. This device is proportional: its output values vary according to the value of the inputs. It is also active: a constant power supply is required.

Many proportional devices have only two outputs. With no signals applied, the supply divides about a splitter to provide equal flow from both outputs. Maximum to minimum flow can be obtained from either output depending on the value of inputs applied. Supply pressures vary but are normally between one to 15 pounds per square inch.

**Laminar and turbulent flow.** In the turbulence amplifier, flow can be prevented from reaching an output by a change in condition. If air at certain pressures is applied

Proportional devices

to channels or tubes of correct size, natural turbulence is reduced to such an extent that air will emerge from the output in a smooth (laminar) condition (Figure 3C). The air is flowing in layers, with the centre at a higher velocity than the outside, due to friction of the passageway. Thus, there is little loss across a gap. Figure 3D shows the stream crossing a gap to provide an output.

With an input applied, Figure 3E, the laminar stream immediately becomes turbulent. It cannot cross the gap with sufficient power to provide an output (input *c* is used in the diagram). Several inputs can be positioned around the laminar stream, each being equally effective in preventing an output. Typical switching times are one to two milliseconds. The turbulence amplifier provides the NOR function because any one input will stop an output and all inputs must be removed before an output is obtained. It is digital, providing full or no output. It is active because a constant supply is necessary, and monostable because maintained input signals are required.

**Vortex.** In Figure 4A a supply applied to a cylindrical chamber forces fluid to move in a circular path to reach the output. This reduces its velocity and output flow. Figure 4B shows that if fluid is applied in the opposite direction, a full flow is obtained because a circular path is no longer followed.

In Figure 4B the supply can flow straight out of the device with little or no hindrance. If an input (control flow) is applied (Figure 4C), however, the swirling action decreases output flow. The higher the value of the input signal, the lower the output obtained. Vortex devices have negative gain characteristics, that is, they require a control input at a higher pressure than the supply pressure. Jet-deflection devices, however, require a control input significantly lower in pressure than the supply.

Both devices described are proportional, but Figure 4A is passive and Figure 4B is active.

Negative gain characteristics

Figure 4: Principles of vortex action (see text).

A typical commercial device based on the principles of Figure 4C can handle flows up to 56 cubic feet per minute at 50 psi, depending on the size used. The controlling pressure has to be about  $1\frac{1}{2}$  to 3 times as large as the supply pressure for maximum effect. This varies with the model and medium used. The output is a large central port, the supply being another large port. The control flow is applied to the smaller ports that are arranged to oppose each other if differential values are required.

**Moving-part devices.** In recent years many moving-part types have appeared. Some common principles are illustrated.

In Figure 5A a supply (30–90 psi) enters from the right-hand side and provides output S by forcing the moving seal against its seat. An input applied at *a* acts upon the diaphragm that moves to the right, forcing the seal to shut off the supply, Figure 5B. Output S is then ex-

Figure 5: Moving-part devices (see text).

(A, B) Moving seal type with seal (A) closed and (B) open. (C) Spool valve in two different positions. (D) Coil spring type in (left) closed position and (right) open position.

From M.J. Moylan, *Fluid Logic in Simple Terms*, The Machinery Publishing Company Ltd.

hausted through the vent. With input *a* removed, the seal is forced back to its original position by supply pressure. Inputs can be applied at *a* or *b* with equal effect because the ball is forced against the opposite input port to block it and prevent leaks. The NOR function is performed because either of the two inputs will stop the output, and an output is obtained only if both inputs are removed.

Another popular valve is the spool valve, which uses a moving member (spool) with suitable seals to divert flow. In Figure 5C, the supply (30–150 psi) provides output S2. If an input were applied at *b*, the spool would move downward and supply would be directed to output S1. Output S2 would be vented. Because the inputs that position the spool need only be pulses, this device can be bistable. If input *a* were a maintained pressure or a spring, however, an input at *b* of a greater value could act against this force to provide a monostable effect.

Figure 5D shows an element using a close-coiled spring as its moving part. With no input applied, an output is obtained. When an input operates the diaphragm, it bends the spring and pressure leaks from the coils. Since air escapes from the coils faster than it can be replaced by the restrictor, no output is possible. The NOR function is performed and the device can handle pressures up to 15 psi.

In all of these digital devices, spool valves have an advantage, because bistable operating positions are maintained even if the supply is removed and reapplied. This is not usually the case with other devices.

#### FLUIDICS IN INDUSTRY

Fluidics has been applied to industrial problems on a wide scale, with no particular industry emerging as an ob-

Back-pressure  
and inter-  
ruptible-  
jet  
sensing

vious choice. Fluidics can operate in hazardous environments and sense objects by methods not available previously.

**Input and output devices.** Fluidic input devices generally employ two principles—back-pressure sensing and interruptible-jet sensing.

When the back-pressure sensor vent (Figure 6A) is not blocked, there is no output because the air supply escapes from the vent faster than it can be replaced through the restrictor. With the vent in close proximity to an object, air cannot leak away fast enough and an output is obtained.

Figure 6: Two types of sensing devices: (A) back-pressure and (B) interruptible-jet (see text).

Simple devices like this have to be very close to an object (about 0.005 inch) before an output is obtained. Latest developments include proximity sensors that provide signals from distances of approximately 0.25 inches.

A typical interruptible jet is shown in Figure 6B. The supply provides two opposing jets. This impact prevents all the restricted supply from being vented and an output is obtained. When the jets are interrupted by an object, the restricted supply can flow from the right-hand jet without opposition, and (as in the back pressure sensor) the output ceases. This device is also non-clogging (continuous air bleed).

Power outputs are provided in various forms to suit fluidic elements. A step-up relay is provided for low pressure elements that will directly control 100 psi power supplies from signals as low as  $\frac{1}{10}$  psi.

Elements that operate at higher pressures can generally use conventional diaphragm or cylinder-operated valves. These respond to signals of about 5 psi and can control 150 psi power supplies.

**Typical applications.** Applications of fluidics are numerous, but on a relatively small scale. Some such applications include a weighing system that selects ten different weights of raw material before machining; air-jet detection of delicate material (the roof lining of an automobile) that would be damaged by mechanical methods; and sonic detectors operating in the highly inflammable, contaminated area of a paint-spray booth. These detectors sense sound waves without disturbing the freshly painted surface.

Modular construction of fluidic circuits is evident as the technology advances. Among the latest advances in fluidics is modular construction of circuits, that is, construction of combinations of components that can be readily fitted together to form whole systems.

A motor governor system converts pulsating frequencies of air motor exhausts into pressure levels, which are then compared to preset values. The difference in pressure is amplified to provide speed regulation of the motor. Converting the frequency of ON/OFF pulses into progressively increasing or decreasing values is called digital proportional. Fluidic devices are stacked in layers to provide a common supply and interconnections.

#### NEWER DEVELOPMENTS

Advances in the technology are continuous. A new development is the edge tone amplifier, which works very much like a musical instrument; air blown at a sharp wedge oscillates at very high frequencies (about 5,000 cycles per second) to produce an output that is virtually continuous. Frequency of oscillation (sound) is controlled mechanically or by varying the force of the air directed at the wedge. Since the flow responds rapidly to

signals, the amplifier shows considerable promise in high-speed switching for the future.

Sound detection is possible with laminar streams that can be made sensitive to certain sound frequencies (as in the paint booth example cited). A beam of sound can span distances for detection without even the slight force exerted by an air jet.

## Fluvial Processes

Over much of the world the reduction of mountains, the building of plains, and the sculpture of the landscape is brought about by the flow of water. As the rain falls and collects in watercourses, the process of erosion not only degrades the land but the products of erosion become themselves the tools with which the rivers carve the valleys in which they flow. The process varies over time and from place to place. Materials eroded from one location are transported and deposited in another, only to be eroded and redeposited time and again before reaching the ocean. At successive locations the riverine plain and the river channel itself are products of the interaction of the mechanics of transport by the flow and the characteristics of the sediments brought down from the drainage basin above.

The fluid in a river is not pure water. Not always visible, the load of the river may be carried in solution, in suspension, or dragged along the bed. Solutes and particulate matter are both organic and inorganic. Neither the discharge of the water nor the related rates of erosion and deposition are constant in time or in space. Steep, narrow, rock-walled canyons may be excavated by corrosion of flowing water armed with abrasive particles aided by corrosion through chemical action. Elsewhere, sediments may be deposited to form broad alluvial fans (q.v.), floodplains, or river deltas (q.v.) in lakes along the river course.

Man manipulates the river environment to suit his needs and desires. Dams create lakes for the storage of water and the production of hydroelectric power, thereby regulating the flow of rivers; the natural river channel may be deepened or walled in to provide for navigation; water may be diverted for cities, industries, and agriculture; harbours may be constructed both at the edge of the continent or along the rivers themselves to facilitate commerce. To the extent that these activities modify an existing system involving the motion of the water of the river and the sediments it carries, such modifications may markedly alter the system. A reservoir constructed on a river that is transporting sediment will become the locus of deposition of a delta where the river joins the newly created lake. Below the dam creating the impoundment the river can be expected to erode the channel and transport newly acquired sediment to replace that left behind in the delta. Changes in the physical environment will in turn induce changes in the biota. In the absence of floods, for example, trees may grow up in the channel. Both upstream and downstream effects of the reservoir may extend for many miles above and below the reservoir itself. If a navigation channel is to operate properly, it must be so designed that the movement of sediment, its deposi-

Man's manipulation  
of the river environment

tion, and redeposition will not interfere with navigation by creating shoals within the channel. Harbours constructed in estuaries (*q.v.*) at the margin of the continents must contend with the results of deposition of sediments brought down from the land to the sea by rivers that flow into the estuary. In every instance, while the pattern of "nature" may be altered, the river processes will continue to operate either to the benefit or to the detriment of the intended purpose.

Both the form of a river channel and the deposits associated with it at any given place and time represent the interaction of basic processes of fluid flow and sediment transport. While myriad combinations of hydrology and geology occur in nature, a few basic principles underlie the complex interactions that constitute the behaviour of rivers. These provide a basis for understanding river channels themselves, a means of analyzing the ways in which the alterations of the river environment will ramify, and in turn, a guide for planning and design of man-made works. See also RIVERS AND RIVER SYSTEMS for additional information on channel form and hydraulic geometry and for a discussion of fluvial landforms.

#### FLOW OF WATER IN A NATURAL CHANNEL

The flow of water in a natural channel may be described in terms of the geometry of the channel and the dynamics of the flow itself. The rate of flow can be written in the form  $Q = AV$ , where  $Q$  is the volume rate of flow per unit time,  $A$  is the area of the cross section, and  $V$  the mean velocity. For a roughly rectangular natural channel, the area  $A$  may be expressed as the product of the width,  $w$ , and the depth,  $d$ .

A difference in elevation at successive points along a river channel provides the source of energy for the flow. If both the velocity and depth of flow remain constant, then the energy provided by the difference in elevation is equal to the heat produced by viscous resistance, a term often referred to as the energy loss due to friction. The energy transformation between successive sections is expressed by an equation of the following form. When  $h_f$ , the loss term, is omitted, the equation is referred to as Bernoulli's equation:

$$d_1 + \frac{V_1^2}{2g} + Z_1 = d_2 + \frac{V_2^2}{2g} + Z_2 + h_f$$

where  $g$  is the acceleration due to gravity,  $h_f$  is the loss in energy, and  $d$ ,  $V$ , and  $Z$  are as shown in Figure 1. Both the depth  $d$  and the elevation  $Z$  represent measures of potential energy, whereas  $\frac{V^2}{2g}$  represents the kinetic energy of the flow.

Figure 1: Steady flow in an open channel showing the relationship between elevation, velocity, depth, and energy loss as well as the relationship between the water surface and the energy slope (see text).

Because neither the cross section nor the bottom elevations of a natural channel are uniform, the velocity and depth vary from section to section. For any flow in a given length of channel there is only one depth at which the mean velocity will remain constant throughout

the reach and the slope of the bottom will be the same as the energy slope (the sum of the energy terms is shown in Figure 1). If the slope of the bed increases, velocity will increase at the expense of depth and vice versa. Similarly, if the cross section contracts, velocity will increase at the expense of depth.

These variations in depth and velocity characterize an interaction or exchange of kinetic and potential energy. In a rectangular channel, if the depth is made smaller and smaller, a value is reached at which the sum (referred to as the specific energy)  $d + \frac{V^2}{2g}$  becomes a minimum. This depth, known as the critical depth, is equal to twice the kinetic energy term  $\frac{V^2}{2g}$ , or  $d_c$ , equals  $\frac{V^2}{g}$ . Expressed in terms of velocity,  $V_c = \sqrt{gd_c}$ , where  $V_c$  is the critical velocity.

In nature one may see critical flow conditions in the passage of a stream over rock ledges or over the riffles or rapids in a trout brook where the flow is swift and shallow.

An important measure of the dynamics of the flow in an open channel can be derived by considering further the expression for the critical velocity. The ratio  $V/\sqrt{gd}$ , called a Froude number after its discoverer, William Froude, the English engineer, is a dimensionless number and in fact represents the ratio of an inertial force to a gravitational force. In addition, the expression  $\sqrt{gd}$  is equal to the celerity of a shallow-water gravity wave of small amplitude in water of depth  $d$ . Thus, when the Froude number,  $V/\sqrt{gd}$ , equals 1, the velocity of flow equals the wave velocity (celerity) and waves formed on the surface appear as "standing" waves. A Froude number of 1 then represents a transition. Below this value, that is when the depth is greater than the critical depth, the flow is termed tranquil. Above it (high velocity and shallow depth) the flow is called shooting. These conditions are important in describing the dynamics of flow as well as the relationship of the flow to the movement of sediment.

A second parameter characterizing the dynamics of the flow is the Reynolds number, after Osbourne Reynolds, the English hydrodynamicist, which is the ratio of inertial to viscous forces. The Reynolds number for open channel flow is  $\frac{Vd}{\nu}$  where  $\nu$  is the kinematic viscosity  $\frac{\mu}{\rho}$

in which  $\mu$  is the dynamic viscosity and  $\rho$  the density of the fluid. At a constant kinematic viscosity as velocity and depth increase, the Reynolds number increases. Or, as velocity and depth increase, the significance of the viscous forces relative to the inertial forces declines.

The parameters that describe the dynamics of the flow in a river channel can be summarized in a simple diagram defined by the two dimensionless numbers. Figure 2 shows four possible regions of flow defined by the relative importance or relative effectiveness of the several forces, as well as some typical examples of flow in each region. These regions simply represent high or low values of the Reynolds and Froude numbers in different combinations. Comparable to the transition at a Froude number of 1, a Reynolds number of about 500 represents a transition from laminar to turbulent flow in an open channel. Because the behaviour of the river channel—including both the flow and the transport of materials—is governed by these conditions, such dynamic parameters are fundamental to the description of river processes.

If the flow in a given section of a natural channel does not accelerate in the downstream direction, then the component of the force of gravity tending to move the water down the channel must be precisely balanced by the resisting forces or "drag" forces along the boundaries of the channel. The component of the weight (gravitational force) tending to move the water down the slope is given by  $\gamma ALS$ , where  $\gamma$  is the weight of a unit quantity of water (the weight equals the product of mass density  $\rho$  and  $g$ , or  $\rho g$ ),  $A$  is the area of the cross section,  $L$  is the length of the channel, and  $S$  the gradient. When

Froude and Reynolds numbers

Flow resistance and bed roughness

Basic principles of flow

Figure 2: Regions of flow defined in terms of the Reynolds number and the Froude number. For Reynolds numbers above 500, flow is turbulent; below 500, it is laminar. Above a Froude number of 1, flow is shooting; below it is tranquil. Examples are of common conditions of flow found in the real world.

the slope is very small, the tangent  $S$  can be substituted for the sine of the angle of slope (Figure 3). If the average shear stress or drag on the boundary is given by  $\tau_0$ , the total drag or resisting force over a unit distance is  $pL\tau_0$ , where  $p$  is the wetted perimeter of the channel. Equating the two forces and solving for the drag gives  $\tau_0 = \gamma \frac{A}{p} S$ . Because many rivers are wide and shallow, the width very nearly equals the wetted perimeter and  $A/p$  nearly equals the depth,  $d$ ; thus,  $\tau_0 = \gamma dS$ . When the flow is turbulent, it has been shown experimentally that the drag is nearly proportional to the square of the velocity, or  $\tau_0 = V^2$ . By equating these two relationships for the shear stress and rearranging the terms, one obtains the expression  $V^2 = \frac{1}{ff} \frac{\tau_0}{\rho}$  in which the coefficient  $ff$  is referred to as a coefficient of resistance. Because  $\tau_0 = \gamma ds$ , the equation states that velocity is directly proportional to the depth and slope and inversely proportional to the resistance coefficient.

Physically the coefficient  $ff$  expresses a measure of the "roughness" of the channel. It reflects those features of the channel including the boundary itself that tend to retard or to increase the resistance to flow. Considering for example an open channel with a bed comprised of uniform, well-packed gravel, one might assume that a significant characteristic influencing the resistance to flow

Figure 3: Resistance to flow in an open channel,  $\gamma ALS$ , in which  $\gamma$  is the weight of a unit quantity of water,  $A$  is the cross-sectional area,  $L$  is the channel length, and  $S$  is the slope. For small angles of slope, sine  $\alpha$  approximately equals tangent  $\alpha$ , which equals  $S$ .

might be the size, distribution, and packing of the particles of gravel themselves. This is indeed true. Where the flow is turbulent, the smaller the particles on the bed for a given depth of flow, the higher the velocity. This is shown on the right hand side of the schematic diagram in Figure 4 for the region of fully developed turbulent flow. At low Reynolds numbers in the laminar flow range, where viscous effects predominate, resistance is a function of viscosity and the conditions of flow. A transition exists in the range of Reynolds numbers between laminar and fully turbulent flow. The Reynolds number for the flow of most natural rivers falls within the turbulent range (Figure 2) where, for a given size of particle on the bed, as the depth becomes greater, the relative effect of the particle is lessened and, hence, velocity increases and resistance decreases.

In a natural river many additional factors contribute to the resistance or retardance of flow. Few rivers have uniform particles on the bed, nor are they perfectly straight and without obstructions. Thus such factors as the range of particle sizes from fine silts and clays to cobbles and boulders, their spatial distribution in the channel, the configuration of the bed, irregularities and curvature of the boundary, as well as the effects of vegetation and other obstructions all tend to influence the velocity and depth of flow that will occur in the channel for a given gradient and quantity of flow. The greater the number of boulders, vegetation, and bends, the greater the depth will be at the expense of velocity.

Figure 4: Resistance coefficient as a function of Reynolds number. Three regions of flow are shown: laminar, a transition range, and fully developed turbulent flow. In fully developed turbulent flow, as the horizon lines indicate, the resistance coefficient is a function of the ratio of the depth of flow to the size of particle on the bed of the stream. Resistance declines as depth increases for a constant particle size.

Although the average flow velocity is the quotient of discharge divided by the area of the cross section,  $V = Q/A$ , the distribution is not uniform throughout the section. At the boundary the velocity is zero and increases rapidly to higher values in the moving fluid nearby. The slower moving fluid near the boundary retards the flow of the more rapidly moving fluid farther away that in turn tends to speed up the slower flow. This momentum exchange is ultimately transmitted to the boundaries and constitutes the drag or the force resulting from the shear stresses acting over the boundary surface. These effects are reflected in the nature of the velocity gradient or rate of change of velocity away from the boundary. For laminar flow molecular exchange of momentum dominates. When the flow is turbulent, the primary exchange of momentum takes place by the random movement of eddies from one region of the flow to another. In both cases, velocity increases with distance from the boundary; however, the exchange of momentum or mixing through the motion of eddies results in a more even distribution of velocity at some distance from the boundary. Theory confirmed by experiment indicates that velocity increases with the logarithm of the depth.

A natural river channel of roughly rectangular form has two boundaries, one with the solid earth and one with

Velocity distribution and boundary velocities

the air at the water surface. Assuming the drag of air to be small relative to that at the solid boundary, because velocity increases with distance from both the bed and banks of the channel, one would expect the highest velocity at or near the free water surface in the centre of the channel at the maximum distance from the boundary. In a wide straight channel, and in many natural rivers, the velocity is at a maximum in the centre near the water surface (Figure 5). Because width is often very much greater than the depth, in a straight channel the velocity distribution may be quite uniform over a considerable part of the channel. Where the flow is curved, however, and the depth small relative to the width, the velocity distribution is asymmetrical and the highest velocity occurs near the outside of the bend and below the surface. Asymmetry results from the higher elevation of the water surface on the outside of the bend and from the fact that the velocity of flow at the surface is higher than the velocity of the flow near the bed. As the water turns in the bend, water moving more rapidly at the surface turns less sharply than the slower moving water near the bed. This difference and the greater depth on the outside of the bend as a result of centrifugal acceleration create a component of flow across the section perpendicular to the direction of flow. Circulation or secondary spirals are created, with components of flow near the bed moving from the outside of the bend toward the inside and a component at the surface moving in the opposite direction. A single circulation spiral usually dominates in the bend. The complete circulation includes then a downward

Figure 5: Velocity distribution in channels (see text).

component at the outer margin and an upward component at the inner section (Figure 5). Very wide channels in nature may exhibit a number of circulation "cells" within a given cross section.

#### ENTRAINMENT AND TRANSPORT OF SEDIMENTARY PARTICLES

Erosion and transport of sedimentary particles is initiated when the drag exerted on the boundaries of a natural channel by the flowing water is sufficient to detach a particle from the boundary. As noted above, the drag or shear stress exerted on the bed and banks is defined by the velocity distribution (Figure 5). From the derivation given earlier, the average shear stress,  $\tau_0$ , is equal to  $\gamma dS$  and in turbulent flow is proportional to the square of the velocity,  $V^2$ .

Initiation of motion of noncohesive particles from the bed of a natural channel occurs when the shear stress,  $\tau_0$ , exerted by the fluid exceeds the forces holding the particles in place. A particle of a given size and weight will begin to move when the shear stress exceeds a component fraction of the weight of the particle under water. The critical shear stress then is defined by the relation  $\tau_0 = kd_s$ , where  $d_s$  is the particle diameter and  $k$  a coefficient that includes the effects of particle shape, distribution, and packing within the bed. The relationship between particle size and increasing critical shear stress is shown in Figure 6. The ability of a stream to move a particle of a given size is sometimes referred to as the competence of the stream.

Because, as the discussion of flow resistance demonstrated, shear stress varies with the Reynolds number of

Figure 6: Critical shear stress required to initiate motion of particles on the bed of a stream channel.

The curve shows some variation of critical shear stress with the condition of flow as defined by the Reynolds number. At high Reynolds numbers, for larger particles, critical shear stress required to initiate movement is directly proportional to particle size. For higher values of  $\tau$ , the rate of transport increases.

the flow, the relationship between particle size and critical shear stress is not linear over the entire range of flow conditions found in nature. In addition, for smaller particles the force or velocity required to dislodge a particle from a matrix of other particles is greater than that required to maintain movement of the particle once entrained within the flow, and thus the velocity at which deposition takes place is less than the velocity required to initiate movement.

Beyond the point of incipient motion, the rate of transport of sediment is primarily a function of the total shear stress available within the fluid. Work must be done by the fluid to initiate and maintain the movement of the particles. A wide variety of theoretical and empirical expressions have been derived to relate the rate of sediment transport to flow parameters such as discharge, velocity, shear stress, or power (the rate of doing work). All depend upon the basic flow laws, which relate the distribution of velocity to a measure of the characteristics of the flow whether laminar or turbulent, to the geometry of the boundary, and to the shear stress. In general, increasing flow accompanied by increasing velocity and shear stress results in progressive entrainment of particles from the bed and higher rates of transport.

There are essentially two distinct physical modes of transport of sediment. Bed load is that portion of the material in transport that is in continuous or partial contact with other particles on the bed; thus the weight of the moving particles is supported by contact with grains in the bed. In contrast, the suspended load is born up by the fluid eddies within the flow itself. Because the turbulent eddies both near the bed and in the fluid vary in intensity from moment to moment, the motion of the individual particles is highly erratic from place to place and moment to moment. In a statistical sense, however, at any distance above the bed, an equilibrium concentration is maintained with the number of particles settling through a given level balanced by an equal number of particles thrust upward by eddies. The concentration of suspended sediment at each level above the bed is a function of the settling velocity of the particles and the intensity of shear stress or turbulent exchange in the fluid at that level. Large particles, which settle most rapidly, are found near the bed, and progressively smaller particles are carried at greater distances above the bed. Similarly, where the particles are all of the same size, larger concentrations of suspended sediment will be found closer to the bed. If the particles are very fine, they may be nearly uniformly distributed with depth. The curves in Figure 7 show the way in which sediment concentration varies with depth for particles of different sizes or settling velocities at a constant condition of flow. Settling velocity is primarily a function of the size of the particle.

Modes of sediment transport

Figure 7: Distribution of suspended load with depth for particles of different sizes. Coarse particles are concentrated closer to the bed, while finer particles, such as silt, are more uniformly distributed with depth.

Assuming the availability of a range of particle sizes in a river, as the flow fluctuates and velocity or shear stress changes, particles transported near the bed at one time may be entrained and move in suspension at a higher flow. With diminution of the flow larger particles cannot be maintained in suspension and will settle to the bed.

Where the bed of a natural channel is comprised of noncohesive particles such as sand, as velocity and depth increase with increasing flow the particles in motion no longer behave solely as discrete individuals but instead the bed itself is deformed, resulting in the formation of sand ripples, dunes, and waves. As the rate of transport increases, these bed forms change progressively with changes in depth and velocity. The sand near the bed moves in a zone close to the dune or ripple surfaces. Particles are carried up the backslope of the dune and deposited usually after sliding down on the steeply dipping face producing the downstream movement of the dune. Under some circumstances the bed form may move upstream. Because deformation of the mobile boundary influences the flow distribution itself, the interaction between the flow, the boundary form, and sediment transport is complex. These interactions, and the progressive changes in bed forms observed in natural channels during passage of a flood, are discussed below, under *Erosion and deposition in natural channels*.

#### MATERIALS TRANSPORTED BY NATURAL RIVERS

The materials actually transported as a clastic or particulate load as well as those in solution in natural rivers are a reflection not only of physical laws governing the competence and capacity of the flow to transport material but also of the availability of materials themselves. For example, pure limestone terrain containing no insoluble materials would supply no sediment to streams draining the region. With the exception of occasional blocks broken off from limestone canyon walls, the rivers would carry only dissolved materials, and the stream

beds would be devoid of sand, silt, and gravel bars. Such extremes, of course, are rare and, in general, rivers transport a mixture with coarser sediment in the bed load, finer particles in suspension, and ions in solution. Although these distinctions represent mechanisms of transport rather than sources of material, the sources are reflected in both the composition and relative abundance of each fraction.

The relative abundance of different portions of the load of materials carried by natural rivers can be obtained by measurement and in part by computations based on formulas developed from theoretical and laboratory studies. Because of the variety and complexity of the conditions found in natural rivers, however, neither measurement nor computation provides wholly satisfactory results. The accuracy of each varies with the local conditions found in different rivers. A few of the methods of measurement and computation are noted here.

Measurements of bed load in rivers are made in three ways: (1) by means of traps set on the bottom of the river with openings that are designed to catch material moving along the bed, (2) by means of trenches dug perpendicular to the flow across the entire channel width, such that the material moving near the bed falls into the trench and is conveyed laterally to a collecting system and there weighted, and (3) by hydrographic surveys of the total load accumulating in ponds, lakes, or deltas. To obtain the bed load, computations may sometimes be made based upon the coarser fraction of the accumulated sediments or a measured suspended load may be subtracted from the total accumulation.

Measurements of the suspended load are made with a streamlined sampling device resembling a fish that is lowered and raised through the flow. Streamlining minimizes interference with the flow. The resulting "depth integrated" sample represents a range of the concentrations weighted by the velocity of flow at each of the points in the vertical. Alternatively, samplers can be lowered in a vertical array and instantaneous samples obtained at specific points in the flow. To obtain a representative sample, sampling is done at a number of verticals across the river section. Because of the design of the samplers, they cannot be placed at precisely the interface between the moving bed and the fluid itself. As a result, the region immediately adjacent to the bed is difficult to sample properly. The significance of this omission varies with the concentrations of flow, particle size, and turbulence near the bed. The resulting observations are referred to as the "sampled" load, which is nearly equivalent to the theoretical suspended load in many cases but is not always so.

Computation of the transport of sedimentary materials in rivers is based on a separation of the mechanisms of transport, as noted above, into bed and suspended load. Because of the complexities of these relationships in natural rivers, the accuracy with which such computations can be made is often quite low. In some instances, however, estimates may be made within an accuracy of  $\pm 20$  percent, depending on the uniformity of the bed material, the variability of the shape and pattern of the natural channel, and the variability of the flow itself. (Roughly speaking the transport of bed material as bed load is proportional to the velocity raised to a power of 2 or 3.) If the concentration of suspended load is known at any point, an equation describing the relationship between suspended load and the shear stress in the fluid can be used to compute the total suspended load in the vertical at a number of sections. The accuracy of this computation under laboratory conditions is quite high, but some of the parameters are difficult to define for natural conditions, and the variability of the results remains large.

Unlike both the bed material and suspended load, which respond to the hydraulic conditions prevailing in the flow, the "wash load" of fine materials such as clays and fine silts derived from the watershed may settle so slowly that the quantity transported depends essentially upon the quantity supplied and not upon the dynamics of the flow. Thus the wash load need not be closely correlated with the velocity and shear stress but may vary over a large range, depending upon such factors as weathering, land

Bed load and suspended load

Wash load and the dissolved load

Dissolved and Suspended Load in Selected Rivers in Different Climatic Regions

river and location	drainage area (square miles)	(000,000 tons per year)		dissolved load as percent of total load
		average suspended load	average dissolved load	
Canadian River near Amarillo, Texas	29,700	6.41	0.12	1.8
Green River at Green River, Utah	40,500	19	2.5	12
Mississippi River, at the mouth	1,245,000	344	123	26
Delaware River, at Trenton, N.J.	12,300	1.0	0.83	45
Juniata River, near New Port, Pa.	3,354	0.32	0.57	64

Congo River, at mouth, Congo	1,425,000	31	98	76

use, and climatic conditions over the drainage basin. So far as measurement is concerned, wash load is a part of the suspended load, but the wash load cannot be computed from the suspended load equations using particle sizes found in the channel bed.

The relative proportions of dissolved and particulate or clastic load as well as the distribution of the clastic fraction between bed load and suspended load are highly variable in nature (Table). In general, the percentage of clastic load increases as the climate becomes more arid. Less effective solution and weathering in arid regions apparently reduce the supply of dissolved solids to the stream channel system, whereas in more humid regions larger quantities of dissolved material are made available to streams. Topography, and particularly the composition of the bedrock, also can markedly influence the composition and quantity of the load. The Saline River in Kansas, for example, has a salinity of 1,000 parts per million by weight, a function of the saline deposits found in the watershed. Similarly, extreme concentrations of sediment have been measured in some rivers such as the Yellow River in China, where sediment comprised 40 percent of the total fluid, or tributaries of the Colorado River, in which 60 percent of the flow was sediment. In general, concentrations of suspended load in natural rivers vary from several hundred to 10,000 parts per million (1 percent) by weight. Some sand channels, such as the Loup River in western Nebraska, may transport 50 percent or more of the total load as bed load, but values of about 10 to 20 percent are probably more common.

EROSION AND DEPOSITION IN NATURAL CHANNELS

The supply and movement of sediment is intimately involved in the determination of the form and pattern of the river channel. A natural river flowing in sediments of its own making can maintain a stable configuration in two ways: first, by a balance of forces in which the drag of the fluid tending to erode the perimeter of the channel at any point is equalled or exceeded by the frictional or cohesive forces tending to resist the eroding force, and second, by maintenance of a rate of deposition equal to the rate of erosion. In contrast, a channel incised in rock is less free to adjust its form and pattern through deposition and erosion, but the bed of the channel will rise and fall with changes in the rate of transport of debris. The first case, in which a precise balance is maintained between the erosive force and the resistance of the boundary materials without any erosion, is relatively rare in nature. The banks of such a channel in noncohesive material are roughly parabolic and, if the flow is large, the channel cross section will consist of a wide central portion with a flat bottom and banks at each side roughly parabolic in form. Ideally, the maintenance of such an erosional equilibrium requires a delicate balance between the opposing forces, a relatively uniform material, and a constant flow, conditions reproducible in the laboratory but only approximated in nature.

A natural river channel in which the rate of erosion is balanced by the rate of deposition and the outflow of sediment to the reach equals the inflow can maintain a stable form while moving laterally across the alluvial plain. A meandering river is the most common illustration of this process. Erosion takes place on the outside of each bend near the point of maximum shear stress as a result of the curvature of the flow. Deposition on the opposite bank is associated with transverse flow near the bed and with

slack water eddies adjacent to the thread of the current. Because the locus of erosion is downstream from the point of maximum curvature, progressive erosion in the downstream direction is associated with progressive deposition as the entire channel bend moves downstream.

Where the channel boundaries are straight, either because of the nice adjustment of discharge, gradient, and sediment, as is the case in some canals, or perhaps as a result of vegetation or channellization by man, sediment and sedimentary forms such as sand and gravel bars may move downstream in a progressive and orderly fashion. The movement of sediment and the configurations of the channel bed associated with such movement may be rather arbitrarily divided into three phases. First, channel bars may be deposited along the banks at sequential positions alternately on one side of the channel and the other. This configuration of alternating bars of gravel or sand in a straight channel is not unlike that which would be observed if the bends of a meander were "pulled out" to make a straight channel. Their spacing of roughly three to five channel widths appears to be related to the discharge and to the width of the channel. Second, sand and silt may move as dunes or ripples, a mode of transport determined by particle characteristics and the interaction of boundary form and the flow. A third mode of sedimentary deposit involves successive movement and deposition of discrete particles. Larger particles may move different distances depending upon their size, shape, and specific gravity. Boulders will move less frequently and, on the average, more slowly than smaller particles, producing a differential rate of downstream migration of particles of different sizes.

Accumulation and movement of gravel and sand in bars appear to resemble the movement of what is called a kinematic wave. Discrete particles do not move independently of one another but interact or interfere with each other in much the same way as automobiles on a highway. As a result of this interaction, the particles accumulate in groups or agglomerations that move downstream as "waves." The average downstream rate of movement is then represented not by the movement of the individual particles but rather by the average rate of movement of the group of particles constituting the wave. This wave phenomenon is similar to that observed on a highway crowded with automobiles, where, when the number of automobiles is low, the automobiles interact very little and each moves at its own rate. With an increase in the number of automobiles, however, interaction takes place and groups begin to form such that there are agglomerations and openings in successive positions along the highway. The celerity or rate of movement of these waves is determined then by the density of particles (or automobiles) in a given length of stream channel (or road), by the characteristics of the particles, and by the conditions of flow.

Because the flow of water in natural channels is not constant, each mode of transport in a river also varies with time. The alternation of high and low flow in most of the rivers of the world not only influences the rate of transport but also the attendant forms of the channels themselves and the deposits associated with them. In the natural world the time scale of variations in flow may be matters of minutes, days, years, decades, or millennia. Peak flows from thunderstorm rainfall may occur in a matter of minutes after the start of heavy rain in streams or in urban rivers. Storms of longer duration may pro-

Sand and gravel bars and kinematic wave theory

Flow and transport variation with time

Equilibrium conditions and the migration of meanders

duce high water lasting for days or weeks. At another time scale are the seasonal or annual variations such as the cyclical rise and fall of the Nile each spring as a result of snow melt and rains in the headwaters, a variation common to many major river systems such as the Colorado, the Rio Grande, the Ganges, and the Yukon. Lastly, successions of dry years may be followed by wet ones. Such climatic variations are less periodic in occurrence and may encompass periods from decades to thousands of years in duration.

Variations in flow rate are associated with variations in transport. The dissolved load, responding to the characteristics of the source rocks as well as the flow, often decreases in concentration as a result of dilution of the salt concentration by the direct runoff from streams. In contrast, suspended load generally increases with increasing flow. Wash load may be readily removed from the watershed, for example, when spring rains follow the melting of snow and particles of soil are detached by cycles of freezing and thawing in early spring and late winter. The first spring rains readily remove the prepared materials to the streams. The transport of bed load also increases in response to increase in velocity and shear stress accompanying the passage of higher flows or floods. As in the theoretical or laboratory condition, the change in flow in the river channel is accompanied by a change not only in the concentrations of dissolved, suspended, and bed materials but by changes in the form of the bed itself as the flow increases in depth and velocity. Changes in the form of the bed associated with the passage of a high flow in a river are shown in Figure 8, whereas Figure 9 shows concurrent changes in flow, velocity, and depth.

Figure 8: Forms of bed roughness in alluvial channels. This sequence of forms is related to the depth and velocity of flow and to the rate of sediment transport.

As noted earlier, after the initiation of movement, ripples and dunes develop on the bed. With increasing depth and velocity of flow in the channel, the dunes grow in size. Experimental and field observations indicate that the amplitude or height of the dune increases until the velocity of flow over the dune prevents further accumulation on the crest. At equilibrium, dunes may cover the bed in the same way that they do the windblown surface of a sandy desert. If velocity increases more rapidly than depth, as the Froude number approaches 1, a transition occurs, dunes begin to be erased, and all or part of the bed will be planar, with dunes covering the remainder. Beyond this transition, continuing increase in velocity leads to the formation of antidunes. Dune forms on the bed move upstream as a result of the displacement of material by scour at the upstream position while net transport continues in the downstream direction. The formation of antidunes is associated with the formation of standing waves on the water surface. Unlike dunes, the crests and troughs of antidunes are in phase with the crests and troughs of the surface waves.

With declining flow in the channel and reduction in velocity and depth, the sequence is reversed. At suc-

cively lower Froude numbers, the bed is transformed from the antidunes to the mixed and planar bed, to dunes, and thence to an irregular bed of sand if the flow declines to zero. A smooth bed is rarely if ever attained inasmuch as declining flow both erodes the dunes and deposits finer sediments on the channel bed. Thus the forms remaining in a sand channel are usually dissected dunes and ripples.

Each of the successive configurations of the bed is associated with a particular set of flow conditions, and with changing discharge a complex interrelationship exists between the geometry of the boundary as defined by the configuration of the channel bed, the concentration of sediment, and the flow parameters such as velocity and depth. In some cases the same discharge on the rising stage of a flood may be associated with a high velocity and a relatively low depth, while on the declining stage the depth may be higher and the velocity lower (Figure 9). From the earlier discussion of resistance it will be seen that the resistance to flow then is greater on the falling than on the rising stage. This difference is presumed to be due primarily to decline in flow so rapid that there is insufficient time for the transition of the bed forms. Dunes of larger amplitude associated with the higher flow remain at the lower stage and these larger forms provide a greater resistance.

The scale of dune forms may be exceedingly large. In a large river such as the Mississippi, at depths of flow from 70 to 90 feet (21 to 27 metres), dunes or dunelike forms of major proportions have been observed, with amplitudes from 15 to 40 feet (5 to 12 metres) and longitudinal spacing from crest to crest of 50 to 500 feet (15 to 152 metres). Dunes can be seen in the beds of many rivers and creeks carrying sand, and dunes of cobbles and gravel occasionally have been observed after the passage of great floods where large depths and high velocity permitted transport of the coarse material.

Variations in flow produce variations not only in the rate of movement of particles of different sizes but also in the distances that these move in successive intervals of time. A large boulder in a small trout stream may be moved only by rare and very large floods. In contrast, material in solution is transported continuously as long as there is flow in the stream. Between these extremes lies a continuous range. Small particles are carried more often and for greater distances during each rise in the flow than are successively larger ones. Huge boulders may be moved a matter of feet or perhaps hundreds of feet by a flood that occurs on the average perhaps once in a hundred years. Sand may be transported continuously in a stream where the flow never declines below the point of incipient motion of the sand particles. Thus individual particles move in steps of varying lengths that depend upon the duration of the flow in which they are transported and their size, shape, and distribution.

Flood events of large magnitude but infrequent occurrence may move very large particles as well as large quantities of material but only for short periods of time. In contrast, more frequent events will move smaller sizes but over longer periods of time. In sand bed channels of ephemeral streams, such as those in the southwestern United States, most of the movement of both suspended and bed materials may occur during relatively infrequent events, which recur perhaps four or five times per year. These few floods not only mold the channel form, but they may transport 80 to 90 percent of the total annual load carried by the river. In contrast, where flow is perennial and of relatively large magnitude, more of the dissolved and suspended load may be transported by flows of modest magnitude throughout a large part of the year. Under such circumstances, the relative contribution of the large and infrequent flood event is thus of lesser significance. To the extent that generalization is possible, existing evidence suggests that the greater the variability of stream flow and the larger the particles to be carried, the more significant are the floods of large magnitude and infrequent occurrence. Similarly, where flow is less variable, dissolved load a significant proportion of the total load, and the suspended load composed of fine particles, more frequent events assume greater importance.

Magnitude and frequency of flow events

Figure 9: Sequential changes in flow (discharge), velocity, depth, and sediment transport associated with the passage of a flood in a natural channel with a sand bed. Changes in bed form and the approximate Froude number at which such changes might be observed are shown in association with changes in the rate of sediment transport.

Scour and fill and environmental conditions

In a given reach of channel, fluctuations in flow, accompanied by changes in the rate of transport of both suspended and bed material, produce a scouring or filling of the channel bed. In a straight channel this may amount to a few inches. In bends or narrow reaches, scour may be to depths of several feet and in rock-walled canyons as much as 20 to 30 feet (6 to 9 metres). The cumulative effect in any given year may result in the temporary lowering of the stream bed. The bed may be lowered in some years and raised in the next or succeeding years. Over a period of time the average elevation will remain constant. A similar process of erosion and deposition characterizes the lateral or down-valley movement of the channel. In

any one year erosion may exceed deposition, but over a period of years the pattern and form of the channel remain the same. Thus, the equilibrium referred to earlier constitutes an adjustment to the quantity of water and sediment delivered to the channel, an adjustment maintained within the natural variations in flow and sediment load normally experienced in a given climate or hydrologic environment. Equilibrium of the river channel then is associated with a constancy of climate viewed as an average over a period of years.

A progressive increase in the amount of rainfall on the watershed, a change in the vegetative cover, or a combination of such factors, however, may produce a progressive change in the hydrologic conditions governing the river channel at any point. Such changes might be climatic, they might result from changes in land use or, for example, they might be brought about by construction of a dam and major reservoir. These long term or progressive changes are referred to as degradation or aggradation in contrast to the processes of scour and fill that encompass fluctuations of short duration. Changes associated with man-made works, in fact, provide a good illustration of the nature of the river response to changes in climate. A reservoir, by impounding flood flows for release during periods of low natural flows, alters the frequency distribution or pattern of river flows. In addition, the reservoir becomes a sediment trap, which reduces the quantity of sediment delivered to a channel below. A river previously in equilibrium with the natural flow and sediment supply is thus subjected to a new set of controls that, in turn, result in a succession of changes in the river channel itself. Thus, where scour took place in one year to be followed by deposition in succeeding years prior to construction of the dam, after construction the elimination of floods and sediment supply produces progressive lowering of the channel bed, or degradation, rather than an alternation of scour and fill.

In contrast, progressive accumulation, or aggradation of material in channels, also results from changes in climate, from man-made works, or at the interface of land and water where sediments accumulate in deltas. In some locations, such as on the Yellow River, the river bed has risen to well above the surrounding countryside in the delta because successive floods deposited coarse sediment along the river banks and on the bed. Elsewhere, changes in climate have resulted in the delivery of large quantities of sediment to river channels, producing alluviation or filling for great distances over entire channel systems.

Rates of accumulation or degradation are highly variable. For over a thousand years the Nile has risen at an average rate of about three feet per hundred years. In contrast, during the period of hydraulic gold mining in the Sierra Nevada the Sacramento River rose as much as ten feet in 35 years. Valley fills or terraces along major rivers in the great plains of the western United States indicate that some rivers may have cut through the alluvial materials in their valleys at rates on the order of ten feet (3 metres) or more in 100 years, although these estimates are crude at best. Below Hoover Dam on the Colorado River, the bed of the channel was lowered ten feet in five years after closure of the dam.

Rates of erosion and deposition

#### RIVER FORMS AND FLUVIAL PROCESSES IN DIFFERENT ENVIRONMENTS

The characteristics of a river and the processes associated with it are determined by a combination of the geology of a region and the climatic conditions responsible for providing the flow in the river. The term geology includes the underlying structure of the region, such as the presence or absence of mountains, as well as the composition and distribution of the bedrock. The latter, in turn, determine the quantity and often the size fractions of the materials delivered to the stream system. In contrast, although the climate may be influenced by the elevation of the region, major aspects of the atmospheric circulation will determine the amount of precipitation and seasonal variations in temperature. Indirectly these will affect the vegetation, characteristics of the soils, and the distribution of runoff or flow to the river system.

Clearly, innumerable combinations of geologic and climatic controls must exist in nature. Each segment or reach of a river will be dominated by a set of conditions of local origin as well as by a set determined from the larger area of the drainage basin upstream. Despite these obvious variations, however, some combinations of controls are sufficiently common to allow rather rough characterization of rivers in different regions. It must be emphasized, however, that the key to understanding why rivers look and behave as they do lies in a knowledge of the mutual interaction of the controlling factors such as discharge, sediment, and rock type. What might be called characteristic regional types simply represent particular combinations of these factors as well as the existence of a control in some regions or environment. Many complex factors are involved in developing a certain type of river or stream; each stream is classified according to the factors affecting it.

Grant Heilman

A boulder-bed high mountain stream, Crandall Creek, Wyoming.

The trout stream and the arroyo

The so-called trout stream, or brook, for example, is indeed a recognizable type of river. It is usually characterized by a vigorous flow (of cool water), high gradient, and a bed of cobbles and boulders bordered by mossy banks and trees. Climate and elevation determine the availability of the flow, whereas the coarse bed material is a function of the steep gradient determined by the geologic structure. A high gradient permits the flow periodically to move some of the larger cobbles producing in time a series of pools and riffles. In some brooks, particularly those in coarse sand or cobbles, the spacing of the riffles or shallows appears to be proportional to channel width.

A second rather distinctive river in an opposing climatic regime is the arroyo of the Spanish-speaking world, the wadi of the Middle East and Mediterranean region. These dry washes, which experience periodic torrential flows, are otherwise dry sand channels comprised primarily of sands, perhaps dissected dune forms, some gravel, and occasional cobbles, depending on the local geology and topography. Because of the aridity and high temperature of the bed, vegetation is usually sparse. The combination of dry bed, absence of vegetation, and rapid changes in flow permit large variations in the configuration of the sand bed and in the amount of scour and fill. In addition, because such channels are often on relatively steep slopes and in noncohesive materials, they tend to be wide and shallow and subject to high velocities at shallow depths, a condition promoting the formation not only of dunes but of antidunes along with rapid rates of sand transport.

Channels in humid-temperate regions

In contrast to these rivers in semi-arid regions, the well-defined channels of the humid region are a response not only to the regularity of the flow but to the presence of fine sediments and vegetation that stabilize the river banks, emerging point bars, and other deposits laid down by the river. These channels, composed of silt banks stabilized with vegetation, are narrower and less mobile.

Not infrequently floods that overtop the banks deposit on the adjacent plain varying amounts of silt, sand, and mud, thus creating a floodplain composed of channel and bar deposits overlain by finer "overbank" deposits. Where the channel is confined or maintains itself within a relatively narrow belt within which it meanders, the fine-grained deposits of floods may predominate in the floodplain.

The preceding descriptions suggest that in alluvial river channels flowing in sediments of their own making, there is a range of channel or river types, from the wandering channel that deposits bars over a vast shallow plain to the well-fixed, stabilized, narrow channel bordered by vegetation. In the former the ability of the channel to alter its course at will by erosion and deposition, a condition common to large rivers flowing on an apron of debris deposited at the front of a glacier, creates a broad flat plain composed of sand and gravel bars deposited within the channel and in rapidly migrating bends, coupled with the overbank materials that are deposited from rapid rises in stage.

At the opposite extreme, the established channel in cohesive material bordered by vegetation will move laterally at a modest rate accompanied by deposition of sediments upon which vegetation will become established. With each flood above the normal bank height (a level attained on the order of once each year or two) sediments may be deposited over nearly the entire width of the valley. Where the river channel traverses the valley with rapidity, the bottomland is virtually all in channel deposits, while in the less mobile environment overbank or nonchannel deposits predominate.

Between the extremes, the wandering and stabilized channels, lies a spectrum of processes and resultant alluvial landforms, each dependent upon the relative rates of lateral migration of the river and of overbank deposition; that is, upon relative rates of erosion and sediment transport, and upon the frequency distribution of river flow. A given channel then may fall anywhere within this spectrum. The channel of the Missouri River along the boundary between northern Iowa and Nebraska, for example, contains many bars that may shift with each flood. At the same time, the river moves laterally in a broad meandering pattern experiencing progressive erosion as well as deposition over broad areas.

Rivers in canyons such as the Colorado in the Grand Canyon, the Yangtze Gorge, or the limestone valleys on a smaller scale in Kentucky and Tennessee in the United States are confined by bedrock walls and valley floors. No longer free to alter either form or pattern save over long periods of time, the characteristics of the river are determined primarily by the rock itself and by slow erosional processes of abrasion and scour of rock material. Falls may occur where resistant beds are in con-

Rivers in canyons

Josef Muench

tact with less resistant ones such as at Niagara, or long smooth stretches may be encountered where, unbroken by changes in lithology or by joints or faults, abrasion by the river has produced smooth polished surfaces. Elsewhere, as in the bottom of the Colorado River, deep pools scoured by the flow may be separated by rocky rapids. In some places lateral abrasion excavates sheltered coves where rockwalls overhang the river itself. Rock canyon sections may occur in any climatic region where water has been or is currently available to scour the bedrock.

In extreme climates, such as in Arctic, Antarctic, or periglacial (cold, frozen ground) regions, the river may be frozen throughout much of the year. Here the river processes will be determined by the configuration of the bedrock geology and by the annual climatic regime, which determines both the way in which the river freezes with the onset of winter and the way in which the ice breaks up in the spring. Some rivers, such as the Yukon, break up throughout the length of the river in a relatively short period of time. The resultant breakup and the rising spring flood with which it is associated produce enormous forces that not only shatter the ice but cause it to accumulate in ice jams, to override the river banks, and to erode the channel banks as the high flow moves down the river.

This type of river presents quite a different pattern from that observed on other kinds of cold region rivers such as the Nelson River in Canada, which flows from Lake Winnipeg to Hudson Bay. The Nelson consists of a series of lakes and open water sections linked by bedrock falls or rapids. Freeze-up and breakup are discontinuous, beginning in the lakelike sections and controlled by the backing up of water above the controls at the rapids. The breakup of the ice is sequential and does not occur over the entire river, but instead the ice melts in the lakes and intervening backwater sections and, as the water rises, it begins to flow through and over the ice covering the falls. The flow scours areas adjacent to the falls themselves and gradually erodes through the ice capping the falls. The presence of ice and the movement of large ice blocks from the bedrock falls provide additional force to scour and to move boulders along the bed of the river.

If these represent distinctive types of rivers, is there a "typical" river resulting from a set of "typical" river processes? The answer is yes and no. Although there is no typical river, there are a set of processes of common occurrence that can be used to define a model case. The discharge in such a river would probably include a seasonal peak and a skewed distribution of daily flows with low flows exceeding the number of high flows. The largest volume of sediment would be transported as suspended load and the dominant mode of movement along the channel bed would be in the form of dunes. As a rule, the sediments comprising the banks would be finer and more cohesive than those in the bed. Whereas the channel would appear roughly rectangular, the ratio of width to depth is large and in many instances the cross section, when drawn to scale, would be nearly saucer shaped. With the passage of a flood, such a river would scour on the order of a foot or two. Some lateral movement of the channel would be accompanied by deposition of bars, and at bends sediments would be deposited opposite loci of erosion on the outside of the bend. Occasional floods would deposit successively finer materials on these channel sediments. Thus, a floodplain would be progressively eroded and recreated by the river that flows within it.

Although these generalizations can be made about the characteristic behaviour of rivers and associated processes in different environments, in reality, of course, a single factor may dominate the scene at a particular point and essentially determine the characteristics of the river at that point. Thus the presence of canyon walls may dictate that the river be narrow and deep. Elsewhere the variability of flow, as for example on the Great Plains of the United States, coupled with sediment sources providing much silt and sand, may ensure that the natural river channel is shallow, characterized by high variability and by broad areas of bare sand. Even in such terrain, a succession of relatively wet years may see the development

of a dense cover of vegetation that gradually inhibits or confines the channel system. A major flood may destroy the vegetation, widen the channel, and once again expose an area of bare sand. This alternation in place and in time can be repeated again and again in the history of the river and reflects the dynamism inherent in the processes that mold the riverine landscape.

(M.G.W.)

## Foch, Ferdinand

Ferdinand Foch, marshal of France and commander of the Allied forces in the closing months of World War I, is generally considered to be the man most responsible for the Allied victory. Marshal Joseph Joffre, one of the French military leaders in World War I, once said, "Intelligence is plentiful, but strength of character is not." Foch had both.

He was born at Tarbes (Hautes-Pyrénées) on October 2, 1851, the son of a civil servant. His family had originally lived in Valentine, a village in the Comminges area to which he used to return every year.

As a very young child he had been inspired by the Napoleonic epic through the stories of the campaigns of his maternal grandfather, who was an officer during the Revolution and then under the emperor, and at the age of six he began to devour the descriptions of military battles he found in historical works. Thus, at an early age, he indicated the direction his career was to take.

After attending several schools, in 1869 he entered the well-known Jesuit school of Saint-Clément in Metz, in order to prepare for the entrance examination for the École Polytechnique (Polytechnic School). At Saint-Clément he also worked out the solid religious training he had received from his family. His religious faith was later to be one of the essential elements of his moral strength; yet, it was to make him the object of petty hostility, even though he remained aloof from politics.

The  
"typical"  
river

Early  
years

Rise in the  
military  
hierarchy

In Metz, the experience of France's defeat in the Franco-Prussian War left an indelible impression on him. When he passed his examinations in July of 1870, the war had already broken out, and cannons were thundering nearby. Once back home, he enlisted in the army but did not take part in the fighting. In 1871, after the armistice, when he returned to Saint-Clément, he was forced to live alongside the German soldiers who were there. Metz had become a German city. His pain and anger dictated the decision that was to give meaning to his life: he would become a soldier in order to return Lorraine and Metz to France.

After two years at the École Polytechnique, he entered the École d'Application de l'Artillerie (the artillery training school) in 1873. As an artillery officer, he proved himself to be both an ardent cavalryman and an experienced technician. After appointment to the Artillery Committee in Paris, he was married in Brittany in 1883 and acquired the château of Trofeunteuniou, which then became his second family home.

In contrast to many officers who sought action in colonial campaigns, Foch chose study and meditation. But his studies were meant to do more than just enrich his knowledge; they were a constant education of his own will. He studied the lives of the great men of history and sought out the duties expected of a leader. Consequently, when difficult times befell him, he was steeled for them.

In 1885 he entered the École Supérieure de Guerre (War College), which for the next 25 years was to be his "laboratory" to prepare for war. He returned there as a major in 1895 to become an assistant professor—and soon a full professor—teaching general tactics. Finally in 1908, when he was a brigadier general, the prime minister, Georges Clemenceau, appointed him head of the school, even though he had to overcome bitter opposition. In the meantime Foch had exercised commands and served on various staffs, thus adding to his experience and judgment. He formulated his doctrine of action in two works: *Les Principes de la guerre* (1903) and *De la conduite de la guerre* (1904).

"Thought" and "will" were the key words of the teachings that his harsh and abrupt, but inspired voice—his disciples called it a prophet's voice—imprinted on the minds and hearts of generations of officers.

After commanding a division in 1911 and briefly commanding an army corps, he was in August 1913 put in command of the XX Army Corps in Nancy, which protected the Lorraine frontier. It seemed to be the crowning point of Foch's career because he would reach retirement age in three years.

When war broke out on August 2, 1914, Foch first fought on the right flank, in Lorraine. On August 28 a dangerous gap appeared in the centre, and the commander in chief, Joseph Joffre, called Foch to command the army detachment—which later became the IX Army—that was being formed there. The enemy tried to break through, but Foch held on. He had taught that "Where there is a will, there is victory." His tenacity made it possible for Joffre to win at the first of the battles of the Marne. The same was true at the battles of the Yser and of Ypres, where he had been sent by Joffre to coordinate the efforts of the English, the French, and the Belgians, who were being severely attacked. King Albert I of Belgium later said of Foch, "That man could make the dead fight."

For two thankless years—1915 and 1916—Foch, commanding the Northern Army Group, vainly tried to break through the German line in Artois and at the Somme. This time his will could not make up for the lack of equipment and supplies.

On May 15, 1917, he was appointed chief of the war minister's general staff, a position that made him adviser to the Allied armies. But advising was not commanding.

Russia was about to collapse, thus allowing Germany to bring all its forces back to the Western Front, where the Belgians, the English, and the French were lined up under separate commands. Foch predicted that, when the battering ram struck this poorly consolidated front, each force would think only of its own fate and that the front

would be broken up. That was why he advocated the establishment of a single command. But the British prime minister David Lloyd George and Clemenceau, who had in November 1917 once again been appointed premier, refused to listen to Foch, believing that an agreement of cooperation between the English and French commanders in chief, Field Marshal Douglas Haig and Gen. Philippe Pétain, would suffice.

Events, however, were to prove Foch right. On March 21, 1918, the British front in Picardy collapsed under the impact of the German attack. On March 23, the Anglo-French agreements were outstripped by events. On March 24, it was already "every man for himself." Douglas Haig was thinking about his embarkation ports, and Pétain was thinking about Paris. The severance of the two armies had begun. The Germans, who saw that the enemy had become nothing more than a body without a head, were already crying victory.

Lloyd George and Clemenceau shared that feeling. They realized that there was only one possible head to fill that void, and that was Foch, the very personification of determination. And so on March 26, on the very brink of disaster, they gave Foch the responsibility of "coordinating the action of the Allied Armies on the western front." These powers were enlarged at the inter-Allied conference in Beauvais on April 3 and were extended to the Italian front on May 2.

The battle of two wills began: Erich Ludendorff, who was in virtual command of the German forces, versus Foch. Ludendorff, who had the initiative and superiority in numbers, redoubled his attacks. Foch had to resign himself to parrying, in order to hold out until the mass arrival of the American armies. Deaf to the calls of distress, he husbanded his meagre reserves, urging his men on to the limits of their endurance. His shrewd tenacity succeeded in stopping Ludendorff in Picardy and then in Flanders. On May 8, Foch received the official title of commander in chief of the Allied Armies.

But, in order to give full support to the English, who were being pushed back to the sea by Ludendorff, Foch did not hesitate to withdraw troops from the French front. Ludendorff took advantage of this. On May 27, he broke through that front, and his troops spread as far as the Marne. On June 9 a new gap appeared at the Oise: Foch stopped it up again. Ludendorff then decided to gamble everything he had, for the Americans were about to join the battle. On July 15 he made a massive attack in Champagne. Two days later he was stopped; he had lost.

Foch's will had gained the upper hand; now it was his turn to strike. In two offensives on July 18 and on August 8—Ludendorff was to call the latter a "black day"—Foch drove him back to a defensive position.

The honour of marshal of France was conferred on Foch on August 6, just as he was intensifying his offensive and unrelentingly striking the German front, giving no respite to the enemy nor to his own troops. Finally, the German Army, already bled white, was threatened by disintegration by the revolution in Germany. It had moreover, been abandoned by its allies and now found itself forced to ask for an armistice the conditions of which were dictated by Marshal Foch in the name of the Allies on November 11, 1918, at Rethondes. On November 26 Foch returned to Metz. He had given Alsace and Lorraine back to France: the lifelong goal that he had set for himself had been reached.

Foch, who had been made a marshal of Great Britain and of Poland and who had been elected a member of the Académie Française and of the Supreme War Council, died in Paris on March 20, 1929. He is buried near Napoleon under the dome of the Church of Saint-Louis-des-Invalides.

**BIBLIOGRAPHY.** FERDINAND FOCH, *Des Principes de la guerre* (1903; Eng. trans., *The Principles of War*, 1918), and *De La Conduite de la guerre* (1904), are works essential for understanding the formation of the Marshal's military thought and of his character. See also his *Mémoires pour servir à l'histoire de la guerre de 1914-1918*, 2 vol. (1931; Eng. trans., *The Memoirs of Marshal Foch*, 1931), a well-balanced review of Foch's thought and action; MAXIME WEYGAND, *Foch* (1947), a major study (in French) by the chief of the general staff

from August 1914 to April 1923, who as Foch's faithful friend, brings alive the personality of the Marshal from his birth to his death; and *Mémoires*, vol. 1, *Idéal vécu* (1953), an excellent account of Foch's wartime activities, particularly those of 1918; and ANDRÉ LAFFARGUE, *Foch et la bataille de 1918* (1967), presently the most complete work on Foch's conduct of operations in 1918, written by a participant in the battles of 1918, who was in personal correspondence with the Marshal. A fine study in English is that of B.H. LIDDELL HART—*Foch: The Man of Orleans* (1931).

(C.A.La.)

## Fokine, Michel

No other single artist had as much influence over classical ballet repertoire in the 20th century as Michel Fokine. His fame rests in large part on his manifesto of 1914, setting out his choreographic principles, and the great variety of choreographic styles that he either developed or initiated. He was the pioneer of the one-act ballet and introduced many of its forms: dance drama (*Petrushka*); pure dance (*Les Sylphides*); lyrical pas de deux (*Le Spectre de la rose*); ballet-divertissement (*Carnaval*); expressive solo (*The Dying Swan*); and ensemble (the *Polovtsian Dances* from *Prince Igor*).

Mikhail Mikhaylovich Fokine was born of a prosperous middle class family in St. Petersburg (Leningrad), Russia, on April 26, 1880. In 1889 he entered the Imperial Ballet School at the Mariinsky Theatre, where he distinguished himself for the breadth of his interests and studies. Fokine was not only talented as a dancer but also as a student of music and painting. He had a fresh and inquiring attitude toward everything connected with the ballet and began quite early to plan choreography, to seek appropriate music in the school library, and to sketch designs. His development as a dancer—he made his debut with the Imperial Russian Ballet on his 18th birthday—was paralleled by his development as a choreographer and designer.

In 1904 he wrote the scenario for his first ballet, which was based on the ancient Greco-Roman legend of Daphnis and Chloe. He sent it to the director of the Imperial Theatre with a note about reforms he wanted to see adopted by choreographers and producers. His crusade for artistic unity in ballet had already begun, but at this stage it made little impact. He was not encouraged to produce *Daphnis et Chloé* (he created it later, in 1912, for the Diaghilev ballet).

All the same, although at St. Petersburg he had no power to implement his beliefs, he began to work as a choreographer. His first ballet, created 1905 for performance by his pupils, was *Acis et Galatée*, based on an ancient Sicilian legend. Fokine's enthusiasm for antiquity owed nothing in origin to the "free dance" ideas of the American dancer Isadora Duncan, although her appearance in Russia in 1905 greatly consolidated his own views. In 1905 he also composed the brief solo *The Dying Swan* for the Russian ballerina Anna Pavlova. He continued to create ballets and three of his Mariinsky works were included in revised versions in the momentous season of the Ballets Russes that the impresario Sergey Diaghilev arranged in Paris in 1909: *Le Pavillon d'Armide*, *Une Nuit d'Égypte* (*Cléopâtre*) and *Chopiniana* (*Les Sylphides*).

Fokine was an integral part of the Ballets Russes's Paris triumph. Diaghilev's genius for bringing artists together in successful collaboration made Fokine, as his chief choreographer, the link between the dancers Tamara Karsavina, Vaslav Nijinsky, and Adolph Bolm; the designers Alexandre Benois and Léon Bakst; and the composer Igor Stravinsky, in such superbly unified creations as *L'Oiseau de feu* (1910; *The Firebird*) and *Petrushka*.

Fokine's relationship with the Diaghilev ballet deteriorated when Diaghilev launched Nijinsky as choreographer; but he remained with the company until 1914, when he returned to Russia. Also in that year, he set down his manifesto on ballet in a letter to *The Times* (London), advocating the creation in each ballet of a new form of movement corresponding to the subject, period, and character of the music; that dancing and mime have no meaning unless they express dramatic action; that conventional

Fokine as Perseus in *Medusa*.

By courtesy of the Dance Collection, the New York Public Library at Lincoln Center, Astor, Lenox and Tilden Foundations

mime should be used only when the style of the ballet requires it; otherwise, meaning should be expressed by the movement of the whole body; that this expressiveness should extend from the individual to the group, to ensembles as much as to solos; and that there should be complete equality in the alliance of the component arts that make up a ballet—dance, music, and scenic and costume design.

Leaving Russia in 1918, Fokine made his home in New York from 1923. He worked with various companies in the U.S. and Europe, creating new ballets, such as *L'Épreuve d'amour* (1936) and *Don Juan* (1936). None of these later ballets, however, had the impact of his earlier work. He created his last ballet, a comedy, *Helen of Troy*, for the American Ballet Theatre. It was premiered at Mexico City on September 10, 1942, after he had died from pneumonia in New York City on August 22. His wife, the dancer Vera Fokina, who had performed in many of his ballets, survived him until 1958.

One of the few choreographers to come to a first rehearsal with very clear and complete ideas for a ballet, Fokine had great facility and speed in choreographic invention, intense musicality, and the ability to memorize an orchestral score. He was by no means equable at work. Tamara Karsavina wrote in her autobiography *Theatre Street* that "he was extremely irritable and had no control of his temper," but she emphasized that dancers became devoted to him.

The vocabulary of classical ballet has been enormously extended since Fokine's day, and subsequent audiences sometimes feel that his choreography is dated. Those of his ballets remaining in production have inevitably suffered distortion. He himself was conscious that this would happen. "The longer a ballet exists in the repertoire," he wrote in his *Mémoires*, "the further it departs from its original version. . . . After my death the public, watching my ballets, will think 'What nonsense Fokine staged!'"

**BIBLIOGRAPHY.** *Mémoires of a Ballet Master*, ed. by ANATOLE CHUJOY, trans. by VITALE FOKINE (1961), is a valuable but unfortunately heavily cut version of Fokine's own memoirs. CYRIL W. BEAUMONT, *Michel Fokine and His Ballets* (1935), is a thorough account to its publication date of the man and his work by an English ballet historian and critic.

(K.S.W.)

## Folk Dance

Folk dance, like "folk" and "folklore," is a controversial term. Though it is most commonly applied to the gay, recreational dances of various nationalities, its precise meaning is the subject of much debate among scholars and has not been fully resolved.

### NATURE AND FUNCTIONS

**Attempts at definition.** Folk dance should be the dance of the folk. Who are the folk? In dictionaries "folk" is synonymous with people. The term is defined succinctly in *Webster's New Collegiate Dictionary* (8th edition):

The great proportion of the members of a people that determines the group character and that tends to preserve its characteristic form of civilization and its customs, arts and crafts, legends, traditions, and superstitions from generation to generation.

The adjective "folk" relates folk products to the common people. In dictionaries there are many definitions of "folklore," including those of rites, dances, and music. Terms such as tradition, anonymity, and peasantry recur in these diverse explanations.

Scholars and dancers differ in what they admit under the label of "folk dance." One may see folk dance as the traditional dances of a country that evolve spontaneously from the everyday activities and experiences of its people. Another may define it as embracing only dances with magical and economic functions, or as comprising all nonprofessional dances.

The discussions dwell upon the confusion between such terms and concepts as "folk dance," "primitive dance," "ethnic dance," and "stage dance" and on the distinction between folk dance and modern recreational forms of ballroom dancing.

Remnants of primitive dance persist in Africa, Oceania, and South America, among peoples who have retained some degree of their aboriginal religion and ways of life. Such dance throws light on the origins of dance of the Western world. In its retention of its original functions, primitive dance is distinct from the dances of more sophisticated people, which may fluctuate between ritual and recreation.

The term "ethnic dance" seems flexible. Some authorities see no difference between the terms ethnic dance and folk dance. The eminent American dancer Ted Shawn, however, would have ethnic dance subsume folk dance as a subspecies. He considers pure, authentic and traditional racial, national, and folk dance to be "ethnic"; he calls the theatrical handling of them "ethnologic," and he refers to the free use of these sources of creative raw material as "ethnological." Although these distinctions are not hard and fast, they reflect the trend of much ethnic dance toward professionalization. In still another view, folk dance is the dance from which the art dance of a nation inevitably grows, both in technique and in spirit. This concept is particularly applicable to such nations and regions as Japan, India, and Andalusia, where art forms of the dance were a natural outgrowth of the traditional dances.

Purists are disturbed by a trend toward the deliberate "staging" of folk dances, and especially by their increasing professionalization: they might call the adaptations folkloric. Professional dance and secular folk dance have been distinguished as one might separate art from craft, even when the scenarios and choreography of modern dance and ballet adopt materials from folk dance or the larger field of folk culture. Most scholars, however, exclude from folk dance the dances of the commercial theatre, television, and film. Though they generally consider jazz dancing an American folk style, they would exclude formal choreographies in jazz style.

These selected points of view indicate the fluctuating boundaries of folk dance, especially in reference to its functions. Although patterns and movement styles are significant, the function and locale of folk dances have greatest weight in distinguishing them from primitive and theatrical manifestations. Frequently the dances of

rural peoples reveal their ritual origins on certain occasions, though they also serve recreational purposes. The origins may be very ancient. Generally, but not always, dances favoured in urban centres have secular purposes and may be of recent, perhaps consciously creative, origin. As in the case of folk song, the origin need not be anonymous, though usually it has been lost in the passage of time. Folk dances have grown out of creative inspiration, and they continue to sprout from the imaginations of individuals and groups, people of all classes who sense the traditions and the aspirations of their environment.

**Functions.** Many folk dances best reveal their ancient functions when performed in their native habitat. Outside this context, in a school gymnasium or on a stage, they lose their aura, but on the village green the British Morris dances and the Abbots Bromley Horn dance speak of renewed May Day vegetation and of Paleolithic elk worship. Again, some dances serve various functions. The Spanish Aragonese jota is best known as a rural entertainment for men and women, but it may enliven funerals or appear on American stages.

The above British examples reflect the transition from pagan to Christian religions and, in more recent times, the change from the attitudes of village and agriculture to those of town and industry and the consequent changes in social relations. As the English scholar Douglas Kennedy pointed out, when primitive religion weakens, some of the mystery and the magic departs from the dances that express it. The dancer becomes less a medicine maker than a performing artist as ritual changes imperceptibly into art. In short, man's social adjustment to the environment, for purposes of survival, created both the original dance rituals and their subsequent functional or formal changes. Vestigial animal dances echo ancient animistic rites. The Ainu tribes of northern Japan still mime bear and fox hunts, portraying the animals very realistically. In West Africa, an antelope hunt in dance has ritualistic overtones, while monkey mimes are for entertainment alone.

A far-reaching example of adjustment and change applies to the Balkans and to Central America. These far-removed parts of the world share ecological circumstances, notably a basically agricultural civilization. Geographically, both narrow into bottlenecks connecting two continents; both combine high and rocky mountain ranges with agricultural lowlands and uplands; both bulge into peninsulas seething with culture. Both have submerged their ancient religious customs to innovations, those of Catholicism and, in the Balkans, of Islām as well. Yet both have maintained their ancient native customs with such compromises as those to the events of the Christian calendar, Christian names, or Islāmic styles. Recently both areas have been receptive to the influx of 19th-century secular European dance forms and have transmuted these importations to suit the native styles.

**Combat and agricultural dances.** In both areas three dance types show varying degrees of modernization. One type, which takes the form of combat, remains highly ritualistic, albeit with a mixture of pagan and Christian elements. A second, agricultural in function, involves more of the community than the combative type and fluctuates between celebrations of sowing and harvest and of social festivities. The third type, derived from central and western Europe, is completely secular and social.

Male combat dances of the Balkans echo ancient pre-Christian rites for initiation into brotherhoods, the heralding of spring and of animal fecundity, and healing. Fierce battles ensue at the seasonal rituals of the Macedonians, of the Slovenes, and of the Romanians. Animal maskers and buffoons enact resurrection dramas. Along the coasts of Croatia and Dalmatia the battling factions have, under Christian influence, been renamed Moors and Christians or Moors and Turks. These battle dances have relatives in other European countries, from Spain to Great Britain. They also have relatives in Central

Dance as ritual and entertainment

Varieties of folk dance

America, where early Spanish missionaries introduced Moors and Christians to replace the earlier ritual combats of the Indian populations.

Rural celebrations of planting and of harvests feature communal round dances, such as the *kolo* of Yugoslavia, the *horo* of Bulgaria, the *hora* of Romania, and a variety of Greek chain dances. The celebrations include vestiges of ancient vegetation festivals, impersonations of fertility deities, and "rain magic." The same rounds, however, appeared also at weddings and other secular or semisecular gatherings. Such rounds survive in the mountains of Mexico as *mitotes*. Although they concluded most Aztec and Mayan ceremonies, they have become scarce since the Spanish Conquest. They are still performed to procure rain and an abundant harvest.

**Secular forms.** Rural and urban gatherings include the social square dances and couple dances for men and women. Within the last century the Bohemian polka, the Austrian waltz, the Polish mazurka, and the Hungarian czardas have appeared in the northern Balkans. In Central America similar social and courtship dances have become increasingly popular. Each region has a version of the dances known as *jarabe* or *huapango*. The *jarabe tapatio* of Jalisco, better known as the Mexican hat dance, combines steps from many European nations. All regional dances use polka or waltz steps and European music. With their lively and showy styles, these couple dances are suited to stage performances and occur as such.

In other parts of the world, folk dancers are shifting from a man-deity and man-nature purpose to a man-man or male-female attitude. This is noticeable not only in adaptations of former dances of supplication but also in dances miming agricultural and other occupations, as the Polish sowing of rye and oats, the Hungarian hay-making, the Swedish flax reaping, the clothes washing of Denmark, and the spinning mime of Spain. Some of these occupational dances derive from enactments by medieval guilds or from the mime in medieval branles. They survive as entertainment in adult couple dances and in children's games, often in settings remote from their origin.

In the course of centuries, changes in the beliefs and in the methods of producing the essentials of life have produced numerous adjustments such as the adaptation of the calendar from a basis in agricultural ecology to a basis in Christian festivals and the resultant shifts in the organization of dance groups.

**Occasions for dancing.** Notwithstanding the trend toward sociable and theatrical objectives, many folk dances celebrate original festivals. In Europe and Europeanized America, however, they show many adjustments to the Christian feasts. In the Balkans, Austria, and other countries the long series of dances for renewed vegetation and life now celebrate Epiphany (Twelfth Night), Carnival, Easter, Pentecost, Corpus Christi, and St. John's Day (June 24). As noted previously, the midwinter dances emphasize male combat and animal impersonations, whereas, the springtime dances dwell on new vegetation, in southerly climates on first fruits. Two festivals are particularly spectacular—Carnival and Pentecost.

Carnival festivals of Europe and the Americas precede Lent, filling the three days before Ash Wednesday. In Austria they perpetuate many pagan dances, particularly in Innsbruck and Imst, with the masked and ghostly phantoms and witches and noisy processions with songs, bull-roarers, drums, and whips. In Spanish and Latin American villages the unruly characters enact a more orderly "combat of winter and summer," in the guise of the ancient Moors and Christians, with the obvious victory of summer. Devils and deaths (*diablos y muertes*) are also on the loose in the role of buffoons. Morality plays are relics of medieval ideology, with speeches in the local vernacular and decorous steppings of Sin, Death, the Devil, Pastorcitas (shepherdesses in white communion dress), and masked animals from the Garden of Eden or bears or tigers.

Urban carnivals bring out animal maskers, deaths, and

devils, without ritual connotations in, for instance, Munich. The famous carnivals of Rio de Janeiro and New Orleans draw huge crowds of tourists to observe the masking, competitive parades of floats, and street and ballroom dancing. In the Brazilian medley the street and ballroom dances show interesting contrasts: the samba in the streets is ecstatic, improvisatory, and disorderly, whereas the samba of the ballrooms is more sedate and has set steps. Such urban carnivals have lost sight of the original ritual purpose.

On the other hand the observances of Pentecost, the springtime feast that falls 50 days after the Christian Easter, fit the dances into a framework that meaningfully combines Christian and pre-Christian, New and Old Testament, forms. The Jewish Shavuot festival follows by the same period the Passover, which often coincides with Easter. The Pentecost, known also as Whitsunday, has since AD 200 commemorated the descent of the Holy Spirit on the Apostles, and the Shavuot, originally a feast of thanksgiving for first fruits, has been associated by rabbis with the giving of the Law at Sinai. Both express the joyous resurgence of animal and spiritual powers and of new vegetation.

In the southerly climates the festival may already celebrate the first fruits. Everywhere Jewish celebrants bring offerings of fruits and flowers to the temple, with chanting and prayers. In Haifa, Israel, white-clad youths and maidens dance and sing. In Yugoslavia and Slovenia girls dance for Pentecost, and the community winds in snakelike kolos. In England the community circles around a tree, then around the church, or it holds a maypole dance. In some villages, such as Bampton-on-the-Bush and those of the Cotswolds region, "Morris men" dressed in clean white caper and leap in a procession or in double files, waving white kerchiefs or green branches. The dancers may have the company of clowns, a Jack-in-the-Green clad in greenery. In some English villages and in British-inspired American locations, such dances take place on May Day rather than Pentecost.

Agricultural festivals, especially harvests, may adjust their dates not only to the local climate but to the particular year's weather. The Iroquois Indians of New York State and Ontario adjust their calendar to the ripening of the crops of berries, beans, and corn. They may hold their thanksgiving rounds for green corn between the third week of August and the middle of September. The square dances of the American farmers were held on the occasion of husking bees—before combines took over the work—whenever the corn was ready. Farmers continue their square dances, or "country dances," in barns or in grange halls at odd times or even weekly. Their urban imitators perpetuate these dances assiduously when square-dance and folk-dance societies, often mingling the traditional American dances with those of immigrant peoples, meet in national halls or centres, school or college gymnasiums, or other locations. The gatherings of these enthusiasts and analogous groups on both sides of the Atlantic are legion.

Certain secular or semisecular celebrations adhere to a definite date. Such political holidays as the French Independence Day (July 14) and the Mexican national holiday (May 5) and Independence Day (September 16) feature regional dances outdoors and at indoor balls. The Guelaguetza at Cerro Fortín, Oaxaca, formerly a ritual festival, now combines religious and regional dances for the general public on July 16. Such festivals attract vast numbers of dance teams, native visitors, and tourists.

#### FORMS AND TECHNIQUES

**Organization of participants.** Although attendance at such public fiestas is haphazard, the participants in many dance gatherings observe closely knit organization and definite rules for the individual's place in the community and in the communal dances. The men in European combat dances belong to a sworn brotherhood of ancient origin. The male and female members of a Mexican votive society, the Concheros, have an intertribal hierarchy paralleling that of the forces of the conquistador Cortés.

headed by a *capitán general*. In second rank are the officials of each local group, first and second captains, sergeants, standard bearers, each with specific duties, followed by the common rank of *soldados* and, finally, such attendant characters as Cortés' interpreter-mistress Malinche, the devil, sorcerers, and mythological figures. At present they do not regulate their rituals according to the calendar, though their ancestors probably did.

Although such societies cut across family ties, other organizations are based on descent, especially among American Indians. Iroquois and Pueblo Indians group their clans into two moieties, or halves, of the entire social scheme, matriarchal and patriarchal respectively. In their ceremonies and social events the Iroquois stress the interaction of moieties, with the alternation of moieties in the dance file. However, the New Mexican Pueblos usually feature separate dances for the two moieties and even assign festivals of the two seasons to the summer and winter moieties.

*Sex and age roles.* These same tribal groups also observe strict regulations according to sex. Iroquois women manage the summer rites for agriculture; the men manage fall and winter ceremonies for animals and cures. Among the Iroquois as well as the Pueblo, men and women hold esoteric dances separately, or men occupy one-half of the dance line and women follow in the second half. In less sacred dances and always in social rounds men and women alternate. Observers report similar customs not only among the natives of the New World but also in the Old, as in Serbia and Great Britain. Men perform the traditional Morris and sword dances, but the sexes mingle in country dances, reels, and quadrilles. The solos in Scottish sword dances are traditionally male performances, but, as a nonauthentic deviation, girls may now execute the tricky steps of the dances.

The traditions of age grades are also becoming diluted. From Greece to New Mexico, almost universally, the older, experienced men and women are the leaders, while the children bring up the rear of dance lines as apprentices. Warrior societies of Great Plains tribes of the United States once observed strict gradations of dance rituals according to age. But these societies are all but extinct, and public war dances admit all ages of males, with females in the background. With the dissemination of folk dances into the schools, children are learning adult routines. However, in remote villages of Europe youngsters have their special dances, and adolescents may enter the adult circles modestly.

*Individual and ensemble dances.* Generally the individual is submerged in the larger society and must fit into the dance group harmoniously. Some peoples, the Pueblo Indians for example, uphold strict standards of restraint, and within the natural variations of greater or less energy, a member of a dance group should not show off. However, other peoples such as the Iroquois appreciate improvisatory clownery or virtuoso display by talented males. In the Balkans the male leader of a dance line may engage in acrobatics—crouches, leaps, or pivots—while the rest of the group adheres to the traditional steps. In the Basque provinces of Spain, in the Ukraine, and in Poland male experts have the opportunity to display high kicks or spectacular leaps. The improvisations of these privileged experts have often led to the introduction of permanent new elements into the dances.

*Styles of movement.* Function, sex, and age all have an effect on a dancer's style of movement. Other psychological factors of group and individual temperament and mood have, for untold centuries, determined the quality and the type of steps and gestures. The climate and topography may have had an effect on the development of regional styles.

*National and regional style.* According to Douglas Kennedy, the ideal of English folk dancers is to hold the body in a straight line from head to toes, creating a vertical equilibrium that makes the dancer light on his feet. This uplifted carriage allows him to reach out and form the contact essential for a unified dance ensemble. This ideal would apply to many folk dance types of

Carriage of  
the body

Europe, the United States, and Canada, and to some Asiatic round dances, but it does not fit the more dramatic dances of the British Isles nor myriad dances in other parts of the world. Even within England, Kennedy points out the frequently bent-up position and the power of male sword dancers.

In Spain the erect ease of Aragonese line dances contrasts with the swaybacked incisiveness of Andalusian flamenco dances. In Yugoslavia the eastern villages have acquired the vibrations of Turkish dancers, and gypsies use more undulating movements than the Serbs about them. In Asia such hill tribes as India's Todas circle with simple steps and an erect posture, whereas demon dancers of the Pariah caste stamp and leap, and the practitioners of the ancient *Nāṭya* style combine elaborate, symbolic hand gestures with body sways and stamps.

Although India's caste system has produced extreme contrasts, differences in occupation and social class have everywhere affected the spirit and quality of movement. During the late Middle Ages and Renaissance the courtiers who borrowed such rural dances as the branle and the bourrée watered down their rustic vigour. In 19th-century colonial California the descendants of upper class Spaniards performed the polkas, mazurkas, and waltzes with an elegance that contrasted with the rowdy renderings by the gold miners.

*Variations by sex.* In modern square dancing the difference between male and female styles is negligible, but in most folk dances the women move more gently than the men, with smaller steps, lower leaps, and less raising of the knees or feet. The women dancers have a more sinuous, alluring style in southern Spain; they spin gently in the Austrian and Bavarian *Schuhplattler* and the Caucasian *lezghinka*, while the men jump, clap, and shout. Among American Indian tribes the women have a more subdued style and often special, tiny steps except in couple dances that have been adapted from the mainstream of Western social dancing.

*Ecological influences.* The setting affects the movement style. Joan Lawson suggests differences due to the natural environment—a theory that will need more investigation. She maintains that in rich agricultural plains or river valleys, such as the Danubian Plains and parts of France, and Denmark, movements are accented downward as if the body were being drawn toward the soil. Dancers perform in large groups, using the same step, closely linked together by fingers, hands, elbows, or shoulders. By contrast, in mountainous areas there is a good deal of leaping and individual display, especially among the males.

*Mimetic and abstract movements.* Regional variations include preferences for mime or for abstract movements. India's folk dancers and, half a world away, those of Scandinavia favour mimetic gestures, respectively graceful and comic. Serbia's peasants are interested in purely decorative steps and Ireland's experts are fond of tricky solo steps or complex group patterns that are in no way imitative of outside phenomena. In general, the mime of folk dancers is stylized, having lost the realism of the primitive animal impersonators and of actors in folk dramas.

Opportunities for mimetic dancing are drastically reduced when the hands are required for other formal patterns of the dances. Most folk dancers use their hands and arms for contact in circles, lines, or couples; they wave kerchiefs, as along South America's Pacific coast; they swing soft balls in complex patterns, as in the *poi* dance of the New Zealand Maoris; the women swirl full skirts, as in Spain and Mexico; or everyone lets the arms hang loose or places hands on hips, thus emphasizing foot and ground patterns.

In India, dance-dramas based on the life of the god Kṛṣṇa (Krishna) are enacted in Manipur by young women who use simplified gestures descended from the large, complex system of hand gestures known as *mudras*. The basic gestural symbols derive from the wrist position, the position of the palm, and the poses of the fingers. Each gesture has its prescribed musical accompaniment. A

Influence  
of the  
physical  
environ-  
ment

Stylized  
gestures  
and  
motions

trembling leaf, for example, is symbolized by the *alapalava*, a rotation of the wrist accompanied by a folding and unfolding of the fingers. In Hawaii, a few older women can execute hula gestures clearly descended from the mudras, but younger dancers have diluted the tradition by introducing purely decorative gesture.

In Scandinavian countries male and female imitators of occupations likewise stylize their harvest motions. The youths who portray rough-and-tumble fights, as in the Swedish oxen dance, duel good-naturedly, pull each other's hair, and pretend to box one another's ears. In this last gesture, as in the German *Watschenplattler*, the aggressor merely pretends to touch his opponent, who claps his hands to simulate the blow.

Slavic men and some other skilled performers use steps recalling former animal mime, as the goatlike caper or cabriole, the pawing horse-step or pas-de-cheval, the side-kicking, cowlike rue-de-vache, and the feline pas-de-chat leap. But folk dancers of many nationalities exploit the imageless mazurka or variants of the polka, waltz, and twostep, all in appropriate rhythms. The walking, running, sliding, skipping, or jumping movements are so universal in folk dance that they cannot, by themselves, be considered mimetic.

On the one hand, line dancers of a single region may develop intricate variations of a basic step. Lawson identifies 15 ways of performing the basic kolo step, a step-to-the-side and close. The variants include gliding, swinging of the free leg, crossing, jumping. On the other hand, a widely disseminated step may appear in many forms in different regions. The triple-time waltz is step-together-step in Austria, with pivots at specific times. As the Mexican *atole* step it is forward-back-forward; in the Venezuelan joropo every first beat is heavily accented. As a ballroom dance it reveals diverse patterns: as a propelling step in Spanish and New Mexican quadrilles, a light-footed waltz may balance from side to side, progress forward or backward, or go round and round.

The type of step depends also on the purpose of the dance, whether a solemn processional or an exhibition of skill in leaps or crouches; on the sex or age of the various participants; and on the type of ground plan.

**Ground plans.** Simple circling leaves the dancer's attention free for elaborate steps, whereas complex ground plans take the mind away from stepping and necessitate the simplest kind of progression by walking or running. Throughout the world the erstwhile ritual dances may involve a simple run, as in the Iroquois corn and bean dances and the serpentine stomp that spread from the ancient Aztecs to Indian agriculturalists of the U.S. Choreographies may combine complexities of step, of rhythm, and of ground plan, like the "game animal dances" along the Rio Grande, but as a rule they emphasize one or another factor.

The Balkan chain dances feature intricate steps and rhythms, but simple formation of closed or open circles. During closed rounds the men and women remain within the same spot as they inch along counterclockwise. Likewise, participants in French branles circle on location, usually clockwise—the typical direction of northwest Europe. In chain dances the circle is not closed. A leader guides the line, linked by hands or a prop, in meanders and spirals perhaps across open fields. On reversal a tail man will guide the meanders. Such serpentine, of ancient origin, are favourites in the Near East; throughout Europe, especially as the French farandole and the Catalan sardana; in North America, in both native and Europeanized dances; and in such parts of Asia as Manipur. They predominate among agricultural peoples, for they originated in chthonic symbolism.

A specialized form of meander is called the hey in England. Two lines of dancers weave past each other in opposite directions. In a circular formation this is known as the square dance "Paul Jones" or, if the participants are attached by ribbons to a central pole, as a maypole dance. Here the two opposing groups are or should be male and female. The most elaborate form akin to the hey is the *kolattam*, a stick dance of South India. In the *pinnal*

*kolattam* the dancers weave in and out, at the same time striking short sticks in precise patterns. (The intricacies were diagrammed by Hildegard L. Spreen: see Bibliography.)

Dances in two parallel lines have a more limited distribution. As in the case of rounds, the performers may start shoulder-to-shoulder or aligned in the same direction. The lines may cross over or circulate in opposite directions, or pairs of dancers can cross directly or diagonally. Morris dancers use a large vocabulary of interlacings, which resemble those of the American "Virginia Reel"; respectively, the participants are men only and men-and-women. Multiple parallel lines of men and women are customary in Southeast Asia and the South Pacific; Cambodian girls display elegant poses; Balinese men carrying spears mass together in the *baris* dance; and while executing the warlike gestures of the *peruperu*, Maori men remain in one spot.

As noted previously, ritual principles often dictate that in more sacred dances the sexes be separated, whereas in more secular dances they usually alternate or are aligned face-to-face. In modern folk dances, couples circulate within circular formations, as in Moravian rounds and American square dances, or in the extremely elaborate Irish reels of eight couples. In ballroom dances couples generally ignore any geometric designs, and individuals ignore the rest of the group.

In the "possession rite" of Ghana's Akhan society, circle dances by devotees, frenzy dances, and circling by everyone alternate with prayers, chants, offerings, and speeches. A similar structure is evident in the possession dances of Brazil and Trinidad and of the Christian Holiness services in the U.S.

**Couples and solos.** In the course of history the general trend, during secularization, has been toward increasing complexity, from round or double file to quadrilles, and then from cohesion to a breakup into couples and solos. This disintegration is distinct from the individualism that may be present in primitive dances, for there the soloist had a mimetically compulsive, even priestly, function and was the focus of group activity. Concurrent with the elaboration of patterns, the symbolism has been disintegrating. The vegetation symbols of meanders and arches have been lost, but the designs remain. Face-to-face formations and couple arrangements retain meaning as courtship actions, and despite the loss of the modern folk dancer's relation to, or attempt to act upon, the physical environment, the social contacts between dancers remain.

The type of ground plan affects the contacts between not only the dancers but also the dancers and the spectators. Square dances offer the maximum possibilities of intermingling within a formation, but they exclude spectators. Chain dances lack the give-and-take, but they may wind about or through the spectators, who may enter at any time. Contact, whatever form it may take, is essential to folk dance.

**Accompaniment to the dance.** The evolutionary process in the relations between the dance and other arts is very similar to the development of the dance itself. From the nearly total integration of dance and life in primitive ritual to modern rock-and-roll, many factors—the passage of centuries, the change from animism to Christianity, the shift from hunting, agriculture, and handicraft to industrialization, the trend from country to city, from sanctuary to village green to stage—have exerted a profound influence on the totality of dance experience.

In the esoteric dance rituals of Australia, in the mythological dance enactments of India and Indonesia, in Nigeria and such of its distant New World derivatives as the vodun, dance is immersed in the larger drama of the rite. The symbolism of the movement patterns is locked into the symbolism of song texts, the traditional music, and the meaning of masks and costumes, not to speak of the setting in a sacred grove. Here and there the decorative invocations to animistic spirits have survived, mysteriously, in the masked animal ghosts of the Austrian Alps, in the "game animal dances" of New Mexico's Tewa Indians. Perhaps these vestiges are not really folk

formations

dances. Perhaps folk dances—that is, dances of the people—do not require the integration of all of the arts for gatherings or programs.

*Music.* In general, the musical accompaniment to folk dances has persevered fairly well. In village and urban hall the devotees use the tunes intended for particular routines, though these tunes may be played on modern instruments. Morris dancers usually preserve the traditional order of a suite—Laudnum Bunches, Bean Setting, Rigs o'Marlow, Shepherd's Hey, Constant Billy. In the execution of isolated kolos, ländler, or country dances, natives and imitators fit the steps to traditional tunes, to live music, piano, or recordings, which may feature old-time clarinets, tabours, drums, and even band arrangements or accordions.

The coordination of tempo and rhythm between dance and music is rarely problematic. It is easy to follow the slow and the fast tempo of a set like the Norwegian *gangar* and *springar*, or the acceleration of an Israeli hora. It is easy to follow the metres of the polka, of the waltz with its accent on the first beat, or of the mazurka with its accent on the second, although the melody may have independent rhythms. It takes more skill to follow some of the Bavarian tunes that shift their metres, and it takes an expert to follow the unusual metres of Greek and Serbian dances, especially when the phrases of the tunes overlap the phrases of steps.

*Self-accompaniment.* It takes practice also to provide self-accompaniment in rhythm or melody. Rarely do folk dancers provide their entire self-accompaniment, as do the Mexican *viejitos* who play small stringed jaranas, or Hawaiian hula dancers who chant and shake rattles. Frequently, the dancers add percussive effects to the accompaniment by special musicians. They stamp on the ground, on the floor, or on a resonant platform with bare feet, boots, or high-heeled shoes, sometimes in complex counter-rhythms. Hungarian men click spurs; Russians click the heels of their boots as they leap. Austrian and Bavarian *Schuhplattler* males swat various parts of the anatomy in set rhythms. Sword dancers click swords; stick dancers click sticks in Spain, Portugal, England, Mexico, Brazil, and India. Andalusians punctuate their incisive foot rhythms with crisp sounds of finger castanets; Greek males click spoons in their *zabakelos*; and American Indians sometimes shake rattles. In such secular dances as the Cuban rumba or Argentinian *carnavalito*, accompanists use rattles. Sound makers may be attached to the costume, as the bell pads of Morris dancers or the ankle bells of India's nautch dancers. In many parts of the world exuberant dancers dispense with instruments and clap or shout at specified times or whenever the spirit moves them. They may also sing to various instruments or without instrumental accompaniment.

*Song.* Self-accompaniment by song is significant for several reasons. First, it is probably one of the most ancient forms of accompaniment because of the independence from any instruments. Second, it is aesthetically pleasing. Finally, the songs have texts of historical, sociological, or ecological importance. Such singing may be in unison, with women's voices an octave higher than the men's; it may employ harmonies characteristic of the region, with intervals of a third or a fourth, and it may involve antiphony between a leader and the dance group or two groups of dancers. Such antiphony occurs in widely separated parts of the world, frequently in connection with serpentine chain dances as in Manipur and in America's Southeastern woodlands. Frequently the responses use nonsense syllables, and they may involve gestural responses, as in the Cherokee "stomp dance" and its predecessor, the ancient Aztec serpent dance.

The song texts are varied. The most frequent topics are courtship, as in the "Llorona" of Mexico's Tehuantepec, or sheer joy, as in the German "Freut euch des Lebens." In the Faeroe Islands the topics are narratives from legends, which are mimed by the round dancers. Sometimes the topic refers to agriculture, as in the French Canadian children's round, "Avoine" ("good grain").

The previous remarks mentioned the sound-producing

items of costumes, as boots and bells. Visually effective items include kerchiefs and female full skirts, which permit numerous manipulations. Other visual effects are the designs of regional dress in the various countries, from the flouncy flamenco skirts to the white trousers of sword dancers. In the United States square dancers sometimes affect full skirts for women and plaid shirts for men.

#### CONTEMPORARY TRENDS

Two contrasting modern trends are the development of American jazz dance and a revival of interest in traditional folk dances of various nations.

*Jazz dance.* The many forms of jazz dance represent virtually the opposite end of the scale from primitive ritual, with only ballroom dancing at a further remove. Jazz dancing owes much of its inspiration to African sources, to various tap dances of the vaudeville and minstrel stage, and to one- and two-steps of early 20th-century ballroom dancing. Decade by decade fashions in ballroom and jazz dancing changed, as the paths diverged.

In an outburst of "danceomania" after World War I, the "shimmy" and "grizzly bear" involved couples in a tight clinch. But soon the leg-flinging Charleston and Lindy demanded solo or couple acrobatics, at their best in Harlem's Savoy Ballroom. In the "swing era," the 1930s, the Big Apple integrated solo and couple improvisations with a group circle. Within a form of refrain and variations, men and women in a circle executed grotesque steps and gestures, cries of "Praise Allah," and the like; then, on a leader's call, an individual or a couple improvised on boogie-woogie steps. The steps had such names as mooch, sand, duck-walk, camel-walk, Rochester, fish-tail, truck-in', and Suzy Q. Despite some of the names, the steps were only vaguely mimetic, and not at all derived from the natural environment. They returned to deepest Africa in the insistent, flat-footed emphasis, the sway-back posture, the bent or overstretched leg, the full use of the entire body in motions at one moment barely perceptible, in the next daringly acrobatic.

This quality persevered into the 1950s, sometimes in orderly patterns of face-to-face lines, as "the stroll"; sometimes in ludicrous pantomime, as the "cowboy chicken" stylizing horseback riding, and "drivin' home," with its imitation of automobile driving.

Gradually the beat changed as rock-and-roll combos usurped television and radio. Couple contact loosened up during the craze of the "twist," about 1962, a craze that spread to all parts of the world including Africa. Then television brought two kinds of rock dancing: trained groups in stylized routines, and jam sessions with increasing isolation of the individual. Subsequently teenagers milled around, squirmed with masklike expressions, and bounced vertically, because crowding prohibited any horizontal formation.

These developments of America's unique folk dance and its worldwide contagion appeared to be on the last lap of dissociation between man and nature, even between person and person. The only possible evolutionary direction might be a return to group cohesion and geometric pattern, a turn back toward a dance more closely allied to nature.

*Revivals.* The other trend, the revived interest in national folk dances, is equally dissociated from ecology, unless a folk dance group has a leader with folkloric knowledge. Folk dancing inspires the weekly gatherings of groups in civic centers, colleges, and other centres, even the entire schedules of summer folk-dance camps. Congresses sponsored by the Folk Dance Federation of California produced a uniform repertoire for groups throughout North America. In addition, new immigrants introduced occasional new dances. Most of these groups dance for the sheer pleasure of dance, and more expert ensembles stage programs and enter contests, both in the New and Old World. But although such revivals and the consequent preservation of traditions were heartening and brought about good fellowship, healthful exercise, and, avowedly, international understanding, such danc-

dances

ing had no connection with the aboriginal purposes of folk dancing, which continued only in villages or on Indian reservations.

#### Role of costuming

The modern style of costuming was a far cry from the masks for spirit impersonators and the symbolic designs painted or woven on all costumes of the ritual dances. Such paraphernalia survived in some dances that straddle ritualism and folk dance, as the animal and corn dances of the Pueblo Indians. But the trend was increasingly toward contemporary dress. Even the Iroquois ritualists usually wore ordinary clothes. Members of folk dance clubs rarely wore traditional costumes at their informal gatherings, although these clothes were customary for staged programs. And the jazz dancers wore the current dress, formerly full skirts, later tight, short skirts for girls and Levi's for boys.

As a contrasting trend, professional folkloric troupes exaggerated costume effects, doubled the volume of skirts, added spangles, and increased the instrumental volume and the tempo. Frequently the directors composed scenarios, as in the reconstructions of Aztec rituals by the Ballet Folklórico de México. Their spectacles had a great audience appeal, compensating in part for the nonkinetic and the prosaic in modern folk dancing.

**Continuity and change.** The folk arts are by and large expressive of traditions deeply rooted in the life styles and in the social organizations of peoples and cultures throughout the world. But as those styles and organizations change over time, in response to environmental, economic, technological, and other factors, so do the concomitant artistic expressions evolve in terms of function, form, and mode of existence. But change has been brought about, too, by the creativity of individuals and of cohesive groups.

#### Influence on other forms of the dance

Professional dancers found folk materials a rich source of inspiration that they used in several ways. Authentic dances were intensified for the stage by such companies as the Philippine Bayanihan troupe and the Ceylon National Dancers. The sophisticated dance-dramas of India's Uday Shankar, who performed widely in the West, often contained folk dances. His work with the Russian ballerina Anna Pavlova in *Radha and Krishna* showed, too, the rich potentialities for East-West collaboration. A folk atmosphere can be evoked without using folk materials, notable in *La Malinche* by José Limón. Finally, seemingly incompatible styles were fused: Mary Wigman was among the first to blend the rather stark idiom of modern dance with the ornate and exotic styles of the Orient.

Although the origins of many traditional dances are lost in a nebulous past, the observed emergence of new forms may give clues to the age-old processes of change. Inspired individuals may have molded the patterns of the ancient round-dance figures much as numerous leaders of dance in the 20th century have invented variations on the steps or devised steps and patterns to fit new rhythms, passing on their innovations by teaching or imitation. Again, creators have developed entire new dance structures from traditional materials, as the choreographers of modern Israeli dances have done most skillfully.

Another inevitable process is that of crystallization. For various reasons—sanctity, nostalgia, or whatever—groups tend to maintain routines through time. But not forever. If a dance does not die of old age, of having totally outworn its function and of having a form or spirit out of tune with a new age, it will continue to gain new life from improvised variations on basic steps or ground plans or from conscious elaborations of its forms by professional directors of ethnic dance groups and programs. Such kinds of creativity, individual and group, contribute to that constant cycle of orderly change within traditional parameters which accounts for the rich variety of the dances of the people.

**BIBLIOGRAPHY.** V. ALFORD and R. GALLOP, *The Traditional Dance* (1935), authoritative, popular account of Europe's ancient ritual dances; C.M. BARBEAU (comp.), *Roundelays: Folk Dances and Games Collected in Canada and New Zealand* (1958), children's mimed rounds from French Canada,

with descriptions, music, and bilingual texts; E. BURCHENAL, *Folk-Dances from Old Homelands* (1922), descriptions of European folk dances, for use in schools; N. CHILKOVSKY, *American Bandstand Dances in Labanotation* (1959), notations of jazz dances, for reconstruction by experts in the Laban system of notation; L.K. ## Folk Literature

Folk literature is the lore chiefly of unlettered peoples transmitted by word of mouth. It consists, as does written literature, of both prose and verse narratives, poems and songs, myths, dramas, rituals, proverbs, riddles, and the like. Nearly all known peoples, now or in the past, have produced it.

Until about 4000 bc all literature was folk literature, but beginning in the years between 4000 and 3000 bc writing developed both in Egypt and in the Mesopotamian civilization at Sumer. From that time on there are records not only of practical matters such as law and business but increasingly of written literature. As the area in which the habitual use of writing extended over Asia, North Africa, and the Mediterranean lands and eventually over much of the whole world, a rapid growth in the composition of written literature occurred, so that in certain parts of the world, literature in writing has to a large extent become the normal form of expression for storytellers and poets.

Nevertheless, during all the centuries in which the world has learned to use writing, there has existed, side by side with the growing written record, a large and important activity carried on by those actually unlettered, and those not much used to reading and writing. And when the earth as a whole is considered, and all those people included to whom the use of writing has not yet come, even now the majority of men and women on the earth are still using folk literature, since it is the only kind they know.

### ORIGINS AND DEVELOPMENT

Of the origins of folk literature, as of the origins of human language, there is no way of knowing. None of the literature available today is primitive in any sense, and only the present-day results can be observed of practices extending over many thousands of years. Speculations therefore can only concern such human needs as may give rise to oral literature, not to its ultimate origin.

Nor can any evolution in folk literature or any overall developments be spoken of explicitly. Each group of people, no matter how small or large, has handled its folk literature in its own way. Depending as it does upon the transmission from person to person and being subject to the skill or the lack of skill of those who pass it on and to the many influences, physical or social, that con-

Early  
develop-  
ment

sciously or unconsciously affect a tradition, what may be observed is not evolution but only continual change. An item of folk literature sometimes shows relative stability and sometimes undergoes drastic transformations. If these changes are looked at from a modern man's point of view, judgments can be made as to whether they are on the whole favourable or unfavourable. But it must be remembered that the folk listening to or participating in its oral literature may have completely different standards from those of their interpreters.

Nevertheless, two directions in this continually changing human movement may be observed. Occasionally a talented singer or tale-teller, or perhaps a group of them, may develop techniques that result in an improvement over the course of time from any point of view and in the actual development of a new literary form. On the other hand, many items of folk literature, because of historic movements or overwhelming foreign influences or the mere lack of skillful practitioners of the tradition, become less and less important, and occasionally die out from the oral repertory. The details of such changes have been of great interest to all students of folk literature.

The beginnings of written literature in Sumer and Egypt 5,000 or 6,000 years ago took place in a world that knew only folk literature. During the millennia since then written literature has been surrounded and sometimes all but overwhelmed by the humbler activity of the unlettered. The emergence of the author and his carefully preserved manuscript came about slowly and uncertainly, and only in a few places initially—the literary authorship that flourished in the Athens of Pericles or the Jerusalem of the Old Testament represented only a very small part of the world of their time. Nearly everywhere else the oral storyteller or epic singer was dominant, and all of what is called literary expression was carried in the memory of the folk, and especially of gifted narrators.

All societies have produced some men and women of great natural endowments—shamans, priests, rulers, and warriors—and from these has come the greatest stimulus everywhere toward producing and listening to myths, tales, and songs. To these the common man has listened to such effect that sometimes he himself has become a bard. And kings and councillors, still without benefit of writing, have sat enthralled as he entertained them at their banquets.

This folk literature has affected the later written word profoundly. The Homeric poems, undoubtedly oral in origin and retaining many of the usual characteristics of folk literature, such as long repetitions and formulaic expressions, have come so far in their development that they move with ease within a uniform and difficult poetic form, have constructed elaborate and fairly consistent plots and successfully carried them through, and have preserved in definitive form a conception of the Olympic pantheon with its gods and heroes, which became a part of ancient Greek thinking.

Not everywhere has the oral literature impinged so directly on the written as in Homer, which almost presents a transition from the preliterate to the literate world. But many folktales have found their place in literature, from the "Cupid and Psyche" of Apuleius down to the present. The medieval romances, especially the Breton lays, drew freely on these folk sources, sometimes directly. It is often hard to decide whether a tale has been learned from the folk or whether a literary story has gone the other way and, having been heard from priest or teacher or doctor, has entered oral tradition and has been treated like any other folktale or folk song. The unlettered make no distinctions as to origins.

Influence  
on  
modern  
literature

As the European Middle Ages lead into the Renaissance the influence of folk literature on the work of writers increases in importance, so that it is sometimes difficult to draw a sharp line of distinction between them. In literary forms such as the *fabliaux* there are many anecdotes that may have come ultimately from tales current among unlettered storytellers, but these have usually been reworked by writers, some of them belonging in the main stream of literature, like Boccaccio or Chaucer.

Only later, in the 16th and 17th centuries, in such works as those of Straparola and Giambattista Basile, did writers go directly to folk literature itself for much of their material.

Since classical times composers of written literature have borrowed tales and motifs from oral narratives, and their folk origin has been forgotten. Examples abound in Homer and *Beowulf*. In their literary form these stories have often lived on side by side with tellings and retellings by oral storytellers. Modern examples of traditions so used are found in Ibsen's *Peer Gynt* and Gerhart Hauptmann's *The Sunken Bell*. Particularly frequent in all literature are proverbs, many of them certainly of folk origin.

In Finland a good example of the direct use of folk literature in the construction of a literary epic is seen in the *Kalevala*, composed by Elias Lönnrot in the 1830s, primarily by fusing epic songs that he had recorded from Finnish singers. The *Kalevala* itself is a national literary monument, but the songs Lönnrot heard are a part of folk literature.

Writers and songmakers have always used themes taken from oral legends and folk songs and in their turn have affected the traditions themselves. In recent years the cinema has presented old folktales to an appreciative public, and interest in folk songs especially has been stimulated by the radio and television. Inevitably this oral literature has become less truly oral, and much pseudofolk literature has been presented to the public, habituated as it is to the usual literary conventions.

Within urbanized Western culture it is clear that folk literature has been gradually displaced by books and newspapers, radio, and television. Persons interested in hearing authentic oral tales, traditions, or songs must make special efforts to discover them. There still exist isolated groups that carry on such traditions—old people, recent immigrant enclaves in cities, and other minority populations, rural or urban. Children are also important for the carrying on of certain kinds of oral traditions such as singing games, riddles, and dance songs. These go on from generation to generation and are added to continually, always within an oral tradition.

During the past few generations folk festivals have flourished. These have become almost worldwide and of the greatest variety. They are likely to revive older dances or bring in new ones from other countries, but they also have some singing and occasionally tale-telling. Usually a real attempt is made to keep them within the authentic local tradition, and they have been a stimulus to the preservation of a disappearing phase of modern life.

If folk literature is actually dying out, the process is very slow. It is now, as it has always been, the normal literary expression for the unlettered of all continents.

#### CHARACTERISTICS OF FOLK LITERATURE

The most obvious characteristic of folk literature is the fact that it is oral. In spite of certain borderline cases it normally stands in direct contrast with written literature. The latter exists in manuscripts and books and may be preserved exactly as the author or authors left it, even though this may have happened centuries or even millennia ago. Through these manuscripts and books the thoughts and emotions and observations and even the fine nuances of style can be experienced without regard to time or distance. With oral literature this is not possible. It is concerned only with speaking and singing or listening, and this depends upon the existence of living people to carry on a tradition. If any item of folk literature ceases to exist within the memory of man it is completely lost.

The oral speaker or singer is carrying on a tradition that he has learned from other speakers and he delivers it to a living audience. It may well be that his listeners have heard this material many times before and that it has a vigorous life in the community, and they will see to it that he does not depart too far from the tradition as they know it. If acceptable to his listeners, the story or song or proverb or riddle will be repeated over and over again

Effects of  
oral trans-  
mission

as long as it appeals to men and women, even through the ages and over long stretches of land.

In some cultures nearly everyone can carry on these traditions, but some men and women are much more skillful than others and are listened to with greater pleasure. Whatever the nature of these tradition bearers, the continued existence of an item of oral literature depends upon memory. As it is passed on from one person to another it suffers changes from forgetting or from conscious additions or substitutions. These may improve a tale or song or damage it through the bungling of unskillful singers or tellers, but in any case the item changes continually.

The more skillful tradition bearers take pride in the exactness with which they transmit a tale or song just as they have heard it many years before, but they only deceive themselves, for every performance differs from every other one. The whole material is fluid and refuses to be stabilized in a definite form. If really skillful, the teller is likely to see places where he can make great improvements and he may well begin a new tradition that will live as long as it appeals to other tellers. It thus happens that in nearly all cultures certain people specialize in remembering and repeating what they have heard. There are semiprofessional storytellers around whom large groups of people assemble in bazaars or before cottage fires or in leisure hours after labour. Some of these storytellers have prodigious memories and with only slight variations from time to time may carry on to a new generation hundreds of tales and traditions that they heard long ago.

Forms and functions

Certain bards and minstrels and songmakers develop special techniques of singing or of telling epic or heroic tales to the accompaniment of a harp or other musical instrument. In the course of time in various places special poetic forms have been perfected and passed on from bard to bard. Such must have been the way in which the remarkably skillful heroic meters of the Greek epics were developed. And so, whether before the princely or kingly audience that we learn about in the *Odyssey* or in *Beowulf* or the more humble groups of modern listeners in eastern Europe, a heroic tradition gradually rises out of the oral stream of narrative and may eventually, after suffering many and strange changes, cease to be oral literature at all and live on in manuscripts or books.

Another special kind of craftsman is found in many parts of the world. He often performs the offices of a priest or religious leader. It is through him and those he has trained that elaborate religious rituals are carried on through the generations. Frequently these rituals must be remembered word for word and are not believed to be effective unless they are correctly preserved. The ideal of such priestly transmitters of oral tradition is complete faithfulness to that which has been passed down to them.

Not least important of the many reasons for the existence and perpetuation of folk literature is the need for release from the boredom that comes on long sea voyages or in army camps or everywhere on long winter evenings. Some folk literature is primarily didactic and tries to convey to simple men the information they need to carry on their lives properly. Among some peoples the relation of man and the higher powers is of especial concern and gives rise to myths that try to clarify this relationship. Cooperative labour or marching is helped by rhythmic songs, and many aspects of social life give rise to various kinds of dance.

A great many of the special forms of literature now in manuscripts and books are paralleled in traditional oral literature, where history, drama, law, sermons, and exhortations of all kinds are found, as well as analogues of novels, stories, and lyric poems.

Relation to folklore and mythology

Folk literature is but a part of what is generally known as folklore: customs and beliefs, ritualistic behaviour, dances, folk music, and other nonliterary manifestations. These are often considered a part of the larger study of ethnology, but they are also the business of the folklorist.

Of special importance is the relation of all kinds of folk literature to mythology. The stories of Maui and his

confreres in the Pacific and of gods and heroes of African or American Indian groups have behind them a long and perhaps complicated history. This is especially true of the highly developed mythologies of India, and the Greek, Irish, and Germanic pantheons. All are the results of an indefinitely long past, of growth and outside influences, of religious cults and practices, and of the glorification of heroes. But whatever the historical, psychological, or religious motivations, the mythologies are a part of folk literature and have been subject to continual changes at the hands of the tale-tellers, singers of stories, or priestly conductors of cults. Eventually singers or storytellers of philosophical tendencies have systematized their mythologies and have created with fine imagination the figures of Zeus and his Olympic family and his semidivine heroic descendants. Though the details of these changes are beyond the scope of this article, stories of the gods and heroes and of supernatural origins and changes on the earth have played an important role in all folk literature.

#### TECHNIQUES OF FOLK LITERATURE

Since the tales, legends, and epic and lyric songs discussed here are a part of the experience of a preliterate group or at least of the essentially unlettered, they differ in many ways from literary works addressed to a reading public. Long forgotten are the person or persons originally responsible for the tradition that has resulted in examples of folk literature. Only the tale or song remains to be repeated and often changed by subsequent storytellers, singers, or bards. In the course of its history it is listened to by generations of the unlettered and the unsophisticated, and its success and its very survival depend on how well it satisfies their emotional needs and intellectual interests.

Since in essence all folk literature is oral and subject to its survival in the minds of men, it is full of devices to aid memory. Perhaps most common of all is mere repetition. Especially in folktales and epics it is common to hear the same episode repeated with little or no verbal change. As the hero encounters his successive adversaries the description changes only enough to indicate the increasing terror of the enemy, always leading to a climax and usually to the hero's success. These long repeated passages often enable the teller of tales or the singer of an epic to extend his performance as much as he desires.

Aside from repetition of entire episodes, folk literature of all kinds is filled with formulaic expressions. It may be the beginning or the ending of a folktale—the "once upon a time" or the "married and lived happily ever after" or sometimes quite meaningless expressions—or standard epithets attached to certain persons or places. These formulas are so characteristic of oral literature that an abundance of such commonplaces seems to be a guarantee of authentic oral origins even of a great epic.

These formulas are matters not only of words but of structure. The storyteller or singer has at his disposal a large variety of conventional motifs and episodes and may use them freely. How appropriately they are made a part of his composition depends on his skill, but his listeners are not likely to be very critical so long as he keeps them interested. Indeed it is remarkable that in spite of this apparent freedom of improvisation so many rather well-articulated plots have lived for centuries retaining all their essential features. It is this combination of a basic narrative type with a freedom of treatment within traditional limits that makes it possible to identify hundreds of versions of the same tale or song as they appear over long stretches of time and space.

Though much of narrative folk literature is frankly fictional and filled with unrealistic events, the successful storyteller or epic singer gives his story credibility by the use of realistic details. Often these are merely homely touches linking the never-never land of the tale or song to everyday life or emotions. For the unlettered listeners such realistic details may allow a stretching of the imagination to embrace a larger world. Heaven or hell it may be or kingly palaces where the peasant hero rules with a splendour only known to those who have never seen a

Technique of repetition in folk tales

court. Often these details are given only to ensure that willing suspension of disbelief characteristic of all fiction, but sometimes a realistic touch, even in the midst of weak motivation and violence, may give nobility to a mediocre tale or song.

Repetition, formulas both in words and in structure, realism enough to support the marvelous in tale or song, violent actions and simple strong emotions—these are generally found in all folk literature. The demands of the listeners are all-important. In some cultures this implies that actions should be well motivated so that listeners may identify themselves with certain characters. But in others, such as in many parts of India and in many preliterate cultures, motivation is often weak or entirely lacking.

For lyric songs, proverbs, riddles, and charms (and often legends), the relation of artist and audience is of little importance.

#### REGIONAL AND ETHNIC MANIFESTATIONS

In many particulars of form and substance there will be found great variations in the ways folk literature is manifested. The interests of people in one culture may differ profoundly from those of people in another. One group may enjoy singing folk songs, another listening to romantic folktales, and a neighbouring group may even be concerned only with legends and traditions. This difference is often geographical, so that the student of folk literature in the Pacific islands who may later investigate a central African tribe will find a completely different emphasis in the two areas. These differences may well depend upon the varieties of religious concepts held by the group or its natural environment, whether islands or jungle or cultivated farm lands, or its stability or mobility. These characteristics are likely to become especially deep seated in groups that have been settled in one place over a long period of history. Frequently they may correspond to national frontiers, but more often they are aspects of the general culture of an area and may well be quite independent of political or linguistic boundaries.

The Russian epic songs are found only in Russia, but the wonder story such as Cinderella or Snow White is a part of the folk literature of a good portion of the world. The Navaho Indians of the southwestern United States place great emphasis on their remarkable chants and lengthy folktales. Their neighbours throughout the Great Plains tell many well-constructed unified stories but confine their rituals largely to the dance. In Europe the Irish excel in storytelling, both of legends and fictional tales, so that even today it has been possible to record a prodigious number for their national archive. But in England and Wales the folktale is little cultivated, preference having been given to legends and ballads. As expected, there is a contrast between the abundance of oral saints' legends in Spain and Italy and their rarity in Scandinavia. Finland, meeting place of Eastern and Western tradition, shows an abundance of nearly every kind of folklore. From eastern Europe to Central Asia the folk epic flourishes.

Tales and origin legends have been collected in great numbers from various parts of Oceania, where there is a common mythological background extending over enormous distances. Except for probable early contact by way of Indonesia, these folktales seem to show little Eurasian influence. In many parts of South America the merging of Iberian, Indian, and Negro materials seems almost complete.

The folk literature of the North American Negroes is in a state of continual change, reflecting their history. Much certainly goes back to Africa, usually by way of the West Indies, and much was borrowed long ago. But the Negroes have themselves in a truly oral fashion developed songs and stories, and particular music styles. Of very special character is the folklore of modern Israel. Jews coming from various lands to the East and the West have brought together folk literature from all these countries. Assimilation of this is a long task, and since divergent language backgrounds are unimportant for

folktales, the problem is to absorb the great variety of forms.

Taken the world over, folk literature is found everywhere, though the emphasis differs from place to place.

#### MAJOR FORMS OF FOLK LITERATURE

**Folk song.** Some kind of singing is almost universal and it is probable that where there are no reports of it information is simply missing. Folk song implies the use of music, and the musical tradition varies greatly from one area to another. In some places the words of songs are of little importance and seem to be used primarily as support for the music. Frequently there are senseless monosyllables and much repetition to accompany the voice or the musical instrument. In much of the world drums and rattles, beating time by hands or feet or the stroking of a harp give a strong rhythmic effect to all folksinging. In others, flutelike wind instruments or bowed fiddles of one kind or another affect the nature of the folk-song texts. In many places these apparently meaningless folk songs are of great importance, serving as excitement to war or love or as a part of religious or secular ritual. Through them the group expresses its common emotions or lightens the burden of communal labour. In certain preliterate groups, and sometimes elsewhere, folk songs are used for magic effects, to defeat enemies, to attract lovers, to invoke the favour of the supernatural powers. Sometimes the magic effect of these songs is so greatly valued that actual ownership of songs is maintained and their use carefully guarded. They may come to the owner in a dream or as the result of fasting or other austerities.

Even when folk songs are not used for such practical purposes but only for the pleasure of singing or listening, the greater part of the world uses them for the expression of ideas or emotions held in common by the group. Only in societies used to the songs of composers or poets does purely personal expression enter into the folk song. This is not frequent, and songs of this type are hardly to be distinguished from some of the simple lyrics of poets such as Robert Burns. Folk songs, essentially expressions of commonly shared ideas or feelings, are often trivial but sometimes they may be profoundly moving.

The lyric folk song in one form or another is found almost everywhere, but this is not true of narrative singing. Unless the reporting of the activities of preliterate cultures has been very faulty, it would seem that the combination of song and story among these peoples has been rare, in spite of a wealth of prose narrative. On the other hand, in major Western and Asian civilizations the narrative song has been important for a long time and has been cultivated by the most skillful singers. In the course of time these songs of warfare, of adventure, or of domestic life have formed local cycles, such as the *byliny* of Russia or the heroic songs of Yugoslavia and Finland or the ballad tradition of western Europe and elsewhere. Each of these cycles has its own characteristics, with its distinctive metrical forms, and its formulas both of events and expression. Any reader of the Homeric poems will be aware of their essentially oral and musical nature, and all the early literary narratives of Sumer and the Near East suggest a long previous development of narrative singing.

**Ballad.** A special tradition of tales told in song has arisen in Europe since the Middle Ages and has been carried to wherever Europeans have settled. These ballads, in characteristic local metrical forms and frequently with archaic musical modes, are usually concerned with domestic or warlike conflict, with disasters by land or sea, with crime and punishment, with heroes and outlaws, and sometimes, though rarely, with humour. Despite a folk culture fast being overwhelmed by the modern world, these ballads are still being sung and enjoyed (see BALLAD).

**Folk drama.** Belonging only remotely to oral literature is folk drama. Dances, many of them elaborate, with masks portraying animal or human characters, and

Ethnic variations in relating folktales

Function of the folk song

Narrative singing

sometimes containing speeches or songs, are to be found in many parts of the preliterate world. Though the action and the dramatic imitation is always the most prominent part of such performances, these may be part of a ritual and involve speaking or chanting of sacred texts learned and passed on by word of mouth.

The ancient Greek mysteries, as well as secret societies even down to the present, have retained this method of transmitting dramatically their traditions and their teachings and commentary. Some dramatic rituals indeed were not secret but part of a public cult. Thus in ancient Greece the feast of Dionysus led eventually to classical Greek drama, and in the Middle Ages the dramatic celebrations of the Christian Church developed into the medieval folk dramas and at long last into the literary drama of the Renaissance and later.

The medieval mummers' plays and their modern survivals, the Passion plays, the Mexican re-enactment of historic scenes such as "The Moors and the Christians," and the modern pageants—all these are based on written texts, however crude, and are beyond the scope of this treatment (see RITUAL and DRAMATIC LITERATURE).

**Fable.** Fables, whether of the well-known Aesop cycle, with animals acting according to their real natures, or those from India, where animals simply act as men and women, are literary in origin. But they have had an important influence on folk literature. In addition to appearing in written collections, a number of these are told by storytellers in many parts of the world. Such fables as "The Ant and the Grasshopper," with appropriate morals, have been frequently recorded along with oral tales and have undoubtedly served as models for new animal stories. Sometimes these new tales have eventually received literary treatment, as in the medieval "Reynard the Fox," and then been carried back around the world by storytellers. In such narratives the borderline between folk literature and other literary expression is impossible to draw.

**Folktale.** The oral fictional tale, from whatever ultimate origin, is practically universal both in time and place. Certain peoples tell very simple stories and others tales of great complexity, but the basic pattern of tale-teller and his audience is found everywhere and as far back as can be learned. Differing from legend or tradition, which is usually believed, the oral fictional tale gives the storyteller absolute freedom as to credibility so long as he stays within the limits of local tabus and tells tales that please.

A folktale travels with great ease from one storyteller to another. Since a particular story is characterized by its basic pattern and by narrative motifs rather than by its verbal form, it passes language boundaries without difficulty. The spread of a folktale is determined rather by large culture areas, such as North American Indian, Eurasian, Central and South African, Oceanic, or South American. And with recent increasing human mobility many tales, especially of Eurasian origin, have disregarded even these culture boundaries and have gone with new settlers to other continents.

In many preliterate cultures folktales are hardly to be distinguished from myths, since, especially in tales of tricksters and heroes, they presuppose a background of belief about tribal origins and the relation of men and gods. Conscious fictions, however, enter even into such stories. Animals abound here whether in their natural form or anthropomorphized so that they seem sometimes men and sometimes beasts. Adventure stories, exaggerations, marvels of all kinds such as other world journeys, and narratives of marriage or sexual adventure, usually between human beings and animals, are common. Much rarer, contrary to the views of earlier students, are explanatory stories. Tales of this description are especially characteristic of Africa, Oceania, and the South American Indians.

In much of the world, especially Europe and Asia, the folktale deals with a greater variety of incidents than just described. In the course of time folktale scholars have given most attention to this area and have classified these

stories so that the vast collections of them in manuscripts or books can be referred to with exactness.

All readers of such collections as those of Grimm will easily recall examples of tales of speaking animals. These may be old Aesop fables or parts of the medieval Reynard epic, but most of them are based on some ancient oral tradition. Such animal stories are especially numerous in eastern Europe. But better known perhaps are the ordinary folktales that deal with human beings and their adventures. For these tales, usually laid in a highly imaginative time and place—a never-never land—and filled with unrealistic and often supernatural creatures, there exists no good English word, so that usually scholars use the German term *Märchen*. Here belong "The Dragon Slayer," "The Danced-Out Shoes," the "Swan-Maiden" tales, "Cupid and Psyche," "Snow White," "Cinderella," "Faithful John," "Hansel and Gretel," and their like. Here also belong certain stories with religious or romantic motivation and tales of robbers and thieves—"Peter at the Gate of Heaven," "The Clever Peasant Daughter," "Rhampsinitus."

A major division of this classification of tales deals with jests and anecdotes. Examples are the many stories of numskulls, of clever rascals, and tall tales filled with exaggerations or lies. Finally come formula tales like "The House that Jack Built."

Among jokes and anecdotes a number are risqué or actually obscene. The indexes of the classification have included only those occurring in the published regional surveys. These surveys, and the books and manuscripts on which they have been based, have been subject to severe editing in order to avoid social or even legal offense. Some of the older anthropologists thought to avoid the eyes of the nonscholar by writing such tales in Latin, but a newer generation is much less squeamish. Folk stories now appear in print covering the gamut of the erotic—tales of seduction, realistic descriptions of normal or abnormal sexual activity, and scatological stories of great indecency.

This index of tale types fits the region for which it was planned and is constantly being improved and expanded, but it was never designed to cover the world. The Eurasian types are usually recognizable in any part of the globe and for them this type index is valuable. But for use with stories on a worldwide basis something less formal is needed, a classification of the possible or likely narrative motifs, minute or extended, and wherever found. Such a motif index has in fact proved useful outside of the Eurasian area, wherever comparative studies are undertaken, for parallels or analogues in simple motifs occur even in far distant places, often presenting extremely puzzling problems.

By use of such indexes and from the labours of many scholars, much material for examination of the folktale is available. These studies have been pursued since the 18th century, though until about 1900 most of them were premature attempts to answer the general question of where folktales come from. Eventually it became clear that no satisfactory solution is available, but that every tale has its own history and can be studied only with laborious attention to detail.

In contrast to a literary story, with its standard text and author living in a definite time and place, the folktale is anonymous. Its originators have long been forgotten and it exists in many versions, all equally valid. Instead of being fixed like a literary document, it is in continual flux. But with hundreds of versions of a particular tale available for study it is possible to establish certain norms of plot structure and to point with some assurance to the varieties of subtypes that give clues to its life history. Such an analytical study of these hundreds of versions usually results in some hypothesis about the original form of the plot and the passage the tale has taken through time and space. In this way some 30 or 40 of the more complicated stories have been studied.

These geographical and historical investigations depend on the fact that the plot of the tale is complex enough to admit of really analytical study. For simpler stories

Jests and  
anecdotes

Folktale  
scholarship

Variety of  
types

and anecdotes scholars have had to be content with less exact methods, usually resulting in nothing more than accounts of their distribution and the known facts of their history.

Most of the attention of students of folktales during the 20th century has been given to historical questions and to preparing the apparatus for studying them—collecting, with ever improved techniques, arranging and archiving materials from manuscripts or books, and indexing types and motifs, so as to make collections even in remote or difficult idioms available to the serious investigator. But the folktale also has given rise to studies that are not strictly historical.

The attempts during the 19th century to find hidden meanings in tales were generally based upon the theory that they were broken-down myths and had lost their original meanings through linguistic misunderstanding. The result was that this “original meaning” was always found to be some conflict between weather or seasonal phenomena (winter: summer; clouds: sunshine; etc.). This type of interpretation has now generally gone out of fashion and has given place sometimes to explanations based upon ancient rituals or to some variety of psychoanalytic treatment. Though both of these possible sources of folk literature merit examination, the resultant interpretations have usually been merely astonishing to those acquainted with the actual history of the tales studied.

A much more fruitful approach to an investigation of folktales has been the studies of the tellers of stories and their audiences. From these has come an appreciation of the way in which folk literature is carried on in a tradition. A great deal more may be expected from such investigations, usually based on an intimate knowledge of the living lore of a single people.

Structural studies, especially of the folktale, have been engaging the attention of more and more scholars. Though particular plots may occur over large parts of the world, the form and literary style of the narrative is likely to be traditional within certain historical or geographic limits. The direction and strategy of these studies of structure are still unclear, but progress is being made.

*Legend and tradition.* Generally folktales are considered both by tellers and listeners as purely fictional. The line, however, between belief and unbelief is vague and varies from culture to culture and even from person to person, and even in the most sophisticated societies legends of strange things from the past or present continue being told and are usually believed.

Credibility  
of the  
legends

Stories about marvelous creatures are worldwide. Often these are merely mentioned or described and the belief in their existence is taken for granted. Frequently, however, there are circumstantial accounts of meetings with them, which result in adventures pleasant or distressing. With such creatures it is sometimes hard to tell whether we are dealing with a fictional story such as that of the dragon slayer of the typical European fairy tale or with a legend actually believed, such as that of St. George and the dragon. Though the folk in all parts of the world handle these stories with varying degrees of belief, there exists everywhere a remarkable resemblance among these supernatural creatures. The dragon, for example, in something of its characteristic serpent or crocodile form, is of great importance in China as well as in Europe and is represented in both places as a guardian of great treasure. Hardly less well known is the unicorn, and various combinations of man and beast such as the centaur and the minotaur, or the combinations of man and dog, have been a part of the legends of the Old World and occasionally of the New. Giant birds carrying men off in the claws, the phoenix reviving from its own ashes, flying horses carrying men through the air, sirens, mermaids and mermen, and unbelievable creatures resembling these appear in traditions all over the world. There are treasure animals of all kinds, not only the goose that lays the golden egg but the cow that furnishes treasure from its ear. The horse may warn the hero of danger or may determine which of two roads he should

take. Important building sites are said to have been determined by the actions of a wise animal. Speaking animals, of course, figure prominently in all folk literature and even in such literary forms as the fable. Animals may speak to each other on Christmas Eve, or they may have governments and elect kings or celebrate weddings. These are only a few of the traditions current with a large part of mankind.

The relation between the animal and the human is very close in all folk literature. In the preliterate cultures of the American Indians, the Pacific Islanders, or the Central Africans, the culture heroes who are responsible for the good and the bad in the life of the tribe may upon one occasion appear as animals and upon another as men. Such was true of the ancient gods of Egypt or Greece. The question whether Coyote of the American Indian tribes is an animal or a man apparently makes no difference to those who tell stories about him.

Aside from these semidivine creatures, now animal or bird or man as they wish, stories are found everywhere about supernatural and ill-defined creatures much more difficult to visualize. Fairies or their counterparts appear in the legends of a good part of the world. It is hard to define them, for in one place they will appear in full human size, in another as little creatures inhabiting mounds or caves or living under the roots of trees. In some countries they are benevolent creatures, helpful to men and women. They reward human services but punish misdeeds. They marry or consort with human beings. In some traditions they are malevolent creatures, and meetings with them always bring disaster or bad luck. Almost every country has produced its own variety of helpful and harmful creatures. Stories of the activity of witches and devils, or water spirits and the supernatural guardians of mountains or trees vary in details from land to land, but many of the incidents related about them are easily transferred from one to another. Stories of visits to quite other supernatural realms, fairyland, for example, may be told in all their details in Russia or Greece. Giants are usually considered to be ogres of one kind or another but they may also be considered the most stupid of all beings and may be the subjects of hundreds of numskull anecdotes. Underground creatures like the dwarfs in “Snow White” are usually helpful and kindly, but other underground creatures bring only disaster.

Super-  
natural  
creatures  
in legends

The widespread belief in the return of the dead has resulted in many stories of encounters with ghosts or of actual resurrection. These stories differ greatly in various parts of the world and are much influenced by the current religious ideas. It is likely that in the whole world of traditional literature the belief in ghosts has survived longest.

Traditions of historic characters have a tendency to repeat themselves from land to land and although they are told as facts may form as definite patterns as any fictional folktale. Such stories as Joseph and Potiphar's wife or the exposure and ultimate return of the hero appear in many places. The expected return of King Arthur from Avalon or of Barbarossa from his cavern are only two examples of a widespread motif of this kind.

It is difficult and perhaps impossible to distinguish the explanatory legend from the myth. Tales explaining the origins of customs or of the shape or nature of various animals and plants, of such distant objects as the stars, or even of the world itself often ascribe such origins to the action of some ancient animal or to some magic transformation. These are often connected with stories of the gods or demigods and may even be a part of the religious beliefs of those who tell them.

Generally, legends and traditions of this kind are simple in their form and contain only a single motif or at most two or three. The problem of proper classification for the purpose of studying these has proved very difficult, for while the materials of these legends and traditions show many interesting parallels and resemblances, they vary greatly from place to place. The relation of these stories to actual history, to mythology, and to the fic-

Historicity  
of some  
legends

tional folktale is of much interest to students of folk literature.

**Proverbs, riddles, and charms.** Three of the shorter forms of folk literature—proverbs, riddles, and charms—are not confined to oral expression but have appeared in written literature for a very long time. The proverb that expresses in terse form a statement embodying observations about the nature of life or about wise or unwise conduct may be so much an oral tradition as to serve in some preliterate societies as a sanction for decisions and may even be employed as lawyers employ court precedents. In literature it dominates certain books of the Old Testament and is found even earlier in the writings from Sumer. There has been a continual give and take between oral and written proverbs so that the history of each item demands a special investigation.

While the proverb makes a clear and distinct statement, the purpose of the riddle is usually to deceive the listener about its meaning. A description is given and then the answer is demanded as to what has been meant. Among examples in literature are the riddle of the sphinx in Sophocles and the Anglo-Saxon riddles, based on earlier Latin forms. In oral literature the riddle may be part of a contest of wits. But even if the answer is known, the listeners enjoy hearing them over and over. In our own culture the riddle is especially cultivated by children.

Charms, whether for producing magic effects or for divining the future, also exist in folk literature as well as in the well-known Anglo-Saxon written form. The study of these extends over all parts of the world and back to the earliest records.

**Children's use of folk literature.** As a part of their play activities children not only play old games but repeat counting-out rhymes and retain play-party songs that have long ceased to be a part of adult activity in Western culture. Although the knowledge of those matters is available to children in their books, in actual practice it is passed on by word of mouth or by imitation, and the tradition may spread from school to school over a continent with great rapidity (see CHILDREN'S LITERATURE).

#### STUDY AND COLLECTION

As abundant as folk literature is and has been everywhere and always, its investigation has been seriously undertaken only within the last two or three centuries. The principal difficulty has been the assembling of material on which to base such studies. Its very oral nature makes it impossible for one man to be acquainted at first hand with more than an extremely small part of this activity. It is only when some sort of written record has been made of the oral material that any general studies are possible.

For the still unlettered peoples, the reports of ethnologists and anthropologists, as a part of their general studies of the cultures of widely distributed groups, have often given good accounts of folk literature and have frequently furnished texts of material they heard. Though these reports are extremely uneven and often fragmentary, they do give a sampling of the literary expression of many and diverse parts of the earth.

When attention is shifted to the ancient world before the use of writing, scholars are almost entirely dependent on analogies from the unlettered groups just mentioned. It will never be known what tales were told or what songs were sung by the builders of the Egyptian Pyramids or the temples in Sumer, but it seems fair to assume that even then these peoples were not silent. Of course it must be remembered that they did eventually develop a written literature, so that the analogy with modern unlettered peoples may not be completely valid.

For folk literature since the development of writing, scholars are dependent on several things. There may be specific references in literary documents to the existence of particular tales or songs and often to their manner of production. The Old Testament is a good source for these, and both the *Odyssey* and *Beowulf* contain good pictures of the performances of folk minstrels and bards.

Many collections of folktales and legends, of lyric and

heroic songs, and of riddles and proverbs have been recovered directly from popular tradition within the past three or four centuries. When the collection of this material began it was nearly always rewritten in the prevailing literary fashion. Excellent examples of such rewritten tales will be found in the collections of Giambattista Basile (1634–36), Charles Perrault (1697), and various German writers such as Johann Karl August Musäus and Clemens Brentano in the 18th and early 19th centuries. The Brothers Grimm with their *Kinder und Hausmärchen* (1812–15) has as their ideal the exact recording of tales as heard from oral tellers, though it is clear that many stories in their famous work are not folk literature at all. In the same way, collections of folk songs and ballads were severely edited well into the 19th century.

Partly as a result of the Romantic movement in literature and partly of the interest in primitivism and the common folk, the recording of all sorts of songs and oral tales since about 1800 has been phenomenal. More and more the attempt has grown to recover material as it actually exists. Many thousands of volumes are to be found in great libraries that give a good sampling of folk literature in all parts of the world. The last century has also seen the development of large regional or national archives, many of them containing hundreds of thousands of items available for study. All of these books and manuscripts have become increasingly valuable as the techniques of collecting have progressed from casual longhand notes and rewritings through various stages to mechanical recording on discs and tapes.

With mechanical recording it has been possible to assemble properly attested folk literary material from all parts of the world. This improved collecting has proceeded at an impressive pace and makes possible comparative studies of all kinds, based on the oral record.

As for the folk literature of peoples predominantly unlettered, these greatly expanded bases for study have brought out not only the characteristics found everywhere but have pointed up the differences found from place to place. Generalizations formerly accepted have to be reviewed in the light of these differences. With increased collecting, for example, do the likenesses or unlikenesses of American Indian tales and legends become more manifest? Does folk literature in a certain part of the world follow culture areas or language boundaries or some other principle? Such problems can now be investigated with the assurance that modern collectors have made every effort to record the oral tradition as it actually exists.

Much the same may be said of the 20th-century folk literature that exists among literate people side by side with written works. The collecting has improved both in quantity and quality. And not only have libraries been receiving new books of folk literature collections from interested persons everywhere but these collectors are better trained and equipped. The greatest improvement, however, in the study of folk literature transcribed in writing has been the development of folklore archives, of which a large part are concerned with various kinds of oral literature. These are growing rapidly, are scattered over much of the world, and are becoming well indexed and accessible.

**BIBLIOGRAPHY.** The best general treatment of the borderline between folk literature and sophisticated literature is H.M. and N. CHADWICK, *The Growth of Literature*, 3 vol. (1932–40). S. THOMPSON, *The Folktale* (1946), gives an introduction and extensive bibliography for the field of oral narrative literature. For myths of all parts of the world, see *Mythology of all Races*, 13 vol. (1916–32), valuable information, though some of the bibliographies are out of date. *The Journal of Folklore Studies* (3/yr.), and *FF Communications* (irreg.), are of primary importance. They include articles in English, French, and German. *FF Communications* is undoubtedly the leading series for all aspects of folklore. A good recent series of folktale collections in English is "Folktales of the World" ed. by R.M. DORSON. Important also is the much larger series in German, "Märchen der Weltliteratur." For the folktales of the ancient world good introductions are W.M.F. PETRIE (ed.), *Egyptian Tales Translated from the Papyri*, 2 vol. (1899);

Preservation of folk material

and S.N. KRAMER, *Sumerian Mythology: A Study of Spiritual and Literary Achievement in the 3d Millennium B.C.*, rev. ed. (1961). The standard Renaissance collection is *The Pentamerone of Giambattista Basile*, ed. and trans. from the Italian of BENEDETTO CROCE by N.M. PENZER, 2 vol. (1932). The commentaries on these tales are especially valuable. The new translation of Grimm's folktales, *German Folk Tales* by F.P. MAGOUN and A.H. KRAPPE (1960), is convenient for English readers. For folktales of the North American Indians, the American Negroes, and the peoples of Oceania and Israel, the following works are standard: W. MATTHEWS, *Navaho Legends* (1897); S. THOMPSON (ed.), *Tales of the North American Indians* (1929, reprinted 1966), an anthology with exhaustive comparative notes, valid until about 1926; M. JACOBS, *The Content and Style of an Oral Literature: Clackamas Chinook Myths and Tales* (1959), tales of a vanishing North Pacific tribe; W.A. LESSA, *Tales from Ulithi Atoll: A Comparative Study in Oceanic Folklore* (1961); K. LUOMALA, *Voices on the Wind: Polynesian Myths and Chants* (1955); R.M. DORSON, *American Negro Folktales* (1967); and D. NOY and D. BEN-AMOS (eds.), *Folktales of Israel* (1963). Types and classifications of folktales and legends are: A.A. AARNE, *The Types of the Folktale*, 2nd rev., trans. and enl. by S. THOMPSON (1961), a standard list of tales of old world provenance; S. THOMPSON, *Motif-Index of Folk Literature*, rev. ed., 6 vol. (1955-58); and R.T. CHRISTIANSEN, *The Migratory Legends* (1958), a classification of European legends. A good example of a survey of tales of a particular country is S. O'SUILLEABHAIN and R.T. CHRISTIANSEN, *Types of the Irish Folktale* (1963). A general introduction to folk song is G. HERZOG, "Song: Folksong, and the Music of Folksong," in *Funk and Wagnall's Standard Dictionary of Folklore*, vol. 2, pp. 1032-1050 (1949-50). A comprehensive introduction and listing of all the classical fables is in B.E. PERRY, *Babrius; and Phaedrus* (1965). The proverb, the riddle, and the charm are treated in A. TAYLOR, *The Proverb* (1962), *English Riddles from Oral Tradition* (1951); and W.R. BASCOM, *Ifa Divination: Communication Between Gods and Men in W. Africa* (1969). Important also is the work of L. DEGH, *Folktales and Society* (1969), a study of a Hungarian storyteller; A. DUNDES, *The Study of Folklore* (1965); V.A. PROPP, *Morphology of the Folktale* (1958); and T.A. SEBEOK, *Myth: A Symposium* (1965), a collection of theoretical treatments of mythology. An outstanding discussion of narrative folk song is A.B. LORD, *The Singer of Tales* (1960). A model historical and geographical study is W.E. ROBERTS, *The Tale of the Kind and the Unkind Girls* (1958).

(S.T.)

## Folklore

No field of learning is perhaps more misunderstood than folklore. The public at large, and many academic persons as well, do not know that folklore is an intellectual subject with its own substantial, worldwide body of scholarship. Part of the confusion lies in the double use of the word folklore to signify both the content and the study of traditional materials. Further misunderstanding results from the varying senses of folklore in different countries. In much of South America and in some European nations, folklore in popular usage generally applies to public performances of song, dance, and festival, and in scholarly usage the term refers to the study of peasant culture. In the United States, the word folklore often conjures up an image of long-haired folksingers or grizzled old-timers spinning yarns of Paul Bunyan and Johnny Appleseed, who are largely contrived heroes. The German term *Folklorismus* and the English term *fakelore* have been coined to distinguish between genuine folk traditions and the synthetic revival or imitation of those traditions.

### THREE APPROACHES TO FOLKLORE

Serious students of folklore by no means agree on the boundaries of their discipline but they tend to follow one of three prevailing perspectives.

**Humanistic perspective.** The humanistic folklorist sees the materials of folklore in large part as "oral literature" and the folk as artistic performers of tale or song. Accordingly, he emphasizes the creative role of the narrator or bard, seeks information on his biography and personality, closely observes his interaction with the audience, and analyzes his total repertoire much as a literary critic assesses the achievement of the novelist, poet, or

dramatist. Usually the exponents of this approach, among the older generation, have entered folklore from departments of modern language and literature or music or classics. A case in point is Albert Lord, professor of Slavic literature at Harvard University, whose folklore interests developed from a concern with the south Slavic oral epic, still sung by bards in Yugoslavia. After collecting and studying these epics, Lord came to the conclusion that each epic singer constructed his narrative song by improvising and elaborating around a stock of fixed images, epithets, and conventional expressions, which he alone kept firmly in mind. This "oral-formulaic" theory Lord then applied to the Homeric epics, which are now known only in their written forms but which he conjectured had been orally composed in the same manner as the contemporary Slavic epic songs. Since the appearance of Lord's work, *The Singer of Tales* (1960), other humanistic folklorists have applied his theory to various traditional texts, from Norwegian ballads to the Anglo-Saxon epic *Beowulf* to medieval romances. The interest in the human carrier of tradition, in his world-view and belief system, his cultural inheritance and acculturative experiences, distinguishes this species of folklorist.

**Anthropological perspective.** The anthropological folklorist examines the materials of folklore using the hypotheses of the social sciences. He looks for cultural norms and values and predictable laws of behaviour that form a consistent pattern in the nonliterate society he has closely observed. Folklore to him is an aesthetic product of this society, mirroring its values and offering a projective screen that illuminates its fantasies. Hence the folkloristic anthropologist frequently reports a one-to-one correlation between the value system and the tale repertoire of a given culture, whereas the humanistic folklorist promptly points out that the same tales are found in many parts of the globe and so can scarcely be said to reflect the ethos of a particular people, even when they have been strongly localized.

At different periods folklore and anthropology have enjoyed an intimate relation in England and America. The father of anthropology in England, E.B. Tylor (1832-1917), drew heavily upon the materials of folklore in his two great works, *Primitive Culture* (1871) and *Researches into the Early History of Mankind* (1865), which in turn contributed to the growth of a school of so-called anthropological folklorists. The leader of this school, Andrew Lang (1844-1912), a versatile man of letters, in many clever essays and books elaborated a theory of "survivals" based on Tylor's hypothesis that from the beliefs and customs held by peasants and contemporary savages the folklorist could reconstruct the ideas of prehistoric man. In the United States, Franz Boas (1858-1942), the father of American anthropology, influenced many doctoral students, later eminent in their own right, to pay attention to folklore in their fieldwork. Boas himself considered that tribal traditions preserved an ethnological record of older culture traits and should be consulted in lieu of written documents. His disciple and successor as editor of the *Journal of American Folklore*, Ruth Benedict (1887-1948), pointed out that the tribal mythology depicted violations of taboos, such as the hero-trickster sleeping with his mother-in-law, which would never be tolerated in real life. Another student of Boas, Melville J. Herskovits (1895-1963), broke with the Boasian concentration on North American tribes to explore African cultures but retained the same emphasis on folklore and inculcated this emphasis in his own students.

American folklore-minded anthropologists all experienced difficulty in employing the term folklore within a culture almost wholly oral and traditional and resorted to various substitutes. William Bascom, a student of Herskovits, suggested the term verbal art to denote the oral aesthetic traditions of tale, proverb, song, and riddle in the culture, leaving out the supernatural-belief system and the plastic arts, which a humanistic folklorist includes in his concept. Bascom also clarified the functional uses of folklore in nonliterate societies, in accord

Emphasis  
on cultural  
norms and  
values

Emphasis  
on  
narrator

with the anthropologists' stress on the social mechanisms that enable a society to perform its business. His book, *Ifa Divination* (1969), demonstrates how Yoruba diviners have recourse to the tribal repertoire of traditional narratives in arriving at their analyses of individual problems. The beans they throw on the Ifa board fall in a series of complex patterns that the diviners key to folktales, whose contents are then applied to the particular situation in hand. English and American anthropologists of the 1960s have in the main moved away from the soft, folkloric parts of culture to the hard, sociological data of kinship organization and political structures.

Emphasis  
on  
behaviour

**Psychological-psychoanalytic perspective.** The psychological-psychoanalytic folklorist views the materials of folklore neither aesthetically nor functionally but behaviouristically. Myths, dreams, jokes, and fairy tales express hidden layers of unconscious wishes and fears. Sigmund Freud drew extensively upon folk sources in such works as *The Interpretation of Dreams* (1899), *Jokes and Their Relation to the Unconscious* (1905), and *Totem and Taboo* (1913). In his view, and that of many writers on folklore influenced by him, folklore texts are to be interpreted symbolically in terms of sexual imagery and the Oedipus complex. In "Jack and the Beanstalk," the stalk is construed as a phallic symbol and Jack's chopping it down signifies a masturbation fantasy. "Little Red Riding Hood" tells a tale of a young virgin, identified by the red cap, a menstrual symbol, who wanders from the straight and narrow path, to be devoured (seduced) by the wolf in disguise of the grandmother, an Oedipal figure. In the modern college legend of "The Hook," a coed narrowly averts assault from an escaped lunatic, one of whose arms has been replaced with a metal hook; the psychological interpretation explains the hook as the phallus and the episode as the coed's fear of the sexual act. When C. G. Jung broke with his mentor Freud and substituted the symbolism of social unconsciousness for the symbolism of sexual drives, he still retained his deep interest in myths, dreams, and tales as psychoanalytic media, and the Jung Institute in Zürich continues to offer courses on the uses of folklore in psychology.

Such a work as *The Trickster*, edited by the American anthropologist Paul Radin, with commentaries by the mythologist Karl Kerényi and by Jung, offers within one volume three psychoanalytical interpretations of the Winnebago cycle of trickster tales. Kerényi, although a collaborator of Jung, takes a Freudian position and sees the trickster as a phallic figure, the spirit of disorder. Jung finds unconsciousness as the chief and alarming characteristic of the trickster, whom he considers the forerunner of the Saviour. Radin synthesizes both Freudian and Jungian analyses in his conception of the trickster as evolving from a psychically unaware to a socially developed being, reinterpreted by each new generation as god, hero, or buffoon. The most committed Freudian folklorist of the 1960s is Gershon Legman, Hungarian by birth, who resides in the United States and France. In *The Rationale of the Dirty Joke* (1968), Legman properly gives attention to the most current folktale genre of modern society but looks beneath the seemingly obvious motivations of dirty jokes to violate sexual and anal taboos and imputes to them such latent impulses as castration fears, female revulsion at the sexual act, and homosexual drives.

The three perspectives of folklore are not mutually exclusive. Anthropologists may at times employ an essentially humanistic approach, as Daniel J. Crowley has done in his detailed ethnography of the styles and repertoires of Bahamian narrators, *I Could Talk Old-Story Good* (1966). They also have shown sympathy for the psychological-psychoanalytical node. A case in point is the study of *Water-Witching, U.S.A.* (1959), by anthropologist Evon Vogt in collaboration with the psychologist Ray Hyman, who explained the widespread phenomenon whereby diviners located underground water with a forked branch as an anxiety-releasing mechanism for depressed farmers. Younger folklorists of the 1960s trained

as humanists have shown an increasing orientation toward social-science methods of model building and statistical techniques.

#### THE ORIGINS OF FOLKLORE

When scholars and other intellectuals began to recognize early in the 19th century the presence in their midst of a vast floating body of folk traditions and practices, they promptly began to speculate on its origins. When in 1812–14 the German philologist Jacob Grimm (1785–1863), together with his brother Wilhelm (1786–1859), published the first volume of the *Kinder und Hausmärchen* (customarily translated as *Grimms' Fairy Tales*), thus initiating the science of folklore, he connected his collecting of village tales to an elaborate mythological system of origins, outlined in his *Deutsche Mythologie*. This influential work was first issued in 1835, and its fourth edition was translated into English (3 volumes, 1883–88) under the title *Teutonic Mythology*. A German nationalist, Grimm postulated a highly developed religious pantheon of pre-Roman times suppressed by the medieval church and surviving only in broken fragments of peasant beliefs and stories. The *Märchen*, or tales, were the detritus of the old myths.

In the mid-19th century, following the discovery of Sanskrit as the ancient classical language of India and the parent of European tongues, a pan-Aryan theory of origins developed. In 1856 Max Müller, a German-born scholar who went to London to translate from the Sanskrit the *Sacred Books of the East* and stayed on at Oxford University, published a long essay on "Comparative Mythology," introducing the new theory. Through a process he called "disease of language," Müller conjectured that myths arose from forgetfulness of the original names of deities, transferring to them metaphorical qualities suggested by the names. Thus Dyâus, the sky deity of old India, would be thought of and narrated about as the sky, or by association, heavens, clouds, storms, and winds. The Greek myths sprang from the Indic—Zeus was the linguistic counterpart of Dyâus—and could be explained on the same grounds. Although Müller applied his theory only to the advanced Indo-European Aryan civilizations, he did point to similar myth-making among primitive peoples. Some of his followers, notably George W. Cox, carried the school of solar mythology to extreme limits and explained all folk narratives, epics, and ballads as originating in early man's poetic rendering of the conflict between the sun and the night.

Tylor added a new conception of the origins of folklore without challenging Müller's solar mythology but by pushing the starting point back beyond the Aryans to prehistoric man. Looking at the universe animistically, primitive man endowed the elements, the animals, the plants, and the rocks with personalities and souls. Such beliefs survived into modern civilization among the unlettered lower classes and formed a crust of folklore. The strongest challenge to Tylor's evolutionary theory of culture and "devolutionary" theory of folklore (in the phrase of Alan Dundes) first emerged in a hypothesis advanced by the German scholar Theodor Benfey in his introduction to the Indian story collection *Panchatantra* (1859). Benfey claimed that India, the seat of an ancient high civilization that had spread to Europe, was the home of the master tales subsequently found in the Grimms' collection. Along with language and mythology, these wonder tales had diffused from India to Europe in ancient times and again in historic times along well-travelled trade routes. Benfey's arguments persuaded other folklorists, notably Emmanuel Cosquin in France and William Alexander Clouston in Scotland, who added to his evidence of story migration from India eastward. In the past century, the primacy of ancient India as the fountain of world folklore has gradually been whittled away by the claims of other dispersal points, such as Egypt and Greece, and by the growing realization that no sweeping generalization could account for folklore origins. According to the Finnish folklorists, whose historical-geographical method attracted most scholars in the first

and  
fertility  
ritual

half of the 20th century, the life history of each complex tale and ballad requires separate investigation. After exhaustively comparing the traits of all the assembled variants of a given tale type, the Finns (specifically Kaarle and Julius Krohn and Antti Aarne) believed they could establish its original form and approximate place and period of genesis. The subscribers to this theory accepted the premise that an anonymous composer had created every substantial folklore item at one point in time, much as a novelist produces a novel.

Various other origin theories have gained attention. The school of Cambridge University anthropologists, theorizing on the great comparative study by Sir James George Frazer, *The Golden Bough* (1st ed., 1890), converged on a central idea of myth-ritual origins of all folklore. In their view, a mythic narrative accompanied and explained a sacrificial fertility ritual among the heathens. In the course of time the myth becomes separated from the rite and floats independently in oral tradition, to splinter in turn into magic tales, popular ballads, nursery rhymes, and other folklore genres. Psychological folklorists ascribe the source of many folk narratives to dreams; the Hungarian Geza Roheim considers that dreams, precipitated by full bladders, engendered the widespread flood myth. Ballad scholars, such as Francis Gummere in *Old English Ballads* (1894) and other works, attributed the composition of ballads not to any single bard but to the joint efforts of a singing, dancing throng.

Origins by social classes have also formed the basis for widely held theories. One thesis, particularly identified with the German Hans Naumann and his term *gesunkenes Kulturgut* (literally, "downsinking cultural value"), contends that folklore originates with the aristocratic upper class, whose court poetry, mimes, bardic recitals, and pageants filter down in debased form to the peasantry. Soviet and east European folklorists have sharply challenged this idea since the 1930s and substituted their own concept that folklore arises from the people, the folk, in expression of protest and outrage against the exploiting nobles and landowners. Hence in the Soviet Union folk bards and storytellers are honoured along with novelists and poets. In "A Theory for American Folklore" (1959), Richard M. Dorson has argued for a distinction between Old World and New World folklore origins. The folk traditions of North and South America combine the imported lore of the conquerors, the aboriginal lore of Indian tribes, and the lore arising since the colonizing period as a result of New World history and geography.

#### THE FORMS OF FOLKLORE

The elusive materials of folklore can best be defined through the formal genres into which they fall. Genre definition has its own pitfalls, since attempts at neat categories invariably slice off related forms, but folklorists agree on certain broad kinds of traditions. These may be divided into oral literature, custom and festival, and material culture.

Genres of  
oral  
literature

**Oral literature.** The genres of oral literature cover spoken and sung expression. They may be further divided into the two large groupings of folk narrative and folk song, and such other smaller genres as proverbs, riddles, and beliefs or superstitions. *Folk narrative* is an umbrella for a wide range of oral prose traditions. Among them can be mentioned the *myth*, a semisacred adventure of a god or demigod set in the remote past; the *Märchen* or *fairy tale* (also *wonder tale* or *magic tale* and sometimes just *folktale* or *tale*), a pan-European popular fiction with aristocratic characters, magical episodes, and a symmetrical structure; the *legend*, a believed report often told conversationally and allusively; the *saga*, a personal, family, or local chronicle of marvellous oral history; the *romance*, a lengthy, adventure-filled narration with realistic characters; the *noodle* or *numskull tale*, relating the comical stupidities of a foolish person or a village of fools; the *jest* or *joke*, a short humorous fiction, often obscene and usually climaxed with a punch line; the *anecdote*, a brief traditional incident concerning a laughable action or saying of a historical personality; the *ani-*

*mal tale*, characterized by talking animals with human traits; the *cante-fable*, a story containing songs or rhymes; and still other forms. Folk song too embraces myriad species. An important aspect of all folk songs is their association of text with tune, requiring the folklorist to trace the melodic as well as the textual history. A major division separates the *ballad*, which embodies a narrative, and the *lyric*, which expresses emotion, although, like *Märchen* and legend, the two basic forms often coalesce. The ballad can be further subdivided into the *Child ballad*, named for Francis James Child, who assembled 305 basic types of the English and Scottish traditional ballad (1882-98); the *broadside ballad*, a later development of the 16th and 17th centuries when balladmongers wrote up sensational events on broadsheets or broadsides and hawked them in the streets; and *European and American ballads*, which have evolved from local events. Other folk song genres range from the Russian *bylina*, or epic songs of a medieval hero, to the *lullaby*, used to sing a child to sleep.

Still another category of oral literature comprises *folk speech*, as distinct from formal or standard speech, and various traditional kinds of expressive utterances. Prominent among them are the *proverb* or folk saying, embodying wisdom in pithy phrases; the *riddle*, an enigmatic question paired with a deceptive answer; the *tongue twister*, a nonsense sentence difficult to pronounce because of its string of assonances; the *toast*, a convivial expression voiced as a drinking salutation; along with other forms involving a special use of language. *Beliefs* or *superstitions* are sometimes expressed as wise sayings, although they may also appear in tales and in customs.

**Material culture.** At the opposite pole from oral literature in the spectrum of folklore lies material culture or folk life, terms used to denote the physical objects produced in traditional ways. Material culture thus embraces folk architecture, folk arts, and folk crafts. Under these headings can be placed the construction of houses, the design and decoration of buildings and utensils, and the performance of home industries, according to traditional styles and methods. The shape of fences, the making of sorghum molasses, and the sewing of quilts all fall under material culture.

**Custom and festival.** Between oral and physical folklore there is a large middle ground filled by custom, ritual, festival, children's games (believed to be versions of adult rituals), folk drama, play parties, rites of passage, folk dances, and equivalent genres involving action, performance, and paraphernalia. To the verbal and tangible elements are added group behavioral traits.

The functions of these three genres vary for individuals and societies, but generally it may be said that material culture fills economic and aesthetic functions, that oral literature fills didactic, recreational, and educational functions, and that custom and festival function to provide psychic reassurance against external dangers. Rites placate gods and demons, tales and songs entertain and instruct, and home-baked bread on a hand-carved table fills the stomach while pleasing the eye.

#### THE GENERAL FUNCTIONS OF FOLKLORE

**A behavioral classification of functions.** Oral literature, like written literature but even more pronouncedly, satisfies the desires of mortals to transcend their mundane world. In the myths the heroes visit the otherworld; in the legends ordinary folk are taken to fairyland; and in the *Märchen* the youngest son or daughter of a peasant family makes a royal marriage. Gold, treasure, and wealth are prominent in narrative folklore. Jason and the Argonauts in Greek myth set out for the Golden Fleece; in fairy tales a magic goose lays golden eggs; and in real life, treasure seekers dig for the buried booty of pirates and outlaws. The Irish tradition of "Seán Palmer's Voyage to America with the Fairies" (in *Folktales of Ireland* by Sean O'Sullivan), told as an actual experience befalling Seán Palmer of County Kerry, combines the traditional theme of fairies transporting mortals to distant cities with a wish fulfillment fantasy. Seán believes the

The  
escapist  
function

fairies take him by boat overnight to the United States, where he visits relatives in New York and Boston and is given money, new clothes, and tobacco. Many Irishmen have relatives in the U.S. whom they consider rich and long to visit.

Another way in which folklore lifts man above his narrow confines is in the breaking of powerful social taboos. What man can never do in actuality without incurring severe punishment the trickster in American Negro narratives, for example, does with impunity, such as John the slave slapping the face of his white mistress. Modern jokes with their heavy emphasis on genital-anal humour similarly arouse merriment by flaunting taboos.

The  
etiolo-  
gical  
function

Mythic narratives and explanatory episodes in other kinds of folktales answer man's perennial questions: How did the world begin? Who created man, the animals, and the plants? The book of Genesis in the Bible gives two versions of a creation myth with worldwide analogies. Myths of origin are always ethnocentric; they explain the creation, by supernatural powers, of the people possessing the myth, a chosen people. The hostile, formidable, mysterious universe assumes a familiar outline through the personification of a creator and his adversary and of associated deities and demons with their own spheres of influence. Tribal peoples need their myths to safeguard their identity. An Ojibwa Indian in northern Michigan asked a researcher on their first meeting, "Do they have thunder storms in South America?" On receiving an affirmative answer the Ojibwa turned morose and taciturn and refused to speak further. He had wished reassurance that thunderstorms existed only in the neighbourhood of Lake Michigan, since the Ojibwa protective deities were thunder spirits. Later, when mollified, he related a version of the creation myth, synthesized with the flood myth. The culture hero-trickster figure, Winabijou, flees from the underneath serpents, who send flood waters after him. He takes refuge atop a pine tree and barely keeps his head above the water that covers the earth. Water animals swim to him, and he sends them down to the bottom; the muskrat comes up with mud in its paws, with which Winabijou makes a little island. Each day the island gets bigger, and Winabijou sends the fox along the shore to circle it and report back. Eventually the island grows to the size of the present earth. "And you can see a fox trotting along the shore today," the narrator concluded. "The shore gets bigger too. Sand multiplies. When I first came here the beach on the cove was only half as big as it is now." The myth satisfactorily accounts for his universe.

The  
justifying  
function

Just as myths are generated to explain the physical world and its inhabitants, so does folklore at large provide support for the institutions and behaviour patterns of a culture. In nonliterate societies the central events of human life—birth, attainment of manhood, marriage, and death—are invested with elaborate ceremonials by which the social organism marks the mortal's progress and final exit to the afterlife. In modern society the quasi-religious character of these passage rites, as Arnold van Gennep has termed them, can be observed in the rituals of baptism, confirmation or graduation, weddings, and funerals, which are sometimes secular, sometimes ecclesiastical, and sometimes a mixture of both. In contrast to supernatural beings, who acquire anthropomorphic personalities and walk the earth (like Winabijou, or Christ and St. Peter), historical heroes acquire supernatural attributes and move heavenward. The illustrious secular heroes and heroines—like Joan of Arc, Confucius, Peter the Great, Julius Caesar, King Alfred, and George Washington—become national symbols, consecrated with monuments, holidays, hagiographic literature, and folk legends. They function in the national culture as standard-bearers of the values and goals of the nation. The legend of young George Washington saying to his father, "I cannot tell a lie, it was I who chopped down the cherry tree," drives home the moral of the proverb ascribed to Benjamin Franklin (but actually common in Europe in the 17th century and earlier), another culture hero: "Honesty is the best policy."

A good deal of folklore, especially the proverbs, fables, cautionary tales, and confessional ballads, serves to instruct and remind members of society of wise codes of conduct. The proverb and the fable may teach the same lesson; "Pride goes before a fall" is illustrated in Aesop's fable of the cat who praised the crow's singing voice, so that the crow up in the tree started to sing and dropped the cheese from her mouth to the ground. Proverbs may sometimes appear contradictory. "Look before you leap" is challenged by "He who hesitates is lost," but each saying contains its truth to be applied to a given situation. A whole ethic may be summarized in a proverb, as is the Protestant ethic of hard work in the saying, "Early to bed, early to rise, makes a man healthy, wealthy, and wise."

Although proverbial expressions are still frequently uttered in industrialized societies, they are used as mild commentary and poetic cliché rather than, as in African societies, for firm codes with the force of judicial precedent. The African novelist Chinua Achebe writes in *Things Fall Apart*, "Among the Ibo the art of conversation is regarded very highly, and proverbs are the palm-oil with which words are eaten." And his novels are sprinkled with proverbs. Actual court cases among the Anang Ibibio of Nigeria in which judges were swayed by proverbs have been recorded by the anthropologist John Messenger. On one occasion the chief judge advised the plaintiff and his witnesses, "If you visit the home of the toads, stoop," when they refused to make their statements under oath and thereby forfeited their case. The equivalent precept, still forceful in modern life, is "When in Rome do as the Romans do." Among the Bambara-speaking people of Mali in Africa, the *griots*, the celebrated epic bards, customarily "warm up" before their recitations and during breaks in their lengthy performances by singing proverbs in rapid sequence. This practice serves the function of gaining the attention and respect of the audience, who think of proverb sayers as wise men knowing how the society works; hence the listeners will be ready to credit the historical tradition that follows.

Besides suggesting rules for conduct, folklore also drives home the need for proper social behaviour by holding up to scorn those who depart from socially accepted norms and by eulogizing those who follow them. Jokes, the most popular form of oral literature in modern society, ridicule stereotyped characters who display traits disparaged by the Establishment. The stingy Scotsman, the miserly Jew, the ignorant Irishman, and the stupid Polack are all caricatured in joke cycles whose implicit values laud the qualities of liberality, generosity, intelligence, and cleanliness. Anecdotes of local characters similarly excoriate the slovenly, shiftless, degenerate, gullible, and naïve. One favourite theme of anecdotes is the lazy man, often identified with some local ne'er-do-well. Starving to death, the lazy man is offered popcorn: "Is it shelled?" he asks, and prefers to starve rather than do the labour of the shelling. Just as proverbs teach the gospel of work, so do such anecdotal legends mock the idle and improvident. Conversely, folklore also exalts individuals who exemplify the virtues considered admirable in the culture. Saints' legends recount the miraculous cures and rescues that the saint revered by the folk (who is not necessarily canonized by the church) has effected for the faithful. Devout members of the Mormon Church continue to relate experiences of succour given them in distress by one of the three Nephites, who appears as a stranger in white garments to render assistance and vanishes as mysteriously as he materializes. Heroes in ballad, legend, and *Märchen* reflect the dominant values of their societies and are rewarded by success. The champion of heroic epics is an invincible warrior. The hero of Negro ballads is a big-talking badman. The modern hero in the anecdotal legends of youthful dissenters is the antihero who sells LSD pills or marijuana and outwits narcotic agents, the police, and draft boards. All these heroes symbolize ideal types for their social groups. Deviation from the ideal brands the nonconformist a coward, an Uncle Tom,

The  
pedagogic  
function

The  
controlling  
function

or an Establishment toady. In the form of folklore known to 17th-century American Puritans as the "remarkable providence," God punished sinners, blasphemers, heretics, witches, marauding Indians, and critics of the state with acts of supernatural vengeance, while rewarding his elect with supernatural assistance during their wilderness trials. Puritan clergy collected and published these providences as lessons and guideposts for their people. In Socialist countries of the 20th century, the governments have taken a hand in the process of regulating conformity by awarding prizes to folk poets and folk narrators who attack bourgeois and capitalist villains and extol peasant and Socialist heroes.

**A cultural-geographical classification of functions.** Generalizations about the functions of folklore need to be qualified by considerations of culture area and social milieu. One kind of distinction should be made between Old World and New World folk traditions, since North and South America were colonized by Europeans, who then transported African slaves to their overseas empires. Consequently, a given country of the New World possesses several coexisting and interacting traditions; the indigenous Indian; the colonizing Spanish, Portuguese, French, or English; the African Negro; the 19th- and 20th-century European and Asian immigrant; and the national and regional, shaped by new historical and environmental factors. The continent of Australia also belongs with the New World in this regard, its folklore being divided between the Aborigines and the English settlers. In the colonized nations, each folk tradition serves to reinforce the group identity of its members in a pluralistic culture. Syncretism, or the fusion of different traditions, is a process especially characteristic of New World folklore. The miraculous appearance of the Virgin of Guadalupe to the Aztec Indian Juan Diego in 1531, who received from her a painting of herself on his cape, brought together Spanish-Catholic and pre-Conquest Indian strains. Mexican Indians and mestizos identified the Virgin with an Aztec goddess Tonantzin, pictured her as dark in hue, and celebrated her with costumed dances of pagan origin but within the framework of Roman Catholic worship and beatification. The ballad of "John Henry," relating the contest between a brawny Negro labourer and a new steam drill on a railroad tunnel in West Virginia in the 1860s, is widely sung by both American blacks and whites. John Henry dies "with his hammer in his hand," and interpreters see him as a symbol of the unequal struggle of the black man against the white, and of man against the machine. Immigration has brought large numbers of Slavs to western Canada, Japanese to Brazil, Italians to Argentina, Germans to Chile, and many peoples to the United States, whose folkways partially survive the transoceanic crossing. The traditional lore physically connected with the original homeland seems to vanish the most quickly; thus the Irish belief in fairies does not survive, since the grassy circular "fairy rings" inhabited by the fairies of the Old Country are not found in America.

Literate  
and  
nonliterate  
functions

Another large distinction in the functioning of folklore separates the so-called nonliterate societies lacking written languages from the advanced civilizations engulfed in print. Reliance on the oral tradition is obviously far greater in the nonliterate cultures. The matter of recording history provides one example: instead of referring to printed books containing a great many facts that no one person could or would wish to keep in his head, the tribal groups depend upon reciters of historical traditions, some of whom, like the *whare wananga* of the New Zealand Maori, the sagamen of 11th-century Iceland, and the *griots* of Mali, have a professional status. These annals and genealogies bear little resemblance to documented written histories and belong properly to the products of oral literature, since they include magical and marvellous episodes of folktales and legends. They do correspond in function to national histories in celebrating the achievements and culture heroes of a chosen people. An ingenious study by two teams of American anthropologists who collected traditions from two rival

Indian tribes in northern California revealed a similar patterning but contrasting roles for the same characters and events. The enemy tribe was always guilty of the provocative incident, fought dishonourably, and suffered defeat.

Even in literate civilizations large enclaves of largely oral, tradition-directed cultures persist. Narrators with enormous repertoires have been located in the 20th century in the Gaelic-speaking highlands and islands of western Scotland and western Ireland. Peig Sayers of the Great Blasket Island related 375 tales to the collectors of the Irish Folklore Commission, many of them long wonder tales taking all evening or several evenings to complete. In modern urban, technological society, such reciters find no audiences. Life has too many distractions and diversions and sources of information. Nevertheless, story-telling continues among the highly literate, in the form of joke-telling sessions, which may last an hour or two; but the jocular narratives are relatively brief, snappy, and quickly climactic. They serve as icebreakers to establish camaraderie in a group, although they may also give offense to some members of a social gathering with differing political or moral views. Ballad making originally made possible the dissemination of sensational news in attractive form and receded with the advent of newspapers, which emulated many of the same techniques of ballad makers in their handling of lurid news items.

Oral and literary cultures are no longer sharply divided. On the lower levels of society cheap printed sources—such as chapbooks, broadsides, jestbooks, mass magazines, almanacs, and newspapers—feed materials into and draw from oral streams of lore. In the electronic age, according to Marshall McLuhan, the literate world is reverting to an oral-aural community.

Folklorists at first identified their subject with the rural peasantry. Seasonal festivals, old wives' remedies, supernatural beliefs in demonic figures, and magic makers flourished in the countryside. Cities were the centres of learning, industry, and wealth, and the spoilers of tradition and folklife. This easy contrast is being revised as folklore scholars turn their attention to the cities where ethnic neighbourhoods and occupational workers form closely knit, tradition-bound societies. A team project of Hungarian folklorists investigating Budapest reported many vigorous manifestations of traditional behaviour, such as May Day celebrations, dancing parties held by tradesmen, housewarming ceremonies, and occupational jokes. In a detailed study of a Tokyo district, R.P. Dore reported on households that maintain traditional festival practices and the ancient Shintō beliefs in *kami* (deities) and *fuda* (shrine amulets). But city life does of course affect traditional ways brought in from the country. The ubiquitous Japanese-peasant conception of the *Kappa*, a dangerous boy-goblin with an inverted saucer on his head containing magical water, is found in Tokyo in newspaper comic strips, on decorative designs, or as a character in a novel by Akutagawa Ryūnosuke. In a series of ethnographic studies in Yucatán, the American anthropologist Robert Redfield compared four communities, ranging from the simple village to the complex town, and found that living rituals in the village become desiccated superstitions in the town.

Field research in the steel-manufacturing cities of Gary and East Chicago, Indiana, by Indiana University folklorists has shown not only a decrease in the folklore genres of the many ethnic groups living there but also an emergence of a new city lore. The chief elements of this lore derive from the human side of the all-encompassing steel industry, from fears and rumours about crime and the Mafia, and from anecdotes and stereotypes about other racial and ethnic groups. This emerging lore provides a sense of solidarity and rootedness in the impersonal, unlovely city.

#### THE DIFFUSION AND ACCULTURATION OF FOLKLORE

Folklore is at once remarkably stable and remarkably shifting. These phenomena have intrigued folklorists.

Correspondence  
between  
oral and  
literary  
cultures

who explain the apparent paradox through the mechanism of diffusion. A complex item of folk tradition, whether an epic song, a house style, a folk drama, or a wonder tale, once it has attained coherent form, may travel across continents and oceans and endure through the centuries. The basic type retains its outline but external features are continuously modified and adapted to new surroundings. Barriers of language, religion, and culture offer no obstacles to the movements of folk products. The most bitter of enemies share the same traditions. Supporters of diffusion challenged the upholders of independent invention in the latter decades of the 19th century and eventually won the day as depth field studies proved clearly the wanderings and migrations of individual texts. The first comparative study of a folktale, Marian Cox's *Cinderella* (1893), brought together 345 variants of the same recognizable story plot. Even legends, seemingly so anchored in time and place to specific historical events and personalities, were shown to migrate and become attached to different localities and heroes. The legend of the Returning Hero, sleeping in the fastnesses of the mountain with his warriors until his people would summon him to their rescue, fastened on to Frederick Barbarossa, King Arthur, and Thomas the Rhymer and is still told of modern figures. How did folklore diffuse? Proponents of diffusion offered various explanations: sailors, merchants, and travellers transported folk matter along the great historic trade routes; Gypsies acted as peddlers of folklore; borders between peoples served as bilingual zones through which songs, tales, and styles easily moved; imperial powers planted the traditions of the mother country in distant places. All these hypotheses have some merit; European tales found among North American Indians, for instance, undoubtedly date back to the period of their first culture contact with French and Spanish missionaries, soldiers, and traders. Yet Indian tales did not lodge in the narrative repertoires of the European settlers. The flow appears to go from literate to nonliterate cultures.

#### Movement of folklore by ac- culturation

Acculturation represents a somewhat different phenomenon of folklore movement. Here not the lore but the folk move, bearing with them their ancestral heritage. What happens to this heritage when peasants of India resettle in Africa, when Chinese move to Malaysia, when European communities pour into the New World? The resulting process of adjustment, adaptation, compromise, and assimilation is called acculturation. But what takes place in this process is not so easily understood. Parts of the Old Country tradition recede into "memory culture," to be recalled on direct stimuli but otherwise lying dormant in the recollections of the first generation. Other parts remain in vigorous use. Still other parts take on New World coloration. Among Greek immigrants in the United States, for instance, the telling of paramythia (or *Märchen*) and the sighting of creatures like the *vrykolakas*, a vampire demon, have virtually ended, but the belief in the power of the evil eye and of the protective power of saints remains as strong as ever. As a general principle, the beings of lower mythology do not transplant into an alien environment, whereas the daily and seasonal rituals and associated beliefs can be maintained within compactly settled groups. The rate of acculturation will vary greatly between immigrant societies, depending upon what conservative forces are at work. Such groups as the Pennsylvania German Amish and the Hasidim in Brooklyn, N.Y., retain a high degree of their magical belief system, folk arts, and ritual observances, because they have made strenuous efforts to wall themselves in from the mainstream of American culture, an effort strengthened by their independent churches. By contrast, Irish-Americans after a century in their new homeland have lost most of their distinctive folklore and blended in with the rest of the general Catholic and middle class population.

The mobility and technology of modern man have noticeably affected the diffusion and acculturation of folklore. People emigrate by airplane, communicate by telephone, and soak information from the mass media. Yet

old ways of thinking and believing show remarkable tenacity. Many folk today discredit the landing of men on the moon as a publicity hoax contrived by the United States government and the television networks. These are the people who have seen flying saucers, been cured by faith healers, and conversed with revenants. Folklore is as old, and as young, as man.

**BIBLIOGRAPHY.** A. AARNE, *The Types of the Folktale*, 2nd rev., trans. and enl. by S. THOMPSON (1961), the standard index and reference work for the most widely distributed European folk narratives; F.J. CHILD (ed.), *The English and Scottish Popular Ballads*, 5 vol. (1882-98), the classic assemblage of 305 ballad types, with variant texts and learned headnotes; W.A. CLOUSTON, *Popular Tales and Fictions*, 2 vol. (1887), an early discussion of the wandering and migrations of folktales between India and Europe; M.R. COX, *Cinderella* (1893), the first comparative study of an international folktale, bringing together 345 variants, and contributing to the thesis of diffusion rather than independent invention of complex tales; L. DEGH, *Folktales and Society* (1969), a depth field study of storytelling behaviour in a Hungarian peasant community, with biographical portraits of leading folk narrators; R.M. (both 1968), a history of the concept of folklore as it emerged in England with the 16th-century interest in antiquities and came to fruition among Victorian private scholars in the late 19th century—the volumes of selections present illustrative writings of the folklorists discussed in the history, and "Folktales of the World" (1963- ), a series of authoritative volumes each of which is prepared by an eminent folktale scholar from the country represented; A.B. FRIEDMAN, *The Ballad Revival* (1961), interest in the ballad in England by antiquaries, poets, and the public treated in terms of literary history; JACOB GRIMM, *Teutonic Mythology*, trans. by J.S. STALLYBRASS, 4 vol. (1883-88), the encyclopaedic and influential work in which Grimm expounded his theory of the degeneration of an ancient high pantheon of Germanic deities into the extant fairy tales and witch beliefs of the contemporary peasantry; F.R.S. RAGLAN, *The Hero: A Study in Tradition, Myth, and Drama* (1956), a highly controversial explanation of all mythic narratives as following a uniform pattern derived from ancient sacrificial fertility rituals; Y.M. SOKOLOV, *Russian Folklore*, trans. by C.R. SMITH, (1950), a history of Russian folklore research given from the Soviet viewpoint regarding folklore as an expression of the class struggle; S. THOMPSON, *Motif-Index of Folk-Literature*, rev. ed., 6 vol. (1955-58), the major reference work in comparative folklore; J. VANSINA, *Oral Tradition* (1961), presentation of an historical methodology for the African historian enabling him to use oral historical chronicles and genealogies as legitimate source materials; D.K. WILGUS, *Anglo-American Folksong Scholarship Since 1898* (1959), a judicious appraisal of the recent schools of interpretation in ballad and folk-song studies.

(R.M.D.)

## Folk Music

Differences between folk music and other types of music, such as popular music and cultivated, art, or classical music, are by no means precise. Typically, folk music lives in oral tradition; it is learned through hearing rather than reading. It is functional in the sense that it is associated with other activities. Primarily rural in origin, it exists in cultures in which there is also an urban, technically more sophisticated musical tradition. Folk music is understood by broad segments of the population, while cultivated or classical music is essentially the art of a small social, economic, or intellectual elite. On the other hand, that widely accepted type of music usually called "popular" depends mainly on the mass media—records, radio, and television—for dissemination, while folk music typically is disseminated within families and restricted social networks. But the introduction of songs from folklore into the mass media blurs the distinction, and folk music in earlier times may be discussed separately from that of the period after World War II. Moreover, while folk music as defined above exists in all cultures in which there is also a cultivated musical tradition, such as Japan, China, Indonesia, India, and the

Middle East, the usefulness of the concept varies from culture to culture. It is most convenient as a designation of a type of music of Europe and the Americas.

#### GENERAL CHARACTERISTICS

Perhaps the most important characteristic of a folk song is its dependence on acceptance by a community—that is, by a village, nation, or family—and its tendency to change as it is passed from one individual to another and performed. This process is known as “communal re-creation.”

Origins and functions

A piece of folk music is the property of the entire community. But contrary to beliefs promulgated in the 19th century, folk songs are normally created not by groups of people but by individuals. When it is first composed, each song is the work of one composer, though it is re-created constantly by the performers who learn and sing it. The composer may create new songs by drawing together lines, phrases, and musical motifs from extant songs, possibly combined with entirely new ones and with standard opening or closing formulas. In European folk music, a small number of tune types account for most of the repertoire. English folk music, for example, is believed to consist largely of about 40 “tune families,” each of which descends from a single song. And the majority of English folk songs are members of only seven such tune families.

There is frequent interchange of tunes between neighbouring countries. A few tune types are found throughout the European culture area. Each country, however, tends to have a repertory of its own, with stylistic features as well as tunes that are not shared with neighbours. Textual types (such as ballad stories) are more widely distributed than tune types.

The 20th century has seen the decline of folk tradition in many areas, particularly those that became heavily urbanized and industrialized. From the Middle Ages until the 19th century, folk music probably had been distributed evenly throughout Europe and the Americas. After 1950, folk music was found most readily in areas that were not heavily industrialized, such as the isolated mountainous regions of North America or of Italy and in the countries of eastern and southern Europe. In the Americas, folk music of European origin became mixed with elements of non-Western music, especially African and (in Latin America) American Indian.

Much folk music can be said to be “functional” in that it is not primarily entertainment or of aesthetic interest but an accompaniment to other activities, particularly ritual, work, and dance. In a traditional folk society, music is a necessity in almost all rituals and festivals. The words of folk song can serve as chronicle, newspaper, and agent of enculturation. In modern industrial nations, folk music is perpetuated by ethnic, occupational, or religious minorities, among whom it is thought to promote self-esteem, self-preservation, and social solidarity. Such functions of folk music have been used by organizations advocating social change, such as the U.S. civil rights and trade unionism movements.

**Transmission.** Folk music is usually transmitted by word of mouth, or oral tradition. This means that a folk song can change as a result of the creativity of those who perform it or of their particular musical style or of their faulty memory. As it is handed down from generation to generation a folk song develops additional forms, called variants, which may differ markedly from each other. For example, a song with four musical lines (e.g., *ABCD*) may lose two of these lines and take on the form *ABAB*. In turn, two new lines may be substituted for the initial two, giving it a form *EFAB*. Folk tunes also change when they cross ethnic or cultural boundaries. A German variant, for example, may exhibit characteristics of German folk music, while its variant in Czechoslovakia, although recognizably related, will assume the stylistic traits of Czech folk music. The degree to which songs change varies from culture to culture. In some, presumably those that value consistency and object to change, such as western Europe, songs change little and

slowly. In others, such as Afro-American cultures, the opposite tendency is found.

In spite of its dependence on oral tradition, folk music tends to be closely related to music in written tradition. Many folk songs originate in written form. For many centuries, popular and classical composers have adapted folk music, and in turn, influenced the oral tradition. A modern analogue of written tradition, recording, substantially influenced the oral tradition, as folk singers could hear various arrangements of folk music in private and commercial recordings. Thus, the transmission of folk music has not been an isolated process but one intertwined with other kinds of musical transmission.

**Composition.** The composition of folk music differs little from that of popular and classical music, except that most folk songs are composed without notation. The relationships among the sections of folk songs and their scales and rhythms are also found in the other music of the same culture. Systematic improvisation as a method of composition is found only occasionally, as in the epic songs of eastern Europe. It is often difficult to ascertain whether the same composer created both words and music in a folk song, but, in many, they are known to come from different sources.

Among the most important genres of folk music are ballads, generally short narrative songs with repeated lines, epics (longer narratives in heroic style), work songs, love and other lyrical songs, songs of a ceremonial nature accompanying the life cycle of man or the annual agricultural cycle, songs accompanying games, and lullabies. These genres are distinguished usually in their texts, but in some cultures, also in their music. Instrumental folk music is most frequently an accompaniment to dance.

**Relationship to other music.** The relationship of folk music to art music became a topic of interest in the late 18th century when Western intellectuals began to glorify folk and peasant life. Folk music came to be venerated as a spontaneous creation of peoples unencumbered by artistic self-consciousness and aesthetic theories and as an embodiment of the common experience of inhabitants of the locale. These traits make folk music a fructifying source for art music, particularly when it is intended to express a particular nation or ethnic group. Another theory is that folk music is not created by the folk but is popular music and art music that has “trickled down” to the folk and undergone various transformations (usually debasements) through oral tradition.

A viewpoint intermediate between these two positions has been widely held since 1950. Folk music is seen neither as merely debased art music nor as an essential component of art music. Rather, it is seen to have a symbiotic relationship to other music in the larger society of which the folk community forms a part. In Europe and the Americas the give-and-take between folk music and art music is well documented. Many folk songs collected in oral tradition have been traced to literary sources, often of considerable antiquity. Folk music has been consciously incorporated into European art music compositions throughout history, especially during periods of “renewal” such as the Renaissance, the late 18th century, and throughout the 19th and early 20th centuries.

Folk music is closely related to popular music in several ways. Societies possessing popular music also have a folk music tradition—or remnants thereof. The partial duplication of repertoires and style indicates such cross-fertilization that a given song may sometimes be called either “folk” or “popular.” With reference to music, the terms folk and popular are two points on a musical continuum, rather than discrete bodies of music. From a sociological viewpoint, however, folk and popular music have less in common. Unlike folk music, popular music is primarily produced by professionals for consumption by an urban, nonparticipating mass audience. The vital criteria of folk music (i.e., oral tradition, communal re-creation, etc.) are not operative.

Folk and popular music tended to merge in the 20th

Variants in folk music

Relation to popular music

century. As folk societies came increasingly within the purview of modern urban society, oral tradition was supplemented or supplanted by the radio and phonograph record. Some folk music thus transmitted maintains stylistic authenticity, but some assumes the characteristics of popular music. Much of what is called folk music in English-speaking countries is a subcategory within popular music. It is the product of urban professionals who appropriate authentic folk music styles for concert and recorded performances.

Relation  
to jazz and  
rock music

There has been some interaction between folk music and rock music, as the generic designation "folk-rock" indicates. Folk-rock arose in North America in the 1960s. In its texts, it is modern urban folk song, with topical subject matter, often on social and moral issues. Musically, however, it has the characteristics of rock in its electrified string band and percussion accompaniment. Other current music that mixes folk and popular elements includes: African high life, American jazz, rhythm and blues, country-western music, and many Latin American forms, such as the tango and bossa nova.

Relationships between church music and folk music must also be noted. Some church music derives from the application of religious texts to secular folk tunes. This practice may be seen, for example, in the hymns of the Protestant Reformation and in the revival hymns of 19th century American camp meetings, which were called "folk hymns" because of their origins and associations with folk-like groups.

There are many types of folk dance, some widespread throughout Europe, others peculiar to nations and regions, each with its typical musical style. Certain musical forms appear most typically in the folk dance music of various parts of Europe. Most prominent is a form type in which each line is repeated once, with a minor variation, usually at the end—e.g.,  $A^1A^2B^1B^2C^1C^2$ . Vocal dance music also exists, and in northern Europe even narrative ballads were used for dancing.

**Melodic form.** The typical melodic form of European folk music is strophic, that is, a stanza consisting of from two to eight lines (but most typically, four lines) is repeated several times in the song between successive stanzas of the text. The relationship among the lines of the repeated stanzas varies. For example, in English folk music, four lines with different content are common ( $ABCD$ ), but forms whose endings revert to materials presented at the beginning are also common (e.g.,  $ABBA$ ,  $AABA$ ,  $ABCA$ ,  $ABAB$ ). Similar forms are found in eastern Europe, where the use of a melodic line at successively higher or lower levels is also important. Thus, in Hungarian folk music, the form  $AA^aA^aA$  or  $AAA.AA$  (the numbers indicating intervals of transposition) is common. In Czech folk music,  $AA^aBA$  is a common form. Despite the variety of arrangement of the musical lines of a song, the textual and musical lines nearly always coincide. In western European folk music, these lines are almost always of equal length; eastern European folk music frequently departs from this principle.

Excep-  
tions to the  
strophic  
form

Among the exceptions to the strophic form are children's songs and ditties and epic songs. The former tend to be simple: they use limited scales and rhythms and small melodic range, and they may consist of only one musical line repeated many times. They appear to form an archaic stratum of European music and tend to be similar in musical content throughout the continent.

Epic folk singing is limited to a small number of folk traditions: Balkan, Finnish, and Russian, as well as non-European cultures. The tendency to repeat and vary a musical line many times is also found in epic singing, which is to some extent improvised.

The influence of popular music on folk music, which became very strong in the 19th and 20th centuries, has tended to limit and to standardize forms. The variety of melodic forms is greater, for example, in older English, Anglo-American, German, and Czech folk music than in later music.

Most folk music is monophonic (that is, with only one melodic line), but polyphonic folk music, with several

melodic lines, is found in some parts of the world. The accompaniment of melody by instruments is widespread as well, though all cultures have many songs that may be sung without it. The accompaniment of folk music in western Europe appears to have changed over the last thousand years. Originally, very simple, perhaps drone-like material was performed by string instruments such as harps, zithers, and psalteries. Later, simple harmonic sequences developed that were closely related to the practices of 18th century classical music and involved a larger variety of instruments, including especially guitars, banjos, and string ensembles. The popular folk music of the modern cities embodies still more complex harmonic idioms.

Polyphonic vocal folk music is far more common in eastern and southern Europe than in western Europe. Styles vary from the simple two-voiced structures using dronelike techniques and parallel singing of the same tune at different pitch levels in Italy and the Balkans to the more sophisticated choral songs in three or four voices, found in Russia, the Caucasus, and the Ukraine. Rounds are found throughout Europe. Heterophony—the simultaneous performance of variations of the same tune by two singers or by a singer and his accompanying instruments—is important among the southern Slavic peoples. Parallel singing is perhaps the most common type of folk polyphony: parallel thirds, that is, singing the same tune at an interval of a third, are found in Spain, Germany, Austria, Czechoslovakia, and farther east; parallel fourths and fifths are sung in the Slavic countries. Instrumental folk polyphony is geographically more widespread than vocal. Bagpipes, for example, which use the drone principle, are ubiquitous in Europe. Scandinavian vocal music is largely monophonic, but complex styles of instrumental polyphony were developed in the repertoires of various types of fiddles, such as the Norwegian Hardanger fiddle.

Mono-  
phonic and  
polyphonic  
forms

Instru-  
mental  
polyphony

It must be borne in mind that certain cultures, such as the British, the Hungarian, and the Cheremis, or Mari people of Russia, while having very little polyphonic folk music, have developed highly complex repertoires of monophonic folk song. Polyphony should not be considered an indication of an advanced state of art.

**Rhythm and metre.** In folk music, rhythm and metre largely depend on the metre of the poetry. Thus, in western Europe, where poetry is organized in metric feet, there is a tendency toward even isometric structure based on one type of metre—typically,  $\frac{4}{4}$ ,  $\frac{3}{4}$ , or  $\frac{6}{8}$ , although  $\frac{5}{4}$  also appears. In eastern Europe, generally, the number of syllables per line is the main organizing factor, regardless of the number of stressed syllables. Accordingly, the number of notes but not the number of measures is important, and repeated but complex metric units (e.g.,  $\frac{7}{8}$ ,  $\frac{11}{8}$ ,  $\frac{13}{8}$ , etc.) appear, particularly in Hungarian, Yugoslav, Bulgarian, and Romanian songs.

Rhythmic structure is closely related to singing style. Singers in the older, ornamented styles frequently depart from rigid metric presentation for melismata (i.e., a single syllable sung to a series of notes) and other expressive effects. Generally speaking, instrumental music is more rigorously metric than vocal. Nonmetric material, some of it consisting of long, melismatic passages, is also found in vocal and instrumental music in parts of Europe influenced by Middle Eastern music, such as the Balkan and Iberian peninsulas.

Metre and  
singing  
style

**Scales.** Generally speaking, the scales of European folk music fit into the diatonic tone system of European art music. On the whole, the scales of folk music in Asian high cultures are closely related to those consisting of two, three, or four tones, typically using major seconds and minor thirds. These scales are normally used in single-line songs, such as children's ditties, game songs, and lullabies, and they resemble the world's simplest music, that of certain tribal cultures. Among the most important scale types in Europe is the pentatonic, usually consisting of minor thirds and major seconds; it is found throughout the continent but especially in songs and song

types not strongly influenced by the art music and popular music of the cities. Diatonic modes are the third important group. The modes most frequently used are Ionian (or major), Dorian, and Mixolydian, but Aeolian, Phrygian, and Lydian are found as well. The Ionian mode is most common in western and central Europe; others are found in eastern Europe, Scandinavia, and England (as well as in English-derived music around the world).

Scales with a predominance of small intervals close to minor seconds are found in the areas once influenced by Middle Eastern music.

**Instruments.** The instruments of folk music vary enormously in type, design, and origin. They can be divided into roughly four classes.

Four  
classes of  
folk  
instru-  
ments

Among the simplest instruments are those that European folk cultures share with many tribal cultures throughout the world. Among them are the following: rattles; flutes, with and without finger holes; the bull-roarer; leaf, grass, and bone whistles; and long wooden trumpets, such as the Swiss alpenhorn. These instruments tend to be associated with children's games, signalling practices and remnants of pre-Christian ritual. They evidently became distributed throughout the world many centuries ago.

A second group consists of instruments that were taken to Europe or the Americas from non-European cultures and often changed. Among them are bagpipes, the folk oboes of the Balkan countries, the banjo, the xylophone, and folk fiddles such as the Yugoslav one-stringed *gusle*.

Another group consists of the instruments developed in the European folk cultures themselves from simple materials. A characteristic example is the *Dolle*, a type of fiddle used in northwestern Germany, made from a wooden shoe. A more sophisticated one is the bowed lyre, once widespread in northern Europe but later confined mainly to Finland.

The fourth group that is of great importance comprises instruments taken from urban musical culture and from the traditions of classical and popular music and sometimes changed substantially. Prominent among these are violin, bass viol, clarinet, and guitar. In a number of cases instruments used in art music during the Middle Ages and later, but eventually abandoned, continued to be used in folk music into the 20th century. Examples include the violins with sympathetic strings found in Scandinavia (related to the viola d'amore) and the hurdy-gurdy, still played in France, and related to the medieval *organistrum*.

**Performance styles.** The manner of both vocal and instrumental performance of folk music may vary greatly. In general, they differ considerably from Western art music. The sometimes strange, harsh, and tense voice in folk song is no more or less natural—or intentional—than the vocal style of formally trained singers. The manner of singing and the tone colour of instrumental music are among the most important characteristics of a folk music. They are less subject to change over a period of time and less subject to influence than other characteristics of music such as scale, rhythm, and harmony.

Speaking very broadly, European folk music is sung in one of two styles, named *parlando-rubato* and *tempo giusto* after studies of east European folk music by the eminent Hungarian composer Béla Bartók. The first style, *parlando-rubato*, is probably older. Stressing the words, it departs frequently from metric and rhythmic patterns and is often highly ornamented. The second style, *tempo giusto*, follows metric patterns more precisely and maintains an even tempo. Both styles are found in many parts of Europe and in European-derived folk music. Using other criteria, the contemporary U.S. folk specialist, Alan Lomax, found three main singing styles in Europe and the Americas. The "Eurasian," found mainly in southern Europe and in parts of Britain, is tense, ornamented, and essentially associated with solo singing. The "Old European," found in central Europe and parts of eastern Europe, is more relaxed. Produced with full voice, it is often associated with group singing

in which the voices blend well. The "modern European," found mainly in western European singing of more recent materials, is something of a compromise between the other two styles.

Before the 20th century members of a community probably tended to sing very much in the same style. In the 20th century—probably because of the influence of popular music, radio, and records—folk singers began to develop intensely personalized repertoires and ways of performing, as may be seen in the work of popular folk singers.

In the Americas, the influence of African performance practices on Afro-American, as well as other folk music, has been important. Among these are the imaginative use of vocal tone colours, antiphonal and responsorial techniques, and complex rhythmic patterns.

#### STUDY AND EVALUATION

Knowledge of the history and development of folk music is largely conjectural. Musical notations of folk songs and descriptions of folk music culture are occasionally encountered in historical records. Such records, however, show not so much the history of folk music as the history of ideas held by the literate classes about folk music. It is assumed that throughout history literate society has possessed a musical culture different from that of their unlettered contemporaries. Their reaction to folk music frequently was one of indifference and, occasionally, derision and hostility. In medieval Europe, under the expansion of Christianity, attempts were made to suppress folk music because of its association with heathen rites and customs. Uncultivated singing styles were denigrated; Thomas Aquinas expressed a common sentiment when he likened artless singers to beasts. Some aspects of European folk music, however, became assimilated into medieval Christian liturgical music, and vice versa.

During the late 15th and 16th centuries, the literate urban classes responded more favourably to folk music than they had in the medieval period. The humanistic attitudes of the Renaissance, such as the elevation of nature and antiquity, encouraged the acceptance of folk music as a genre of rustic antique song. Some music in Renaissance manuscripts is presumed to be folk song by virtue of its musical simplicity and the rural and archaic evocations of its texts. It may, of course, have incurred stylization and change. Renaissance composers made extensive use of folk and popular music. Typical genres include polyphonic folk song settings and folk song quodlibets, or combinations of familiar songs. Folk tunes were often used as structural and motivic raw material for motets and masses, and Protestant Reformation music borrowed from folk music.

Folk music seems to have receded somewhat from the consciousness of the literate classes during the Baroque period. Folk song material in the music manuscripts and prints of the period is scarce, and there is less folk influence in cultivated music, with the notable exception of stylized dance-music forms.

During the late 18th century folk music again became important to art music, especially among the Viennese classicists. They incorporated folk tunes and the general style of folk music into their instrumental music. The growth of national historical consciousness and the idealization of the rural milieu led to the collection, preservation, and study of folk song in the late 18th and early 19th centuries. Folk song came to be considered a "national treasure" and of considerable artistic merit vis-à-vis cultivated poetry and song. National and regional folk song collections were published. Revitalization of folk music became a means of promoting nationalistic sentiment and a conservative ideology. Governmental encouragement of folk music became common after the early 19th century.

**Scholarship.** The search for origins and processes of development that motivated much 19th and early 20th century intellectual activity was reflected in folk music scholarship. Among the influences on research in folk music in the 19th century were anthropological con-

History  
and devel-  
opment of  
folk music

Vocal  
quality of  
folk music

cepts of cultural processes and the theory of evolution. Many scholars believed folk music to be a repository of archaisms—a legacy from which the prehistory of music, language, literature, and other cultural traits could be adduced. While later scholars concede that some traits of folk music may be centuries or even millennia old, they are less inclined to speculate on the age of archaic elements of folk music or to offer historical reconstructions other than tracing variants of individual songs or types of songs.

Scholars who specialize in folk music usually have training in ethnomusicology, a discipline concerned with elucidating music in a cross-cultural perspective. Research in the words of folk song remains the province primarily of folklorists and students of language and literature. Folk music theories are concerned mainly with how folk genres and styles and individual folk songs originated, and how, if, and why they change when diffused. Theories of folk music have been beclouded by the difficulties in recognizing, isolating, and defining a phenomenon as elusive and complex as folk music.

Since the last decade of the 19th century, folk music has been collected and preserved by mechanical recordings. The application of print and recording technology to folk music has made possible the revival of folk music where traditional folk life and folklore are moribund. Folk songs are frequently a part of public school music curricula; various clubs, organizations, and societies focussing in one way or another on folk music, often in conjunction with folk dance, have arisen; festivals of folk music and dance are an annual event in many communities throughout the world; conservatories of music have been established for the training of folk musicians, particularly in the Socialist nations; radio stations devote substantial portions of their programming time to the broadcasting of folk or folklike music—again, particularly in Socialist nations.

The literature on folk music is sparse in theoretical works, in historical studies, and in materials integrating and comparing the various styles of folk music in Western culture. There is a great deal of literature showing the relationship between folk music and cultivated music. Most plentiful, however, are collections of music and texts, particularly of individual countries or regions, and even of individual singers. These collections are useful for scholarly comparisons of melodies; they give an imperfect picture of performance practice, however, because Western notation cannot give a detailed description of all aspects of music. After World War II, the availability of commercial records did much to fill this gap, and archives of field recordings were developed at many institutions throughout the world. In the U.S., those of the Library of Congress and Indiana University are most important; national archives exist in most European countries, and particularly in Hungary, Czechoslovakia, Germany, and Scandinavia. Such archives provide ample research material for an enormous diversity of projects. Research has usually dealt with "authentic" (*i.e.*, older) material not heavily influenced by urban popular music and the mass media. Popular folk music has not been studied widely. Several organizations for the study of folk music exist, particularly the International Folk Music Council and the Society for Ethnomusicology.

**BIBLIOGRAPHY.** Among the scholarly periodicals devoted primarily to folk music, the most important are the *International Folk Music Council Yearbook* (1969– ), formerly the *International Folk Music Council Journal*; *Ethnomusicology* (1953– ); and the *Journal of American Folklore* (1888– ). General works on folk music of Europe and the Americas are BRUNO NETTL, *Folk and Traditional Music of the Western Continents* (1965); WERNER DANCKERT, *Das europäische Volkslied* (1939); the lengthy and subdivided article on the folk music of many countries in *Grove's Dictionary of Music and Musicians*, 5th ed. (1955); and GEORGE HERZOG, "Song," in *Funk and Wagnalls Standard Dictionary of Folklore, Mythology and Legend* (1950). An important survey of the world's folk music in its relationship to certain characteristics of cultures is ALAN LOMAX, *Folk Song Style and Culture* (1968). WALTER WIORA, *Europäischer Volkslied*

(1952), provides an anthology of formal and melodic types in folk music; *Europäische Volksmusik und abendländische Tonkunst* (1957) explores the relationships between folk and classical music throughout European history. BELA BARTOK, *Hungarian Folk Music* (1931), is a classic study of one folk music style. A.B. LORD, *The Singer of Tales* (1960), deals with the epic traditions of eastern Europe. C.J. SHARP (comp.), *English Folk Songs from the Southern Appalachians*, 2 vol. (1932), is the pioneer collection of Anglo-American song; the total tune repertory of the most important traditional ballads in England and North America is published in B.H. BRONSON, *The Traditional Tunes of the Child Ballads*, 4 vol. (1959–70). The best general survey of Anglo-American folk song is R.D. ABRAHAM and G. FOSS, *Anglo-American Folksong Style* (1968). The history of folk music research is treated in D.K. WILGUS, *Anglo-American Folksong Scholarship Since 1898* (1959). The modern urban folk song movement has given rise to a series of popular folk music periodicals, most of them ephemeral; notable American examples include *Broadside* (1962– ), and *Sing Out!* (1950– ).

(B.N.)

## Folk Visual Arts

In the broadest sense, folk art refers to the art of the people, as distinguished from the sophisticated, elite, or professional product that constitutes the mainstream of art in highly developed societies. The term in this comprehensive context combines some quite disparate categories of art; therefore, as a workable field of art-historical study, folk art is generally treated separately from certain other kinds of unsophisticated arts, notably the primitive (defined as the work of prehistorical and pre-literate peoples). Historically, the terms folk and popular have been used interchangeably in the art field, the former being specific in English and German (*Volkskunst*), the latter in the Romance languages (*populaire*, *popolare*); the term folk, however, has increasingly been adopted in the various languages, both Western and Oriental, to designate the category under discussion here. Currently, the term popular art is widely used to denote items commercially or mass produced to meet popular taste, a process distinguished from the manner of the folk artist, who typically creates by hand (or with limited mechanical facilities) objects designed for use by himself or his own circumscribed group. The distinction between folk and popular art is not absolute, however: some widely collected folk art, such as the chalkwares (painted plaster ornamental figures) common in America and the popular prints turned out for wide distribution, may be seen as the genesis of popular art; and the products and motifs long established in folk art have provided a natural source for the popular field.

Although the definition of folk art is not yet firm, it may be considered as the art created among groups that exist within the framework of a developed society but, for geographical or cultural reasons, are largely separated from the sophisticated artistic developments of their time and that produce distinctive styles and objects for local needs and tastes. The output of such art represents a unique complex of primitive impulses and traditional survivals subjected both to sophisticated influences and to highly local developments; aside from aesthetic considerations, the study of folk art is particularly revealing in regard to the relationship between art and culture.

As industry, commerce, and transportation begin to offer all people free access to the latest ideas and products, a true folk art tends to disappear; the integrity and tradition that formed its inherent character decline, and the heritage of home-produced products is undervalued for the very qualities that made it distinctive. Subsequent revivals, extensively sponsored by organizations, craft groups, governments, or commercial enterprises, are no longer the same thing.

The recognition of folk art as a special category came about during the late 19th century and was at first limited to the so-called peasant art of Europe, the "art of the land." The new intellectual climate of the time, with a romantic value attached to the simple life and the "folk soul," and the increasing spread of democratic or nation-

Definition  
of folk art

Contem-  
porary  
scholar-  
ship

alistic ideas brought the art of the common people into focus; and it was recognized that their simple tools, utensils, and crafts had aesthetic aspects. Prior to industrialization, such folk art was widespread throughout Europe, exhibiting almost everywhere local styles created by people who had no access to the products of the wealthy and who were engaged largely in agricultural, pastoral, or maritime pursuits. As sophistication advanced, localism began to break down along major routes, but the folk arts continued on the periphery, particularly in geographically isolated regions, where they had an opportunity not only to survive but also to elaborate.

Having only limited contact with the outside world, the inhabitants preserved their traditions, art forms, and methods of workmanship over a long period and, at the same time, had to rely on their own invention to create new styles and products at need. These outstanding regional arts provide a well-defined core of material in the field of folk art.

As the early colonists emigrated to undeveloped parts of the world, they, too, were isolated from the cultural developments of the homeland and forced to rely on their own skills for most of their products. The arts they took with them were transformed, and new arts emerged under the stimulus of a different environment and through contact with native cultures; the notable folk arts of the Americas were one result.

In time it was recognized that the great Oriental civilizations offered a distinction between the sophisticated and the folk parallel to that in Europe, and the rise of Oriental folk-art scholarship established the subject on a worldwide basis.

While it is generally agreed that a folk type of art has occurred at some time in many parts of the world (and may yet appear in newly developing countries), there are various areas in which such art has so far been ignored or has not been studied as a separate category. For instance, with the notable exception of Roman folk art, the folk distinction is not usually applied to the art of ancient civilizations nor to Islamic or Western medieval art. A summary at the present time is, therefore, necessarily concentrated on the more studied areas: European folk art of the 17th–19th centuries, colonial and postcolonial folk arts, and the folk art of certain major Eastern countries. In addition to the major folk regions, this article will deal with the categories, styles, content, and motifs of folk art.

#### GENERAL CONSIDERATIONS

Patterns of development

The extensive studies of European and American folk art over the past century have revealed certain patterns of folk-art development. Though these patterns are subject to revision as the field expands or is refined, they provide a basis on which cultural variations and less widespread or random occurrences may be considered.

**The utilitarian aspect of folk art.** Typically, the people who created the art were immediately concerned with producing the necessities of life; as a result, the art is often described as predominantly functional or utilitarian, in spite of the fact that there are important categories that are definitely not utilitarian, such as the widespread miniatures created simply for pleasure. It is true, however, that much artistic effort was absorbed in meeting everyday requirements. In the folk group, in which occupations were often seasonal or dependent on weather and where people had to provide their own amusements, the creation of useful objects became also a leisure-time activity on which creativity was lavished; a shuttle might be transformed with carving or a chest with painted designs, and even the corset stay came to be an art form. For this reason, folk art is best studied (as is primitive art) with the entire handmade product included and attention devoted to its cultural as well as its aesthetic significance. It differs from the study of sophisticated art, in which there is a long-standing distinction between fine and applied arts and a tendency to exclude, or at least segregate, the utilitarian from more strictly aesthetic forms.

Folk art was not created for museums. Certainly, some was designed to endure, such as documents, family portraits, and gravestones; occasional types were made purely for display, such as the "show towel" of the Pennsylvania Germans and the sampler (a piece of needlework with letters or verses embroidered on it as an example of skill); and certain household treasures were preserved for generations. In general, however, there was an indifference to permanence, so long as the function was served; and much of the art was expected to be either consumed or discarded after a celebrative appearance. There is a substantial percentage of intentionally ephemeral folk art—the marriage bowl broken after the ceremony, paper objects burned at funerals, festival breads, carnival figures, graffiti, snowmen; temporary symbolic designs were drawn on the threshold on feast days in India, for example, and were formed of flower petals for religious processions in Italy. Folk-art collections, thus dependent at least in part upon the accidents of survival, must be supplemented by photographic and written documentation in order for a representative view of the whole art to be obtained.

Art to be destroyed

**The role of continuous tradition.** The element of retention (prolonged survivals of tradition) is considered fundamental in folk art, as it is in folklore. In an isolated situation, the sophisticated ideas that penetrate are generally belated and simplified, and there is a natural trend toward conservatism. Both local and ancient traditions maintain a strong hold. Serviceable forms and familiar motifs are likely to persist, and changes are gradual in comparison to the sudden innovations possible in sophisticated art.

Yet a constant individuality and ingenuity affect the familiar mode, and an art uninhibited by arbitrary aesthetic rules takes many fresh directions. Thus, the fluctuating combination of retained and inventive elements is of significant interest.

**Characteristic materials and techniques.** The most easily distinguished characteristics of folk art as a whole relate to materials and techniques. Most commonly used were the natural substances that came readily to hand; thus, various materials that have little or no place in sophisticated art, such as straw, may figure importantly in folk art. Sophisticated media, such as oil painting, might be adopted if they could be manipulated, and manufactured products—notably paper, which was cheap and versatile—might be used where available. The unique forms evolved in these sophisticated media illustrate the way in which folk art draws upon the general culture in a limited way, while developing along original lines of its own.

Tools were usually few and often multipurpose: delicate Polish cut-paper designs were often executed with clumsy sheep shears; and in woodwork, chip carving (with ax or hatchet) and notch carving (V-shaped cuts with a knife) were widely used.

Some arts were well within the compass of folk technology; textiles often rival the sophisticated hand-made product in workmanship (differences being a matter of styles and themes). In many crafts, however, the folk artists evolved simpler methods of their own. Cut tin, in silhouette shapes or decorated by hand painting or pricking (marking out a design with small punctures), for example, is a common folk medium, whereas full-round bronze sculpture was not likely to be attempted. Again, the French Canadians used wood for "cathedrals" that were carpentered adaptations of their European stone prototypes.

Large-scale figures often reveal special devices that were invented to overcome technical deficiencies; some are crudely assembled from parts; many maintain a simple overall shape with details merely incised; feet might be represented by pegs inserted into bored holes. In pictorial representation, the difficulties of three-dimensional modelling, while readily solved by some groups, frequently resulted in a preference for outline and flat shapes; for the easier, profile view; and for the evolution of such forms as the silhouette and the shadow picture, made by outlining and filling in the shadow of a head

Devices used to overcome technical deficiencies

cast onto the wall or paper. The limitations forced a mutation in forms.

**Folk art in the urban environment.** Folk art is by no means restricted to characteristic regional groups or rural arts. It occurs, for example, among minority groups bent on preserving their ethnic or religious traditions and their typical products. There are various folk manifestations within an urban environment, particularly in connection with the celebrative arts, which have a strong traditional hold; for example, at Christmastime in Warsaw, the people carry about the city models they have made of their cathedral. Covered with salvaged coloured foil, the models incorporate a Nativity scene and are lighted by candles or, more recently, by small bulbs and batteries.

**Collective versus individual art.** While many folk artists are known by name and many specialized in a particular art form, the skills were mainly available to all (with a distinction between the crafts of men and women), and most of the people were productive. The originality that delights the collector was not emphasized by the people themselves, who were concerned with producing the best examples they could of the desired object decorated with the appropriate and traditional image. Without consideration of the group involved and of the circumstances of folk culture in general, the art can scarcely be interpreted.

**Categories of folk art.** Only a part of folk art falls into the recognized sophisticated categories of visual art, and even that part has its own adaptations.

**Architecture.** In architecture the focus is naturally on the basic dwelling and on a simple public or religious building. One of the oldest and most remarkable dwelling forms survives in the *trullo* of Puglia, in Italy. A circular dry-stone structure with a tall conical roof, it is often decorated with symbolic designs splashed in white; for multiple rooms, the basic construction is simply re-

islands, combining basic cubic forms with a variety of free shapes and inventive projections of balconies, overhangs, and exterior stairways, has been extensively studied and acclaimed by modern architects—as have the wooden churches of eastern Europe, with their delicate, needlelike wooden spires, and the wooden-stave churches of Scandinavia. Other unique forms are the Alpine house, with its steep, wide-eaved roof designed for snow; the cave dwellings of Spain, some with several rooms and a constructed exterior front; the adobe house; and the log cabin. A characteristic design may evolve for such outbuildings as the granary (notably the *hórreos* of Galicia), the dovecote, the straw shepherd's hut, or the barn. In community building, the walled agricultural villages with radial pathways to surrounding fields, the fishing villages which are oriented to a harbour, and the American stockade cluster as well as the village common exemplify the close relationship of folk design to folk activities.

**Painting.** The idea of a picture to be hung on the wall is by no means universal in folk art. It occurs in Europe, notably as the *ex-voto*, or votive offering, hung in churches and chapels, and in America, where portraits and local scenes were executed in oil, pastel, or water-colour. More typically, the painted depictions that occur in folk art are incorporated into other objects; for example, the American clock faces bearing local landscapes. A feature of some folk art is the "picture" displayed like a painted one but executed in such nonpaint media as fern, cork, shells, or embroidery. Oil paints and prepared canvasses are sophisticated materials and, though sometimes available, were often replaced by house paint or chalk and by silk, linen, or cotton fabric. Painting on velvet and underglass painting emerged as specific folk types. The amount of decorative painting on a particular object is often very extensive; among German and German-American groups, for example, every inch of a chest, bed, or chair surface might be covered. Walls or beams were commonly decorated with geometric and floral motifs and occasionally with scenes, though the available space did not encourage anything approximating the sophisticated mural. Painting on exterior walls was a feature in some areas, including parts of North Africa and India as well as Europe. Stencil painting, widely used for furniture and walls, illustrates the folk capacity for achieving varied effects within technical limitations.

In America the technique was applied to "theorem painting" (painting on velvet through a stencil, usually done with a dauber or pad and with some attempt at shading).

**Sculpture.** Some form of figural sculpture and a quantity of incised or relief decoration applied to a variety of objects appear to be almost universal. Work in wood was particularly widespread, though stone, a more difficult material, was also used, especially for gravestones and religious sculpture. Papier-mâché, with its quick and bold effects, was widely adopted both in the East and West for carnival and votive figures and for a multitude of toys. The folk artist was often at his best in making small things, delighting in toys, small-scale representations of daily activities, and such oddities as ships carved inside bottles. Miniature sculptures were often skillfully executed in elaborate groups; in Russia, for example, an entire herd of cattle was mounted on a jointed trellis designed to provide a scissorlike movement to the whole. Some figural types were created to be set up in groups, as were the European *crèche* figures (making up the Nativity or manger scene), toy soldiers, and Chinese miniature wedding processions. The creation of useful objects in an overall sculptured shape, both in pottery and wood, is also typical. In southern Europe or in Mexico, a bottle, flask, or candlestick might take human, fish, or other forms; a Moravian beehive, for example, might be a sculptured head.

**The folk print.** The wood block (also used for stamping textiles) was the natural folk medium for making prints. Usually simply cut and sometimes crudely coloured or stencilled, they served to illustrate popular

peated. The whitewashed stone architecture of the Greek

Miniatures

subjects, with more interest often in the idea than in the depiction itself. Small prints of various saints were widely produced in Europe. Comic themes were popular, such as the "topsy-turvy world" and "man reversed" (e.g., "the fish catches the man") and stock characters. Block printing was also used to produce games, announcements for travelling shows, and forms for certificates. The English broadsheets and the Mexican *calaveras* (literally "skulls," a category of prints, sometimes made from lead cuts) offer outstanding examples of the cheap printed sheets that combined a verbal message (verses, proverbs, polemics, pious themes) with illustration. The 19th-century trade cards (notice for a shop or service) are sometimes included in folk art, but doubtfully so; they were often machine printed. In fact, it is difficult to segregate the print of truly folk character from the voluminous field of either "popular" or commercial printing.

**Other arts.** In the folk field, the minor arts can hardly be called minor, for such universal necessities as pottery, textiles, costume, and furniture and more unusual forms such as weather vanes and scarecrows provided the most frequent opportunities for creative expression and often absorbed the aesthetic impetus that, in the sophisticated world, was associated more with the fine arts.

Both pottery and textiles range from the everyday to elaborately decorated forms that are often symbolic or highly pictorial; even common examples are typically ornamented with design in a simple slip (a mixture of clay and water) or a woven band.

Folk costume is justly included in many general works on costume, but it differs significantly from the sophisticated in several respects: in a localism so extreme that even a particular town or valley may have its own prized style and every region is distinctive; in the complete differentiation of the festival costume from ordinary cloth-

In metalwork, the materials used to produce tools and other essentials were also turned by the craftsmen into such art forms as toleware (painted tin or tinned iron), incised copper or silver, pewter toys, and lead figurines. European wrought-iron grave crosses and shop signs are distinguished by intricate scrollwork and inventive linear depictions. Delicate bone carving is very widespread, appearing on such objects as implements, game pieces (such as chessmen), figures (notably crucifixes), and ornaments. An art peculiar to North America is the whalebone carving (scrimshaw) made by sailors while at sea.

The theatrical arts are spectacularly represented by puppetry, ranging from toy theatres, finger puppets, and the ubiquitous Punch and Judy shows to the famous puppet theatres of Sicily and Indonesia. Among the apurtenances of travelling shows and miracle plays, dating from the earlier phase of European folk art, was the hobbyhorse, which had a counterpart in festival performances in India. Musical instruments offer a profusion of types, often preserving ancient features of construction, principles of sound, and decoration: the heavy ratchets and rattles of the Alpine festivals; the shaggy bagpipes of the Abruzzi mountains; fiddles such as the rudimentary *gusle* of Yugoslavia, with its typical horse-head or horseman scroll, and the more complicated Norwegian *Hardangerfele*, with underlying sympathetic strings; and innumerable ornamented flutes, harps, horns, and dulcimers. The simple, painted clay whistle or flute is widespread, often in mimetic bird shape.

**Specific folk categories.** Any attempt to analyze folk art in terms of the established, sophisticated categories, though revealing in comparison, fails to take into account a substantial bulk of the art. Many characteristic products not subject to sophisticated aesthetic treatment have become specific fields of study and collection because of the ingenuity expended upon them—mangles (laundry beaters), molds, decorated eggs, weather vanes, decoys, powder horns, trade signs, scarecrows, and figure-heads, to name a few. There are also significant objects categorized according to function; for example, animal gear represented by the woven harness of donkeys in Spain, carved and painted ox yokes and sheep collars, brass-studded and tasselled headpieces, and ornaments supposedly endowed with protective powers. Other widespread types are decorated vehicles such as gypsy and circus wagons, boats bearing symbolic motifs, and toys and miniatures in countless media.

**Freedom of media.** While some of the art is executed in a recognized sophisticated medium like wood carving, many other materials, such as hide, horn, straw, bamboo, and palm leaf, are characteristic in certain regions or for certain objects. In fact, there is scarcely an available material that is not utilized somewhere in folk art, from the hickory-nut doll to the commemorative picture made of human hair, and materials are often combined. This free-wheeling employment of any sort of material rivals the fertile adaptations of "found objects" in 20th-century sophisticated art—as many other modern "innovations" have a long-standing precedent in the spontaneous art of the folk. Collage, and assemblage are an old story in this field; embroidered pictures had faces painted in watercolour, and festival figures were made of anything that came to hand. Weather charms in southern Germany were often collages of—among other things—saints' pictures, amulets, and seeds. There is also a great deal of kinetic art: manipulated masks; jointed dolls, figures, and toys; whirligigs (spinning toys); pin-wheels spun by wind or candle heat; and balance figures set in motion by a touch. Folk festivals, with their impromptu processions, costumed personages, antics, and props, offer almost a prototype of the 20th-century "happening."

**Style.** Although the folk artist had his own criteria of function and craftsmanship, design in the theoretical sense was not a part of his training; rather, it was the natural result either of his continued use of established patterns or of instinctive methods of organization. In special instances there was deliberate imitation of well-known works of art, as in the American portraits of

Theatrical  
arts

ing; and in a prolongation of style that is little affected either by changes of fashion or by individual taste. The motifs which are typical of festival costumes, such as the twin, cone-shaped buttons symbolizing fertility in Sardinia, are too deep-rooted in the tradition of the area to be discarded.

Furniture tends toward basic, repeated shapes, which may be left purely functional but are often extensively carved or painted. The Alsatian chair, for instance, has an upright-board back, carved with a pierced, silhouetted, bilateral design; some hundreds of variations of this simple design have been recorded within the area. Certain occupational forms emerged, according to need, such as the milking stool, the cobbler's bench, and the rocking bench, or "mammy settle."

Kinetic  
art

George Washington and folk versions of famous Virgins and Buddhas.

Any particular folk art will necessarily share the style of its general cultural area; Chinese folk art is Chinese as well as folk. Thus, analysis of the style and recognition of its folk origin is dependent upon knowledge of the "high art" with which it interacts, as well as of the folk situation that sets it apart. When a folk piece is compared with an adjacent sophisticated one produced at the same time, the differences become apparent, whether in the nature of the object as a whole or in its material, execution, content, or style. Stylistically, the time lag is significant; for example, the Baroque curve survived in simple country churches, and elaborate floral ornament in furniture decoration, long after sophisticated European art had become neoclassical.

Commonly accepted notions of folk style

One of the commonly accepted notions of folk style is that it is naïve; it is thought to be childlike and fresh, despite the fact that some of its 19th-century critics condemned its "meaningless repetitions" and its "degenerate" forms. Repetitiveness is to be expected in the production of objects needed by all; but the artists saw only a few neighbouring examples, and to the practiced eye their art reveals many variations. Folk art is often associated with bright colour and an appealing charm, qualities sufficiently present to account for a wide popularity but counterbalanced by the sombreness and seriousness of many pieces, notably in religious art. In fact, few commonly accepted notions of folk style apply to the entire field. Execution may be free or meticulous. Representations of figures may be highly literal (even to the inclusion of actual hair and clothing), almost abstractly simplified, or monstrously exaggerated and distorted, as in, for example, the boldly painted papier-mâché carnival figures of Europe or the fantastic animal figures of the Far East.

The focus on utilitarian production leaves its mark in two opposite ways: often there is a strong decorative orientation, with a wealth of surface ornament lavished on objects that maintain a prescribed shape; on the other hand, certain categories of folk production, such as simple tools, and the work of certain groups are characterized by a functionalism so complete as to seem in tune with modern sophisticated design. Technical limitations and the demand for a quantity of certain necessary objects are conducive to simplification; the reverse may be true of such an object as the bridal bedspread, for which custom dictates extreme elaboration.

The particularly long retention of traditional forms and patterns generally results in increasingly stylized versions of themes; in crewel embroidery, for example, the representation of landscape elements is commonly reduced to a tree and hills, the hills typically shown as three simple, rounded humps; in American portrait painting, the bust or figure is conventionalized in a simple frontal form, repeated over and over again and sometimes painted in advance of a sitting, leaving only the features to be filled in. More important, perhaps, is the fact that the adoption of materials not used in sophisticated art, the forcing of a limited technology toward artistic expression, and the adaptation of rather remotely perceived sophisticated ideas to the folk artists' concept of the realities of life result in some highly original stylistic solutions.

**Content and motifs.** Whereas sophisticated art often reaches out for the esoteric and the unusual, the content of folk art is closely related to immediate human concerns. The major events of life were universally celebrated on the folk level in ways that demanded of art special costumes, implements, vessels, and auspicious gifts. For the newborn there might be amulets and decorated birth certificates. The period of courtship occasioned a love token, often a beautifully carved feminine implement such as a shuttle or needle case; traditional in England was a double spoon symbolizing union and plenty, whereas in Czechoslovakia it was often a painted egg or carved stick. In many regions elaborate wedding chests were carved or painted for the bride. The bridal bedspread or bed curtain, like the wedding costume, was

ornate and highly symbolic, with such motifs as Adam and Eve, the tree of life, and mating birds considered appropriate. Both weddings and funerals required processional equipment, standards, and special vehicles. In some places there were gifts for the dead, which in China took the form of paper models burned at funerals. There were memorials such as grave sculpture, pictures, and documents.

Specific memorial motifs crystallized in two American forms: the "mourning picture," executed in embroidery or watercolour, often depicting grieving figures draped around a tombstone under weeping willows, and the gravestone carved with a winged death's-head or, later, with the urn-and-willow motif.

**Religious art.** The prevailing religion puts its stamp on every group, providing common elements in areas that share the same religion, even though the groups are not in contact. Catholicism in the West (and, similarly, Buddhism in the East) provided rich visual conceptions that spilled over into folk art. Crucifixes, Virgins, and saints were required as images for village churches and wayside shrines; they were set up over gateways and tombs, in arches, and in homes and were used as motifs on countless objects, where they were often freely combined with secular decoration. Religious observance demanded many objects decorated with Christian symbols—baptismal scoops, altar cloths, pilgrimage bottles, lavabos (holy-water vessels). There is even a special category of "nuns' work," including small devotional objects, many in collage, as well as vestments and church textiles. A particular German sculptural type is the *Palmesel*, a half-size figure of Christ on the donkey, which is drawn through the streets on its wheeled base on Palm Sunday.

An outstanding category of Catholic folk art is the crèche, made up of figurines displayed at Christmas in homes or churches to re-enact the birth of Christ. The main characters of the event (holy family, Magi, shepherds, and angels) were supplemented by hundreds of lively figures drawn from peasant or village life and shown pursuing their daily activities or bearing gifts to the Christ child similar to those enumerated in folk carols.

The Protestant and Jewish faiths made fewer demands on the visual arts, but the popularity of Biblical themes

Influence of Catholicism

R.F. Bussabarger

Festival votive figures of Durgā, pith and tinsel, 1961, West Bengal, India. Height 5.2 m.

is apparent. A favorite motif for the American weather vane was the angel Gabriel blowing his trumpet, often executed in a style that survives from the puffing zephyrs of classical art. The noteworthy Jewish folk art of Poland was largely lost during World War II, though records of the unique folk synagogues have been preserved by the Institute of Polish Architecture. The Jewish folk-art collection in the Musée Alsacien, Strasbourg, France, includes such specific religious objects as pointers (carved sticks used to guide the reading of sacred texts) and candelabra.

Since antiquity, some form of votive art has occurred in connection with religion. In India, outdoor shrines may be surrounded by a veritable crowd of paper-mâché figures set on the ground as offerings. Catholic churches and chapels throughout the world are hung with countless small ex-votos, usually cutouts of stamped tin or silver in the shape of an afflicted part of the body—an arm, a leg, or an eye—or of the heart or other symbol. In Canadian Jesuit missions, ex-votos were even made of wampum. In Seville small ivory carvings of religious figures were left in the cathedral by soldiers going to war. Clay plaques made from molds, common in the Mediterranean area, show an inheritance from Greek times, when small clay molds of the head of Athena were stamped out in quantity as votive objects. The most significant art, however, occurs in the painted ex-voto, which provides a major type and some of the best examples of folk painting. In sophisticated art, paintings of standard religious themes were often donated to churches in fulfillment of a vow. In folk art, this votive urge found expression in small narrative paintings (only occasionally large, as in Mexico) depicting an accident, illness, or other disaster from which the victim was saved by the intervention of a saint or the Madonna.

The recognized religion, however, is only a part of folk belief, which is impregnated with concepts from earlier times. The decorated Easter egg, for example, is an evo-

*Festival art.* A major folk category is festival art, which owes its genesis and much of its content to ancient seasonal celebrations. Since antiquity, the solar manifestations of the summer and winter solstices and the vernal and autumnal equinoxes have been bound up with the idea of sowing and reaping, death and rebirth, year's end and year's opening; at such times it was traditionally believed that supernatural forces were in control and should be propitiated. Re-enactment of the roles of malign spirits called for the production of grotesque masks and demonic costumes and also of clamorous noisemakers (bells, horns, rattles, and the like) to drive them away. Harvest figures invoked or celebrated a good crop yield. Special foods in symbolic shapes were prepared and consumed. Varying according to the culture, many other appurtenances were created—decorated trees and poles, lanterns, banners, processional vehicles, sculptured figures and dolls, household and shrine adornments—all bearing their motifs of life symbolism.

While the magical significance of the primordial festivals may have been largely forgotten and the events reduced to horseplay and merrymaking, the customs and the art objects associated with them persisted. In Europe, masqueraders continued to impersonate such "characters" as death, the devil, the goat, the old man, and the mischief-maker; their masks were often makeshift and ephemeral, but many carved of wood and decorated with other materials are preserved and highly prized. Such personifications were also painted on banners or created by assemblage and carried about, as were the Mexican skeletal death figures.

Oriental festivals often featured plant and animal motifs. In China the dragon of the New Year was a great paper creation made to undulate by the dancing steps of the bearers underneath. In the Japanese boys' festival, painted paper carp were flown from poles as symbols of strength and virility. In Indonesia, towering decorative constructions of vegetables and fruits were borne about to celebrate the harvest.

The assimilation of ancient seasonal celebrations—the winter solstice and the Roman Saturnalia with Christmas, for example—has been extensively studied in European folklore. In folk art, it occasioned an intermingling of pagan and Christian elements, enriched by many inventions created in an exuberant festival atmosphere and readily incorporating local and current themes. The celebrative instinct found expression also in many purely local festivals commemorating a local saint, historical event, or an episode in folk life, such as the setting out of the fishing boats or the onset of rains. In Japan alone, there were hundreds of such festivals.

*Other sources of folk motifs.* The traditional survivals that play so significant a part in folk art stem from other sources as well. Certain motifs diffused from the earliest cultures provided a repertory of stylized symbols to meet decorative demands; for example, the rosette (a disk divided variously into petallike segments), the rayed disk and the swastika (both associated with sun symbolism), the tree of life, the chimera and other fantastic beasts, and such human-animal combinations as the siren or mermaid. The extent to which such motifs retain their meaning or may become simply an appropriate decoration for a certain type of object (as the mermaid is for boats) is problematical, but there is undoubtedly a high symbolic content in the art.

Some aspects of classical mythology fed into folk art, partly by way of later European sophisticated art, and many medieval themes remained popular; the Saracen of the Crusades is a figure that still appears as a Sicilian puppet and as a revolving target in tilting games. Early Renaissance conceptions of paradise and landscapes with stylized trees and towered towns oddly recur in 19th-century folk painting, sometimes imparting an esoteric flavour to a local scene. In fact, the body of tradition retained in folk art may be seen as growing or shifting from one century or one place to another. A folk version of the horse-and-rider motif, in typical profile view, served with only a slight change of uniform for both the Napoleonic and the American Revolutionary soldier.

Ancient  
pagan  
seasonal  
celebrations

Painted Easter egg from Czechoslovakia, 20th century.

lution of the egg as an ancient symbol of renewed life, and the fat, laughing figure of the Japanese Hotei (god of luck) is both a deity and a ubiquitous folk charm. There are many survivals from local pagan cults, particularly of motifs associated with life, fertility, and protection; in Calabria an animal stake may be carved with the head of the blank-eyed mother-goddess, expected to protect the tethered beast, and similar elemental forms were preserved in Czechoslovakia. Lying at the root of human experience, such themes were never completely abandoned by the folk and may appear in curious juxtaposition with Christian themes or secular uses: a Sardinian clay bowl, for example, contains a modelled wedding group with the priest standing before an altar on which a small, nude hermaphroditic deity is seated, and the Christian loaves of bread appear along with pagan phallic and fertility symbols.

Use of  
medieval  
and Renaissance  
themes

Although themes may fall into disuse, they do not become obsolete so readily as in sophisticated art. Yet, folk art is not merely a repository for tradition; new themes constantly evolve from old ones or out of new circumstances. In the wine-producing area around Alsace, Bacchus astride a barrel became the common motif for carved bungs (the stopper of a cask), thus utilizing the classical Bacchus for a specific local commodity. In America, the Indian was widely adopted for weather vanes, trade figures, and other objects. Similar use was made of the personification of Liberty and the emblematic eagle.

Geometric  
and plant  
and animal  
motifs

All decorative design draws heavily on geometric and plant and animal motifs. In the folk use of this material there is often such concentration on one or two motifs that they become strongly identified with the regional style, as the tulip is in Pennsylvania German art; there is also a tendency to attach a particular motif to a particular object, for which it is used repeatedly. The prevalence of animal themes reflects the importance of animals in folk life.

Aside from their frequent appearance as realistic depictions, miniatures, and design elements, some animals also have strong symbolic aspects: the snake, the horse, and the cock, for example, occur with varying significance in many parts of the world.

Representational and narrative art other than the religious is often devoted to local subjects: the family portrait, the individual farm or church, or a typical activity. In Switzerland a favourite theme was the *Alpengang*, depicting the transferral of the cattle to high pastures in the spring. Folk artists also drew upon legend, popular romance, history, and the more famous literary and visual art themes that reached them from the sophisticated world. In Sicily the deeds of Roland (Orlando), derived from the poetic accounts by Torquato Tasso and Ludovico Ariosto, were repeatedly painted and enacted in puppet shows. From history, the patriot Giuseppe Garibaldi was as popular in Italian folk art as George Washington was in American; and the Prince of Wales was a favourite figure for pub signs in England.

Account must also be taken of the folk capacity for satire. The anticlerical humour of Italy has a folk mani-

festation in caricatures of impious monks and nuns. The Russians evolved stock figurines of the snobbish officer, the vain woman, the greedy merchant, the pretty girl riding on a rooster. The early prints of London and Paris had their lampoons, and Mexico had its effigies of personages who did not meet popular approval. Out of the slow exolutions typical of a strongly traditional art, there emerges an astute view of the human situation.

#### MAJOR FOLK REGIONS

The major recognized folk regions in most cases have been prolific in such crafts as textiles, pottery, and carving and in the production of implements and utensils; they also often have localized costumes. This common art output forms a broad basis underlying the more distinctive arts peculiar to particular areas. The material is so voluminous that most attempts at general survey are admittedly samplings.

General summaries are commonly organized by nation, a convenient expedient, because major collections are centred in great national museums and because folk art is often studied and promoted as part of the national heritage. However, the national summary divides some groups that are homogeneous, such as the Basque region in Spain and France; and it combines, under Italy, for example, such diverse arts as the Alpine and Sicilian.

Any effort to group regions for comparative study will most logically be based on such factors as the traditional retained sources, the prevailing religion, the nature of the related sophisticated culture, and the environmental conditions that affect materials and activities.

**Western. Mediterranean.** Viewed in terms of these four factors, the European folk arts of the Mediterranean area obviously have much in common. First, there was a direct transmission from ancient Near Eastern and Greek civilization, accentuated by Greek colonization in the West and followed by Roman domination. These sources, plus the local cults that occurred everywhere, may be traced even in recent art in the continuance of a rich pottery tradition from Greek times onward and in the preservation of many motifs. Second, the religion, chiefly Roman Catholic or Greek Orthodox, demanded extensive imagery. Third, in the sophisticated cultures throughout the historical period, art of all kinds was a major activity, developing high skills that penetrated to some extent even to the more isolated folk. Finally, contact was facilitated by active trade along an extensive coastline, and varied materials were available; yet the area industrialized very slowly, so that the folk arts could continue to thrive in some localities even to the present.

Thus, it is not surprising that the arts of this region are outstanding in quantity and variety. The level of skill is apparent, sometimes in bold and facile styles, sometimes in meticulous craftsmanship. Many folk artists were capable of expert full-round sculpture, realistic painting, fine metalwork, and other difficult techniques. The motifs are varied and freely intermingled.

Among the long-surviving regional arts are those of Epirus in Greece, where an important folk centre has been established at Metsovon; the islands—the Aegean with its stone architecture, Sicily with its spectacular carved and painted carts, puppets, and pottery, and Sardinia, noted for gold ornaments, textiles, and costumes still in use; and Puglia, Calabria, and the Abruzzi region in Italy, the latter having fine lace, silver filigree (openwork), and weaving.

Southern France is affiliated with this area, as is evidenced by the style of the fine ex-votos and Nativity figures of Provence. So is the Iberian Peninsula, though in that region there are also special factors. The Moorish influence was felt particularly in Andalusia—as in the use of ivory as a material and in the arabesque tracery (ornate, interlaced openwork) of the ironwork—and the Atlantic coastline provided other connections. The Portuguese use of cork was distinctive. Galicia and the Basque region, each with a population of distinct linguistic background, developed in prolonged isolation, the results of which are clearly visible in their exceptional

Outstanding  
quantity  
and variety  
of Mediterranean arts

arts: the architecture presents unique features, and the Basques are unusual in their lack of pottery, though they developed remarkable dance costumes. The difficulty of communications preserved a strong folk character not only in Galicia and the Basque region but throughout the peninsula. The painted and glazed tiles (*azulejos*), the textiles (notable in Salamanca), and carved furniture are among the products notably Iberian in character. Traditional survivals were strong in the northeast, with much religious art, including prints, centred in Catalonia.

*Slavic area.* Another possible grouping is the Slavic area in eastern Europe and Russia. There the influences from the ancient Near East and Greece penetrated less far in early times but were transmitted (and transmuted) by the way of the Byzantine Empire and the Eastern Church. Much folk art in the area was strongly affected by the Byzantine style.

Among the transmitted elements were the themes and styles associated with icons, which were commonly hung—at wells, for example—until the mid-18th century, when their production was discouraged in Russia and thus dwindled. Two centuries of Mongol rule introduced other traditions stemming from the East and marked by the so-called animal style. Finally, in modern times, these countries have mostly had Communist governments, whose policy includes promotion of the folk arts, organization of artists into cooperatives, and even the introduction of crafts from one area into another. Although this has been a stimulus to the study of folk art, it tends to blur the distinction between the strictly folk and the revived or commercialized product. Even earlier, Russian folk art was subject to extraneous influences in a way not typical elsewhere: in the 17th century, craftsmen were requisitioned from many parts of Russia to supply products for the national economy or to work on palaces, and they were also assembled around monasteries for prescribed output.

The Russian products probably best known elsewhere are toys—intricate constructions of wood or vivid earthenware miniatures. Some of the Vyatka toys are thought to be survivals of idols made for homes, representing the innumerable local deities that preceded Christianity. Other notable arts include ceramic tiles, wooden and ceramic figurines, and bone carving in the Siberian tradition.

In eastern Europe, where national boundaries have been particularly confused and the population comprises various minorities, studies of the art may follow ethnic lines. The geography provides a number of distinct regions, which are as varied as coastal Dalmatia, Transdanubia, and the isolated Tatra mountains. With a heavily forested landscape, the work in wood was outstanding. It appeared in church architecture, architectural sculpture, vessels and implements, and in such special forms as the sculptured grave-post; even a corn bin might be covered with rosettes. The area was rich in festival arts, with a strong retention from pre-Christian traditions and magic rites. In Czechoslovakia there were special wedding effigies and candlesticks. Among many ancient motifs, such as vase-and-tree, sun, and heart, the cock appeared as a protective symbol that might be set on roof ridges or carved on cheese molds. Some of the art is strikingly primitive.

Eastern  
European  
woodwork

One of the complications arising in the study of eastern European arts is the fact that the countries involved are culturally borderline, having an affinity with Catholic Europe in the West (exemplified by the ex-votos in the brilliant Czechoslovakian glass painting) and with the Byzantine Empire in the East. The arts bracketed as Polish, including some of the finest decorative art in paper, once extended far to the east and yet are northern European.

*Northern Europe.* The situation in northern Europe was very different from that in the south, and not merely in climate. The tradition involved a different mythology, and the society lacked the sophisticated centres that had crystallized early in Greece and Italy. The Roman influences that reached northern Europe had far to travel; consequently, the transmitted motifs were fewer, and emphasis might be placed on technical execution rather than on variety. This can be seen in the prevalent and superb use of two motifs, the acanthus and the vine-and-tendrill. It can also be seen in the animal style from the East, which penetrated and persisted, for example, in some fine architectural carving, with the tendency typical of this style toward flat and pierced rather than full-round rendering. Finally, although religious art was by no means lacking, the Reformation, which in itself was a popular movement, curbed the use of extensive Catholic imagery as well as the demand for religious objects.

The festival arts drew heavily on northern pagan themes, and the impulse that gave rise to pre-Lenten carnivals of the south was likely to find expression rather in municipal and occupational processions with comic giant figures drawn through the streets.

Some parts of the far north demonstrate that density of population is a factor in folk art; where farms are many miles apart and isolated; the art forms may tend to be few or even nonexistent. Even so, there may be one or two special crafts, such as the bone and horn carving of Lapland. Also, where materials are scarce, as in Iceland, variety of product depends on imports likely to be allocated to the sophisticated, not the folk. In more densely populated France, Germany, and The Netherlands, on the other hand, it is clear that peasant arts existed everywhere in the earlier periods but that the

early establishment of trade routes and urban centres pushed the folk arts into special categories or into the peripheral areas.

Among the Scandinavian regions, Norway is noted for the rose painting of Hallingdal and Telemark Fylke, the needlework of Hardanger, and the pictorial weaving of Gudbrandsdalen. Sweden, among varied arts, had a unique type of built-in furniture and wall hangings that were either painted or woven with biblical and Icelandic motifs. Finland had a specific linear ornament called "dark drawing," made by bending a strip of wood until the ends meet, and metal ornaments of prehistoric origin in Karelia. Distinctive folk-art regions in Denmark include the Hedebo (now Hedeboeye) area, with its linen embroidery; the Fyn archipelago, with its colourful floral painting; and Jutland and Slesvig, with notable cabinetmaking. In the Baltic area there were many survivals of ancient motifs (swastikas, rayed disks, snakes, horse heads) used on varied products, including the remarkable crosses and roofed poles, often with symbolic wrought-iron finials (crowning ornaments).

*Central Europe.* In the heart of Europe, two areas demonstrate two factors involved in the formation of folk culture: the Rhineland, where wine production provided a number of special objects and motifs; and the Alpine regions, which, though extending into several countries, share a pattern of living dictated by the mountain territory. The latter region, which includes several well-defined areas—such as the Appenzell in Switzerland, the Tirol in Austria, and the Alto Adige in the south Tirol, now a part of Italy—is rich in festival arts, ceremonial foods, and implements associated with dairying (even musical cowbells).

In France, The Netherlands, and Germany, the proximity of folk groups to sophisticated culture made its mark in the variety of products, high skills, and lavish decoration of such objects as furniture. Invention was devoted to new figural types, such as the hod carrier common to lower Germany and Austria; and events such as the Napoleonic Wars made a rather quick impact, as with the soldier motif and the appearance of handwritten and ornamented documents relating to military service. The mechanical genius that made the Germanic peoples leaders in the field of sophisticated automata found folk expression in innumerable animated toys, clocks, chimes, figures, and other gadgets. While the folk art associated with Paris itself is not to be ignored, the more easily analyzed French groups are outlying, as in Brittany, with its many-figured outdoor calvaries (representations of the crucifixion) and other enduring forms.

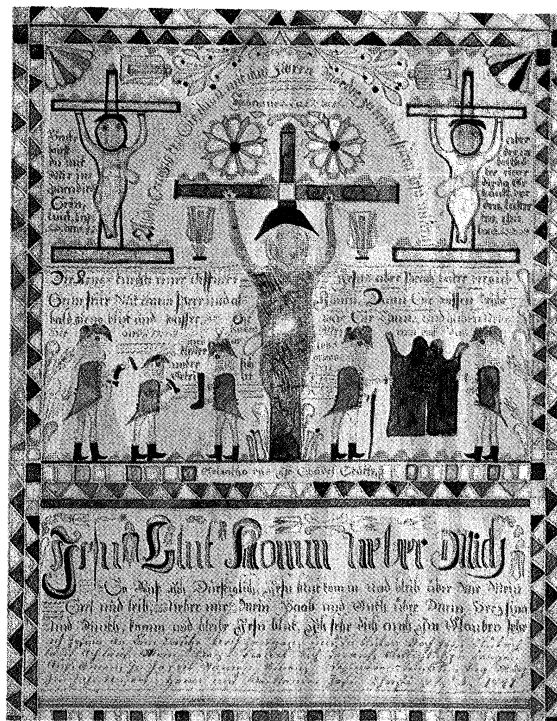

*Britain and Ireland.* The tendency to separate British from other European folk arts is an oversimplification, for a number of forms are shared with northern Europe; for example, the famous horse brasses (circular harness ornaments often retaining ancient protective motifs), giant processional figures such as the Salisbury dragon, and the May tree, a celebrative decoration in pole form. England is a small country that industrialized rapidly, a factor that tends to shorten the folk-art period. Some arts that required expanding technical skills, however, could develop as folk forms: for example, the printed arts (such as the broadside, or sheet printed on one or on both sides and folded) and the hand-propelled roundabout (later the mechanized carousel), which became increasingly elaborate. Tunbridge woodwork, of glued coloured strips, is merely one example of local invention. Among the well-known categories of folk art are the inn signs (both hanging and "effigy" signs), wrought-iron work, and tombstones. Hebridean textiles and Highland plaids and sporrans (the pouch worn in front of the kilt) are also familiar products. Both Scotland and Ireland have interesting grave crosses bearing ancient symbols. Ireland, however, serves as a reminder that the creative urge of a folk group may not focus primarily on the visual arts; Irish folk art does not compare with the contribution to oral lore in that area. (The same may be said of the Negro folk minority in the United States, whose musical contribution was spectacular but whose visual art traditions were largely cut off.)

*North America.* The colonization of the Americas in the 17th and 18th centuries, stemming largely from Europe at a time when European folk art was flourishing, resulted in a second general area of major folk-art development. This art can be divided into that of the United States (loosely called American folk art); Canadian folk art, which has much in common with that of the United States, with its scrimshaw, ship carving, and western pioneer art, but which also has products of its own (for example, French-Canadian wood carving in Quebec); and Latin-American folk art, which has quite a different character.

For the first century and a half, the art of the eastern seaboard of the United States may be described as predominantly folk. Although there were European imports and works produced by sophisticated American artists, they were generally a pallid reflection of the art then developing in Europe, and they made little impact on a people bent on making a home in a new world. The so-called Yankee ingenuity produced a wealth of material, sometimes reminiscent of European prototypes but often new. There were, for example, dozens of handmade lighting devices and many specialized contrivances such as the trammel, for raising and lowering pots in the fireplace, and the corn planter. Fresh decorative styles,

special forms, and new motifs contributed to an art that, either in evolution or invention, was typically American.

American folk painting is outstanding. Although there was once a tendency to view as sophisticated the artists who closely followed European styles and as folk those who worked in the rapidly emerging American manner, many of the latter have become individually known creators of a valuable body of work and have taken their place in the history of American art, some no longer viewed as belonging in the folk category. The more typical folk product comprised thousands of portraits and scenes by anonymous or local craftsman-artists or itinerant painters, who provided a vivid, if often crude, extensive record of America's ancestors and their surroundings.

As America advanced, a pattern of regional differentiation appeared, just as in Europe. In general, geographical

American  
folk  
painting

isolation was overcome rather quickly, one exception being the sparse settlements of the Appalachian Mountains, where Scots-Irish descendants maintained a handicraft tradition. People of varying origins, however, had brought to the "melting pot" of America their different art traditions. While they were often content with preserving a few objects and customs, some groups chose to maintain a separate identity, set apart by religion or national origin, and among them some fresh regional arts developed. The strict religious beliefs of the Shakers in New England and New York state, with their emphasis on simplicity, gave rise to clean, functional lines in furniture and architecture and to some psychologically interesting "spirit drawings" executed under the influence of religious visions. The Pennsylvania Germans (popularly called Dutch) not only had a distinctive religion but clung tenaciously to the language and traditions of their native Pfalz (Palatinate, now in the state of Rhineland-Pfalz and in Bavaria), which in art included such crafts as fine painted furniture and such motifs as the tulip, heart, and vine. Thriving in the flourishing countryside of their new home, they produced a notable body of art: Fraktur (embellished documents), painted wedding chests, decorated ceramics (including elaborate pieces created for special occasions), unique barns with exterior painted symbols ("hex signs"), pictorial embroidery, weaving, and other forms.

The American settlers who moved westward were again thrust into a folk situation comparable to that of their forebears, and a pioneer art developed. Saddlery was one of its important crafts; the covered wagon was its distinctive vehicle; and the board structures of mining towns and the sod houses of the plains were solutions to the problem of immediate housing. The flatboat and keel-

boat of the Mississippi River arose from specific navigational requirements.

The southwest, including part of California, is an area apart, producing art distinct from what is often called "western Americana." There the architecture was influenced by the Spanish mission and adobe styles, and a Catholic religious art was encouraged among the natives, resulting in the carved or painted imagery of saints (*bultos* and *santos*) with a strong native flavour overlying the Spanish derivation. These arts are more allied with the Latin American (as may be seen in the Museum of International Folk Art in Santa Fe).

**Latin America.** The different character of Latin-American folk art may be ascribed in part to the modification of a primitive culture resulting from contact with an advanced one. The settlers on the eastern seaboard of North America moved in on a primitive Indian population whose arts were relatively limited and who were rapidly pushed back or disoriented; the folk art of that area was thus essentially the product of the white settlers.

In Latin America, however, where there were some highly developed pre-Columbian cultures as well as tribal arts, intermingling was freer; this was partly because the missionary program—which included the teaching of crafts and Catholic symbols to the native population and the use of native craftsmen for church construction and for the production of religious objects—accepted an infusion of native techniques and styles. Thus, Indian crafts and motifs had a better chance of survival, and a greater degree of syncretism could occur. Furthermore, the colonizers, predominantly Spanish and Portuguese, brought with them the wealth of Mediterranean tradition and the varied imagery and forms of their home regions.

Under circumstances as favourable as these, a virtual explosion of folk art can occur, as it did, notably, in Mexico. Because Mexico seems to have a peculiar receptivity to art impulses regardless of source, the area is distinguished by a folk imagination that can create a towering, multfigured, ceramic candlestick, elaborate figures and models of straw, and fantastic fireworks. Craft motifs are handled with great spontaneity, and the festival arts are remarkable, with such original creations as the Judas figures, the skeletal musicians associated with the Day of the Dead (*día de los difuntos*), and the skulls (*calaveras*) that appear both as confections and as a theme in popular prints. The religious arts are also outstanding, with many ex-voto paintings (*retablos*) and Nativity figures in varied materials. Art that combines features of the Mediterranean and native Indian traditions occurs also in other Latin-American countries, as in the Portuguese-oriented areas of Brazil and in Argentina, which developed some arts related to the life of the cowboy of the pampas (*gaucho*). In some regions of Latin America, however, the indigenous Indian culture long remained unaffected and little influenced by the European colonies.

In the Caribbean and coastal areas there is evidence of African-Indian-European interaction: saints are painted with African physiognomy, and African decorative motifs appear on crosses, votive sculptures (the *milagre* of northeastern Brazil, for example), and such objects as laundry beaters and peanut pounders in Surinam.

**Other regions.** During the 16th–19th centuries, European exploration, trade, and culture expanded into many parts of the world. Colonization elsewhere, however, was not so conducive to folk evolution as in the Americas, where many settlers emigrated early, bearing folk traditions with them and expecting to make a life with their own skills. Because in many places the Europeans maintained a sophisticated enclave closely tied to the homeland, the native arts were preserved intact, inhibited, or exploited. This was fairly typical in Africa and the primitive Pacific areas, where settled colonization took hold only in the late 19th century. In South Africa, where it occurred earlier, only the Dutch (who built farmhouses of Dutch character) tended even to take their families with them.

**Non-Western.** In many parts of the world there have been tribal arts, some of which have nonprimitive aspects. These are sometimes bracketed with the primitive in a general category of ethnic art and are sometimes considered as folk art. But although they may have folk-like crafts and links with the outside world, they differ from true folk cultures in that they constitute homogeneous societies with traditions that are specifically ethnic rather than shared with a broad area of sophisticated culture. Such tribal folk art occurs in the Saharan Berber and Siberian areas, among the Ainu people of Japan, and in various parts of Asia.

The Eastern art recognized as truly folk has been studied, as in the West, chiefly in the areas where it exists as the unsophisticated art within a great culture. The Oriental traditions were often relatively uninterrupted, and effects from industrialization were late; while all folk dating is problematical and much of the art has perished, it is likely that some folk art in the East has a history extending back to ancient times. In Japan, however, it is usually understood as beginning in

the Edo period (17th century). Interest in folk art is particularly strong in India and Japan, where there are art scholars familiar with the Western folk concept but dedicated to the preservation of their Eastern traditions. Indian folk art was discovered in an emotional climate reminiscent of the European discovery of the folk soul; Ananda Coomaraswamy, a leader in the movement, called folk art the "main road," as distinguished from the sophisticated "bypaths." Both in India and Japan, there were sophisticated artists who deliberately identified themselves as "folk."

**India and Pakistan.** In India, where all of the crafts are distinguished by variety, skill, and a strong com-

Balinese votive doll, dried palm leaves, c. 1880. In the Museum of Childhood, Edinburgh. Height 38 cm.

ponent of strictly Indian tradition, the folk distinction is not always clear-cut. It is most apparent in such objects as toys (for example, the mother-and-child figure probably related to fertility concepts), masks, works in papier-mâché (votive and animal figures, for example, and dancing dolls balanced on wire), the symbolic motifs painted on the houses of the poor, and other works of art related to local custom or primitive belief. Particularly in southern India, small religious and other sculptures were created in quantity in an unmistakably folk manner; there are also some distinctive tribal arts, notably those of Assam. Pakistan has some highly regional arts: for example, the fine house carving and the ceremonial fans of Swāt, the silver ornaments of Gilgit, and the tombstones and matrimonial objects produced in the arid regions of Baluchistan.

Pakistani  
regional  
arts

**Japan.** Pottery and toys are probably the most widespread kinds of Japanese folk art; but there are also innumerable typical objects—lanterns, fans, umbrellas, nested boxes, and kites—exhibiting skillful use of bamboo and paper, as well as wood, lacquer, and other materials. There are thousands of wayside images, as well as sculptures for shrines and graves, in a folk style characterized by shallow carving on a simple, coarse-stone shape. An outstanding type of folk painting flourished in the Ōtsu region from the 17th to the 19th century. Clearly distinct from the sophisticated ukiyo-e painting, it was executed by farmers and artisans and depicted folk as well as Buddhist deities, popular animal motifs such as the cock-and-hen, and popular characters and genre scenes, often satirical. There are also votive pictures, some portraying the horse and traceable to the ancient horse offering. One of the late-surviving folk regions in modern Japan is on Sado island, where small cylindrical stone images were thrown into the sea to invoke pregnancy.

**China.** Chinese folk art must have been as extensive as any in the world, as evidenced by the descriptions of Western travellers and the souvenirs they collected and by various cultural and craft studies; but the problem of collating and analyzing the material as a folk category is forbidding. Every Chinese region has its own styles, and the entire art output is enormous. The art associated with weddings, funerals, and festivals is extravagant, even among the poor. In the country where paper was invented in antiquity, papermaking is a common skill, and the art of paper cutting is learned from childhood. Paper is used for the banner-like shop signs that give a special character to Chinese streets and for many complicated models and festival objects.

**Indonesia.** In its effect on folk culture, the spread of Buddhism in the Far East has some parallels with the spread of Christianity in the West. In Indonesia, for example, where Buddhism penetrated an area whose local traditions were strong enough to survive and intermingle with the new concepts, there is much temple art of a folk character. Among the abundant ephemeral folk art of Bali are the vegetal offerings and the beautifully stylized symbolic objects woven of palm leaf. Indonesian puppets and printed textiles are world famous.

(Ma.Ha.)

## Food, New Sources and Products

Since prehistory man has survived on a diet consisting of  
a relatively few species of plants and animals that he do-  
mesticated so long ago that their origins are forgotten.  
Three cereals—wheat, rice, and corn—supply the bulk of  
human energy, protein, and vitamin requirements. Since  
about the 1940s, however, the unprecedented rate of popu-  
lation growth, the development of new technology, and  
a variety of economic factors have changed traditional  
concepts of food supply and led to the discovery of new  
sources of food, especially protein, and new ways in  
which these materials can be marketed.

The demand for increased food supplies is related both  
to population increase and income. At very low levels of  
per capita income, small increases go primarily for pur-  
chasing food. In regions where population growth is  
highest and income lowest, the demand for food promises  
to increase very rapidly through the 1970s and 1980s and  
at a much faster rate than in more developed and stable  
regions.

Part of the new demand will be met by an agricultural  
revolution, under way in the 1970s, based upon new var-  
ieties of plants, intensive fertilization, and irrigation; but  
the diets of some of the world's population, especially  
young children and nursing mothers, must be supple-  
mented by additional protein even if traditional agricul-  
tural foods such as cereals supply sufficient calories. Fur-  
ther, some of the rapidly rising demand for such tradi-  
tional foods as milk, cheese, meat, and seafood will ex-  
ceed potential sources and will therefore need to be met  
by synthesized substitutes similar in appearance, taste,  
and texture.

Cultural habits and traditions universally create food  
preferences and inhibitions, complicating the introduc-  
tion of new sources of food. In Western countries, rice,  
which has about the same nutritive value and table use  
as wheat products, remains less preferred, a situation re-  
flected in prices of the two foods. In Southeast Asia, sea-  
food products are preferred with a strong fish flavour,  
but in Western countries the same flavour is considered  
objectionable.

Current food research has been largely stimulated by  
the rapidly growing world demand, but technological ad-  
vances in other areas also have contributed. The fibre-  
spinning processes developed for synthetic fabrics and  
the U.S. and Soviet space programs have had impact.  
Similarly competition among food producers has pro-  
vided impetus for research.

### NEW SOURCES OF FOOD PROTEIN

The most significant aspect of the search for new food  
sources is probably the need for adequate protein, espe-  
cially in regions where meat and fish are available in  
limited quantities.

**Oilseeds.** Potentially, 80,000,000 tons of oilseed pro-  
tein are available per year for human feeding. The cur-  
rent rate of production, however, is far below this. The  
world production of major oilseed crops (in millions of  
metric tons) is: soybeans, 46.5; peanuts, 18.1; cottonseed,  
22.1; and copra, 3.4. The primary purpose of cultivation  
of various oilseeds is to obtain edible oil for the table or  
for use by industry in the manufacture of margarine or  
shortening.

The basic process for extracting the oil is essentially the  
same for all oilseeds and involves either pressing or sol-

vent extraction or a combination of the two. The material  
remaining after removal of the oil contains primarily fi-  
bre, carbohydrate, and protein. The protein can comprise  
up to 50 percent of this residue, depending upon the par-  
ticular oilseed. This material is either discarded, used as  
fertilizer (actually it is a poor source because it decom-  
poses too slowly), or used as a source of protein in animal  
feeds. Currently only a small percentage is recovered in  
a form suitable for use in human foods. Food applica-  
tions of these materials are limited because of the overly  
strenuous conditions under which many of them are han-  
dled to remove the oil and because of their market image  
as fertilizers or animal feed. Each of the oilseeds has spe-  
cific problems of processing as well. The oilseed proteins  
are the least expensive of all of the potential new pro-  
teins in their simplest edible state, but additional refining  
doubles or trebles the price.

It should be noted that there is no certain method for  
comparing the nutritive values of various proteins; their  
actual worth depends upon a variety of external environ-  
mental factors, such as the other components of the diet.  
An approximate comparison of proteins tested in labo-  
ratory research gave the following relative nutrient  
values: egg, 100; casein, 60–70; soy, 40–50; yeast, 40–60;  
and fish protein concentrate (FPC), 70–80.

**Soybeans.** Soybeans are the most important of the oil-  
seeds. Soybean oil is recovered primarily by solvent ex-  
traction, and the residue is approximately 50 percent  
protein. The defatted soy contains a number of unde-  
sirable constituents that must be removed or inactivated,  
particularly a number of physiologically active proteins.  
One that inhibits the important digestive enzyme trypsin  
must be inactivated by heat. This process must be car-  
ried out with great care, because the desirable proteins  
also are affected by heat in a manner that reduces their  
solubility and nutritive value. Other factors limiting the  
usefulness of soy protein are a bitter, beany off-flavour  
and the presence of two soluble carbohydrates (raffinose  
and stachyose) that lead to distension of the human gut  
and flatulence. Each of these factors may be ameliorated  
by processes that purify the protein and yield products  
of higher protein content. These processes will be de-  
scribed briefly.

Traditionally, Oriental peoples use three forms of soy-  
bean: soy milk, a watery extract produced by cooking  
the beans at high temperature; tofu, a protein curd that  
is precipitated from the soy milk; and miso, shoyu, and  
other food products that are manufactured by fermenta-  
tion processes.

The simplest method of purification used in Western  
countries involves immobilization of the protein and re-  
moval of extraneous materials. This is accomplished ei-  
ther by extraction with aqueous alcohol or by extraction  
with water at the isoelectric point; that is, the point at  
which the acid-alkaline factor in the substance makes it  
electrically neutral. The minimum solubility of soy pro-  
teins, on the pH scale of acidity-alkalinity, is at pH 4 to  
5, moderately acid. Either process removes most of the  
undesirable soluble carbohydrates and some of the off-  
flavour, giving a product approximately 70 percent pro-  
tein, called soy protein concentrate, a valuable food ad-  
ditive.

An even more refined product is created by carrying out  
a process the reverse of the above; the protein is made  
soluble by extraction at an alkaline pH and separated  
from the insoluble residue. The protein is then precipi-  
tated by readjustment of the pH back to the region of  
minimum solubility. The cycle can be repeated a number  
of times to increase the purity of the protein. Products of  
this type, called soy protein isolates (SPI), are 90 to 99  
percent protein.

Almost all of the objectionable characteristics have  
been removed from the SPI, and the material can be in-  
corporated in a large variety of food products. This ma-  
terial can be texturized by spinning into edible fibres  
(more fully described later).

Completely different products, full-fat soy flours, are  
made from dehulled beans by heating at high tempera-

Three  
forms of  
soybean

Food  
cultural  
habits

tures for short periods in an extrusion apparatus. The heating denatures the proteins and provides a greatly expanded surface that absorbs the oil to such an extent that a dry free-flowing powder can be obtained. These products are much less expensive than soy protein concentrate and are of particular interest in countries where oil is in surplus.

**Cottonseed.** Another potentially important source of protein, cottonseed, has very little current use in food supply. The protein of this plant is a tertiary by-product of cotton fibre and oil production, and the seed is rarely handled under conditions that would allow ultimate human consumption. Cottonseed has very small glands (a few thousandths of an inch) containing a pigment called gossypol, which is toxic to nonruminant animals. This pigment also can react with the protein to inactivate the nutritionally important amino acid lysine, reducing its nutritive value. The processing of the protein therefore must remove the gossypol without extensive damage to the protein.

These criteria for recovery of the oil can be met by a combination of prepressing and solvent extraction. In

the pressing, sufficient heat is generated to inactivate the gossypol but not destroy the protein, and the last traces of oil are removed by extraction. The resulting product contains 50 to 55 percent protein, and the nutritional value can be improved greatly by addition of lysine. This protein is the basis for a vegetable protein mixture called Incaparina, which has been used in parts of Central and South America for a number of years to prevent protein malnutrition.

A newly developed glandless form of cotton without gossypol may significantly affect the future use of cottonseed protein if the yield and quality of the cotton linters can be adequately accounted for. Another development, a centrifugal process for separation of a high-protein (70 percent), low-gossypol fraction from the meal, produced by a straight solvent-extraction process, may find application if the costs involved in such a process can be lowered.

**Other oilseeds.** The peanut, coconut, rapeseed, and sunflower are potentially significant oilseeds. The peanut finds considerable use as a whole food because it has no toxic or indigestible components. It is important as an

processes

### Radiation-Induced Plant Mutations

crop	variety name	place of release	date of release	improved features	crop	variety name	place of release	date of release	improved features
White mustard	Primex	Sweden	1950	greater seed yield and oil content	Barley	Hellas	Sweden	1967	resistant to lodging and straw breakage; increased yield, especially with heavy fertilization; resists sprouting at harvest time
Summer oil rape	Regina II	Sweden	1953	seed yield and oil content	Barley	Kristina	Sweden	1969	resistant to lodging and straw breakage; very high yield; outstanding malting quality
Pea	Weibull Stral-art	Sweden	1953	5-10% higher yield	Rice	SH 30-21	Rep. of China	1957	higher yield; short growing period
Winter barley	Jutta	Germany, East	1953	winter hardiness; yield of grain; lodging resistance	Rice	KT 20-74	Rep. of China	1957	higher yield; short growing period
Pea bean	Sanilac	Michigan	1956	bush type; disease resistance	Rice	YH 1	Rep. of China	1963	higher yield; short growing period
Spring barley	Pallas	Sweden	1958	tolerance to heavy nitrogen fertilization	Rice	Reimei	Japan	1966	short straw; lodging resistance, especially with heavy fertilizer; less variation with location and year; tolerates lower temperatures, especially during germination and seedling stages
Peanut	N.C. 4-X	North Carolina	1959	tougher hull (better for shipping); high yield	Soybean	Tainung No. 1 (R)	Rep. of China	1962	vigorous, dropping-resistant variety with the characteristics of long branches and higher yield
Oats	Florad	Florida	1960	resistant to stem rust; superior grain quality and straw stiffness	Soybean	Tainung No. 2 (R)	Rep. of China	1962	vigorous, dropping-resistant variety with short internode, large seed, and adapted to acid or alkaline soil
Pea bean	Seaway	Michigan	1960	bush type; virus resistance	Soybean	Raiden	Japan (Tokyo district)	1966	earlier maturity; shorter stem (resists lodging); maintains high yield and nematode resistance of original variety*
Spring barley	Mari	Sweden	1960	early maturity (8 days); stiffer straw	Soybean	Raiko	Japan (Tōhoku district)	1969	earlier maturity; shorter stem; resists lodging; higher yield; maintains nematode resistance of the original variety*
Oats	Alamo-X	Texas	1961	disease resistance	Pea bean	Seafarer	U.S.	1967	very early maturity; bush type; resistant to alpha, beta, and gamma races of anthracnose and bean commonmosaic races 1, 15, and 123
White mustard	Seco	Sweden	1961	seed yield; crude early maturity; stiff stalk	Haricot bean	Saparke 75	U.S.S.R.	1967	surpasses the initial variety on average by 55 dt/ha in green pod yield and 5.2 dt/ha in seed yield; green pods are devoid of fibre and fixed on the stem at least 5 cm higher, making mechanical harvesting possible; improved resistance to bacterial diseases
Bread wheat	NP 836	India	1961	awned to resist bird damage; higher yield without irrigation	String bean	Universal	Germany, West	1950	early maturity, higher yield; good resistance to anthracnose
Spring barley	VR <sub>z</sub>	Czechoslovakia	1962	higher yield of grain; stiff straw	String bean	Unima	Germany, West	1957	immune against anthracnose; resistant to <i>Pseudomonas phaseolicola</i>
Pea bean	Gratiot	Michigan	1963	better seed type	Spring oil rape	Regina vāraps elite F	Sweden	1962	higher seed yield and percent oil
Barley	Pennrad	Pennsylvania	1963	improved winter hardiness	Castor bean	Aruna	India	1969	very early (120 days versus 270 days for mother variety); yield slightly higher
Bread wheat	Sharbati Sonora	India	1967	amber grain colour (preferred in India); short straw; early maturity; high protein and high lysine to protein ratio	Peach	Magnif 135	Argentina	1968	bigger fruits with deeper red skin colour; 7 days earlier maturity
Bread wheat	Lewis	U.S.	1964	lodging resistance; early maturity; high yield					
Bread wheat	Stadler	U.S.	1964	early maturity; strong straw; good yield; excellent soft quality grain; good disease resistance and winter hardiness					
Bread wheat	Sinvalcho Gama	Argentina	1962	more resistance to black stem rust and leaf rust					
Bread wheat	Zenkouzi-komugi	Japan	1969	earlier maturity; shorter culm; higher yield (10-15%)					
Bread wheat	Novosibirskaja 67	U.S.S.R.	1969-70	lodging resistance; baking quality					
Durum wheat	Castel del Monte	Italy	1969	lodging resistance; high yield					
Barley	Vienna	Austria	1959	high yield; high 1,000-kernel weight; mildew resistance; lodging resistance					
Barley	Milns Golden Promise	U.K.	1966	shorter and stiffer straw with good grain yield and malting properties, but mildew susceptible					
Barley	Midas	U.K.	1970	short, stiff straw; erectoides habit; mildew resistance					
Barley	Luther	U.S.	1967	shorter straw; increased grain yield and lodging resistance, especially with heavy fertilization					
Barley	Diamant	Czechoslovakia	1965	very high yield; short stem; very good grain and malting quality; lodging resistance					

\*Raiden, Raiko and their original variety form a set of varieties of different maturities but of similar grain quality.

oilseed in India, and the protein could be very significant to that country.

A problem, not necessarily peculiar to peanut meal, is the production of highly toxic mold metabolites during unfavourable storage conditions. One toxin, aflatoxin, is a dangerous carcinogen. It has been excluded from such food supply by industrial screening. Peanut meal is approximately 50 percent protein and is poorer nutritionally than soy protein.

Coconut usually is processed by sun drying to copra, which is not an effective starting material for a protein concentrate; the protein content of the oil-free residue is only 20 percent.

Sunflower is becoming significant in European oil markets, as is rapeseed in Canada and northern Europe. Little is presently known about the value of these proteins for human consumption.

**Radiation-induced plant mutations.** Some mutant varieties of crops have shown increased protein content, higher yields, and resistance to plant disease. Radiation-induced mutant varieties of durum wheat, for example, have shown superior performance, and the Food and Agriculture Organization of the United Nations has recommended that some countries use them to replace their entire wheat acreage. Castor beans formerly took 270 days to mature in India and were therefore at the mercy of changes in the rainy season. A new variety, evolved from radiation-induced mutations (see RADIOISOTOPES, APPLICATIONS OF), matures in 120 days; now farmers can be assured of a good crop each year and can use the 150 days' time saved to grow other crops. Similarly, an increase in yield of maize has been achieved by a radiation-induced mutation, the first on an open-pollinated rather than self-pollinated crop.

The table lists some of the successful radiation-induced plant mutations that provide additional food crops.

**Leaves, grasses, and waterweeds.** There is an enormous untapped source of food in leaves, grasses, and waterweeds, which is currently utilized only by conversion to animal feeds. Some of the proteins present in the dry matter of these materials are potentially of high nutritive value.

Leaf protein concentrate

The preparation of protein from leaves and similar materials, called leaf protein concentrate (LPC), is relatively simple. The vegetable material is pulped with an excess of water, the juice pressed from the insoluble residue, and the protein precipitated by heating with or without acidification. The resulting press cake is dark green because of its high chlorophyll content and includes 40 percent dry matter, which is 60 to 70 percent protein. Improvement of the colour and flavour of the cake requires extraction of the chlorophyll and lipid with an organic solvent.

If this process were to be carried out on a large program, so that economies of scale could be reached, the cost of collection and transport to a central location would be considerable. If, on the other hand, the material is produced in small, rural village units in tropical countries, other problems arise. Such areas usually suffer from shortages of potable water and lack of cheap electricity or fuel, commodities readily available in industrial areas and essential to LPC production. There also appear to be unresolved questions concerning the digestibility of some LPC's by animals and human infants.

**Marine sources.** The sea is an exceedingly large resource for food and protein. Predictions of the total sustainable annual harvest that could be attained vary from 200,000,000 to 2,000,000,000 tons. This would yield between 32,000,000 and 320,000,000 tons of high-quality protein. (These figures exclude fish farming or aquaculture.) The lower figure is based on the use of present fishing techniques and is undoubtedly conservative. Most of the sea's protein is in forms that are not commonly accepted as food fish and have little present commercial value. They are either "trash" fish, such as hake or menhaden, or fish that are too small or contain too much oil for conventional processing. Going further down the food chain, the use of plankton as a source of food

is faced with technological and biological barriers, among which are collection costs, possible toxic species, and high mineral content.

A solution to the problem of how to use trash and fatty fish may be to utilize whole fish and remove the fat and water to obtain a product that can be economically stored and transported without spoilage or off-flavour. Fish protein concentrate (FPC) is such a product and is defined as any inexpensive, stable, wholesome product of high nutritive quality, hygienically prepared from fish, in which the protein and other nutrient materials are more concentrated than they were in the original raw material. Two solvent processes have been developed, and work is being done on biologically based processes using enzymes or micro-organisms.

Fish protein concentrate

The major advantage of FPC is the high nutritive value of the protein, which approximates that of animal proteins. The problems include high cost and poor performance of the material in food products. The technological problems probably can be solved, but the process can be economical only where fish is plentiful and inexpensive and probably where an FPC process can be integrated directly into an existing fishing industry.

**Single-cell protein sources.** Single-cell protein, or SCP, refers to any crude or refined source of protein from unicellular or simple multicellular organisms, such as bacteria, yeast, fungi, algae, and perhaps protozoa. The production of SCP is more complex than that of FPC and is shown schematically in Figure 1. Some or all of the steps

Figure 1: Manufacturing processes in the production of single-cell protein.

indicated would be required in an individual process. Most SCP processes are similar except for the type of organism and type of carbon substrate. A major attraction of SCP is that it can be produced without an agricultural base. SCP probably will be most economical in very large processing plants producing hundreds of thousands of tons of material annually. The use of SCP is relatively old in terms of human history, but the use of large quantities in food was made possible by developments in fermenta-

tion technology during and after World War II. Potentially, SCP can approach soy in cost. SCP is lower in nutritive value than FPC.

Most of the world's interest is in processes that utilize hydrocarbons or derivatives as the sole energy source for growth of the SCP micro-organism. These include petroleum products, molasses, starch, sulfite waste liquor from paper manufacture, cheese whey, and cellulose. The choice of raw material depends on the region. Natural gas or methane is abundant in the Middle East and the North Sea. Methane is very cheap and leaves no residue in the final product, but it has disadvantages: it requires a sophisticated fermentation system to prevent formation of hazardous gas mixtures; it is limited to growth of bacteria; it requires large quantities of oxygen and produces more heat; and a culture of suitable commercial performance has not yet been found.

Petroleum gas oil has been used extensively in Europe for animal-feed products, but it is doubtful that such a product would be permitted in human food because of potentially harmful residues. Most work has been on highly purified paraffinic hydrocarbons that, in themselves, would be safe in food.

Sulfite liquor and whey are of interest in locales where they are waste products, and they may be used along with starch and molasses to produce cells by conventional fermentation technology.

Another carbohydrate, cellulose, is ubiquitous in nature and of potential future interest. The main problem is the conversion of cellulose to metabolizable sugar in a manner that would be economically competitive with more readily available fermentable carbohydrates.

Bacteria, yeasts, fungi, and algae are under active study. *Spirulina maxima*, a blue-green alga, has been consumed since ancient times by peoples near Lake Chad in Africa and probably by the Aztecs of medieval Mexico. The use of this and other algae is limited by economic factors, and in some cases there are problems of flavour and protein digestibility. Yeasts are the most popular organisms and are more familiar to human experience. They have been used in foods as vitamin additives and flavouring agents. Their protein contents are about 50 percent of dry weight, and they are easier to recover from fermentation broths than are bacteria. Species of interest are mainly *Saccharomyces* and *Candida*. Bacteria have higher growth rates and higher protein contents than other organisms but are less familiar in human nutritional experience.

**A potential synthetic source.** Proteins are natural polymers of amino acids, and individual amino acids, in turn, might be synthesized and added to food. This may not be feasible for the near future, but there are some amino acids that could be added to such foods as cereals to improve the nutritional quality. Lysine can be made by chemical synthesis or by fermentation from carbohydrates. Methionine can be made by chemical synthesis. Tryptophan can be made by combined chemical synthesis and fermentation. Threonine is best made by fermentation. Very large quantities of glutamic acid are made by fermentation for use as a flavouring agent.

#### NEW MARKET FORMS OF FOOD

The appearance of a number of new market forms of familiar foods during the 1950s and 1960s, at first primarily a reflection of market competition, showed signs of considerably broader significance. Formerly technological control extended only over external forces applied to food; now alterations can be made in food composition, wholly new forms can be fabricated, and substitutes for established forms can be made acceptable. Advances in formulations, in packaging, and in preservation techniques are continuing in the 1970s.

**Advances in packaging and processing.** One of the most striking developments in this area was the packaging of complex dishes for preparation with minimum time and effort. The package itself often serves as a cooking utensil, an innovation that required development of materials such as foil-plastic laminates and high-speed

sealing equipment. Convenience packaging brought with it some unforeseen disadvantages, it is true, when certain types of containers created a solid-waste disposal problem.

Processing and packaging have been combined in the food-service industry to deliver specific products that by now may be considered traditional, such as turkey loaves and simulated meat. Foods can be prepared commercially by such methods as microwave cooking—which is too expensive for ordinary home use—to eliminate the dangers of overcooking and undercooking, and microbiological health hazards can be minimized.

The food-service industry in many countries is growing in importance in schools, hospitals, military institutions, restaurant chains with centralized food preparation or portion control, and in vending operations.

**Special-purpose and dietetic foods.** These are foods of novel composition or substitutes for ordinary foods or foods in which some component has been modified or replaced. Snack items have been developed with novel flavour, texture, and improved nutritive value as a result of development of such ingredients as protein concentrates and modified starches. Special equipment designed for extrusion, puffing, and cooking has yielded a variety of new shapes and forms of such familiar foods as potato chips and popcorn.

Synthetic milks and coffee whiteners have been formulated using protein concentrates and new types of fats formed through conversion of natural fats and fatty acids. The melting range of the fat must be close to human body temperature. Such foods promise not only to be economical sources of proteins and fats but to overcome religious and cultural food problems in many parts of the world. The nutrient value of these products may be subjected to control by law because of their importance to nutrition of children.

New and recently developed dietetic foods include low-calorie substitutes for weight reduction, low-sodium foods for persons with certain types of heart or circulatory problems, and low-sugar foods for persons with diabetes. Low-calorie foods may make use of nonnutritive bulking agents, such as cellulose derivatives, and may vary in form from cookies to soups to beverages. Low-sugar foods usually are formulated with synthetic sweeteners.

**Texturized food products.** Unique new foods have been developed from protein concentrates that texturally simulate meat, fish, and shellfish. The potential benefits of these products include low cost, controlled nutrient composition, and the possibility of restructuring and improving poorer cuts of meats.

The simplest approach to texturization is the fabrication of chewy granules that simulate ground meat. The basis is isolated gluten at concentrations high enough to produce stiff doughs. These doughs, containing suitable flavour and colour, are extruded, sliced, and dried. When rehydrated they may be used directly, for example, in casseroles.

Another approach to texturization employs thermal denaturation of dissolved protein to form chewy gels. This process can be made more or less continuous by employing cooker-extruders such as are used in the fabrication of snack products or in the preparation of full-fat soy flours.

The products are based mainly on soy proteins, and preparations containing as low as 70 percent protein can be utilized. The texture of the final products can be varied over a wide range, from tough to tender. They are intended mainly for use in stews and casseroles.

The most sophisticated texturization process, and the most expensive, utilizes oriented protein fibres (see Figure 2). The fibres are made primarily from soy preparations of over 70 percent (usually 90 percent or more) protein and 95 percent solubility at alkaline pH. The protein is dissolved in alkali at pH 12 at a concentration of 12 to 14 percent to give a viscous dope. This is then extruded through spinnerets into a coagulating bath of acid and salt to set the fibres. Approximately 16,000 fine fi-

service  
industry

Oriented  
protein  
fibres

Petroleum  
sources

bres form a tow of ropelike consistency. The tow is taken up from the bath onto a series of reels that stretch the fibres while excess salt and acid are washed away. The final products are made by blending the fibres with fat, flavours, colouring, supplemental nutrients, stabilizers, and protein binders. The protein binder is usually egg albumen, which is used because of its thermosetting properties. This ingredient adds significantly to the cost of the product. The blended fibres then are placed in a

blender cooker and finally are fabricated into slices, cubes, bits, or granules. The entire process, from extraction of soy protein to final fabrication, can be carried out on a continuous basis. The composition of these products is approximately 40 percent soy fibre, with the remainder made up of variable quantities of the other ingredients. The optional ingredients may include low-cost cuts of meat that contribute flavour and colour.

#### FOODS DEVELOPED FOR SPACE EXPLORATIONS

The extraordinary constraints imposed by space-flight conditions on food-system design have stimulated research that may have wider application. A basic question from the beginning of manned space flight has been whether to rely on having adequate storage facilities for the total food requirements of flights, including very long flights, or to develop a regeneration system to fill part or all of the requirements. In the early 1970s such a system still promised only a low level of reliability, but work continued in the anticipation of manned interplanetary exploration and manned orbiting space stations. Regenerative, or recycle, systems under study are usually SCP generators or chemical synthesizers.

Space foods developed in the 1960s were designed to meet both engineering constraints, in the form of limited payloads, zero gravity, and acceleration pressures, and biological constraints deriving from the cramped space and remote distance from external assistance. Foods for space explorers must meet highly demanding standards for protection against microbiological contamination and must be readily and completely digested. One direction of space-food development was toward reduction of payload by providing partially or completely dehydrated items, since water has been available as a by-product of the hydrogen- and oxygen-powered fuel cells that have provided spacecraft with electrical power.

At present there are three categories of dehydrated foods: rehydratable solids, rehydratable powders, and bite-size foods consumed without rehydration. The rehydratable solid foods are formulated, cooked when necessary, molded into single-portion sizes, freeze dried, and vacuum packaged in a flexible, clear plastic package. This package is fitted at one end with a spring valve designed to receive the nozzle of a water-dispensing gun by

which the food is rehydrated. The other end of the package is fitted with a feeding tube.

The bite-size foods do not need to be rehydrated and are placed directly in the mouth. They are slightly different from the rehydratable items in that some moisture is left in the pieces to give them a softer texture. These soft-moist items usually contain added plasticizing agents, such as glycerol. The reduced moisture content and the added glycerol reduce water activity in the food, preventing the growth of almost all micro-organisms. Sorbic acid is added in small amounts to prevent mold growth and an antioxidant to inhibit rancidity.

Probably the direction of space-food research that offers the best prospect of application to world food problems is the search for food energy that, like SCP, can be manufactured without resort to any agricultural base. Such products may be uneconomical for ordinary use for the immediate future, but technological advances may make them practicable eventually. The most likely compounds are the polyols, which even today can be made at reasonably low cost (though not as low as sugar). Particularly important is the compound 1,3-butanediol and its fatty-acid esters. This material mixes with water and becomes liquid at room temperature. It has been used extensively in the plastics industry, is completely synthetic, and is available in large quantities. It is a high-energy compound containing approximately 50 percent more energy per pound than carbohydrate, the dietary component it would replace.

Another high-energy compound is a special fatty acid that is metabolized in the body like a carbohydrate. A prototypical example is 2,4-dimethylheptanoic acid. These compounds should be compared to carbohydrate with respect to energy density because of the way they are metabolized; they provide approximately 100 percent more energy per pound.

Another method of food synthesis involves simulation of prebiotic conditions; that is, conditions associated with development of life. Basic industrial chemicals such as ammonia and methane, together with water, subjected to irradiation, electric discharge, or a variety of other effects, produce amino acids and sugars. In some cases, surface-active catalysts like clays accelerate these reactions. An example is the synthesis of the formose sugars from formaldehyde. A very complex mixture of such compounds can be prepared at low cost, but not all of them can be metabolized—that is, made to yield nutrient value. If suitable methods for separation of the useful components can be found, these materials could be of tremendous future significance.

Finally, techniques of submerged culture or of tissue culture can be used to produce plant foods without an agricultural base. These products would not have the traditional fresh form but might provide the familiar nutrient content and texture. Even the flavour can be wholly synthetic.

Dehydrated foods

## Food, Quality Control of

Every food has a number of attributes, or qualities, which may be desirable, undesirable, or even harmful. Food quality is the sum of all of these attributes, both obvious and hidden. The consumer judges a product by such obvious qualities as flavour, texture, and appearance. Composition is a hidden quality, requiring more technical evaluation, and includes nutritional value, presence or absence of various substances, and microbiological levels. Keeping quality, or shelf life, is another hidden factor.

### FOOD QUALITY AND ITS EVALUATION

Quality audit is the evaluation of the overall quality of the finished product. Information gained through the audit determines whether or not finished products meet predetermined standards and may bring attention to the need for correction of faulty production procedures.

Quality control includes all of the activities influencing the overall quality. Its objectives are the creation of the most favourable conditions for production of foods of a consistent quality and the minimization of the possibility of faulty production.

The application of scientific principles to food manufacture began in France in 1810, when Nicolas Appert published a work describing his method of food preservation by heat sterilization. As industrialization of food production increased, maintenance of uniform quality became essential; and with the development of food science, scientific quality-control methods were introduced.

**Development of food quality control.** Quality control began with the single operator or craftsman, who still performs the control function in such small-scale operations as making hand-dipped chocolates. As manufacturing operations grew larger, a foreman quality-control system developed, still used in the manufacture of many highly specialized products. But for modern, large-scale food processing, separation of quality control from production became clearly desirable. Adequate sampling of raw materials and finished products was not possible; therefore statistical methods were adopted for both sampling procedures and for interpretation of data obtained by chemical analysis. Personnel entirely divorced from production—either employed by the manufacturer, supplied by the industry, or imposed by the government—did the sampling and analyzing.

Finally, the concept of total quality control was introduced in the 1960s; in this concept quality development, quality maintenance, and quality improvement efforts of the various groups within an organization are coordinated with the goal of producing the most economical fully satisfactory food at maximum production efficiency.

**Quality standards.** Quality can be evaluated only in relation to a standard. The quality-control department within a food-manufacturing company defines and formalizes standards and is responsible for keeping deviations from these standards within predetermined limits. It provides other departments with the technical advice and information needed to achieve and maintain desired quality standards. It must also assure that the final product meets all specifications, complies with relevant laws and regulations, and reaches the consumer in satisfactory condition. Control of microbiological quality is especially important for prevention of food-borne disease and to retard microbial spoilage. Yet quality control cannot be the exclusive responsibility of the quality-control department because it must be exercised not only in the manufacturing process but earlier: in the selection of raw materials and, subsequently, in the packaging, storage, and distribution.

Most governments set food-product standards, defining chemical composition, specifying essential ingredients, stating maximum or minimum concentrations of certain ingredients, regulating food additive use, and setting tolerance limits for such contaminants as toxic metal and pesticide residue. Such government standards, enforced by a system of inspection, guarantee the consumer a satisfactory product.

Most food quality control, however, is exercised within

the manufacturing organization; the following description, though generalized, applies principally to such enterprise control.

**Specifications.** Specifications are issued by the quality-control department after consultation with relevant production departments. Specifications are necessary for raw materials, intermediate products, finished products, and packaging materials.

**Buying specifications.** Buying specifications describe the material, including its source; give its analytical composition with agreed tolerances; state limits on the degree of chemical and bacterial contamination; indicate packing methods; and list satisfactory conditions of delivery, such as suitable temperature. An agreed sampling and analytical procedure is often included. When objective definition of an essential characteristic such as flavour is not possible, it is customary to stipulate that deliveries should correspond to an agreed and retained sample. The specification also usually states that the purchased material must satisfy all relevant legal requirements.

**Processing specifications.** Specifications for processing and for intermediate products describe processing methods and stipulate all controllable aspects of intermediate condition and composition.

**Finished-product specifications.** Finished-product specifications provide detailed packaging and storage instructions and advice on sampling and testing procedures.

### SENSORY EVALUATION

The main objective of quality control is to keep to a minimum deviation from agreed standards. Ideally, accurate and objective chemical and physical methods should be used; but despite progress in this area, the human senses are still frequently more efficient than instrumentation in evaluating flavour and texture, and they provide a more rapid response. The reliability of information obtained through human senses can be heightened by selection and training, providing suitable environment, and using appropriate testing procedures.

The three basic sensory assessment methods are difference testing, product rating, and acceptability appraisal. Difference testing, perhaps the most frequently employed, involves assessment of the difference between the sample examined and a standard, which may exist solely in the memory of the examiner.

Testing is not limited to formal testing panels. Raw materials are usually tasted by an experienced worker before acceptance of deliveries, and food products are ordinarily tasted at various stages of the manufacturing process to allow avoidance or immediate correction of production faults.

**Taste panels.** Prospective taste panel members are tested for sensitivity to the primary tastes (salt, sweet, sour, bitter), for reactions to the type of foodstuff concerned, and for their ability to detect small differences in relevant characteristics. Because sensory evaluations are influenced by the environment, good ventilation and lighting are essential, and distractions minimized. Tasters are isolated in booths provided with a hatch for introduction of samples and facilities for mouth rinsing and disposal of materials. Tasters do not necessarily swallow test samples. Isolation of each panel member precludes any mutual influence, although subsequent discussion of the results between members may be valuable in maintaining interest and improving reliability.

**Testing procedures.** Tasting panels usually judge complete food products but, especially in the examination of raw materials, may judge specific ingredients, such as spices and flavourings, or other food additives. Sweet flavourings are tasted in the form of sugar syrups; spices are added to flour suspensions in water. Such procedures, however, are suitable only for rough sorting-out tests; final judgment must be based on tasting the ingredients as constituents of the actual products.

**Difference tests.** Difference testing is applied in a number of test designs, including pair comparison, duo-trio, and triangle tests. In pair comparison the judges are asked to indicate whether or not they find a difference

Quality  
audit

Quality-  
control  
depart-  
ments

Sensory  
assessment  
methods

between two coded samples, and they may also be asked to state the nature of the difference for a specific attribute. In the duo-trio test, one sample is used as a standard, and the tasters are asked which of two remaining coded samples is identical with the standard. Since the probability of a correct answer being given by chance is one in two, the triangle test, reducing the chance to one in three, is preferable. Of the three samples submitted, two are duplicates; the judges are asked to select the odd sample.

**Ranking tests.** In ranking tests, used for a small number of samples, the judges place a number of coded samples in order of merit based on one specified attribute. Scoring tests, suitable for the comparison of a number of test samples with a standard, require expert judges having identical understandings of the descriptive terms used. Values may be distributed with zero representing the lowest level and ten indicating the highest degree of excellence. Hedonic scaling, in which numerical values are attached to degrees of acceptability, does not require extensive training of the judges and provides suitable results for statistical examination. As in scoring tests, the choice of wording is important. To determine the lowest detectable concentrations of substances, dilution or extinction tests are used, in which amounts of the test substance are gradually reduced to zero.

Flavour  
profile

The flavour-profile method of descriptive sensory evaluation requires sophisticated judging. Judges must recognize the four basic tastes at appropriate dilutions; be able to recognize odours; have the ability to express associations—for example, acetic acid and vinegar; and must be able to characterize and describe flavours. A closed session, in which each judge evaluates the samples separately, is followed by open discussion of the recorded results. Discrepancies in evaluation are resolved by repetition of the procedure until unanimous judgment is reached. Although the flavour-profile method offers a high degree of reproducibility, the required training time for judges and the operation itself are expensive, and results are not suitable for statistical treatment.

**Consumer acceptance tests.** Consumer acceptance and preference test results influence quality control, although they usually are not part of the activities of a quality-control department. Consumer preference and consumer acceptance practices do not necessarily evolve from each other. Food acceptance depends upon various social, economic, and cultural factors; preference implies the possibility of choice.

In surveying sensory quality factors that may determine preference, other factors that may influence judgment are removed from the test situation. Public attitude toward a product is usually ascertained by the use of questionnaires and interviews; the validity of the result is affected by the care used in wording the questionnaire and the objectivity of the interviewer.

#### OBJECTIVE EVALUATION METHODS

Chemical composition is a hidden food quality governing nutritional value. Food-product specifications state both chemical composition and tolerance limits for deviations from the specified formula.

**Chemical analysis.** Chemical food analysis methods are recommended and constantly revised by various organizations, among them the Association of Official Analytical Chemists (U.S.), the British Standards Institution, the Society for Analytical Chemistry (U.K.), the International Standards Institution, the International Union of Pure and Applied Chemistry, and the International Dairy Federation. Analytical methods to be used for specific determinations are sometimes prescribed by government legislation.

Subjective testing methods are used for reference; objective methods, frequently more rapid but less precise, are often applied in routine quality control. Automatic methods may be applied when large numbers of similar analyses are required.

**Measurement of physical properties.** Instruments used for food-product examination may be general types, often giving results in absolute physical units, such as

viscosimeters, which measure resistance of liquids to flow, and spectrophotometers, which measure the amount of light absorbed; or they may be devised for use by specific industries and calibrated in arbitrary units, such as the Brabender Farinograph, which measures the physical properties of dough.

Viscosimeters use various devices to measure product viscosity. The Ostwald viscosimeter is based on rate of flow through a capillary tube; some viscosimeters measure the time in which a given volume will flow through an orifice of a specified size; others measure time required for a weight to fall through a column of the liquid; rotary viscosimeters include the Brookfield or Ferranti instruments, which measure the resistance of the liquid to the rotation of a spindle, and the MacMichael viscosimeter, which measures the influence of a rotating liquid on a suspended plunger.

The Brabender Farinograph and the Simon "Research" Extensometer are used in the baking industry to determine physical characteristics of dough, such as time required to attain standard consistency during mixing and length of time this consistency can be maintained. Gel firmness may be determined by the Bloom Gelometer; gelatin is graded on the basis of "Bloom strength," the amount of pressure required to produce a specified depression.

Instruments have been devised to measure such texture-related characteristics as resistance to shearing forces and compressibility. The vegetable industry uses such devices as the tenderometer, an instrument that determines the maturity of peas by measuring the amount of force required to produce shearing; the meat industry uses the Bostwick Consistometer to determine consistency by measuring the time required for a viscous food to flow down an inclined plane; and an instrument has been developed for making compressibility and shear tests on baking-industry products.

The spectrophotometer is used to measure colour of clear liquids. The Munsell colour-measurement system uses three or four spinning colour discs adjusted to match visually the appearance of the test object. The edible-oils industry uses the Lovibond Tintometer, or its American equivalent developed by Wesson, to compare the colour of the oil with that of standard glasses.

**Microbiological evaluation.** Microbiological quality control is concerned with ensuring absence of pathogenic, or disease-causing, organisms and with ascertaining levels of contamination by those micro-organisms that cause spoilage. Normal micro-organism counts in foodstuffs vary according to composition and processing methods. Some canned products are expected to be sterile; others, such as canned hams, contain some bacteria. Cheeses, fermented milk products, and raw cured meat products may have counts of harmless organisms ranging into the millions. Specifications for those processed foods not expected to be sterile state the maximum acceptable organism level as determined by a total viable count, usually at temperatures between 30° and 37° C (86° and 100° F) and by a count of coliform bacteria. For some foods, counts may also be made of lipolytic organisms, anaerobic bacteria, yeasts, and molds. When the presence of pathogenic organisms is suspected, tests are made for such harmful bacteria as *Salmonella*, *Staphylococcus aureus*, *Clostridium welchii*, and *Clostridium botulinum*. In testing canned products, sample cans are first incubated, then examined for signs of deterioration.

#### CONTROL AND REGULATION OF FOOD QUALITY

**Raw-material evaluation.** No food product can be better than the raw materials in its production. Quality control requires acceptance procedures for raw materials that ensure that quality satisfies specification requirements. Daily sampling and examination of all of the raw materials are impossible, and priority is given to testing the dominant raw materials, especially for those attributes affecting the quality of the final product. Economic considerations may dictate special attention to the more expensive ingredients, such as vanilla beans, or to ingredients that may be paid for on a quality basis, such as

Viscosim-  
eters

Bacteria  
counts

milk. Although raw materials are ordinarily tested upon acceptance from suppliers, they may be stored for some time before use. When there is a possibility of deterioration during storage, periodic resampling and testing procedures are established and recorded in the raw-materials specification.

**Additives.** In addition to the main nutrients, food products contain additives. There is at present no internationally accepted definition of this term. The Food and Agriculture Organization of the United Nations (FAO) defines an additive as a nonnutritive substance intentionally added to food, generally in small quantities, to improve appearance, flavour, texture, or storage properties.

Most governments issue lists of permitted additives, stating the highest acceptable concentration, defining food products in which they may be used, and sometimes recommending the maximum daily consumption. Such legislation is revised periodically, and products may be added to or deleted from permitted lists because of additional scientific knowledge and experience in their use.

**Nutrients.** The most important group of food additives includes vitamins, amino acids, and minerals, which are nutrients added to foodstuffs to compensate for losses occurring during processing or to provide additional sources in diets that might otherwise be deficient in such nutrients. Examples of their use include fortification of margarine with additional vitamin A and the addition of thiamine, riboflavin, and niacinamide to flour or bread. Salt, a nutritionally indispensable additive, often has a small amount of iodide added to it to avoid a diet deficiency that can cause goitre development.

**Colourings.** Appearance is an important factor in food appeal, and legislation in most countries permits the addition of both natural and synthetic colouring matter. Although there are at least 46 separate dyes prepared specifically for use in food, only six of these are common to the permitted lists of most countries. In the 1960s a joint committee of the Food and Agriculture Organization and the World Health Organization was working to develop greater coordination on colouring standards.

**Flavourings.** Flavouring materials are added to basic foodstuffs to provide a characteristic product flavour or to supplement or modify the original flavour. Most flavouring materials are still of natural origin, but progress in organic chemistry has made it possible to analyze flavouring materials and to synthesize products identical with those found in nature. Although some countries permit use of synthetic equivalents on the same basis as their natural counterparts, other countries require extensive biological testing before such substances may be used. Testing methods may differ in various countries, and in the 1960s an FAO/WHO committee was attempting to bring about standardization.

**Flavour enhancers.** Flavours can also be influenced by the addition of a flavour enhancer such as monosodium glutamate, which intensifies perception of flavour.

**Antimicrobial preservatives.** The food industry generally relies on such physical factors as heat, cold, and low moisture for product preservation, but the use of antimicrobial preservatives is growing. Most countries control their use by legislation stating the maximum permissible concentration for each preservative for specified foods.

**Plant and process control.** The production of food products of consistently uniform quality is complicated by the biological variability of raw materials. In addition to the definition and maintenance of relevant processing conditions, effective quality control requires a system that will allow for rapid changes in processing conditions to compensate for seasonal or other changes in raw materials. Because raw materials may vary between deliveries, sampling and examination of each delivery is necessary to allow for appropriate modification of processing procedures.

**Industrial hygiene.** The keeping quality of foodstuffs, determined by microbiological factors, depends not only on the quality of the raw materials but also on cleanliness of premises used for manufacture, design and layout of plant and equipment, efficiency of cleaning and steriliz-

ing procedures, and the standard of personal hygiene observed by operators. In order to avoid hygiene hazards, quality-control experts are usually consulted before construction of new buildings, installation of new machinery, or development of new manufacturing processes. The quality-control organization is then responsible for enforcing cleaning and sterilizing procedures and meeting required product microbiological standards.

**Automatic processing.** Various automatic devices are used in modern food processing. Ingredient mixing is carried out automatically, either by weight or by volume. Processing time and temperature are recorded by instruments. Such factors as acidity-alkalinity, viscosity, pressures, and flow rates can be continuously recorded, and there are facilities for continuous sampling from pipelines. Detectors can monitor foods packed in nonmetal containers for contamination by ferrous metals. Reliable automatic methods are not yet available to detect the presence of other foreign bodies in prepacked food; the manufacturer has to rely on washing, screening, visual inspection of the raw materials, filtration, and general plant hygiene to minimize this hazard.

Labels on prepacked foods state the quantity present in the container, either by volume or by weight. Some machines dispense weighed amounts of foodstuffs for packaging, but most products are dispensed by volume, although the quantity declared on the packet is expressed by weight. Frequent checking is required to assure that the machine is actually dispensing required amounts. If weight is stated but a volume is dispensed, it is essential to avoid variations in product density, especially in such aerated products as ice cream. Modern machinery continuously weighs the packets moving along a belt, rejecting overweight or underweight items. A similar method can sort a batch of products, such as eggs, into several graded sizes.

**Packaging.** The quality of foodstuffs at the time they reach the consumer usually depends on the efficiency of the packaging operation. Most foods deteriorate eventually, but efficient packaging delays such deterioration. Loss of quality may be due to mechanical damage, moisture content changes, oxygen absorption, flavour loss, or absorption of harmful substances or foreign odours either from the packaging material itself or through the packaging materials. Quality control of packaging must ensure that all packaging materials delivered to the factory conform to previously determined specifications that cover all relevant chemical and physical characteristics of the packaging materials; dimensions and acceptable tolerances of the made-up containers; and a reference to the type of packaging machine on which the materials will be used. Quality control also requires monitoring of factory packaging operations, including checking efficiency of closures and the accuracy of date codings.

**Statistical evaluation.** Statistical methods are applied at various stages of food manufacture. It is sometimes possible to submit raw materials to 100 percent inspection, as in veterinary inspection of carcasses, but examination is usually limited to samples of deliveries or of finished products. The information acquired from such samples is an indication of the average quality of the consignment and the probable number of items in the consignment falling below a defined standard. The sampling rate is determined by previous experience with the product, the cost of sampling, and the cost of testing, which may involve destruction of the samples. New products, or materials known to show considerable variability, require sufficient sampling to determine mean values for important attributes and also standard deviations and the probability of a proportion of the products falling outside the acceptance limits for some attribute. Appropriate statistical methods allow prediction for a given sampling rate of the danger of not detecting faulty items in a consignment.

Control charts are widely used in the food industry, mainly as an aid to process control. Charts indicate the need for corrective action when a point falls beyond the outer limits, and their study may also give advance warning of undesirable trends. Similar charts can be used for

Control charts

deliveries or on production lines to record compliance with specifications.

**Storage and distribution.** Unsuitable storage and distribution conditions may cause rapid spoilage. Factors affecting keeping quality are temperature, humidity, exposure to light, mechanical damage, and stock rotation. For a full discussion of methods of protecting against spoilage, see FOOD PRESERVATION.

#### FOOD REGULATION

**National legislation.** The earliest rules affecting food choice resulted from religious or health considerations. Later regulations were aimed at prevention of adulteration of individual foodstuffs. The first general legislation concerned with food quality was introduced in 1860 in the U.K. under the title An Act for preventing the Adulteration of Articles of Food or Drink. This narrow approach was characteristic of the earlier era; the Food and Drugs Act of 1955 greatly widened the scope of government activity by regulating food hygiene, foodstuff composition, food additive use, and processing conditions. Further consumer protection was provided by the Weights and Measures Act 1963 and by the Trade Description Act 1968.

Similarly in the U.S., where both the federal and state governments are responsible for food legislation, the earlier approach, used in the Federal Food, Drug and Cosmetic Act of 1938, was narrow; the turning point came in the Food Additives Amendment of 1958. As in the U.K., primary concern with prevention of adulteration was replaced by the desire to protect consumer health from any hazards in food processing.

The 1958 amendment divided added food chemicals into three groups: (1) Those generally recognized as safe (GRAS), (2) those with prior sanction, and (3) food additives. Food additives have to be proved harmless by means of appropriate tests before sanction can be obtained for their use in specified foodstuffs or beverages. The manufacturer is responsible for the cost of such tests. Substances included in the GRAS list are considered to be normal constituents of foodstuffs, and their use is not limited to specified products. The GRAS concept exists only in the U.S. food law system and has no equivalent in European food laws. The U.S. government has an exceptionally large number of departments concerned with food quality control. The Public Health Service has issued standards applying to drinking water and dairy products and has made recommendations regulating catering and drinking establishments and the vending of foods and beverages. Most other food regulation, such as meat and poultry inspection, is under the Department of Agriculture. Standards for the grading of fish have been published by the Department of the Interior's Bureau of Commercial Fisheries. The Department of Defense regulates the quality of food purchased for the armed forces and may establish required standards. The Treasury Department is responsible for standards applied to alcoholic beverages. Still other standards are promulgated by the Department of Commerce, the Federal Trade Commission, the Veterans Administration, and the General Services Administration.

In Canada, the principal food law is the Food and Drugs Act 1953, concerned with protection of consumer health and enforcement of honest trading. Food standards are essentially treated by separate legislation (e.g., the Canada Agricultural Products Standards Act 1955).

On the continent of Europe, the six European Economic

Community (EEC) countries (France, Federal Republic of Germany, Italy, Belgium, The Netherlands, and Luxembourg) had separate food legislation in the early 1970s, but the EEC Commission was seeking to bring about uniformity of such legislation, and directives on antioxidants and colourings had already been issued.

**International quality control.** The most important development in international food quality control has been the setting up under joint FAO/WHO auspices of the Codex Alimentarius Commission. The Commission draws up voluntary international standards that on adoption by a member country become national, statutory, or legal minimum standards with all the necessary powers of enforcement. Some countries may wish to have more restrictive internal standards but, on acceptance of the Codex standards, must permit the importation of foods satisfying the Codex standards, although suitable differentiations may be made in the labelling.

The Codex Alimentarius is a collection of internationally adopted food standards presented in a uniform manner and aimed at protecting consumer health and ensuring fair food-trade practices. Codex standards specify: (1) the product designation, definition, and composition; (2) its hygiene requirements; (3) weight and measure requirements; (4) labelling requirements; and (5) sampling, testing, and analytical methods. Publication of standards is intended to guide and promote the elaboration and establishment of definitions and requirements for foods, to assist in their harmonization, and to facilitate international trade.

The Codex Alimentarius will eventually include standards for all principal foods distributed to consumers, whether processed, semiprocessed, or raw. Materials used for further processing into food will be included to the extent necessary to achieve the defined purposes of the Codex Alimentarius. It will also include provisions for food hygiene, food additives, pesticide residues, contaminants, labelling and presentation, and analysis and sampling methods.

**BIBLIOGRAPHY.** S.M. HERSCHDOERFER (ed.), *Quality Control in the Food Industry*, 3 vol. (1967-72), is concerned with those factors influencing the quality of a finished food product. The first volume treats the general aspects of quality control in the food industry; the second and third deal with quality control in specific branches. A. KRAMER and B.A. TWIGG, *Quality Control for the Food Industry*, 3rd ed. (1970), is an extension of material used in the quality-control training program at the University of Maryland. M.A. AMERINE, R.M. PANGBORN, and E.B. ROESSLER, *Principles of Sensory Evaluation of Food* (1965), is an authoritative monograph including many references. T.A. FURIA (ed.), *Handbook of Food Additives* (1968), a detailed and well-documented treatment of direct food additives, emphasizes U.S. food and drug legislation in its discussion of the legal aspects of food-additive use. F.L. GUNDERSON, H.W. GUNDERSON, and E.R. FERGUSON, JR., *Food Standards and Definitions in the United States* (1963), provides detailed information on U.S. standards and definitions.

(S.M.H.)

## Food Preservation

Techniques for preserving food from natural deterioration, following harvest or slaughter, date to prehistoric times. Among the oldest methods are drying, refrigeration, and fermentation. Such dried foods as pemmican were widely known to ancient hunters and gatherers, who also used caves and other cool places for storage. Fermentation was known by the third millennium BC in Meso-

Codex Alimentarius

potamia and Egypt; pickling was also developed in the ancient world. Modern methods of preservation include canning, invented early in the 19th century; freezing, developed early in the 20th century; and the addition of chemicals. Packaging has played an increasingly important role in modern food preservation.

The principal causes of food spoilage are growth of micro-organisms, enzyme action, oxidation, and dehydration. The form of spoilage to which a food is susceptible depends on its composition, structure, specific micro-organisms, and storage conditions. Micro-organisms themselves are affected by temperature, moisture, oxygen concentration, available nutrients, degree of contamination with spoilage organisms, and the presence or absence of growth inhibitors. Control of one or more of these factors usually suffices to inhibit microbial spoilage.

METHODS OF PRESERVATION

**Low-temperature preservation.** Storage at low temperatures prolongs food life by decreasing the respiration rate of fruits and vegetables and by retarding the growth of most spoilage micro-organisms. Recommended cold-storage temperatures for selected foods are listed in Table 1. A temperature at the freezing point of water (32° F,

Table 1: Recommended Cold-Storage Temperatures for Selected Foods	
food	temperature (°F)
Butter*	34
Cheese (cream)	30–36
Cheese (soft)	32–36
Condensed milk (bulk)	35–40

Olive oil	35–40
Sauerkraut	34–38
Wine	40–45

\*If butter is to be stored for longer than two or three weeks, it should be held at 0 to –10° F.

0° C) reduces the rate of oxygen consumption and carbon dioxide production (respiration) and, consequently, inhibits micro-organism growth. There are two principal low-temperature techniques: cooling (refrigeration) and freezing.

**Refrigeration.** The life of many foods may be increased by storage at temperatures below 40° F (4° C). Cold storage is less successful with fruits and vegetables having high water content, such as melons, tomatoes, cucumbers, bananas, and pineapple. Meats profit tremendously from such refrigeration, a fact discovered early in food history. In early times ice was employed as a refrigerant principally to preserve meat.

Fruits, vegetables, eggs, dairy products, and meats are often harvested, gathered, or slaughtered some time before being refrigerated, thus allowing deterioration to begin. Refrigeration cannot improve the quality of decayed foods; it can only retard deterioration. It does, however, afford substantial protection against carbohydrate loss, the major nutrient change occurring during the respiration of fruits and vegetables. One problem of modern mechanical refrigeration—that of dehydration of food-stuffs due to moisture condensation—has been overcome through humidity control within the storage chamber and by appropriate packaging techniques.

**Freezing.** Meat and fish have long been frozen for preservation by Eskimos and other northern peoples. Modern mechanical freezing is applied also to a variety

of other foods, and has proven highly effective because of its severely inhibiting effect on micro-organisms. Most microbial forms cannot grow at temperatures below 32° F and may be seriously damaged by slow freezing.

Just as the freezing point of a solution is lower than that of a pure solvent, the freezing point of food is lower than that of pure water. Thus, solid freezing usually occurs at temperatures between 32° F and 25° F (0° C and –4° C). The temperature of the food undergoing freezing remains relatively constant until the food is almost completely frozen, then the temperature rapidly approaches that of the freezing medium. In the quick freezing process, the temperature of the food passes through the zone of maximum ice-crystal formation (32° to 25° F) in 30 minutes or less. The basic principle of any rapid-freeze method is speedy removal of heat from food. These methods may employ cold air blasts, direct immersion in a cooling medium, contact with refrigerated plates in a freezing chamber, or freezing with liquid air, nitrogen, or carbon dioxide. Freezing in still air is the poorest method; circulating cold air greatly accelerates freezing.

Different foods freeze over a wide range of temperatures, and their specific freezing points are identifiable. Evaluation of the freezing curve for a food under controlled conditions reveals the phenomenon of supercooling, which is cooling below the freezing point without solidification or crystallization. Observation of a thin section of food tissue demonstrates that, following supercooling, the temperature of the cooled section then rises to the actual freezing point as solidification proceeds. If refrigeration is continued, this change in phase continues until all the free water turns to ice.

Under normal conditions, water temperature must fall below 32° F before ice crystals form. When an ice water slurry is forming, its temperature returns to 32° F.

Slow freezing forms large, needlelike ice crystals; rapid freezing results in smaller crystals, producing a finer texture. If partial melting and refreezing are repeated several times, larger and larger crystals are formed, and hence a rougher texture.

Homemade ice cream, when prepared by freezing a mixture in a freezer or refrigerator-freezer compartment, develops large ice crystals, resulting in coarse texture; the rapid freezing employed in commercial ice cream production creates a velvet-smooth consistency, because of the smaller ice crystals. Strawberries frozen by the home method lose their characteristic texture when thawed because the large, needlelike crystals formed by this slow method puncture the tissue cells. Upon thawing, the pierced cells lose their juices, leaving the berry flabby and poorly formed.

The cells of meat, poultry, fish, shellfish, fruits, and vegetables contain a jellylike protoplasm. To fix this jellylike mass, the rate of freezing must be sufficiently rapid to promote formation of minute, uniform crystals throughout the tissues. When the quick-frozen tissue is thawed, it reabsorbs the water as the ice crystals melt. If the product is refrozen slowly, or if fluctuating storage temperature encourages formation of larger crystals, the resulting punctured cells cannot reabsorb all of the fluid; it remains as free liquid, and the thawed tissues cannot return to their original jellylike state.

In addition to the effect of ice-crystal growth on frozen food quality, freezing may irreversibly change colloidal structure, fusing suspended particles as in protein coagulation in thawed milk, or curdling in thawed sauces, and causing separation.

The phenomenon of milk in an unprotected bottle or carton expanding as it freezes is well known. Such expansion on freezing occurs with many foods and must be allowed for in freeze-packaging. Not all food products increase in volume; pure water increases about 10 percent, but when large amounts of sugar are added, expansion is greatly reduced and volume may actually decrease. The sugary solution in strawberry jam occupies the same, or possibly less, space in the container in frozen form as unfrozen.

Frozen-food packaging must provide protection from dehydration resulting from sublimation (a change direct-

Freezing techniques

Problems of frozen-food packaging

ly from solid to vapour state) and other conditions of frozen storage. Adequate packaging inhibits freezer burn, an irreversible change in the colour, texture, flavour, and nutritive value of frozen foods. Freezer burn typically gives roast beef the appearance of light brown paper.

The most complicated packaging problems involve processing and distribution of individual-serving packages (i.e., frozen dinners), which often contain several different types of food in a single unit.

Low temperatures promote retention of nutrients in stored foods; freezing does not destroy nutrients, but some oxidation and destruction of vitamins may occur during the processing that precedes freezing.

Effect of  
freezing on  
nutrients  
and  
enzymes

Freezing produces little change in the nutritive value of protein, although such conditions as repeated freezing and thawing may alter food appearance and quality by reducing solubility and promoting coagulation of proteinaceous materials, eventually leading to irreversible changes such as curdling.

Fat and oil deteriorations are usually temperature dependent, and freezing is the most efficient preservation method for many fatty foods. Nevertheless, oxidative deterioration of fats and oils may occur even in frozen foods. Plant tissues are least susceptible. Fats in frozen fish tissue tend to become rancid faster than the fats in frozen animal tissues. Animal tissue reaction varies. Pork fat may become rancid after six months' storage at 0° F (−18° C); beef fat may retain good quality after two years of storage at that temperature. Rancid fats tend to have lower nutritive values than fresh, sweet fats. Rancidity development in frozen fatty tissues is greatly reduced at −30° F (−34° C). Oil and water emulsions may become destabilized by freezing, causing serious defects in precooked frozen foods and food products.

Enzyme activity is slowed by low temperature, although some enzyme activity continues at temperatures as low as −100° F (−73° C). For this reason, enzyme destruction with a short heat treatment, or blanching, before freezing and storage is the most efficient control method.

Freezing destroys certain parasites in foods. For example, *Trichinella spiralis*, the worm that causes the disease trichinosis in man, may be destroyed at all stages of development by reducing the temperature of infected food to 0° F or lower. As frozen foods are not suitable for parasite growth, freezing prevents insect infestations.

Although the complex physical, chemical, and biological changes that occur during food freezing and subsequent thawing are not completely understood, the design of a successful food-freezing process requires consideration of these changes. The basic refrigeration capacity of any unit must be adequate to lower the temperature of the food to its freezing point, freeze the food at that temperature, and lower the temperature of the frozen food to the temperature of the storage chamber. It must allow for heat produced by lighting, electrical equipment, and the entrance of air when the chamber is opened for the addition or removal of stored items. When the refrigeration requirement for a particular installation is determined, an additional 10 percent is usually allowed as a safety margin. Since refreezing a thawed mass of food may produce quality changes, storage temperatures must be maintained at a constant level—no higher than 0° F (−18° C), preferably at −10° F (−23° C), with best results at −30° F (−34° C). Animal tissues appear less subject to damage sustained in thawing than are fruit and vegetable tissues; fruits are particularly sensitive.

**Preservation by drying.** The terms evaporation and desiccation both refer to drying, and the term dehydration indicates an artificial drying process.

The drying of foods by fire was an ancient practice in both the New and Old worlds. Hot-air dehydration was developed in France in 1795; the device was a vegetable dehydrator employing a flow of hot air (105° F; 41° C) over thin slices of vegetables.

Cereal grains are preserved by drying, and the natural process is usually so efficient that no additional treatment is required. When climatic factors interfere with proper drying in the fields, heat must be applied artificially to avoid decomposition.

Essentials  
of  
adequate  
frozen  
food  
storage

Legumes, nuts, and some fruits also mature on the plants and are dried by warm winds. Drying, in fact, is the preservation process most frequently applied to fruits. Natural sun-drying yields a highly concentrated quality product, but is not always efficient because of the unpredictability of weather.

Foodstuffs may be dried in air, superheated steam, vacuum, inert gas, or by direct application of heat. Air is the most generally used drying medium, because it is plentiful and convenient, and permits gradual drying, allowing sufficient control to avoid overheating that might result in scorching and discoloration. Air may be used both to transport heat to the food being dried and to carry away liberated moisture vapour. The use of other gases requires special moisture recovery systems.

Dehydration is an effective means of inhibiting microorganism growth. Most molds can grow on foods with as little as 16 percent moisture content; a few can grow in foods with less than 5 percent. Bacteria and yeasts usually require moisture levels greater than 30 percent. Grains, which are dried to about 12 percent moisture, receive added protection from their high solids content. Fruits, usually dried to 16 to 25 percent moisture, will still mold if exposed to both high humidity and air.

Pathogenic (toxin-producing) bacteria occasionally withstand the unfavourable environment of dried foods, causing food poisoning when the product is rehydrated and eaten. Control of bacterial contaminants in dried foods requires high quality raw materials having low contamination, adequate sanitation in the processing plant, pasteurization before drying, and storage conditions that protect from infection by dust, insects, and rodents or other animals.

Some parasites also can survive the drying process, and organisms such as *Trichinella spiralis*, a parasite found in pork muscle, must be destroyed by heat treatment before drying.

Loss of moisture content produced by drying results in increased concentration of nutrients in the remaining food mass. The proteins, fats, and carbohydrates in dried foods are present in larger amounts per unit weight than in their fresh counterparts, and the nutrient value of most reconstituted or rehydrated foods is comparable to that of fresh items. The biological value of dried protein is dependent, however, on the method of drying. Prolonged exposure to high temperatures can render the protein less useful in the diet. Low temperature treatment, on the other hand, may increase the digestibility of protein.

In vitamin content, dried meat is usually less satisfactory than fresh meat. Most of its vitamin C is lost. Thiamine is reduced, with the greatest loss occurring at high drying temperatures; small losses of riboflavin and niacin also occur.

Dried eggs, meat, milk, and vegetables are ordinarily packaged in tin or aluminum containers. Fiberboard or other types of material may be employed, but are less satisfactory than metal, which offers protection against insects and moisture loss or gain and which permits packaging with an inert gas.

In-package desiccants (drying agents) improve storage stability of dehydrated white potatoes, sweet potatoes, cabbage, carrots, beets, and onions, and give substantial protection against browning. Retention of ascorbic acid (vitamin C) is markedly improved by packaging at temperatures up to 120° F (49° C); the packaging gas may be either nitrogen or air.

Dehydration has long been practiced commercially in the production of spaghetti and other starch products. As a result of advances made during World War II, the technique was applied to a growing list of food products, including dried skim milk, potato flakes, soup mixes, instant coffee, and prepared baby foods. The reduction in weight and volume offered important economic benefits in distribution.

A related technique, freeze-dehydration, employs high vacuum conditions, permitting establishment of specific temperature and pressure conditions to maintain the solid material, or substrate, at the best level for successful dehydration, encouraging satisfactory rehydration. In this

Effect of  
drying on  
nutrients

Freeze-  
dehydra-  
tion  
process

process, the solid material remains frozen while the liquid portion escapes as vapour.

Exact temperature control is essential in freeze-dehydration of flesh products because of the possibility of muscle protein deterioration, but is less critical in the processing of fruit and vegetable tissue.

Adequate control of processing conditions contributes to satisfactory rehydration, with substantial retention of nutrient, colour, flavour, and texture characteristics. The first significant application of freeze-drying was in the production of an improved type of instant coffee; later experiments involved the development of shelf-storage prepared meals. Increased application of the technique is likely.

**High temperature preservation: canning.** In commercial canning, carefully prepared raw food is placed in a sealed container, subjected to definite elevated temperatures for the proper period of time, and finally cooled. Heating the contents of the can destroys spoilage organisms that may be present, and reinfection through exposure to air is prevented by the can's permanent seal.

Nicolas Appert, a Parisian confectioner, first succeeded in preserving certain foods in glass bottles that had been kept in boiling water for varying lengths of time. In 1810 his work was published in a treatise entitled *L'art de conserver, pendant plusieurs années, toutes les substances animales et végétales*. Appert could give no logical explanations for the effects of canning, but believed that the application of heat to a sealed container, together with the exclusion of air, combined to retard or eliminate the process of decomposition. Chemistry was in its infancy and bacteriology unknown, and a half century passed before the true causes of food spoilage came to be understood.

Peter Durand, an Englishman, conceived and patented the idea of using tin cans instead of bottles, and by 1839, tin-coated steel containers were widely used.

The modern tin can, composed of 98.5 percent sheet steel with a thin coating of tin and manufactured on high-speed, automatic machinery, is the cheapest and most serviceable container for mass production. The sanitary or open-top can, developed about 1905-08, eliminated the use of solder in sealing the can, and a perfect closure was guaranteed by the double seamed top and bottom. Differentially coated electrolytic tin plate was used, beginning in 1951, to save tin and improve resistance to interior corrosion and exterior rusting. By 1960 containers of aluminum and of plastic material had been found commercially feasible for a restricted number of products, and improved glass jars and bottles were also in use. Enamel coatings had also been developed to replace tin as the interior lining of the can for certain foods.

An early obstacle to volume production was the time necessary for processing the filled cans of food in boiling water. In 1861 it was discovered that calcium chloride added to boiling water raised the temperature of processing from 212° F (100° C) to 240° F (116° C) or higher, and the time necessary to ensure safety in the process was reduced from 4-5 hours to 25-40 minutes. The average production in a first-class cannery was increased from 2,500 cans to about 20,000 cans per day. In 1874 the introduction of the closed steam-pressure retort further shortened the time necessary for processing, and reduced accidents and spoilage.

Products available for canning include almost every fruit, vegetable, meat, and marine product. Many specialty products are packed in small quantities. The relationship between grower and canner is often close, and the growing of crops for canning has become a highly specialized branch of agriculture.

Hand labour in the cannery has largely been supplanted by automatic machinery. Machines include washers, graders, peelers, corn huskers and cutters, bean snippers, and filling machines. Electronic devices often are used for regulating and controlling operations.

Operations commonly included for fruits, vegetables, milk, fish, meat, and specialty products include cleaning, preparatory operations, blanching, filling and exhausting, can sealing, thermal processing, cooling, labelling, casing, and storage.

Raw materials used in canning must be thoroughly cleaned. Cleaning is usually effected by automatic passage of the raw-food material through tanks of water or under high-pressure water sprays. Washing machinery of special design is used for certain products (e.g., flotation washers for whole kernel corn and peas), and only potable water may be used. Some products (peas, spinach) are cleaned by air blasts or shaking to remove inedible or extraneous materials before water washing.

Preparatory operations are varied, but all aim at the removal of inedible or undesirable portions of the food and conversion of the food into the desired or necessary form for subsequent operations. Such preliminaries include sorting, trimming, vining (peas); husking, cutting, silking (corn); size or maturity grading (peas); sectioning (citrus fruits); slicing, dicing, peeling, and coring (fruits); pitting (cherries); soaking (dry beans, cherries); evaporation (milk); and many others. Many of these operations are performed by special machinery; in other instances hand operations are required.

Some products (beets, carrots, spinach, peas) require a blanching by immersion in hot water or steam to shrink or wilt the product in order to obtain desired or legal weight in the final container, and also to inactivate enzymes and thereby improve the colour and flavour of the product. Blanching must sometimes precede such operations as peeling, slicing, and dicing. Occasionally, the necessary shrinkage must be obtained by precooking rather than by blanching, as with certain meat products. In addition to its other functions, blanching in some products serves as an additional cleansing operation, removing objectionable flavouring materials acquired by the raw foods from inedible portions of plants (e.g., the vine flavour of peas).

Automatic filling machines, adaptable to specific products or types of products (solid, semisolid, or liquid) and capable of high-speed operation, are employed to place the prepared food in the can. The washed, open cans are mechanically conveyed to and from the filling machines. With some foods (certain fruits, tomatoes) hand-filling methods are used.

After being filled, the open cans containing the food, especially that of nonhomogeneous type, are usually thermally exhausted by passing automatically through a hot-water or steam bath in an exhaust box. Thermal exhausting heats and expands the food and releases gases (carbon dioxide and oxygen) from the cells. Air is also excluded by expansion of the food; after sealing, heat sterilizing, and cooling the can, the contraction of the contents produces a partial vacuum in the container. Thermal exhausting may also be effected by heating the food before it is put into the cans (as with cream-style corn). Certain products are packed chiefly by the vacuum-pack method, in which the cans are mechanically exhausted by sealing machines that withdraw air and other gases and seal the cans while they are still under vacuum.

Special automatic sealing (closing or double seaming) machines capable of operating at various speeds (from 10 to 250 cans per minute, depending upon the can size and the nature of the product) are used to seal or close the covers on the sanitary type of can. The cans are usually mechanically conveyed to and from the sealing machine, where the covers are placed automatically on the cans and the sealing operation completed. The curl on the can cover and the flange on the can body are first rolled into position and then flattened together. The thin layer of gasket material or compound originally present in the rim of the cover is dispersed between the layers of metal to ensure a hermetic (air-tight) seal on the container. Some vacuum-closing machines mechanically exhaust the can just before the double seam is formed; other types of closing machines seal cans in an atmosphere of an inert gas such as nitrogen, carbon dioxide, or helium. The vent-hole types of cans (evaporated milk, certain meat products) are sealed on special tipping machines that close the vent hole with a small drop of solder.

Heat sterilization, or thermal processing, essentially consists of subjecting the food (usually contained in the

Table 2: Classification of Canned Foods on the Basis of Processing Requirements

acidity classification	pH value	food item	food groups	spoilage agents	heat and processing requirements
Low acid	7.0	lye hominy ripe olives, crabmeat, eggs, oysters, milk corn, duck, chicken, codfish, beef, sardines	meat fish milk poultry	mesophilic spore-forming anaerobic bacteria	high-temperature processing (240°–250° F)
	6.0	corned beef, lima beans, peas, carrots, beets, asparagus, potatoes	vegetables	thermophiles naturally occurring enzymes in certain processes	
Medium acid	5.0	figs, tomato soup	soup	lower limit for growth of <i>Cl. botulinum</i> non-spore-forming aciduric bacteria	boiling-water processing (212° F)
	4.5	ravioli, pimentos	manufactured foods		
Acid		potato salad tomatoes, pears, apricots, peaches, oranges	fruits	acidic spore-forming bacteria	
	3.7	sauerkraut, pineapple, apple, strawberry, grapefruit	berries	naturally occurring enzymes	
High acid	3.0	pickles relish cranberry juice lemon juice lime juice	high acid foods (pickles) high acid–high solids foods (jam–jelly)	yeasts molds	
	2.0		very acid foods		

Heat  
sterilizing  
the cans

sealed can) to a known temperature long enough to destroy spoilage and pathogenic organisms that might be present in or on the raw-food material. Cannery follow time and temperature processing schedules established by laboratories associated with the canning industry. The heat treatments necessary to preserve canned foods are determined by a number of factors; important among these is the acidity of the food or food product. Acid foods may be adequately processed by subjecting them to the temperature of boiling water. Nonacid foods must be processed at high temperatures. Processing requirements for canned foods in various acidity classifications are listed in Table 2. Most commercial processing temperatures for such foods fall in the range of 240° F (116° C) to 265° F. This temperature is attained by use of steam under pressure in a closed chest, or canner's retort.

Thermal processing equipment is of two general types: still retorts for batch operation and continuous cookers. Both types operate either at 212° F for the acid foods or under steam pressure for the nonacid products; in either case, the time of processing or cooking is regulated in order to subject the cans to the processing temperature for the proper time. Later processing installations include automatic retort controllers that regulate and record the process.

Following thermal processing, the sealed cans are cooled in cold water or in air. In water cooling, the hot cans are conveyed directly from thermal processing through tanks of cold water or through cold-water sprays; cans of large diameter must be pressure-cooled by water under pressure. Pressure cooling prevents outward straining or buckling of the can ends during the time when the internal pressure of the can is being reduced through loss of the heat of sterilization. Water cooling is continued until the can contents have an average temperature of about 100° F (38° C). At this temperature the food usually contains sufficient heat to dry the cans and prevent external rusting of the tin containers.

In air cooling, the cans are stacked in rows to permit free air circulation. Many foods cannot be cooled suitably in air.

Cans are labelled by special machines and may be placed in fibre or wood cases by hand or by machine. Cans are frequently stored without labelling, and the labelling operation is performed just before shipment. Canned foods are stored in cool, dry warehouses that are free of wide variations in temperature or humidity.

Normal vacuum cans of food are slightly concave on the ends. Bulged ends may be caused by microbial, chemical, or physical actions. Such cans may progress through various stages of swelling and finally explode.

Considerable investigation has been devoted to the effects of commercial canning on foods. Canning procedures have no practical effect on proteins, carbohydrates, and fats. When syrups or brines containing sugars are

added in canning, the natural carbohydrate content of the foods is enhanced. Research has established the effect of canning on the known vitamins. In general, vitamin A and carotene (provitamin A), if protected from atmospheric oxygen, are not materially affected by the heat treatments given canned foods; vitamin D and riboflavin also appear to be unaffected. The stability of vitamin B<sub>1</sub> is dependent not only upon the heat treatment accorded it but also upon the acidity of the food in which it is contained. For the more acid foods there is practically no loss of this vitamin during canning; in the less acid foods, which require longer processing times at higher temperatures, the degree of retention is not great. Vitamin C is especially subject to destruction at elevated temperatures under conditions that permit free access to atmospheric oxygen. But in canning, the food is protected to a large degree from contact with oxygen; consequently, vitamin C is substantially retained.

**Fermentation and pickling.** Although micro-organisms are usually thought of as causing spoilage, they are capable under certain conditions of producing desirable effects, including oxidative and alcoholic fermentation. The micro-organisms that grow in a food product, and the changes they produce, are determined by acidity, available carbohydrates, oxygen, and temperature. Untreated meat, for example, molds and putrefies; the addition of brine or salt causes different organisms to grow.

An important food preservation method combines salting to control micro-organisms selectively and fermentation to stabilize the treated tissues. The process for cucumbers is called pickling and is applied also to many other food commodities.

**Pickled fruits and vegetables.** Fresh fruits and vegetables soften after 24 hours in a watery solution and begin a slow, mixed fermentation-putrefaction. The addition of salt suppresses undesirable microbial activity, creating a favourable environment for the desired fermentation. Most green vegetables and fruit may be preserved by pickling.

When the pickling process is applied to a cucumber, its fermentable carbohydrate reserve is turned into acid, its colour changes from bright green to olive or yellow-green, and its tissue becomes translucent. The salt concentration is maintained at 8 to 10 percent during the first week, and is increased 1 percent a week thereafter until the solution reaches 16 percent. Under properly controlled conditions the salted, fermented cucumber, called salt stock, may be held for several years.

Salt stock is not a consumer commodity. It must be freshened and prepared into consumer items. In cucumbers this is accomplished by leaching the salt from the cured cucumber with warm water (110° to 130° F; 43 to 54° C) for 10 to 14 hours. This process is repeated at least twice, and in the final wash, alum may be added to firm the tissue, and turmeric to improve the colour.

Effect of  
canning on  
nutrients  
and vita-  
mins

Salt stock:  
basic stage  
in pickling

Freshened salt stock is used in the preparation of many types of pickles and relishes. Sour pickles are prepared by reprocessing freshened salt stock with weak vinegar. Sweet pickles are prepared by adding a sweet spice and vinegar solution to freshened salt stock. Processed dill pickles require the addition of dill herb and spices to the acidified brine.

Natural dill pickles are prepared from fresh cucumbers rather than from salt stock. The fresh cucumbers are packed into barrels with a mixture of brine, dill, and other spices; the acid develops naturally. These dill pickles are rarely packaged in vinegar. They are perishable unless repackaged and pasteurized.

Sauerkraut is made by bacterial fermentation of cabbage controlled by the use of salt; the acid that develops during fermentation acts as a preservative and develops the flavour.

Green olives are harvested when they have reached their full size, but are not yet fully ripe. They contain a bitter alkaloid, oleuropein, which is largely removed by a 2 percent sodium hydroxide solution. The lye is permitted to penetrate nearly two-thirds through the fruit, but not completely to the pit; a small amount of bitterness remains, imparting a characteristic flavour. The treated olives are washed to remove the lye.

*Pickled meat.* Meat may be preserved by dry curing or with a pickling solution. The ingredients used in curing and pickling are sodium nitrate, sodium nitrite, sodium chloride, sugar, and citric acid or vinegar.

Various methods are used: the meat may be mixed with dry ingredients; it may be soaked in pickling solution; pickling solution may be pumped or injected into the flesh; or a combination of these methods may be used.

Curing and  
smoking of  
meats

Curing may be combined with smoking. Smoke acts as a dehydrating agent and coats the meat surfaces with various chemicals, including small amounts of formaldehyde.

*Deterioration of fermented and pickled products.* Fermented foods and pickled products require protection against molds, which metabolize the acid developed and allow the advance of other micro-organisms. Fermented and pickled food products placed in cool storage can be expected to remain stable for several months. Longer storage periods demand more complete protection, such as canning.

Nutrient retention in fermented and pickled products is about equal to retention for products preserved by other methods. Carbohydrates usually undergo conversion to acid or to alcohol, but these are also of nutritive value. In some instances, nutrient levels are increased because of the presence of yeasts.

**Concentrated moist foods: preserves and candied fruits.** Foods with substantial acidity, when concentrated to 65 percent or more soluble solids, may be preserved by mild heat treatments. High acid content is not a requirement for preserving foods concentrated to over 70 percent solids.

Fruit-jelly and fruit-preserve manufacture, an important fruit by-product industry, is based upon the high-solids-high-acid principle, with its moderate heat-treatment requirements. Fruits that possess excellent qualities but are visually unattractive may be preserved and utilized in the form of concentrates, which have a pleasing taste and substantial nutritive value.

Jellies and other fruit preserves are prepared from fruit, with added sugar, concentrated by evaporation to a point where microbial spoilage cannot occur. The prepared product can be stored without hermetic sealing, although such protection is useful to control mold growth, moisture loss, and oxidation. In modern practice, vacuum sealing has replaced the use of a paraffin cover.

The jelly-forming characteristics of fruits and their extracts are due to pectin, a substance present in varying amounts in all fruits. The essential ingredients in a fruit gel are pectin, acid, sugar, and water. Flavouring and colouring agents may be added, and additional pectin and acid may be added to overcome any deficiencies in the fruit itself.

Jam is similar to jelly, but in the former the whole fruit

is used, including pulp, rather than the fruit juice only. Fruit butter is a smooth, semisolid food prepared from at least five parts by weight of mashed or sieved fruit pulp to each two parts of sugar, sometimes with spices. Marmalade, usually made from citrus fruit, is the jellylike concentrate of prepared juice and sliced peel combined with sugar. Other fruit preserves are made in much the same manner, except that fruit pulp and fruits are often used. Fruit pastes are concentrated from fruit purees; they have a high solids content and usually no gel structure.

Candied and glacéed fruits are made by slow impregnation of the fruit with syrup until the concentration of sugar in the tissue is sufficiently high to prevent growth of spoilage micro-organisms. The candying process is conducted by treating fruits with syrups of progressively increasing sugar concentrations, so that the fruit does not soften into jam or become tough and leathery. After sugar impregnation, the fruit is washed and dried. The resulting candied fruit may be packaged and marketed in this condition, or may be dipped into syrup, becoming coated with a thin glazing of sugar (glacéed) and again dried.

**Chemical preservation.** Chemical food preservatives are substances which, under certain conditions, either delay the growth of micro-organisms without necessarily destroying them, or prevent deterioration of quality during manufacture and distribution. The former group includes some natural food constituents which, when added to foods, retard or prevent the growth of micro-organisms. Sugar is used partly for this purpose in making jams, jellies, and marmalades, and in candying fruit. The use of vinegar and salt in pickling, and of alcohol in brandying, also falls in this category. Some chemicals foreign to foods are added to prevent the growth of micro-organisms. The latter group includes some natural food constituents such as ascorbic acid (vitamin C), which is added to frozen peaches to prevent browning, and a long list of chemical compounds foreign to foods and classified as antioxidants, bleaching agents, acidulants, neutralizers, stabilizers, firming agents, and humectants.

*Organic chemical preservatives.* Sodium benzoate and other benzoates are among the principal chemical preservatives. The use of benzoates in certain products in prescribed quantity (usually not exceeding 0.1 percent) is permitted in most countries, some of which require a declaration of its use on the label of the food container. Since free benzoic acid actually is the active agent, benzoates must be used in an acid medium in order to be effective. The ability of cranberries to resist rapid deterioration is attributed to their high benzoic acid content. Benzoic acid is more effective against yeasts than against molds and bacteria.

Other organic compounds used as preservatives include vanillic acid esters, monochloroacetic acid, propionates, dehydroacetic acid, and glycols.

*Inorganic chemical preservatives.* Sulfur dioxide and sulfites are perhaps the most important inorganic chemical preservatives. Sulfites are more effective against molds than against yeasts and are widely used in the preservation of fruits and vegetables. Sulfur compounds are extensively used in wine making and, as in most other instances when this preservative is used, much care has to be exercised to keep the concentrations low in order to avoid undesirable effects on flavour.

Oxidizing agents such as nitrates and nitrites are commonly used in the curing of meats.

*Antibiotics.* Some European food-preserving agents containing antibiotics appeared on the market in the late 1940s. The use of antibiotics has since spread, though limited in most countries by government regulation pending better understanding of their operation.

*Government regulation.* Most governments attempt to control the addition of foreign substances to foods and the occurrence of toxic residues in foods. Regulations concerning the use of food additives, including chemical preservatives such as boric acid and hydrogen peroxide, change frequently as new compounds become available

Varieties

Uses of  
chemical  
substances

Irradiation: sterilization at low temperatures

or as the desirable or undesirable properties of agents in use become better understood.

**Irradiation (ionizing radiation).** Radiation sterilization allows preservation of foods without marked change in their natural character. Radiation processing of foods may eliminate refrigeration requirements; limited radiation may prolong the storage life of cut meats, fresh fish, and fresh fruits and vegetables. Parasites, food-poisoning organisms, and insects in various life-cycle stages may be destroyed. Sprouting may be inhibited in potatoes and onions. Irradiation may be used in preparation of sterile enzyme solutions, tenderization of meat, coffee-bean roasting, and aging of wines.

Sterilization of foods by irradiation requires only one-fiftieth of the energy needed for thermal sterilization. It permits sterilization of substances with a temperature rise of only about 5° F (3° C).

Despite the negligible temperature rise, ionizing radiations produce widespread chemical changes in irradiated materials and under ordinary conditions can oxidize any oxidizable substance and reduce any reducible material. Enzymes are more resistant to irradiation than microorganisms, and it may be desirable to inactivate enzymes by other means, in complement to the irradiation action. Nutrients are somewhat reduced in irradiation processing, and development of protective methods requires further study. In the early 1970s, the safety of foods treated by irradiation was still the subject of testing and evaluation.

**Semimoist preservation.** The availability of wholesome, inexpensive antimicrobials (mold inhibitors) that are effective at low levels of addition permits the development of a new category of semimoist, or intermediate-moisture food products. Semimoist technology was still being developed in the early 1970s.

In the preservation of canned bread, increased storage stability has been obtained by lowering the moisture content to 35 percent, heating, and then hermetically sealing the still-hot product to prevent reinoculation by microorganisms.

Polyunsaturated fatty acids are effective antimicrobial-fungistatic agents. They have been used to prevent molding of meat, cheese, and many other refrigerated, packaged foods.

One of the problems involved in the development of semimoist foods was the need for control of enzyme activity by a nonheating process.

#### FOOD STORAGE AND PACKAGING

**Storage.** Since most foods can be stored for many years under appropriate conditions, it is important to establish the conditions and storage periods that afford the optimum balance between the cost of storage and the changes in quality of stored products. Further study is needed concerning changes in colour, odour, flavour, texture, nutrients, moisture content, staling, and rancidity. Information is also needed on the characteristics of rigid and flexible packages filled with various foods, and their interaction under various storage conditions. Experimentation has already provided important information regarding changes resulting from storage conditions.

A wide range of natural temperature and humidity conditions exist in warehouses, dugouts, shelters, and natural caves used for food storage. These can be highly satisfactory if conditions are sufficiently constant to allow prediction of storage life of the foods.

The temperatures maintained in above-ground natural-storage houses vary with site and geographical location, from below freezing to above 100° F (38° C) at relative humidities from almost 100 to 20 percent or lower.

Temperatures in caves or deeper excavations may fluctuate less than 10° F (6° C) annually. Utilization of these or similar sources of natural cool storage can yield advantages over above-ground storage in more uniform quality and increased life, or can reduce the cost of holding under refrigerated storage.

**Packaging.** Because it is possible to preserve food-stuffs by altering their immediate environment, packaging has become an important element in preservation.

Satisfactory packaging requires consideration of protection, economy, convenience, and appearance. Factors affecting the choice of packaging materials include product properties, storage conditions, and properties of economically available materials.

Packaging-material specifications for tensile strength, tearing resistance, heat-sealing ability, and other factors are determined by the properties of the food product to be contained and by the storage time and conditions.

Packaging is affected by the tendency of food to gain or lose moisture, its free oil or fat content, its particle size, its tendency to sift, and its susceptibility to spoilage by light, oxygen, and organisms.

Internal and external failures of both rigid and flexible containers frequently reduce quality or storage life of products. Resistance to moisture, corrosion, leakage, and package fatigue are needed to withstand high temperatures or humidities, or the corrosive action of certain products high in salt, fats, natural acids, or sulfur compounds.

Damage to containers by moisture, drying, heat, and other unfavourable conditions is cumulative. Selection of suitable containers can be as important as formulation of foods for long-term storage.

**Effect of storage and packaging.** Colour stability varies widely among different products and storage temperatures. The only significant change at 0° to -20° F (-18° C to -29° C) is a slightly lighter appearance, and there is no significant change in any product at 32° F (0° C). Temperatures of 47° F (8° C) result in significant changes, particularly in the less stable items.

At temperatures from 70° to 100° F (21° C to 38° C) products tend to darken, brown, fade, and lose flavour or become stale.

Extremes of temperature have adverse effects on texture. Freezing causes sufficient damage to such items as tomatoes and beans to reduce them to substandard grades. Most sauces and gravies separate with freezing; and noodles, spaghetti, and other starches tend to soften or slough. Less serious freezing damage occurs in the softening of cheeses and most vegetables. Beef and pork exhibit an increased tendency to break apart, and salmon to fragment. Frozen and thawed ham and bacon are more easily separated into strings or fibres.

At 70° F to 100° F there is softening of some meat products, drying out of certain bakery and confectionery products and syruing of others, and leakage of fats or oils from such items as cereal bars, meat bars, chocolates, and peanut butter. The storage life of various food products at 70° F is listed in Table 3. Softening or drying is

Effects of storage temperature extremes

Table 3: Useful Storage Life of Plant and Animal Tissues

food product	generalized storage life (days), 70° F
Animal flesh	1-2
Fish	1-2
Poultry	1-2
Dried, salted, smoked meat and fish	360 and more
Fruits	1-7
Dried fruits	360 and more
Leafy vegetables	1-2
Root crops	7-20
Dried seeds	360 and more

seldom as serious as changes in colour or flavour in such products, but leaking of syrups or fats results in damage to wrappers and enamel linings of cans and tends to increase development of stale or rancid flavours. Insect and rodent infestation is encouraged when such products are packaged in nonrigid containers.

Loss of vitamins and nutritive values may be a more serious deterrent to long storage than loss of sensory appeal, particularly at temperatures in the 70° to 32° F range.

Two vitamins, thiamine and ascorbic acid, decrease faster in storage than either colour or palatability. Losses

of 30 to 50 percent of these vitamins have been found in some samples where sensory quality remained satisfactory. It is apparent that vitamin retention, rather than sensory quality, should be the criterion in determining temperature and length of storage for foods that are important sources of thiamine or ascorbic acid. As noted above, there are no significant changes in  $\beta$ -carotene; and changes in niacin and riboflavin are relatively minor.

**BIBLIOGRAPHY.** N.W. DESROSIER, *The Technology of Food Preservation*, 3rd ed. (1970), is a comprehensive text on food preservation. L.B. JENSEN, *Man's Foods* (1953), provides a historical perspective. Food and health are treated in G.M. DACK, *Food Poisoning*, 3rd ed. rev. (1956); F.W. TANNER, *The Microbiology of Foods*, 2nd ed. (1944); and *Food-Borne Infections and Intoxications*, 2nd ed. (1953). The UNITED STATES DEPARTMENT OF AGRICULTURE, *Composition of Foods* (Handbook No. 67), provides the composition of various preserved foods; the AMERICAN SOCIETY OF HEATING, REFRIGERATING AND AIR-CONDITIONING ENGINEERS, *Refrigeration Handbook* (1969), gives detailed information on the refrigerated storage of specific commodities. Basic documents covering market diseases of fresh fruits and vegetables are in the U.S.D.A. Handbook No. 66. D.K. TRESSLER (ed.), *The Freezing Preservation of Foods*, 4th ed. (1968), is an authoritative and useful presentation of all aspects of the frozen-food industry; canning and pickling of foods is treated in W.V. CRUESS, *Commercial Fruit and Vegetable Products*, 4th ed. (1958); and in C.H. CAMPBELL, *Campbell's Book: A Manual on Canning, Preserving and Pickling* (1954). W.B. VAN ARSDEL and M.J. COPLEY (eds.), *Food Dehydration*, 2 vol. (1963-64), is a detailed treatment of the ancient practice of food drying. The CHEMICAL PUBLISHING CO., *Handbook of Food Additives* (1968), discusses the use of chemicals in foods.

(N.W.D.)

## Food Service Systems

Food service systems are designed for the purpose of planning, preparing, and serving food outside the home and in large volume; in addition to commercial outlets (see RESTAURANT), the industry includes such institutional food services as those operated by schools, hospitals, industrial plants, and military services. In the U.S., where 25 percent of the retail value of food consumed is prepared and served outside the home, food service is the country's fourth largest industry. It is achieving comparable status in Europe and Japan.

**Historical development.** Although technological advances in food processing methods and distribution equipment have revolutionized preparation and delivery systems since World War I, quantity food service operations date much further back. Quantity food production and service, for example, characterized the monasteries, abbeys, princely households, and colleges of the Middle Ages. Then as now the principal factors affecting the organization of food service systems were the type of institution and the availability of food and labour.

**Industrial food service.** Provision of food for labour forces has been a necessity since earliest times when labour was either forced or hired to work in the fields, construct monuments, man ships in commercial navigation, and enlist in armies. Long before the Industrial Revolution brought the mass production factory, employers provided board and lodging for apprentices and journeymen. In 1815, Robert Owen, a mill operator in Scotland, concerned with the exploitation of children in the textile industry, established a large kitchen and eating room where meals were served at a nominal price to employees and their families. In Europe it became customary for employers to provide areas where food from home could be reheated and supplemented by beverages or other items sold at cost. In the United States the policy of subsidizing meals has been characteristic of employee food systems from early times, and by the 1890s many factories, banks, department stores, and telephone exchanges were providing food services for employees.

World Wars I and II fostered advances in mass-feeding technology; World War I saw the introduction of cafeteria service to replace less efficient table service and World War II the spread of vending machines and other quick-service equipment. The wars also stimulated the

development of fabricated, prepackaged food, a trend that was stimulated by the need to meet such peacetime logistics problems as those associated with mining, exploring, and other remote-location activities. Several innovative techniques for packaging and controlling food quality for extended periods of time resulted, notably as a product of space exploration.

**Commercial food service.** The establishment of inns and taverns as public eating places for travellers was the earliest forerunner of present-day commercial food service. The beginning of the concept of the restaurant, a public eating place exclusive of provisions for sleeping, is attributed to the cookshops of France in the 18th century, which were licensed to prepare ragouts to be eaten on the premises or taken to inns for consumption. From these beginnings commercial food services grew into the 20th century's range, which includes conventional restaurants, quick-service and self-service shops, in-flight meals aboard commercial aircraft, and others.

**School and college food service.** The gradual restriction of child labour was an influential factor in the development of the school lunch movement. In some European countries, public concern for education resulted in the provision of low-cost lunches to encourage school attendance. Canteens for school children were established in France as early as 1849. Victor Hugo is credited with initiating school feeding in England in 1865 by providing warm lunches in his home on the island of Guernsey for children in the local school.

Organized school feeding in the U.S. dates to the mid-19th century, when to persuade slum children to go to school, the Children's Aid Society of New York City opened an industrial school in 1853 and offered to feed all students. Federal legislation in the 1930s provided loans and surplus commodities for local programs; in 1943 schools were allocated cash assistance, and in 1946 the National School Lunch Act authorized federal grants-in-aid. Legislation enacted in 1970 amended and improved the national school lunch program. The law authorized funds for nutrition education for children and placed a positive mandate on each state to provide a free or reduced-price lunch to all needy children.

Food service in colleges is as old as the university itself; the first endowed student hostel of the Middle Ages appeared at the University of Paris in 1180. Students were responsible for the management; some later endowed houses were under the direction of the university. The question of management remained characteristic of student food services, but the principle of endowed programs remained in force into the 20th century.

In both school and college food service, the trend in the early 1970s was toward centralized food purchasing and preparation through a commissary operation. Prepared food items were transported either as individual servings on plates or in bulk to satellite areas for finishing, assembly, and service.

**Hospital food service.** Although the first hospitals of medieval Europe provided food for patients, the idea of therapeutic diets for patients developed in 19th-century military hospitals, notably the British army hospital at Scutari, Turkey, in the Crimean War (1853-56), in which Florence Nightingale organized a diet kitchen. Alexis Soyer, a London chef, contributed his services as manager to the barrack's hospital kitchen. The idea was soon copied by civil as well as military hospitals. As the nutritional and therapeutic significance of food gained recognition, so did the need for a dietitian. The functions of the hospital dietary department grew to comprise the organization and management of the total hospital food service, including the education of patients and nurses in nutrition and often extending to the preparation of food for elderly or incapacitated persons who are not hospitalized. Trends in hospital food systems of the early 1970s included automated meal-delivery systems, centralized or off-premise food preparation, preprepared and preportioned foods, and computer-assisted management procedures.

**Characteristics of a food service system.** To provide effective and efficient meal preparation and delivery, a

food service system integrates a number of interdependent resources. These may be grouped in four categories: (1) human: direct and indirect labour; (2) material: food and supplies; (3) facility: equipment and space; and (4) operational: time and capital. Menu planning, procurement of foodstuffs, food preparation, and meal assembly and delivery comprise the basic functions of the system. To implement these functions, subsystems are designed to forecast required quantities, allocate and schedule resources, process information, handle materials, and control cost and quality.

Food service systems are obviously comparable in many ways to conventional manufacturing industries. Both acquire foodstuffs in various states of processing, convert the individual items into a product, and sell and deliver the product at a cost compatible with the objectives of the institution.

The basic end product of the food system is the meal or the individual menu items that form the meal. The menu and its associated recipes constitute the product-design specifications. Standardized recipes dictate the specific kind and type of food ingredients required, the production quantity relative to demand, and the amount and type of labour and equipment necessary to produce the meal within a prescribed time interval.

The general objectives of any food service system are to provide nutritional, safe, and palatable meals. The achievement of these objectives is dependent on the organizational structure, the application of scientific food-preparation techniques and management principles, and the effectiveness of the personnel.

The food service director plans, implements, and controls operational procedures to insure the production of quality food and service. Food-preparation techniques influence nutrient retention, acceptance, and bacteriological safety of the food. The conditions of preparation best suited to the retention of colour, flavour, aroma, and texture tend also to preserve the nutritive value. Minimum standards for sanitation and safety in food services are widely established and enforced by national and local legislation.

**Current trends in food service systems.** The 1960s and 1970s witnessed rapid developments in food service, especially in new market forms of food, such as frozen and dehydrated, and more automated preparation and delivery equipment. These changes have brought about new concepts in meal assembly and distribution, facility layout, labour use, and operational analysis.

**Production and distribution techniques.** The trend toward centralization of food preparation either on the premises or at a commissary apart from the point of service is accelerating. Many food service systems utilize centralized materials-handling methods to facilitate the movement of raw materials from storeroom to preparation area. This technique facilitates the control of product quality and cost as well as the use of unskilled personnel for supporting tasks such as weighing, assembling, and transporting ingredients. Operations with a large volume of production have implemented central purchasing, warehousing, and commissary production with distribution to satellite service units.

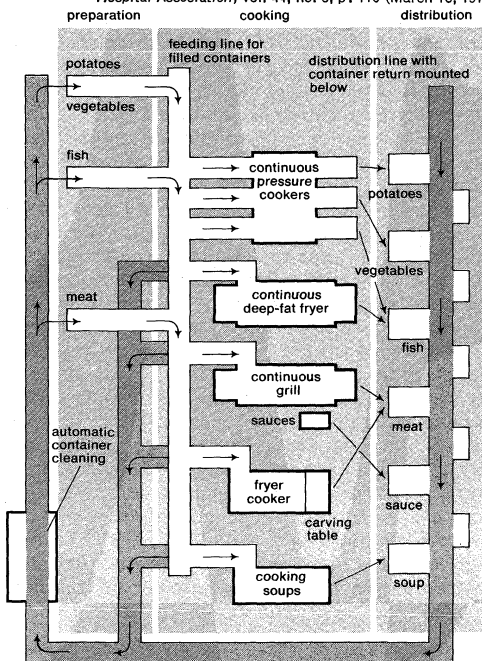

The centralization of production and the development of continuous batch-processing equipment have resulted in the use of the food factory concept by which products are produced in assembly-line fashion. Individual menu items are produced either for immediate service or warehouse storage depending on perishability. This technique smooths production scheduling, provides for more effective use of equipment and space, and allows menu items to be withdrawn from storage on demand.

The availability of pre-prepared and convenience menu items through commercial production or institution-operated commissaries has placed increased emphasis on meal reconstitution and delivery techniques, as illustrated by heat-and-serve or frozen preportioned meals available on mobile pallets that can be moved directly into heating equipment at the point of assembly or service. Cold food items, such as salads, may be purchased preportioned on disposable ware, in bulk form ready for por-

tioning, or may be produced on premises. When a complete ready-to-serve meal is distributed to numerous satellite units, cold and hot foods are assembled on a continuous belt and transported by automatically dispatched horizontal or vertical delivery systems.

**Preparation and delivery equipment.** West Germany, France, Switzerland, and Sweden are the leading designers and manufacturers of large-scale food production and meal-delivery equipment. Innovations include a vertical cutter and mixer, forced-air oven, tilting frying pan, continuous grill, automatic food-supply devices, and monorail and automatic-car meal-transport systems.

Continuous cooking and distribution system.

A German meal preparation and assembly system in use in several hospitals in Europe (see illustration) incorporates automatic food preparation with continuous processing equipment. The tray-assembly system is equipped with an electronically controlled guidance mechanism that indicates individual food orders at each assembly station. The system uses auxiliary electronic data-processing equipment and provides assembly control and rapid distribution of meals.

A system of supplying food via pneumatic tube at the point of patient-tray assembly was developed for hospitals in Sweden. Singly portioned, packaged, sealed, and frozen items are ordered from storage by remote control. Fresh food items are released from storage and carried on a conveyor belt directly into the automatic dispatcher of a pneumatic tube. Items to be eaten hot are brought to serving temperature in a conveyorized microwave oven before delivery via the pneumatic tube. The items are released onto a collecting belt where they are assembled according to the patients' selection.

A system designed for the University of Cologne, West Germany, can feed 2,500 patients and 4,000 employees and students in 125 locations, in 17 buildings scattered over nine city blocks. The food is processed in containers that convey food through heat zones set at predetermined temperature and cooking mediums. In the assembly section, food is portioned into plates on conveyor belts. This part of the meal is blast-frozen (a quick-freezing method) and loaded into containers to be stored according to a computer-assisted allocation and inventory system. At the time of service, fresh meal components are coordinated with frozen items. Completed trays are filed in a transfer unit to be hoisted onto a monorail for delivery. When the tray reaches the point of service, the frozen portion is heated in a microwave oven.

Assembly-line food

A meal distribution and delivery technique developed in the U.S. and used by both hospitals and airlines is based on the principle of loading hot foods over hot foods and cold foods over cold foods in thermal insulated trays, creating thermal columns for temperature retention. Hot foods for flight are precooked, frozen, and taken aboard under refrigeration. Before serving they are heated to proper temperature.

**Application of scientific management.** In order to achieve an optimum balance between food-production costs, product quality, and consumer satisfaction, food service administrators must know how much people are to eat, how many people are eating, and, in free-choice situations, what they will want to eat, in order to make the decisions required of them. Operational procedures are planned, kept current, and evaluated through the use of systems analysis, work measurement, and other program evaluation and review techniques.

Operations-research techniques are used to develop methods of forecasting demands for service on the food system and allocating and scheduling the utilization of system resources. Computer-assisted menu planning employing linear programming techniques (see OPERATIONS RESEARCH) has been developed to determine the optimum combination of menu items that satisfies predetermined nutrient and cost constraints. Computer simulation techniques have been used to schedule food preparation, determine optimum inventory levels, and study the effect of various patterns of customer traffic flow on the efficiency of cafeteria systems.

Computer-assisted procedures in support of managerial and operational functions have been implemented in numerous food service systems. Current applications include menu planning, production-demand forecasting, recipe sizing, purchasing, ingredient issue, inventory control, and cost accounting. The advent of the computer has provided food service directors with the opportunity to develop a management system that provides a means of common control over a number of complex and interrelated food-system functions.

## Food Supply of the World

Throughout history, the food supply of mankind, worldwide, has oscillated between scarcity and plenty. To the fertile valleys of the Tigris-Euphrates and the Nile came drought or flood and the seven lean years that toppled dynasties. When the population of Rome exceeded its food supply, foreign conquest provided grain supplies from Africa and Thrace.

When, in the mid-19th century, Europe's population suddenly began to multiply and starvation threatened, its emigrants opened up temperate lands in other continents to provide the needed grain, meat, and dairy products. Since World War II, another population explosion has started, this time in the developing countries and much more rapid than anything previously seen, and will, some say, result in widespread famine. The successes of scientists and the many possibilities of applying agricultural technology in the developing countries, however, offer hope that with appropriate effort sufficient food can be produced for all people. The United Nations has projected that world population may stabilize at some 12,000,000,000 to 15,000,000,000 around the middle of the 21st century. Technically—in terms of the world's resources of soil and water and knowledge of agricultural

techniques—it would be possible to feed this many people; whether it will be possible in practice remains to be seen.

In primitive societies each family was self-sufficient. Nonagricultural occupations gradually emerged—those of the carriers, the priests, the artisans, who gave their services or products in exchange for food. Thus came into existence the market economy, which grew in volume and geographical extent as villages and towns increased in size. As early as Roman times it was possible to speak of a "world market" for certain foodstuffs. Portions of the market collapsed with the empire and did not re-emerge until innovations in transportation and other inventions beginning in the mid-19th century created a new "world market," this time extending beyond Eurasia and Africa and covering the entire planet.

Nevertheless, a large part of mankind remains only partially linked to markets, as may be deduced from statistics that show the proportion of farm output retained on farms—that is, subsistence production. The figure, barely 1 percent in the United Kingdom and 3 percent in the United States, exceeds 50 percent in southern Asia and 80 percent in many parts of Africa. In the developing countries, with the expansion of cities and the spread of industrialization, subsistence production can be expected to decline rapidly in favour of market production.

Just as family self-sufficiency in food denoted security, so, also for reasons of security, national self-sufficiency has been a preoccupation of many governments. Most countries today are more than 90 percent self-sufficient in food, though they may have to depend on imports for exotic products such as coffee or cocoa. Significant exceptions are the United Kingdom, which produces only 60 percent of its food, and countries with poor agricultural resources such as Norway and Switzerland, which produce an even smaller proportion. Because food output in many advanced countries is increasing faster than the demand for food, their degree of self-sufficiency has tended to increase since about 1955. But because of population growth and a tendency to neglect agricultural development in favour of industry, the opposite has happened in several developing countries.

### THE FOOD SHORTAGE IN DEVELOPING COUNTRIES

**Trends in population and food production.** In 1975 the population of the world reached 4,000,000,000, sharply divided in terms of social and economic welfare between 3,000,000,000 in the developing countries and 1,000,000,000 in the developed countries. (As used in this article, "developed countries" include Europe, the Soviet Union, North America, Australia, New Zealand, and, for the postwar years, South Africa, Japan, and Israel; "developing countries" include, unless otherwise indicated, all other countries.) The trends in food production in each group are shown in Table 1, as of August 1977.

Contrary to popular belief, total food output in the developing countries has expanded as rapidly as in the developed. It is in relation to population that the picture becomes quite different. Taking the average of the years

1961–65 as 100, production per person in the developed countries rose from 81 in 1948–52 (that is, just after World War II) to 94 in 1956–60 and 115 in 1971–76. In developing countries production per person rose fairly steadily after the war till about 1958. Thereafter it was almost stagnant. Population increase each year, about 2.3 percent, absorbed most of the increase in production.

The disquieting paradox persists: the already well-fed peoples are able to expand their food production faster than their requirements grow—despite the fact that in some of the rich countries, notably the United States, governments have deliberately restrained production—whereas for poorly fed peoples the reverse is the case. At the very end of the 1960s, as a result of the “green revolution,” there were some signs of an upsurge in food production in certain developing countries, notably in Asia. During the 1970s, however, the surge was not maintained.

Since 1972 the world has been close to crisis in its food supply. In that year, poor crops were harvested in most of the major cereal-producing areas, particularly in the Soviet Union, India, and North America. World stocks were almost depleted. Stocks of cereals (outside China and the Soviet Union), which had been 26 percent of total consumption in 1970, had already fallen to 19 percent in 1972. In 1973, as a result of the poor harvests in 1972, they had been drawn down to 14 percent, and in succeeding years they went even lower.

Beginning with the 1973 season, the crop situation was complicated by both shortages and very high prices of fertilizers. Partly but not wholly because of the dramatic rise in petroleum prices, prices of fertilizers rose four- to fivefold. The rise in food and fertilizer prices hit particularly those developing countries, such as India, that did not have oil or some other product that benefited from the price boom. At the end of the 1960s there was a worldwide surplus of fertilizers, prices were very low, little new capacity was installed, and some plants were closed down. But with world demand increasing rapidly (about 13 percent a year in developing countries), production capacity fell below worldwide demand.

As a consequence of the earlier trends, the developed countries exported larger and larger quantities of food to the developing countries. Beginning in the mid-1950s, this trade doubled, while the agricultural exports of the developing group recorded only a modest increase. At the same time the imports of food into developing countries increased more rapidly than food imports into developed countries. Using 1961–65 as 100, the ratio of exports to imports in 1973 had risen to a favourable 125 for developed countries, while that of developing countries had deteriorated to 78. This imbalance was a major cause of the worsening balance of payments experienced by the developing countries, even though an important proportion of their food imports was obtained on non-commercial terms.

The Food and Agriculture Organization (FAO) of the United Nations has calculated that, if these trends in population and food production continue, the net cereal deficit of the developing market economies would have to rise from 16,000,000 tons in 1969–71 to almost 85,000,000 tons by 1985 in order to meet the projected increase in demand. Since it is entirely unlikely that the poor countries could finance imports of this magnitude or that rich donor countries would give so much away, ways and means will have to be found to enable the developing countries to feed themselves.

**The nature of the problem.** The food supply problems of the two groups of countries are therefore radically different. In the advanced countries, where food production increases at 2.7 percent per year, population at 1 percent, and per capita food consumption hardly at all, the central problem has been one of supply management. This is dwarfed by the much vaster and more urgent food supply problems of the developing countries, in which large segments of the population are malnourished or actually hungry. By 1985, simply to cover expected increases in population and modest increases in pur-

chasing power, the food supply of the developing countries will have to expand at an average rate of 3.6 percent a year.

To this challenge, no single or simple solution exists. Progress has to be organized in several directions concurrently; for instance, by making better use of existing food supplies, by increasing agricultural inputs, by strengthening research, agricultural services, and rural institutions, by pursuing appropriate national economic and population policies, and by a concerted expansion of international trade and foreign aid. Objectives in most of these fields were proposed by the FAO in its *Provisional Indicative World Plan for Agricultural Development*, published in 1969, and were subsequently updated in the proposals presented to and broadly agreed on by the United Nations World Food Conference, held in Rome in November 1974.

#### MAJOR PROBLEMS OF FOOD SUPPLIES

**Crop production.** Since World War II, food production has expanded more rapidly than during any comparable period in history. Had it not been for the equally rapid rise in population in developing countries, the problem of hunger and malnutrition would have been nearly solved. In the developed countries, almost all the increased output came from higher yields per acre, cereal acreages showing little change except in the Soviet Union, where virgin lands in the east and southeast were brought into cultivation. Wheat yields in Europe, for example, rose from 14.7 quintals per hectare (1,310 pounds per acre) in 1948–52 to 30.2 (2,690) in 1975, an annual increment of 3.1 percent. In the U.S. the average yield of corn (maize) was 24.9 quintals (2,220 pounds) in 1948–52 and 54.1 (4,830) in 1975, an annual increase of 3.5 percent. In the developing countries during the 1960s, expansion of area was responsible for about 40 percent of increased production, higher yields for the remainder.

Some of the increased cereal output in developed countries has been exported (especially from North America to developing countries that faced shortages), but the greater part has gone to livestock feeding. In the years ahead, most of the developed countries will require more feed grain but less wheat, whereas the developing countries need more cereals for both food and feed. To meet this need, intensified use of existing farmland appears generally more economic than expansion of area. Indeed, in Asia and the Near East many countries have little choice. In Africa and Latin America, although large areas remain uncultivated, the cost of opening them up and in particular of building up the means of transport needed to make them accessible would be extremely high. Bringing new land into cultivation would help to provide additional employment, however.

To increase yields per acre requires a judicious combination of physical techniques and supporting services. Plant breeding, including increasing the supplies of the much-publicized high-yielding varieties of wheat and rice, should play a major role. In the Far East the Mexican wheat and the Philippine rice seed, together with vastly improved varieties from other sources, already account for 54 percent of the wheat area and 20 percent of the rice area. Elsewhere may be found significant “islands” of progress; e.g., hybrid maize in Kenya, wheat in Turkey, improved rice in Madagascar and Brazil, and wheat throughout Mexico. The area of wheat planted to high-yielding varieties in the Far East rose from 9,000 hectares (22,000 acres) in the 1965–66 season to approximately 15,000,000 hectares (37,000,000 acres) in 1973–74. Over the same period, areas under high-yielding varieties of rice rose from 49,000 hectares (121,000 acres) to approximately 17,000,000 (42,000,000).

In order to succeed, the new varieties require ample balanced fertilizer—as much as 120 kilograms of nitrogen per hectare (about 107 pounds per acre) plus appropriate quantities of phosphate and potash, for example. Fertilizer consumption between 1949–51 and 1972–73 rose in developed countries from 22 to 102 kilograms of plant nutrient per arable hectare (from about 20 to 91 pounds per acre) and in developing coun-

Exports  
and  
imports  
of food

Food  
scarcity in  
developing  
countries

Plant  
breeding  
for high  
yield

tries from 1.4 to 1.7 kilograms (from 1.25 to 1.50 pounds). The FAO's *Indicative World Plan* calculated that in these latter countries fertilizer consumption should increase from 2,600,000 tons (1962) to more than 31,000,000 tons (1985).

#### Irrigation

A second essential element is water. Around 1962 irrigation was used on some 72,000,000 hectares (178,000,000 acres), or 19 percent of the harvested crop area, in the countries studied by the FAO in the *Indicative World Plan*. The plan proposed to double this area by 1985, with greater emphasis than previously on groundwater, at a cost of some \$36,000,000,000 plus another \$11,000,000,000 for drainage, flood control, and related works.

Other necessary elements include crop protection with pesticides to combat loss of potential production, a loss estimated at more than \$50,000,000,000 in the developing countries in 1965. Also, mechanization is expected to increase yields and reduce harvesting losses by more timely sowing and reaping; in suitable environments it makes multiple cropping possible. But the economics of applying mechanical power require careful study where, as in the majority of the developing countries, the farm labour supply is already excessive and destined to become more so.

Better cultivation practices can contribute much; e.g., terracing, contour plowing, planting of shelter belts, growing of grass or legumes in rotation with grain or tilled crops, mulching, and growing legumes in rotation. There is no set formula. Measures must vary according to the environment and are very different, for example, in low rainfall areas of more or less level terrain from those in mountainous terrain. In the former, the chief aim would be to prevent wind erosion and to improve penetration and retention of moisture by such practices as chisel plowing, construction of small embankments or ridges, strip cropping, and stubble mulching. In the uplands, the aim would be to prevent excessive runoff and water erosion by plowing against the slope or, on steeper slopes, by building terraces. In some areas, planting of shrubbery as windbreaks serves to protect the soil and crops.

Where annual winter rainfall exceeds 400 millimetres (16 inches) in the Near East, northwest Africa, and the northern Indo-Gangetic plain, it probably would be profitable to replace the cereal-fallow rotation by alternate rain-fed cropping of cereals and fodder legumes, such as clovers and lucerne (alfalfa), with the possibility of more comprehensive rotations—including grain legumes, such as lentils and chick-peas (gram), oilseeds, or other cash crops—in areas of higher rainfall.

#### Multiple cropping

One of the best formulas for providing more employment and at the same time increasing incomes undoubtedly is multiple cropping. In Hong Kong, for instance, 80 percent of the vegetable farmers plant more than four crops a year and 45 percent plant seven to nine crops. While these examples cannot be imitated everywhere, there are many regions of dense population, suitable climate, and good water supply in which multiple cropping could be, but is not, practiced.

**Livestock and fish.** To the world's protein supply, livestock products contribute 35 percent and fish 6 percent. Formerly the production of both was concentrated in a few favoured areas. More than half of the world's milk and nearly half of its meat is produced in Europe and North America. Most of the food fish comes from waters adjacent to Europe, North America, and Japan.

**Table 2: Meat Production in Developed and Developing Countries**

item	1948-52 (000,000 metric tons)	1976	index (1948-52 = 100)	growth rate compound (percent per year)
Developed countries	32.3	81.9	254	4.0
Developing countries	16.5	39.7	241	3.7
World	48.8	121.6	249	3.9

Source: Food and Agriculture Organization, Rome.

Between the immediate postwar period (1948-52) and 1976, numbers of cattle increased by 34 percent in Europe (excluding the Soviet Union), 60 percent in North America, as much as 68 percent in Africa, and 63 percent in Latin America. As shown in Table 2, world meat production more than doubled during that period, both in developed countries (including the Soviet Union) and in developing countries (including China).

Fish production between 1950 and 1975 increased only modestly in North America and by 100 percent in western Europe; in the Soviet Union, however, it rose 507 percent, in East and Southeast Asia (including Japan) 205 percent, and in Africa 266 percent. Especially noteworthy was the Latin-American expansion from 640,000 tons to 15,000,000 tons (1970), mainly accounted for by the anchoveta (a small anchovy), processed in Peruvian fish-meal plants for export to industrial countries. Thereafter the catch of anchovetas declined—probably temporarily—because of changes in ocean currents. During the 1960s exports of fish meal from the Soviet Union and Latin America increased 30-40 percent, while those from Africa increased 60 percent.

It is in consumption of livestock products that the greatest difference between rich and poor peoples is observed. Thus, meat consumption approaches 230 grams (8.1 ounces) per person per day in the United States and is even higher in Argentina, Australia, and New Zealand; by contrast, it reaches only 58 grams (2.03 ounces) in Mexico, 19 grams (0.7 ounce) in Nigeria, and four grams (0.14 ounce) in India. Similarly, the consumption of milk products, which exceeds 700 grams (25 ounces) per person per day (in terms of fresh milk equivalent) in Scandinavia and 670 grams (23.6 ounces) in the United States, reaches only 75 grams (2.6 ounces) in Tanzania and 13 grams (0.46 ounce) in Thailand.

Since World War II the application of mass-production methods in the poultry industry, notably in North America and Europe, has greatly reduced the price of poultry relative to other meats and has stimulated consumption. Some further increase in beef consumption can be expected, especially in Europe, but it takes time to increase cattle numbers. Beef prices, moreover, have not become sufficiently attractive to farmers; in potential supplying regions such as Latin America and parts of Africa, disease problems inhibit the expansion of beef exports to North America and Europe. A measure of the inferiority of the cattle of developing countries is shown in Table 3. In western Europe the combined output of meat and milk per head of cattle is about 25 times that of Asia and five times that of Latin America.

#### Consumption of livestock products

**Table 3: Relative Productivity of Cattle by Region, 1976**

region	cattle (000,000)	meat (000,000 tons)	production milk total* (000,000 tons)	ratio of production to numbers of cattle	
Western Europe	101	8.0	125	205	2.03
United States and Canada	142	13.4	62	196	1.38
Soviet Union	111	6.2	89	151	1.36
Australia and New Zealand	43	1.8	13	31	0.72
Latin America	266	7.9	31	110	0.41
Near East	46	0.8	7	15	0.33
Africa	130	1.7	5	22	0.17
Far East	254	0.9	11	20	0.08

\*In milk equivalent, one ton of meat being taken as equal in production to 10 tons of milk.

Many lines of attack can be pursued simultaneously. Some of the major grassland areas of the developing countries are understocked, and others are hopelessly overgrazed. The introduction of range management would in time greatly augment the carrying capacity of these lands. Fodder crops can be much more widely grown, especially on irrigated land, once the national supply of food crops has become adequate. By-products, often wasted, can be turned into feed concentrates; an

example is the successful use of molasses combined with urea for fattening beef cattle. In some regions—*e.g.*, in many parts of Africa—customary forms of land tenure and the hoarding of animals as investment capital impede the introduction of modern cattle raising, as do religious beliefs in parts of southern Asia. Eradication of the tsetse fly from Central Africa would make available 7,000,000 square kilometres (2,700,000 square miles) for cattle raising. The Dairy Development Scheme of the FAO would link the dried milk surpluses of exporting countries to the building of dairy industries in developing countries. These programs will take time. Much more rapid expansion of meat supplies can be achieved by first developing large-scale poultry production and, where acceptable, pig production, though this, as well as beef and dairy expansion, requires the introduction of modern market structures—cold storage, transport, inspection services—and stronger price incentives. A precondition for commercial poultry and pig production is availability of grain supplies beyond human needs.

#### Expanding fisheries

Fisheries could also expand, since the demand for food fish and fish meal is expected approximately to double between 1965 and 1985. Necessary measures include the introduction of powered vessels and modern gear where these are yet unknown, investment in port facilities, the training of fishermen, and the creation of facilities for cooling the product during storage and distribution. In oceans intensively fished, governments will need to agree upon management and conservation measures, while areas such as the Indian Ocean, the South Pacific, and the Antarctic could be more fully utilized. The culture of fish, especially mollusks, is generally profitable in shallow coastal waters, as is the growing of carp in freshwater ponds. Possibly within the next two decades the limit of the supply potential of currently used species will have been reached, but there remain many unexploited species to which consumer taste could adapt, such as lantern fish and Antarctic krill, the latter capable of supplying perhaps 50,000,000 tons a year when economic harvesting methods have been devised.

#### Preventing wastage

**Better use of existing supplies of food.** Another approach to increasing food supplies is to cut down the wastage that occurs at all stages. At the very start of the production process, the land itself in many regions is abused by shifting cultivation, overgrazing, lack of terracing or of tree cover, or poor drainage. The water supply is misused, with wastage of up to 50 percent through faulty design of irrigation systems, overpumping that turns groundwater brackish, or pollution that renders water unusable for either agriculture or fish culture. Animal manures in many countries are used for fuel or simply wasted, and the nutrient value of chemical fertilizers may be partially lost through incorrect application. Investment in extension services to advise farmers about correcting these malpractices would produce important and immediate benefits.

In crop husbandry, weeds, pests, and diseases can each cause losses of up to 30 percent. Birds and locusts take a heavy toll, as do primitive harvesting and winnowing methods; even in the United States, with all its modern equipment, studies show grain losses of 5 to 10 percent in the field. In developing countries the percentage is far higher.

In the animal husbandry of the developing countries, high rates of infertility and prenatal mortality are caused by reproductive disorders; poor nutrition results in gastrointestinal parasitism; endemic diseases such as inflammation of the udder reduce milk yields; and other diseases, such as foot-and-mouth disease in Latin America, impede the development of what could be a valuable export business.

Storage losses are notorious. The United States reports 3 to 7 percent grain losses in storage, but in Africa, for example, up to one-third of stored maize may be lost. Yet plastic sheets for drying grain can be had cheaply, and the construction of rat-proof bins and the fumigation of stored grains are not prohibitively expensive.

In the case of perishables, losses are even more serious and the remedies more costly. Thus, in parts of Africa,

up to 40 percent of the fruit, vegetables, and eggs sent to urban markets may be lost as a result of faulty packing, infrequent transport, and lack of cold or other suitable storage. In some Near Eastern countries, half the sheep's milk goes bad because of the lack of coolers. In the tropics, fish becomes inedible within 24 hours after removal from the water, which restricts boats without refrigeration to a narrow fishing range. The installation of cold-storage facilities becomes profitable when a sizable urban market has developed and when regular supplies can be counted on. To aid in distribution, governments are beginning to encourage the creation of marketing co-operatives and other producer organizations and to provide inspection services and market intelligence reports.

Another approach to better utilization of food is through nutritional education. The governments of certain developing countries have equipped mobile kitchens from which home economists teach housewives improved methods of cooking and of food preservation. Through school garden programs, as in Turkey, villagers are taught the nutritional value of vegetables and fruit and how to grow them. Such programs involve the modification of traditional eating habits; change comes gradually.

**Agricultural policies.** In addition to the technical and scientific progress involved in improving the world's food supply, the social and economic aspects count for as much. In these fields governments have a major responsibility, whether in price and tax policies, in agrarian reform, in creating institutions and services, or in promoting foreign trade.

**Prices and taxation.** It is not enough for governments to announce a guaranteed price for a product; they must ensure that producers receive that price rather than only half or two-thirds of it. Farmers in developing countries sell their produce at unfavourable moments either because they have insufficient storage, are short of cash, or have been misinformed. In Colombia, for instance, the price of potatoes after harvest falls to one-third of the preharvest level. Remedies include the creation of a sufficient number of local buying points at which official prices are posted and inspectors are present; the construction of more storage space to permit orderly crop disposal; and the provision of credit facilities to relieve farmers from the need to make forced sales.

Taxation policy toward agriculture continues to be of much interest in developing countries. Governments cannot afford to exempt from taxation the farm people who constitute 50 to 80 percent of the total population, and yet they must ensure that taxes as well as price policies encourage rather than discourage maximum food production.

**Agrarian reform.** In many regions, traditional modes of land tenure interfere with expansion of food production either in direct ways or through the perpetuation of a nonprogressive social structure. Where feudal-type estates still exist, for example, the policy of subdividing them must compromise between the need to satisfy land hunger and the desirability of creating farms large enough to be profitable; and, simultaneously with subdivision, new organizations must be established for the marketing, credit, and other services formerly provided, though imperfectly, by the landlords. In several regions of Africa, customary tenures that impede rational land use are being gradually converted to individual or group ownership. In nomadic pastoral economies, where the settlement of nomads may be neither practicable nor desirable, reforms concentrate not on tenure aspects but rather on more rational stocking and range management, on the creation of more water points, and on the provision of veterinary services and supplementary feed supplies. Finally, in districts facing the problem of an excess of very small or badly fragmented farms, costly investments are involved in the consolidation of holdings. Wherever unsatisfactory tenure systems still prevail, nevertheless, bold measures of agrarian reform, although expensive and often politically difficult, are a prerequisite to the creation of the social climate in which a farming community can modernize.

**Institutional support.** The rapid increases in food out-

#### Nutritional education

put in advanced countries must be attributed in large part to the research and other agricultural services that were built up during previous decades. These services are still embryonic in many developing countries.

For instance, until the mid-20th century almost all of the world's agricultural research (except in regard to certain plantation crops) was conducted in temperate countries and was concerned with the problems of temperate farming. Yet much of the developing countries' agricultural land is located in the tropics. Funds are being made available by private foundations, by the World Bank, and by governments and other institutions to establish or extend in the developing countries research centres that focus not solely on the scientific problems of crops and animal husbandry but also on the social and economic aspects, which are in many cases equally influential.

Some national governments, sometimes with outside assistance, are building up their agricultural extension services, deliberately linking them to farm credit and marketing facilities, and encouraging the creation of farmers' organizations. To provide recruits for these services and to give farmers some basic agricultural education, training programs at all levels are being established. In some countries, the doubling or even tripling of trained personnel seems to be required.

These and many other programs involve large investments that the governments of most developing countries can ill afford. A question of priorities is involved. Starting in the mid-1960s, a number of governments—the Soviet Union and India are prominent examples—in their investment programs greatly augmented the share allocated to agriculture, recognizing that farming is a basic factor in general economic development; other governments were contemplating similar action. The Food and Agriculture Organization has estimated that research and development expenditures in developing countries ought to be increased from around \$360,000,000 in 1970 to about \$1,250,000,000 in 1985; of the latter sum, about \$350,000,000 would be provided by advanced countries and international agencies.

**Agricultural trade.** Although less than 10 percent of the world's food crosses national frontiers, and only a few countries, notably in western Europe, import as much as half their supplies, a number of countries, including most of the developing countries, rely on agricultural exports to furnish more than half of their foreign currency earnings. Table 4 illustrates the contrast, with respect to trade in agricultural products.

Table 4: Value of Total Agricultural Trade, 1976\*

item	exports (000,000,000 \$ U.S. at current prices)	imports
Developed market economies	79.6	95.4
Soviet Union and eastern Europe	6.6	16.8
Total developed countries	86.2	112.2
Developing market economies	40.2	27.0
Asian centrally planned economies	2.5	3.0
Total developing countries	42.7	30.0
World total	128.9	142.2

\*The definition of agricultural trade follows that of the FAO *Trade Yearbook*. Agricultural trade excludes forestry and fishery products, with the exception of fish meal and marine oils. Re-exports are normally included.  
Source: Food and Agriculture Organization, Rome.

Paradoxically, the well-fed countries are net importers and the poorly fed net exporters of food. The developed countries' major agricultural exports are composed chiefly of cereals and rice (43 percent); oilseeds, vegetable oils, and sugar (27 percent); and nonfood agricultural products (13 percent). Those of the developing countries include beverages (30 percent); nonfood agricultural products (26 percent); sugar, oilseeds, and vegetable oils (23 percent).

During the decade 1963–73, the volume of the developed countries' agricultural exports rose 73 percent, but that of the developing countries rose only 21 percent

(Latin America, 25 percent; Far East, 21; Near East, 35; Africa, 7). Over the 1960s the developed countries benefited from an increase of some 10 percent in the unit values of their exports, whereas those of developing countries suffered a more than 10 percent decline. Trade in fishery products doubled during the decade, mainly among developed countries, with some export to the developed countries from developing countries (especially fish meal from Latin America). Developing countries themselves do not import much fish.

Many developed countries have maintained tariff and nontariff barriers that shield their farmers from the competition of cheap food imports. Many meetings related to the General Agreement on Tariffs and Trade (GATT) have been devoted to a search for ways of liberalizing trade in farm products, but with little success. Major countries continue to make use of the "waiver" under which they absolve themselves from applying to agriculture the general trading rules of GATT.

Strong fluctuations in world market prices have always been a particular hazard for countries that are heavily dependent on agricultural exports. Although the most dramatic instances occurred during the Great Depression of the 1930s, price fluctuations persisted during the 1950s and '60s and were particularly marked during the early 1970s. Interested governments have attempted to negotiate international commodity agreements containing price stabilization provisions. Because of economic and political complexities, few such agreements have been concluded, and even in these cases (for example, in wheat) it has often proved to be impossible to hold the price within the prescribed limits. More modest, but often more successful, has been the work of commodity study groups, in which the principal exporters and importers of a product meet regularly to review developments and on occasion to conclude informal trade arrangements. (See also COMMODITY TRADE, INTERNATIONAL.)

PROSPECTS

In assessing food-supply prospects, an attempt must be made to determine the expected increase in demand and to see how fully this demand could be met by carrying through the technical and economic programs described above.

**Demand for food.** What economists call "effective demand for food" is the amount that people want to buy given the money that they have. Future effective demand depends mainly on two factors: growth of population and growth of income.

**Population.** The biggest challenge facing the world's food supply is the population explosion in the developing countries. During the 1950s, population in these countries (excluding China and other areas of Asia having central planning) grew at 2.4 percent per year (compared with 1.2 percent in developed countries); during the 1960s the rate rose to 2.7 percent in the developing countries (and dropped to 1 percent in developed countries). The rate of growth has been increasing in the developing group but decreasing in the developed.

As shown in Table 5, the developing countries are expected to increase their populations, in the 20-year period from 1965 to 1985, by 72 percent. During this same period China and other centrally planned countries of Asia

Latin America	247	426	72

\*Excludes China and other centrally planned countries of Asia, for which data are lacking.  
Source: Based on UN "medium" population assumption as assessed in 1973; *World Population Prospects as Assessed in 1973*, New York.

may increase from 800,000,000 to 1,200,000,000. The developed group, numbering about 1,000,000,000 in 1965, is expected to increase by less than 19 percent. About 86 of every 100 persons added between 1965 and 1985 will be born in developing countries. Although the governments of a number of developing countries are currently adopting policies regarding population, it would be unrealistic, bearing in mind the profound changes required in social attitudes, to expect a significant slowing down in population growth in the near future.

**Income.** Estimates based on accepted hypotheses as to the likely rate of growth of national income in the developing countries indicate that between 1969–71 and 1985 per capita demand for food will increase by about 9 percent. Combining this with the expected population growth gives an estimated increase of 66 percent in total food demand. Of the two growth factors, population and income, population will be by far the more influential, accounting for seven-tenths of the estimated increase. The increase in demand will not apply to all foods equally. Urbanization and gradually rising incomes in the developing countries will affect the composition of people's diets, bringing a modest increase in cereals and starchy foods and a large increase in livestock products, vegetables, and fruit.

**Requirements for food.** In the developed countries dietary energy supplies exceed estimated requirements by about 23 percent, while in developing countries they fall short by 5 percent; but 5 percent is an average, and many individuals' diets fall far below the average.

Protein  
needs

The protein problem is more complex. The advanced countries have an average of 96 grams (3.4 ounces) of protein per person per day, of which more than half is animal protein; this exceeds requirements. The people of the developing countries have an average intake of only 57 grams (2 ounces) of protein per day, much of which is diverted from its true protein functions in an attempt to meet energy deficits. Among developing countries wide differences occur, largely because of ecological and cultural conditions. In moving from the diets of developed countries, which have animal products as the main source of protein, through diets based on wheat, maize, sorghum, or rice, and on to root and tuber diets, the protein intake diminishes, the quality of dietary protein declines because of imbalances in the amino acid content, the protein-energy balance deteriorates, and the gap between intake and recommended allowances widens.

Because good-quality proteins occur mainly in more expensive foodstuffs, the maldistribution of protein between income groups is more serious than that of energy supplies; and because expectant and nursing mothers and young children have special protein requirements, the deficiencies particularly affect these groups. (See also NUTRITION AND DIET, HUMAN.)

**Prospective supply.** In the developed countries, apart from a few poorer regions of Europe, no change in dietary energy supplies is anticipated in the near future; but in the developing countries—to eliminate the present shortage, cover the population and income increase, and provide a 10 percent safety margin—energy supplies will have to be almost doubled between 1969–71 and 1985. This lies within the capacity of most, though not all, of the developing countries, provided that they pursue vigorous policies of agricultural investment and modernization. Some will lack the physical resources for so large an expansion of food production, and perhaps some will fail to mobilize available resources sufficiently. Such countries will have recourse to larger food imports, or, if they cannot afford these, their more disadvantaged population groups will continue to experience deficiencies in energy supply.

In developed countries, no overall supply problem exists for protein. What is expected to occur is a rearrangement of the sources of protein; namely, an increase in the proportion represented by animal protein. Public assistance to supplement the incomes of specially disadvantaged groups may remain necessary, since protein foods will still be relatively expensive items in the diet.

In developing countries, it is improvement in the quality of protein and its availability to poorer people that requires attention. Part of the problem is to change traditional dietary habits through nutrition education in order to diversify the diet and obtain a better use of the available food supply. Part lies in asking the plant breeder to develop species of, for example, rice and wheat, with nutritionally more satisfactory amino acid content, as is being attempted with maize. Pulses and high-protein oilseeds can become significant supplements to cereal and starchy root diets. Much can be accomplished and relatively quickly in expanding the production of pigs, poultry, and fish. Further, the fortification of certain staple foods with amino acids, minerals, and vitamins, though costly, might be justified in particular circumstances in which specific nutrient deficiencies have been identified. Formulated protein-rich foods of this kind (e.g., "superamine" in Algeria) are being developed for the feeding of the vulnerable population groups.

More unconventional sources of protein are already being developed in advanced countries: "artificial meat" from soya meal; fish protein concentrate, an odourless flour for mixing into other foods; food yeast from the by-products of pulp and paper manufacture. Certain seaweeds are eaten in Japan and, to a lesser extent, in other Far Eastern countries. Interest has focussed on *Chlorella*, an alga that multiplies itself at fantastic speed and that, if it could be made acceptable for human consumption, would constitute an almost unlimited source of protein. Not least important is the work on single-cell protein; several factories already transform petroleum waxes into protein intended for animal feeds, and there is potential for human use as well. (See also FOOD, NEW SOURCES AND PRODUCTS.)

The relevance of these experiments to the protein deficiencies in developing countries will depend on whether the new products can be made sufficiently acceptable and sufficiently cheap. For some years to come, at least, principal reliance will continue to be placed on conventional foodstuffs.

#### INTERNATIONAL AID

The task of feeding the huge populations of the 1980s and feeding them at least somewhat better than today presents a challenge to scientists, educators, economists, administrators, and farmers. The greatest efforts are needed in the countries least equipped to carry out the needed programs. The rich nations already have the necessary knowledge and skills; the poor have first to attain them. Indubitably the main impetus must come from the peoples of the developing countries themselves; they and their governments must mobilize the investments and train the manpower. Yet a role remains for assistance and aid from the rich countries. Those who have plenty in terms of capital, skills, and commodities can do much to help the less fortunate nations win their battle against poverty.

**Food aid.** In the 1950s the United States began a large program for transferring much of its surplus food on concessional terms to needy countries. Other advanced countries also initiated such transfers on a more modest scale. Finally, in 1962, the FAO World Food Program was established to undertake multilateral food aid. Its activities include emergency feeding after such disasters as earthquakes or floods and economic and social development projects such as maternal and child feeding, animal production and dairy development, land development and improvement, land settlement, and forestry. Care is exercised that food transferred under these programs jeopardizes neither the market for the output of farmers in recipient countries nor the market for normal commercial exporters. Of course food aid, bilateral and multilateral, cannot be contemplated as a permanent element in the food supply of the poorer countries, which ultimately must become economically independent; but it does provide valuable assistance during the transitional period in which they are modernizing their agriculture. The World Food Conference agreed on a minimum target of 10,000,000 tons of food aid a year.

New foods

The FAO  
World  
Food  
Program

**Technical and financial aid.** The net flow of financial resources to developing countries for all purposes, according to calculations by the Organization for Economic Co-operation and Development (OECD), rose from \$9,200,000,000 in 1961 to about \$40,000,000,000 in 1975. Of this, \$16,000,000,000 was official assistance and \$22,000,000,000 private capital flow; but official development assistance, in terms of the gross national product of donor countries, fell from 0.52 percent to 0.36 percent. A more positive element has been the increasing attention given to agriculture. Total OECD assistance to the agricultural sector was \$2,633,000,000 in 1975. In 1968 the World Bank announced its intention of quadrupling its assistance to agriculture over the following five years; already in fiscal 1971-72 World Bank and International Development Association loans and credits to this sector totalled \$436,000,000. By 1975 it was \$1,858,000,000, but in fiscal 1976 the total dropped to \$1,628,000,000. Technical assistance has expanded more rapidly than financial aid, indeed by more than 10 percent a year. Of expenditure through the UN system, agricultural projects during 1964-74 accounted for about one-third. Aid in the form of fertilizers and other production requisites has also expanded and will become increasingly crucial if the "green revolution" is to continue without too great a drain on the scarce foreign exchange resources of the developing countries.
